Allows municipalities to encourage energy efficiency and renewable energy without putting their general funds at risk	Some resistance by lenders whose priority in default may be reduced

Source: DOE (2013).

because many property owners may not own the building long enough to enjoy the savings as opposed to the initial cost. Other owners simply will be hesitant to use scarce financial resources when they might not benefit directly from lower utility bills.

Table 7 summarizes the key advantages and disadvantages of PACE for property owners.

Key steps local governments may follow to implement a commercial PACE program include the following:

1. **Review and address issues:** Become familiar with issues related to PACE and factor their consequences into program design and implementation.
2. **Establish supporting framework:** Lay a solid foundation for the program in the areas of team composition, goals, legislation, and assessment district formation.
3. **Choose capital sourcing approach(es):** Choose whether the projects will be funded using private capital, and if so, whether the program will use an open- or closed-market approach.
4. **Determine whether and how to deploy credit enhancement:** Decide how to achieve the best interest rates for the program and how best to apply and leverage any available funds to fit the program's design.
5. **Choose eligible property types:** Select the commercial property types eligible for the program.
6. **Assemble eligible project measures:** Determine what types of improvements can be financed based on enabling legislation and program goals.
7. **Choose energy audit requirements:** Decide the types of energy audits applicants will be required to undergo to assess expected project energy/cost savings.
8. **Choose program eligibility criteria:** Determine the program underwriting/eligibility criteria that applicants and their properties must meet. See DOE (2013) for guidance.
9. **Leverage existing utility rebate/incentive programs:** Investigate local utility rebate/incentive programs and how best to leverage them.
10. **Plan quality assurance/quality control:** Decide how the program will ensure that project work meets program quality standards and how to guard against fraud.
11. **Design application processing procedures:** Design the process for reviewing applications and either approving or rejecting them.
12. **Specify contractor requirements:** Specify the requirements for energy auditors and contractors to participate in the program.
13. **Market and launch program:** Decide what kind of outreach will be made to property owners and contractors, and launch the program.

Note that many steps are carried out concurrently and not necessarily in this exact order. Often, an additional step for procurement is appropriate to choose capital and/or administration entities.

Note that although PACE is an alternative to traditional financing, as with all energy saving or performance-based methods, the actual performance data, parameters, and assumptions of energy modeling and analysis of projected costs, along with real-world operating conditions and operators' varying skill levels, lead to changing energy and life-cycle costs.

District Energy Service

District energy service is increasingly available to building owners; district heating and cooling eliminates most on-site heating and cooling equipment. A third party produces treated water or steam and pipes it from a central plant directly to the building. The building owner then pays a metered rate for the energy that is used.

A cost comparison of district energy service versus on-site generation requires careful examination of numerous, often site-specific, factors extending beyond demand and energy charges for fuel. District heating and cooling eliminates or minimizes most costs associated with installation, maintenance, administration, repair, and operation of on-site heating and cooling equipment. Specifically, costs associated with providing water, water treatment, specialized maintenance services, insurance, staff time, space to house on-site equipment, and structural additions needed to support equipment should be considered. Costs associated with auxiliary equipment, which represent 20 to 30% of the total plant annual operating costs, should also be included.

Any analysis that fails to include all the associated costs does not give a clear picture of the building owner's heating and cooling alternatives. In addition to the tangible costs, there a number of other factors that should be considered, such as convenience, risk, environmental issues, flexibility, and back-up.

On-Site Electrical Power Generation

On-site electrical power generation covers a broad range of applications, from emergency back-up to power for a single piece of equipment to an on-site power plant supplying 100% of the facility's electrical power needs. Various system types and fuel sources are available, but the economic principles described in this chapter apply equally to all of them. Other chapters (e.g., Chapters 7 and 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*) may be helpful in describing system details.

An economic study of on-site electrical power generation should include consideration of all owning, operating, and maintenance costs. Typically, on-site generation is capital intensive (i.e., high first cost) and therefore requires a high use rate to produce savings adequate to support the investment. High use rates mean high run time, which requires planned maintenance and careful operation.

Owning costs include any related systems required to adapt the building to on-site power generation. Additional equipment is required if the building will also use purchased power from a utility. Costs associated with shared equipment should also be considered. For example, if the power source for the generator is a steam turbine, and a hot-water boiler would otherwise be used to meet the HVAC demand, the boiler would need to be a larger, high-pressure steam boiler with a heat exchanger to meet the hot-water needs. Operation and maintenance costs for the boiler also are increased because of the increased operating hours.

Costs of an initial investment and ongoing inventory of spare parts must also be considered. Most equipment manufacturers provide a recommended spare parts list as well as recommended maintenance schedules, typically daily, weekly, and monthly routine maintenance and periodic major overhauls. Major overhaul frequency depends on equipment use and requires taking the equipment off-line. The cost of either lost building use or the provision of electricity from an alternative source during the shutdown should be considered.

6. ECONOMIC ANALYSIS TECHNIQUES

Analysis of overall owning and operating costs and comparisons of alternatives require an understanding of the cost of lost opportunities, inflation, and the time value of money. This process of economic analysis of alternatives falls into two general categories: simple payback analysis and detailed economic analyses (life-cycle cost analyses).

A simple payback analysis reveals options that have short versus long paybacks. Often, however, alternatives are similar and have similar paybacks. For a more accurate comparison, a more comprehensive economic analysis is warranted. Many times it is appropriate to have both a simple payback analysis and a detailed economic analysis. The simple payback analysis shows which options should not be considered further, and the detailed economic analysis determines which of the viable options are the strongest. The strongest options can be accepted or further analyzed if they include competing alternatives.

Simple Payback

In the simple payback technique, a projection of the revenue stream, cost savings, and other factors is estimated and compared to the initial capital outlay. This simple technique ignores the cost of borrowing money (interest) and lost opportunity costs. It also ignores inflation and the time value of money.

Example 1. Equipment item 1 costs $10 000 and will save $2000 per year in operating costs; equipment item 2 costs $12 000 and saves $3000 per year. Which item has the best simple payback?

Item 1 $10 000($2000/yr) = 5-year simple payback

Item 2 $12 000/($3000/yr) = 4-year simple payback

Because analysis of equipment for the duration of its realistic life can produce a very different result, the simple payback technique should be used with caution.

More Sophisticated Economic Analysis Methods

Economic analysis should consider details of both positive and negative costs over the analysis period, such as varying inflation rates, capital and interest costs, salvage costs, replacement costs, interest deductions, depreciation allowances, taxes, tax credits, mortgage payments, and all other costs associated with a particular system. See the section on Symbols for definitions of variables.

Present-Value (Present Worth) Analysis. All sophisticated economic analysis methods use the basic principles of present value analysis to account for the time value of money. Therefore, a good understanding of these principles is important.

The total present value (present worth) for any analysis is determined by summing the present worths of all individual items under consideration, both future single-payment items and series of equal future payments. The scenario with the highest present value is the preferred alternative.

Single-Payment Present-Value Analysis. The cost or value of money is a function of the available interest rate and inflation rate. The future value F of a present sum of money P over n periods with compound interest rate i per period is

$$F = P(1 + i)^n \tag{1}$$

Conversely, the present value or present worth P of a future sum of money F is given by

$$P = F/(1 + i)^n \tag{2}$$

or

$$P = F \times \mathrm{PWF}(i,n)_{sgl} \tag{3}$$

where the single-payment present-worth factor $\mathrm{PWF}(i,n)_{sgl}$ is defined as

$$\mathrm{PWF}(i,n)_{sgl} = 1/(1 + i)^n \tag{4}$$

Example 2. Calculate the value in 10 years at 10% per year interest of a system presently valued at $10 000.

$$F = P(1 + i)^n = \$10\,000(1 + 0.1)^{10} = \$25{,}937.42$$

Example 3. Using the present-worth factor for 10% per year interest and an analysis period of 10 years, calculate the present value of a future sum of money valued at $10 000. (Stated another way, determine what sum of money must be invested today at 10% per year interest to yield $10 000 10 years from now.)

$$P = F \times \mathrm{PWF}(i,n)_{sgl}$$
$$P = \$10\,000 \times 1/(1 + 0.1)^{10}$$
$$= \$3855.43$$

Series of Equal Payments. The present-worth factor for a series of future equal payments (e.g., operating costs) is given by

$$\mathrm{PWF}(i,n)_{ser} = \frac{(1+i)^n - 1}{i(1+i)^n} \tag{5}$$

The present value P of those future equal payments (PMT) is then the product of the present-worth factor and the payment [i.e., $P = \mathrm{PWF}(i,n)_{ser} \times \mathrm{PMT}$].

The number of future equal payments to repay a present value of money is determined by the capital recovery factor (CRF), which is the reciprocal of the present-worth factor for a series of equal payments:

$$\mathrm{CRF} = \mathrm{PMT}/P \tag{6}$$

$$\mathrm{CRF}(i,n)_r = \frac{i(1+i)^n}{(1+i)^n - 1} = \frac{i}{1-(1+i)^{-n}} \tag{7}$$

The CRF is often used to describe periodic uniform mortgage or loan payments.

Note that when payment periods other than annual are to be studied, the interest rate must be expressed per appropriate period. For example, if monthly payments or return on investment are being analyzed, then interest must be expressed per month, not per year, and n must be expressed in months.

Example 4. Determine the present value of an annual operating cost of $1000 per year over 10 years, assuming 10% per year interest rate.

$$\text{PWF}(i,n)_{ser} = [(1+0.1)^{10} - 1]/[0.1(1+0.1)^{10}] = 6.14$$
$$P = \$1000(6.14) = \$6140$$

Example 5. Determine the uniform monthly mortgage payments for a loan of \$100 000 to be repaid over 30 years at 10% per year interest. Because the payment period is monthly, the payback duration is 30(12) = 360 monthly periods, and the interest rate per period is 0.1/12 = 0.00833 per month.

$$\text{CRF}(i,n) = 0.008\ 33(1+0.008\ 33)^{360}/[(1+0.008\ 33)^{360} - 1]$$
$$= 0.008\ 773$$
$$\text{PMT} = P(\text{CRF})$$
$$= \$100\ 000(0.008\ 773)$$
$$= \$877.30 \text{ per month}$$

Improved Payback Analysis. This somewhat more sophisticated payback approach is similar to the simple payback method, except that the cost of money (interest rate, discount rate, etc.) is considered. Solving Equation (7) for n yields the following:

$$n = \frac{\ln[\text{CRF}/(\text{CRF} - i)]}{\ln(1+i)} \quad (8)$$

Given known investment amounts and earnings, CRFs can be calculated for the alternative investments. Subsequently, the number of periods until payback has been achieved can be calculated using Equation (8).

Example 6. Compare the years to payback of the same items described in Example 2 if the value of money is 10% per year.

Item 1

cost = \$10 000
savings = \$2000/year
CRF = \$2000/\$10 000 = 0.2
n = ln[0.2/(0.2 – 0.1)]/ln(1 + 0.1) = 7.3 years

Item 2

cost = \$12 000
savings = \$3000/year
CRF = \$3000/\$12 000 = 0.25
n = ln[0.25/(0.25 – 0.1)]/ln(1 + 0.1) = 5.4 years

If years to payback is the sole criteria for comparison, Item 2 is preferable because the investment is repaid in a shorter period of time.

Accounting for Inflation. Different economic goods may inflate at different rates. Inflation reflects the rise in the real cost of a commodity over time and is separate from the time value of money. Inflation must often be accounted for in an economic evaluation. One way to account for inflation is to substitute effective interest rates that account for inflation into the equations given in this chapter.

The effective interest rate i', sometimes called the real rate, accounts for inflation rate j and interest rate i or discount rate i_d; it can be expressed as follows (Kreider and Kreith 1982):

$$i' = \frac{1+i}{1+j} - 1 = \frac{i-j}{1+j} \quad (9)$$

Different effective interest rates can be applied to individual components of cost. Projections for future fuel and energy prices are available in the *Annual Supplement to NIST Handbook* 135 (Rushing et al. 2010).

Example 7. Determine the present worth P of an annual operating cost of \$1000 over 10 years, given a discount rate of 10% per year and an inflation rate of 5% per year.

$$i' = (0.1 - 0.05)/(1+0.05) = 0.0476$$
$$\text{PWF}(i',n)_{ser} = \frac{(1+0.0476)^{10} - 1}{0.0476(1+0.0476)^{10}} = 7.813$$
$$P = \$1000(7.813) = \$7813$$

The following are three common methods of present-value analysis that include life-cycle cost factors (life of equipment, analysis period, discount rate, energy escalation rates, maintenance cost, etc., as shown in Table 1). These comparison techniques rely on the same assumptions and economic analysis theories but display the results in different forms. They also use the same definition of each term. All can be displayed as a single calculation or as a cash flow table using a series of calculations for each year of the analysis period.

Savings-to-Investment Ratio. Most large military-sponsored work and many other U.S. government entities require a savings-to-investment-ratio (SIR) method. Simply put, SIR is the ratio of an option's savings to its costs. This ratio defines the relative economic strength of each option. The higher the ratio, the better the economic strength. If the ratio is less than 1, the measure does not pay for itself within the analysis period. The escalated savings on an annual and a special (nonannual) basis is calculated and discounted. Costs are shown on an annual and special basis for each year over the life of the system or option. Savings and investments are both discounted separately on an annual basis, and then the discounted total cumulative savings is divided by the discounted total cumulative investments (costs). The analysis period is usually the life of the system or equipment being considered.

The SIR is the sum of a series of operation-related savings from a project alternative divided by the sum of its additional investment-related costs. Typically, this is over a period of years (5, 10, or 20 years, or the typical expected life span).

The general equation for the SIR simply rearranges these two terms as a ratio:

$$\text{SIR}_{\text{A:BC}} = \frac{\sum_{t=0}^{N} S_t/(1+d)^t}{\sum_{t=0}^{N} I_t/(1+d)^t} \quad (10)$$

where

$\text{SIR}_{\text{A:BC}}$ = ratio of PV savings to additional PV investment costs of (mutually exclusive) alternative A to base case BC
S_t = savings in year t in operational costs attributable to alternative
I_t = investment-related costs in year t attributable to alternative
t = year of occurrence (where 0 is base date)
d = discount rate
N = length of study

A more practical SIR base-case equation for buildings is as follows:

$$\text{SIR}_{\text{A:BC}} = \frac{E + W + \text{OM\&R}}{I_o + \text{Repl} - \text{Res}} \quad (11)$$

where

$\text{SIR}_{\text{A:BC}}$ = ratio of operational savings to investment-related additional costs computed for alternative A to base case BC
E = $(E_{\text{BC}} - E_{\text{A}})$, savings in energy costs attributable to alternative relative to base case
W = $(W_{\text{BC}} - W_{\text{A}})$, savings in water costs attributable to alternative
OM&R = difference in OM&R costs; $\text{OM\&R}_{\text{BC}} - \text{OM\&R}_{\text{A}}$
I_o = additional initial investment cost required for alternative relative to base case; $(I_{\text{A}} - I_{\text{BC}})$
Repl = difference in capital replacement costs; $(\text{Repl}_{\text{A}} - \text{Repl}_{\text{BC}})$

Res = difference in residual value; ($Res_A - Res_{BC}$)

where all amounts are in present values.

Example 8: SIR Computation. For this example, the numerator and denominator are defined as follows:

Numerator:

PV of operational savings attributable to the alternative = \$91 030

Denominator:

PV of additional investment costs required for the alternative = \$7239

Thus,

$$SIR_{A:BC} = \frac{\$91\ 030}{\$7239} = 12.6$$

A ratio of 12.6 means that the energy-conserving design generates an average return of \$12.6 for every \$1 invested, over and above the minimum required rate of return imposed by the discount rate. The project alternative in this example is clearly cost effective. A ratio of 1.0 indicates that the cost of the investment equals its savings; a ratio of less than 1.0 indicates an uneconomic alternative that would cost more than it would save.

Summary of SIR Method

- An investment is cost effective if its SIR is greater than 1.0; this is equivalent to having net savings greater than zero.
- The SIR is a relative measure; it must be calculated with respect to a designated base case.
- When computing the SIR of an alternative relative to its base case, the same study period and the same discount rate must be used.
- The SIR is useful for evaluating a single project alternative against a base case or for ranking independent project alternatives; it is not useful for evaluating multiple mutually exclusive alternatives.

Internal Rate of Return. The internal rate of return (IRR) method calculates a return on investment over the defined analysis period. The annual savings and costs are not discounted, and a cash flow is established for each year of the analysis period, to be used with an initial cost (or value of the loan). Annual recurring and special (nonannual) savings and costs can be used. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method assumes savings are reinvested at the same calculated rate of return; therefore, the calculated rates of return can be overstated compared to the actual rates of return.

Another version of this is the **modified** or **adjusted internal rate of return (MIRR** or **AIRR)**. In this version, reinvested savings are assumed to have a given rate of return on investment, and the financed moneys a given interest rate. The cash flow is then discounted until a calculated discount rate is found that yields a net present value of zero. This method gives a more realistic indication of expected return on investment, but the difference between alternatives can be small.

The most straightforward method of calculating the AIRR requires that the SIR for a project (relative to its base case) be calculated first. Then the AIRR can be computed easily using the following equation:

$$AIRR = (1 + r)(SIR)^{1/N} - 1 \quad (12)$$

where r is the reinvestment rate and N is the number of years in the study period. Using the SIR of 12.6 from Equation (10) and a reinvestment rate of 3% (the minimum acceptable rate of return [MARR]), the AIRR is found as follows:

$$AIRR_{A:BC} = (1 + 0.03)(12.6)^{1/20} - 1 = 0.1691$$

Because an AIRR of 16.9% for the alternative is greater than the MARR, which in this example is the FEMP discount rate of 3%, the project alternative is considered to be cost effective in this application.

Life-Cycle Costs. This method of analysis compares the cumulative total of implementation, operating, and maintenance costs. The total costs are discounted over the life of the system or over the loan repayment period. The costs and investments are both discounted and displayed as a total combined life-cycle cost at the end of the analysis period. The options are compared to determine which has the lowest total cost over the anticipated project life.

Example 9. A municipality is evaluating two different methods of providing chilled water for cooling a government office building: purchasing chilled water from a central chilled-water utility service in the area, or installing a conventional chiller plant. Because the municipality is not a tax-paying entity, the evaluation does not need to consider taxes, allowing for either a current or constant dollar analysis.

The first-year price of the chilled-water utility service contract is \$65 250 per year and is expected to increase at a rate of 2.5% per year.

The chiller and cooling tower would cost \$220 000, with an expected life of 20 years. A major overhaul (\$90 000) of the chiller is expected to occur in year ten. Annual costs for preventative maintenance (\$1400), labor (\$10 000), water (\$2000) and chemical treatments (\$1800) are all expected to keep pace with inflation, which is estimated to average 3% annually over the study period. The annual electric cost (\$18 750) is expected to increase at a rate of 5% per year. The municipality uses a discount rate of 8% to evaluate financial decisions.

Which option has the lowest life-cycle cost?

Solution. Table 8 compares the two alternatives. For the values provided, alternative 1 has a 20-year life-cycle cost (LCC) of \$769 283 and alternative 2 has a 20-year life-cycle cost of \$717 100. If LCC is the only basis for the decision, alternative 2 is preferable because it has the lower life-cycle cost.

Computer Analysis

Many computer programs are available that incorporate economic analysis methods. These range from simple macros developed for popular spreadsheet applications to more comprehensive, menu-driven computer programs. Commonly used examples of the latter include Building Life-Cycle Cost (BLCC) and PC-ECONPACK.

BLCC was developed by the National Institute of Standards and Technology (NIST) for the U.S. Department of Energy (DOE). The program follows criteria established by the Federal Energy Management Program (FEMP) and the Office of Management and Budget (OMB). It is intended for evaluation of energy conservation investments in nonmilitary government buildings; however, it is also appropriate for similar evaluations of commercial facilities.

PC-ECONPACK, developed by the U.S. Army Corps of Engineers for use by the DOD, uses economic criteria established by the OMB. The program performs standardized life-cycle cost calculations such as net present value, equivalent uniform annual cost, SIR, and discounted payback period.

Macros developed for common spreadsheet programs generally contain preprogrammed functions for various life-cycle cost calculations. Although typically not as sophisticated as the menu-driven programs, the macros are easy to install and learn.

Reference Equations

Table 9 lists commonly used discount formulas as addressed by NIST. Refer to NIST *Handbook* 135 (Fuller and Petersen 1996) for detailed discussions.

7. SYMBOLS

AIRR = modified or adjusted internal rate of return (MIRR or AIRR)

c = cooling system adjustment factor

C = total annual building HVAC maintenance cost

C_e = annual operating cost for energy

$C_{s,assess}$ = assessed system value

$C_{s,init}$ = initial system cost

Table 8 Two Alternative LCC Examples

Alternative 1: Purchase Chilled Water from Utility

	Year 0	1	2	3	4	5	6	7	8	9	10
First costs		—	—	—	—	—	—	—	—	—	—
Chilled-water costs		$65 250	$66 881	$68 553	$70 267	$72 024	$73 824	$75 670	$77 562	$79 501	$81 488

20-year life-cycle cost	$717 100										

$C_{s,salv}$ = system salvage value at end of study period
C_y = uniform annualized mechanical system owning, operating, and maintenance costs
CRF = capital recovery factor
CRF(i,n) = capital recovery factor for interest rate i and analysis period n
CRF(i',n) = capital recovery factory for interest rate i' for items other than fuel and analysis period n
CRF(i'',n) = capital recovery factor for fuel interest rate i'' and analysis period n
CRF(i_m,n) = capital recovery factor for loan or mortgage rate i_m and analysis period n
d = distribution system adjustment factor
D_k = depreciation during period k
$D_{k,SL}$ = depreciation during period k from straight-line depreciation method
$D_{k,SD}$ = depreciation during period k from sum-of-digits depreciation method
F = future value of sum of money
h = heating system adjustment factor
i = compound interest rate per period
i_d = discount rate per period
i_m = market mortgage rate
i' = effective interest rate for all but fuel
i'' = effective interest rate for fuel
I = insurance cost per period
ITC = investment tax credit
j = inflation rate per period
j_e = fuel inflation rate per period
k = end of period(s) during which replacement(s), repair(s), depreciation, or interest are calculated
M = maintenance cost per period
n = number of periods under analysis
P = present value of a sum of money
P_k = outstanding principle on loan at end of period k
PMT = future equal payments
PWF = present worth factor
PWF(i_d,k) = present worth factor for discount rate i_d at end of period k
PWF(i',k) = present worth factor for effective interest rate i' at end of period k
PWF$(i,n)_{sgl}$ = single payment present worth factor
PWF$(i,n)_{ser}$ = present worth factor for a series of future equal payments
R_k = net replacement, repair, or disposal costs at end of period k
SIR = savings-to-investment ratio
T_{inc} = net income tax rate
T_{prop} = property tax rate
T_{salv} = tax rate applicable to salvage value of system

Table 9 Commonly Used Discount Formulas

Name	Algebraic Form[a,b]	Name	Algebraic Form[a,b]
Single compound-amount (SCA) equation	$F = P[(1+d)^n]$	Uniform compound-amount (UCA) equation	$F = A\left[\frac{(1+d)^n - 1}{d}\right]$
Single present-value (SPV) equation	$P = F\left[\frac{1}{(1+d)^n}\right]$	Uniform present-value (UPV) equation	$P = A\left[\frac{(1+d)^n - 1}{d(1+d)^n}\right]$
Uniform sinking-fund (USF) equation	$A = F\left[\frac{d}{(1+d)^n - 1}\right]$	Modified uniform present-value (UPV*) equation	$P = A_0\left(\frac{1+e}{d-e}\right)\left[1 - \left(\frac{1+e}{1+d}\right)^n\right]$
Uniform capital recovery (UCR) equation	$A = P\left[\frac{d(1+d)^n}{(1+d)^n - 1}\right]$		

where

A = end-of-period payment (or receipt) in a uniform series of payments (or receipts) over n periods at d interest or discount rate

A_0 = initial value of a periodic payment (receipt) evaluated at beginning of study period

$A_t = A_0(1+e)^t$, where $t = 1, \ldots, n$

d = interest or discount rate

e = price escalation rate per period

Source: NIST *Handbook* 135 (Fuller and Petersen 1996).

[a]Note that the USF, UCR, UCA, and UPV equations yield undefined answers when $d = 0$. The correct algebraic forms for this special case would be as follows: USF formula, $A = F/N$; UCR formula, $A = P/N$; UCA formula, $F = An$. The UPV* equation also yields an undefined answer when $e = d$. In this case, $P = A_0 n$.

[b]The terms by which known values are multiplied are formulas for the factors found in discount factor tables. Using acronyms to represent the factor formulas, the discounting equations can also be written as $F = P \times$ SCA, $P = F \times$ SPV, $A = F \times$ USF, $A = P \times$ UCR, F = UCA, $P = A \times$ UPV, and $P = A_0 \times$ UPV*.

Field Survey for Energy Audit	39.37
TAB Reports	39.39

SYSTEMS that control the environment in a building change with time and use, and must be rebalanced accordingly. The designer must consider initial and supplementary testing and balancing requirements for commissioning. Complete and accurate operating and maintenance instructions that include intent of design and how to test, adjust, and balance the building systems are essential. Building operating personnel must be well trained, or qualified operating service organizations must be hired to ensure optimum comfort, proper process operations, and economical operation.

This chapter does not suggest which groups or individuals should perform a complete testing, adjusting, and balancing procedure. However, the procedure must produce repeatable results that meet the design intent and the owner's requirements. Overall, one source must be responsible for testing, adjusting, and balancing all systems. As part of this responsibility, the testing organization should check all equipment under field conditions to ensure compliance.

Testing and balancing should be repeated as systems are renovated and changed. Testing boilers and other pressure vessels for compliance with safety codes is not the primary function of the testing and balancing firm; rather, it is to verify and adjust operating conditions in relation to design conditions for flow, temperature, pressure drop, noise, and vibration. ASHRAE *Standard* 111 details procedures not covered in this chapter.

1. TERMINOLOGY

Testing, adjusting, and balancing (TAB) is the process of checking and adjusting all environmental systems in a building to produce and meet the design objectives. This process includes (1) balancing air and water distribution systems, (2) adjusting the total system to provide design quantities, (3) electrical measurement, (4) establishing quantitative performance of all equipment, (5) verifying automatic control system operation and sequences of operation, and (6) sound and vibration measurement. These procedures are accomplished by checking installations for conformity to design, measuring the quantities of fluid that need to flow in the system to meet design specifications, and recording and reporting the results.

The following definitions are used in this chapter. Refer to *ASHRAE Terminology* (www.ashrae.org/ashraeterms) for additional definitions.

Test. Determine quantitative performance of equipment.

Adjust. Regulate the specified fluid flow rate and air patterns at terminal equipment (e.g., reduce fan speed, adjust a damper).

Balance. Proportion flows in the distribution system (submains, branches, and terminals) according to specified design quantities.

Balanced System. A system designed to deliver heat transfer required for occupant comfort or process load at design conditions. A minimum heat transfer of 97% should be provided to the space or load served at design flow. The flow required for minimum heat transfer establishes the system's flow tolerance. The fluid distribution system should be designed to allow flow to maintain the required tolerance and verify its performance.

Bump test. A test consisting of bumping the part and measuring its response. The part will vibrate at its natural frequency, which shows up as a response peak on the analyzer. Usually the bump test is accomplished by placing an accelerometer on the device under test (DUT) and tapping or bumping the DUT with a rubber hammer.

Procedure. An approach to and execution of a sequence of work operations to yield repeatable or predictable results.

Report forms. Test data sheets arranged in logical order for submission and review. They should also form the permanent record to be used as the basis for future TAB work and/or system maintenance.

Terminal. A point where the controlled medium (fluid or energy) enters or leaves the distribution system. In air systems, these may be variable- or constant-volume boxes, registers, grilles, diffusers, louvers, and hoods. In water systems, these may be heat transfer coils, fan-coil units, convectors, or finned-tube radiation or radiant panels.

2. GENERAL CRITERIA

Effective and efficient TAB requires a systematic, thoroughly planned procedure implemented by experienced and qualified staff. All activities, including organization, calibration of instruments, and execution of the work, should be scheduled. Air-side work must be coordinated with water-side and control work. Preparation includes planning and scheduling all procedures, collecting necessary data (including all change orders), reviewing data, studying the system to be worked on, preparing forms, and making preliminary field inspections.

Air leakage in a duct system can significantly reduce performance, so ducts must be designed, constructed, and installed to minimize and control leakage. During construction, all duct systems should be sealed and tested for air leakage.

Water, steam, and pneumatic piping should be tested for leakage, which can harm people and equipment.

Design Considerations

TAB planning begins with design functions, because most of the devices required for adjustments are integral parts of the design and installation. To ensure that proper balance can be achieved, the engineer should show and specify a sufficient number of dampers, valves, flow measuring locations, and flow-balancing devices; these should be properly located in required straight lengths of pipe or duct whenever possible for accurate measurement. Testing depends on

The preparation of this chapter is assigned to TC 7.7, Testing and Balancing.

system characteristics and layout. Interaction between individual terminals varies with pressures, flow requirements, and control devices.

The design engineer should specify balancing tolerances. Minimum flow tolerances are ±10% for individual terminals and branches in noncritical applications and ±5% for main air ducts. For critical water systems where differential pressures must be maintained, tolerances of ±5% are suggested. For critical air systems, recommendations are the following:

Positive zones:

Supply air	0 to +10%
Exhaust and return air	0 to −10%

Negative zones:

Supply air	0 to −10%
Exhaust and return air	0 to +10%

Balancing Devices. Balancing devices should be used to provide maximum flow-limiting ability without causing excessive noise. Flow reduction should be uniform over the entire duct or pipe. Single-blade dampers or butterfly balancing valves are not acceptable for use as balancing devices because of the uneven flow pattern at high pressure drops. Pressure drop across equipment is not an accurate flow measurement but can be used to determine whether the manufacturer design pressure is within specified limits. Liberal use of pressure taps at critical points is recommended.

Stratification

Normal design minimizes conditions causing air turbulence, to produce the least friction, resistance, and consequent pressure loss. Under some conditions, however, air turbulence is desirable and necessary. For example, two airstreams of different temperatures can stratify in smooth, uninterrupted flow conditions. In this situation, design should promote mixing. Return and outdoor airstreams at the inlet side of the air-handling unit tend to stratify where enlargement of the inlet plenum or casing size decreases air velocity. Without a deliberate effort to mix the two airstreams (e.g., in cold climates, placing the outdoor air entry at the top of the plenum and return air at the bottom of the plenum to allow natural mixing), stratification can be carried throughout the system (e.g., filter, coils, eliminators, fans, ducts). Stratification can freeze coils and rupture tubes, and can affect temperature control in plenums, spaces, or both.

Stratification can also be reduced by adding vanes to break up and mix the airstreams. No solution to stratification problems is guaranteed; each condition must be evaluated by field measurements and experimentation.

3. AIR VOLUMETRIC MEASUREMENT METHODS

The pitot tube traverse is the generally accepted method of measuring airflow in ducts. The primary objective for other ways to measure airflow at individual terminals is to establish repeatable measurement procedures that correlate with the pitot tube traverse.

Laboratory tests, data, and techniques prescribed by equipment and air terminal manufacturers must be reviewed and checked for accuracy, applicability, and repeatability of results. Conversion factors that correlate field data with laboratory results must be developed to predict the equipment's actual field performance.

Air Devices

Airflow-measuring instruments should be field verified by comparing to pitot tube traverses to establish correction and/or density factors.

Check correction factors given by air diffuser manufacturers by field measurement and comparing them to actual flow measured by pitot tube traverse.

A capture hood is frequently used to measure device airflows. Correction factors should be established by field measurement and comparison to actual flow measured by pitot tube traverse for hood measurements with varying flow and deflection settings.

Rotating vane anemometers are commonly used to measure airflow from sidewall grilles. Effective areas (correction factors) should be established with the face dampers fully open and deflection set uniformly on all grilles. Correction factors are required when measuring airflow in open ducts (i.e., damper openings and fume hoods [Sauer and Howell 1990]).

Duct Flow

The preferred method of measuring duct volumetric flow is the pitot tube traverse average as detailed in ASHRAE *Standard* 111. When using airflow measuring stations, these airflow measurements should be checked against a pitot tube traverse.

Power input to a fan's driver should be used as only a guide to indicate its delivery; it may also be used to verify performance determined by a reliable method (e.g., pitot tube traverse of system's main) that considers possible system effects. For some fans, the flow rate is not proportional to the power needed to drive them. In some cases, as with forward-curved-blade fans, the same power is required for two or more flow rates. The backward-curved-blade centrifugal fan is the only type with a flow rate that varies directly with power input.

If an installation has an inadequate straight length of ductwork or no ductwork to allow a pitot tube traverse, follow Sauer and Howell's (1990) procedure: use a vane anemometer to read air velocities at multiple points across the face of a coil to determine loss coefficient.

3.1 MIXTURE PLENUMS

Approach conditions are often so unfavorable that the air quantities comprising a mixture (e.g., outdoor and return air) cannot be determined accurately by volumetric measurements. In such cases, the mixture's temperature indicates the balance (proportions) between the component airstreams. Temperatures must be measured carefully to account for stratification, and the difference between outdoor and return temperatures must be greater than 10 K. The temperature of the mixture can be calculated as follows:

$$Q_t t_m = Q_o t_o + Q_r t_r$$

where

Q_t = total measured air quantity, %
Q_o = outdoor air quantity, %
Q_r = return air quantity, %
t_m = temperature of outdoor and return mixture, °C
t_o = outdoor temperature, °C
t_r = return temperature, °C

Pressure Measurement

Measured air pressures include barometric, static, velocity, total, and differential. For field evaluation of air-handling performance, pressure should be measured per ASHRAE *Standard* 111 and analyzed together with manufacturers' fan curves and system effect as predicted by AMCA *Standard* 210. When measured in the field, pressure readings, air quantity, and power input often do not correlate with manufacturers' certified performance curves and proper correction is necessary.

Pressure drops through equipment such as coils, dampers, or filters should not be used to measure airflow. Pressure is an acceptable means of establishing flow volumes only where it is required by, and performed in accordance with, the manufacturer certifying the equipment.

4. INSTRUMENTS

No one established procedure applies to all systems. The bibliography lists sources of additional information.

Air Testing and Balancing

Inclined Manometer. The inclined manometer is made of a single tube, inclined (usually 10:1 slope), to enlarge the reading. Alcohol or special oils are normally used in place of water. Such oils have a lower specific gravity than water which serves to further enlarge the reading. Manometers using these fluids have scales calibrated in pascals corresponding to the pressure indicated on the oil of a known specific gravity. Recommended for use with pitot tubes or static pressure probes.

The **combination vertical-inclined manometer** is constructed of an inclined fluid column with a scale of 0 to 250 or 500 Pa connected to a vertical fluid column with scales of 1250 or 2500 Pa. Recommended for use with pitot tubes or static pressure probes.

Limitations:

- Not to be used to measure air velocities less than 3 m/s. A micromanometer, hook gage, or another sensitive instrument should be used to decrease the uncertainty of measurements between 2.3 and 3 m/s.
- The manometer must be carefully leveled during use and held in a rigid position so that when zero pressure is registered, the end of the meniscus arc of the fluid exactly bisects the center of the zero line.
- Calibration is required. The manometer must be verified by comparison to a recently calibrated reference instrument. If the reading on the instrument to be verified is not within 2% of the reading on the reference instrument, then the manometer must be calibrated by an ISO-certified air speed laboratory before it can be used.

Pitot Tube. A pitot tube, used in conjunction with a manometer, provides a basic method of determining the air velocity within a duct. The typical pitot tube is of a double concentric tube construction, consisting of an 3.2 mm OD inner tube concentrically located inside a 7.9 mm OD outer tube that measures total pressure. The outer static tube has eight equally spaced 1.02 mm diameter holes around the circumference of the outer tube, located 63.5 mm back from the nose or open end of the pitot tube tip. At the base (tube connection) end, the inner tube is open ended, as is the head. The outer tube has a side outlet tube connector perpendicular to the outer tube, directly parallel with and in the same direction as the head end of the pitot static tube. Recommended for measuring an airstream's

- Total pressure, by connecting the inner tube outlet connector to one side of a manometer or draft gage
- Static pressure, by connecting the outer tube side outlet connector to one side of a manometer or draft gage
- Velocity pressure, by connecting both the inner and outer tube connectors to opposite sides of a manometer or draft gage.

When used with a manometer or micromanometer, the pitot tube is very reliable and rugged. Its use as a direct measurement tool is preferred over many other methods for the field measurement of air velocity, system total air, outdoor air, return air quantities, fan static pressure, fan total pressure, and fan outlet velocity pressures where such measured quantities may be required and within the range or capabilities of the instrument.

Instruments that may be used with the pitot static tube include the following:

- Micromanometer: very low pressure differential, less than 250 Pa
- Inclined manometer: moderate pressure differential, 0 to 2500 Pa
- U-tube manometer: medium pressure differential, greater than 2500 Pa
- Diaphragm-type pressure gage
- Electronic differential pressure meters

Limitations:

- Pitot tubes should not be used to measure velocities below 2.3 m/s, regardless of the electronic sensors used to identify differentials in pressure, because of the inherent high uncertainties in pitot measurement.
- Accuracy depends on uniformity of flow and completeness of traverse.
- A reasonably large space is required adjacent to duct penetrations for maneuvering the instrument.
- Care is needed to avoid pinching or puncturing instrument tubing.
- Because of the distance between the impact and static holes, the pitot static tube cannot be used to measure flow through orifice-type openings.
- Pitot static tubes are susceptible to plugging in airstreams with heavy dust or moisture loadings.
- Acceptance of the standard pitot static tube rests in its accuracy on the correct determination of the static pressure. The total pressure is not affected by yaw or angularity up to approximately 8° on either side of parallel flow. The static pressure, however, is extremely sensitive to direction of flow.

Accuracy of field measurement. Rigorous error analysis shows that flow rate determinations by the pitot static tube and manometer combination method can range from 5 to 10% error. Experience shows that qualified technicians can obtain measurements within 5 and 10% accuracy of actual flow under good field conditions. It has also been determined that suitable traverse conditions do not always exist, and measurements can then exceed a ±10% error rate.

Chronometric Tachometer. The chronometric tachometer is a hand-held instrument that combines an accurate timer and a revolution counter. After the instrument tip is placed on the rotating shaft, pushing the stopwatch button simultaneously activates the counter and the stopwatch. After the timer has run for either 3 or 6 s, the instrument stops counting revolutions even though it is still in contact with the rotating shaft. The scale is calibrated to give readings directly in rpm. Instrument accuracy is within ±0.5% of full scale. Hand tachometers (e.g., dial face [Eddy current], solid-state with digital readout) can produce instantaneous rpm measurement readings, with accuracy within ±1% of full scale. Tachometers are recommended for determining the speed of any shaft having a countersunk end.

Limitations:

- The shaft end must be accessible and countersunk.
- Calibration is required. Readings must be verified with a recently calibrated chronometric tachometer on each project. If the reading is not within ±2% of the recently calibrated tachometer, have the instrument recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within one-half of a scale division mark.

Clamp-on Volt-Ammeter. This instrument has trigger-operated, clamp-on transformer jaws that allow current readings without interrupting electrical service. Most volt-ammeters have several scale ranges, in amperes and volts. Two voltage test leads are furnished that may be quick-connected to the bottom of the volt-ammeter opposite the end used for measuring current. Some models have a built-in ohmmeter. Instrument accuracy is within ±3% of full scale. Recommended for measuring operating voltages and currents of electric motors and of electric resistance heating coils.

Limitations:

- The proper range must be selected. It is desirable for readings to occur about mid-scale. When in doubt, begin with the highest range for both voltage and current scales. Accuracy of reading low currents can be improved by looping the conductor wire around the jaw once and dividing the current reading by 2.

- Depending on conditions at the point of measurement and the size of the volt-ammeter, access for measurement may be restrictive. Caution is required, particularly when taking measurements under confined conditions.
- To avoid distortion of current readings by other fields, move the meter along the wire to verify that the reading remains constant.
- Calibration is required. Readings must be verified with a recently calibrated clamp-on volt-ammeter on each project. If the reading is not within ±2% of the recently calibrated instrument, have the instrument recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is ±3% of full scale.

Anemometers. There are several types of anemometers. The **deflecting vane** anemometer consists of a pivoted vane enclosed in a case. As it passes through the anemometer, air exerts a pressure on the vane. Movement of the vane is resisted by a hairspring. The instrument gives instantaneous readings of directional velocities on an indicating scale, and can be supplied with various remote- and direct-connected measuring tips (jets). Recommended for measuring air quantities through both supply and return air terminals using the proper air terminal factor A_k (effective area) for airflow calculation, as well as for indicating low velocities (0.5 to 1.5 m/s) where the instrument case itself with the appropriate probe attached is placed in the airstream.

Limitations:

- It should not be used in extremely hot, cold, or contaminated air.
- It is affected by static electricity.
- The instrument duct probe is sensitive to presence and proximity of duct walls, and tends to read high on the suction side and low on the discharge side of a fan.
- Accuracy is affected by position.
- Calibration is required. Readings must be verified with a recently calibrated deflecting vane anemometer on each project. If the reading is not within ±2% of the recently calibrated instrument, have the instrument recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within ±10% when the instrument is calibrated and used in accordance with the manufacturers' recommendations. Air inlet and outlet device flow A_k factors are a function of duct and damper conditions, which affect velocity immediately before the device. Use under conditions not identical to the manufacturers' test conditions produces measurement error. The instrument must be calibrated in the field for correction factor by pitot tube traverse within the limitations of the system.

The **revolving vane** or **propeller anemometer** can be either mechanical or direct-reading digital. For the **mechanical type**, a mechanical propeller or revolving vane anemometer consists of a light wind-driven wheel connected through a gear train to a set of recording dials that read the linear feet of air passing through the wheel in a measured length of time. The instrument is made in various sizes, but 75, 100, and 125 mm are the most common. Each instrument requires individual calibration. The required instrument accuracy of calibration is 1 to 3% of scale (using a corrective chart). Recommended for measuring supply, return, and exhaust air quantities at air inlets and outlets, as well as air quantities at the faces of return air dampers or openings, total air across the filter or coil face areas, etc.

The **direct-reading digital type** differs from the mechanical type mainly in that it uses a powered electronic circuit to convert a pulse generated by the rotating vane into a small electric current to give a meter reading calibrated directly in air velocity units. Generally, these instruments have microprocessor software to compensate for any nonlinearity. Recommended for measuring supply, return, and exhaust air quantities at air inlets and outlets; air quantities at the faces of return air dampers or openings; total air across the filter or coil face areas, etc.

Limitations:

- For mechanical anemometers, each reading must be corrected by the instrument's calibration chart.
- The air inlet or outlet device manufacturers' specified flow A_k factor for the device must be used in computing air quantities.
- Total inlet area of the instrument must be in the measured airstream.
- It is not suitable for measurement in ducts.
- It is fragile and cannot be used in dusty or corrosive air.
- The instrument has a turbine wheel of very low inertia, so be cautious regarding reliability of readings in nonuniform, turbulent, or stratified airstreams. This is likely to occur downstream of dampers, face-and-bypass coils, or any device that causes turbulence in the airstream being measured.
- The mechanical anemometer is not direct reading and must be timed manually.
- At low velocities, the instrument's friction drag is considerable. To compensate, a gear is commonly used. Thus, the correction is additive at the lower range and subtractive at the upper range, with the least correction in the middle of the range. Most of these instruments are not sensitive enough for use below 1 m/s, although ball-bearing models claim ranges down to 0.15 m/s. The useful range is from 1 to 10 m/s.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the anemometer recalibrated by a qualified testing lab.

Accuracy of field measurements:

- Smooth flow: ±5% of reading above 1 m/s. Not recommended for velocities below 1 m/s.
- Nonuniform flow: ±30% (or greater, for direct-reading digital type).
- The instrument must be calibrated in the field for a correction factor by pitot tube traverse within the limitations of the system.

Operation of the **thermal anemometer**, which can be either single point or omnidirectional, depends on the fact that the resistance of a heated element changes with its temperature. As airflows over the element in the probe, the temperature of the element changes from its temperature in still air. The resistance change is indicated as a velocity on the indicating scale of the instrument. Instruments are available using a heated thermocouple, heated thermistor, or a heated wire. They have similar characteristics regarding uses, limitations, and accuracy. Some instruments are also provided with temperature scales that can be used by setting the proper selector button. Others can measure static pressure with provided accessories. Recommended uses include measuring the following:

- Very low air velocities, such as room air currents and airflow in hoods (0.05 to 3.0 m/s)
- Air movement at grilles and diffusers
- Velocity measurements in ducts

Limitations:

- The instrument probe is very directional for velocity readings and must be located at the exact location and orientation on the air inlet or outlet device, as specified by the air device manufacturer.
- Probes are subject to fouling by dust and corrosive air.
- The instrument probe must be used in the direction of calibration.
- In general, these instruments should not be used in flammable or explosive atmosphere. However, there are special thermal anemometer probes available for use in these environments.

- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the anemometer recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is ±3% above 0.5 m/s. The instrument must be calibrated in the field for correction factor by pitot tube traverse within the limitations of the system.

Thermometers. Dial thermometers are of two general types: stem and flexible capillary. Their dial heads can be 45 to 125 mm, with stainless steel encapsulated temperature sensing elements. Hermetically sealed, they are rust-, dust-, and leakproof and are actuated by sensitive bimetallic helix coils. Some can be field calibrated. Sensing elements range in length from 60 to 600 mm and are available in many temperature ranges with or without thermometer wells.

Small dial thermometers usually use a bimetallic temperature-sensing element in the stem. Temperature changes cause a change in the twist of the element, and this movement is transmitted to the pointer by a mechanical linkage.

The flexible capillary dial thermometer has a rather large temperature-sensing bulb connected to the instrument with a capillary tube. The instrument contains a Bourdon tube, the same as in pressure gages. The temperature sensing system, consisting of the bulb, capillary tube, and Bourdon tube, is charged with either liquid or gas. Temperature changes at the bulb cause the contained liquid or gas to expand or contract, resulting in changes in the pressure exerted within the Bourdon tube. This causes the pointer to move over a graduated scale as in a pressure gage, except that the thermometer dial is graduated in degrees. The advantage of this type is that it can be used to read temperature in a remote location. In using a dial thermometer, the stem or bulb must be immersed a sufficient distance to allow this part of the thermometer to reach the temperature being measured.

Recommended uses include checking both air and water temperature in ducts and pipe thermometer wells.

Limitations:

- Dial thermometers have a relatively long time lag, so enough time must be allowed for the thermometer to reach equilibrium and the pointer to come to rest.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the dial thermometer recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within one-half of a scale division mark.

There are four basic types of **digital electronic** thermometers: thermocouple, thermistor, resistance temperature detector (RTD), and diode sensors. They consist of a portable, handheld, battery-powered, digital thermometer connected by a short cable to various interchangeable probes that are designed for sensing the temperature of air or other gases, immersion in liquids, or contact with a solid surface. Some instruments have a calibration reference, which allows calibrating out offsets introduced by mechanical shocks, ambient temperature variations, or component drift. Some instruments can switch between I-P and SI units and between resolutions of 0.1 and 1.0. Response times are 1 to 10 s for liquids and solids, and 5 to 50 s for gases. Instrument accuracy is ±0.3°C where the range is below 350°C and ±0.8°C for broader ranges. The lower-range instruments should be used unless the expected measurements will be out of their range.

Recommended uses include all TAB temperature measurements, including air and other gases, liquids, and surfaces of pipes and other components with the appropriate probe. The manufacturers' directions must be followed regarding proper use of probe and maximum allowable temperature for the probe and or thermometer. Equipment is available to measure from –230 to 1230°C. A common range is –10 to 120°C.

Limitations:

- Batteries must be recharged or changed when required.
- In piping applications, it should be remembered that the surface temperature of the pipe is not equal to the fluid temperature and that a relative comparison is more reliable than an absolute reliance on readings at a single circuit or terminal unit.
- Be sure measurement is taken at least as long as response time.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the digital electronic thermometer recalibrated by a qualified testing lab.

Accuracy of field measurements. When properly used, the instrument accuracy shall be attainable in the field.

Fluid Testing and Balancing

Pyrometers. Pyrometers normally used in measurements of surface temperatures in heating and air conditioning applications use a thermocouple as a sensing device and a millivoltmeter (or potentiometer) with a scale calibrated for reading temperatures directly. A variety of types, shapes, and scale ranges are available. The required instrument test accuracy is ±1% of full scale. Recommended uses include

- Balancing water circuits thermally, whenever balancing with flow measurements are not practical.
- For evaluation of some types of boilers, furnaces, ovens, etc., where temperatures are over 40°C.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the pyrometer recalibrated by a qualified testing lab.

Limitations. In piping applications, remember that the surface temperature of the conduit is not equal to the fluid temperature, and that a relative comparison is more reliable than an absolute dependence on readings at a single circuit or terminal unit.

Accuracy of field measurements. Accuracy is within one-half of a scale division mark.

Calibrated Pressure Gage. Test gages should be at least Grade A quality; have Bourdon tube assemblies made of stainless steel, alloy steel, monel, or bronze; and have a nonreflecting white face with black lettering conforming to ASME *Standard* B40.1-1985. Test gages are usually 90 to 150 mm in diameter, with bottom or back connections. Many dials are available with pressure, vacuum, or compound ranges. Minimum accuracy is within 1% of full scale. Recommended uses are checking pump pressures; coil, chiller, and condenser pressure drops; and pressure drops across orifice plates, venturis, and other flow calibrated devices.

Limitations:

- Anticipated working pressure range is in the middle two-thirds of the instrument's scale range, and the gage should not be exposed to pressures greater than the maximum dial reading. Where there is exposure to vacuum, use compound gage.
- Reduce or eliminate pressure pulsations by installing a snubber or needle valve in waterline.
- Do not mount on vibrating equipment or piping. Wall mounting is preferred; another alternative is to install pressure/temperature test ports that can be used with a portable stem probe and gage (or thermometer) through an elastic, durable, self-sealing material. Cap the test port when not in use for additional sealing security.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within

±2% of the recently calibrated instrument, have the pressure gage recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within one-half of a scale division mark.

Differential Pressure Gage. This instrument is a dual-inlet, Grade A, dual Bourdon tube pressure gage with a single indicating pointer on the dial face that indicates the pressure differential between two measured pressures. It can be calibrated in Pa or kPa. The required instrument accuracy minimum is ±1% of full scale. At lower differential pressure ranges, recommended for use with water hose flexible connectors for water distribution balancing (similar to how a mercury U-tube manometer is used). At higher differential pressure ranges, these instruments can be used in lieu of the two combination high-pressure gages mounted on the mercury U-tube manometer board.

Limitations:

- Some applications require use of a snubber or needle valve. A three-valve cluster for shutoff and bypass is necessary to prevent over-pressure damage when used as a portable test gage.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the pressure gage recalibrated by a qualified testing lab.

Accuracy of field measurements. Within one-half of a scale division mark.

Differential Pressure Manifold Gage. This is a single-port, Grade A, Bourdon tube, calibrated test gage attached to the bull of a tee. Each branch is fitted with a tight shutoff ball valve and a length of hose, terminating in a union and nipple for attachment to a conventional gage port at each measuring point. Recommended use is to indicate pressure at each point by alternating valve opening and closing. Using a single gage eliminates potential error from using two separate permanently mounted gages, which are subject to possible vibration damage and differences in calibration.

Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the pressure gage recalibrated by a qualified testing lab.

Other Air or Fluid System Measurements

Revolution Counter (Odometer) and Timing Device. The revolution counter is a small handheld counting device that is pressed to the center of a rotating shaft for a period of 30 to 60 s. Reasonable accuracy can be obtained by using a good watch with a sweep second hand or a digital watch if a stopwatch is not available. Recommended use is for determining shaft speed on any shaft having an accessible shaft end with a countersink.

Limitations:

- Not to be used on flat-ended shafts without the correct adaptor. Otherwise, slip and inaccurate readings are inevitable.
- Some types have a clutch engagement in which a certain amount of force is required to activate the recording mechanism.
- Must be used and coordinated with an accurate timepiece.
- Normally cannot be reset to zero; the shaft speed measured is the difference between the initial and final instrument readings divided by the time interval.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the odometer recalibrated by a qualified testing lab.

Accuracy of field measurement. Accuracy is ±2%, when used properly.

Electronic Tachometer (Stroboscope and Photoelectric). The stroboscope has a controlled high-speed electronic flashing light whose frequency is electronically controlled and adjustable. When the frequency of the flashing light is adjusted to equal the frequency of the rotating machine, the machine appears to stand still. This unit need not be in contact with the machine during use. Instrument accuracy is generally within 1.5% of the indicated value, and within 1% if a magnetic pickup is used.

The **solid-state photoelectric tachometer** is an optional instrument that is pointed at the device to be measured and the revolution speed is directly read on the dial face. A reflective paint or material must be spotted on the rotating device; this spot is counted and electronically integrated over time to give an instantaneous reading. The instruments usually have several ranges, and no electrical or physical contact with the device is necessary. Accuracy is within ±1% of the dial scale reading when properly calibrated.

Recommended use is for measuring rotational speeds when instrument contact with the rotating equipment is not feasible.

Limitations:

- Care must be taken to avoid reading multiples of the actual rpm when using the stroboscope. Readings must be started at the lower end of the scale.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the tachometer recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within one-half of a scale division.

Dual-Function Tachometer. This instrument provides both optical and contact measurements of rotation and linear motions. Many allow a choice of ranges, depending on the application. A digital display always indicates the unit of measurement to identify the operating range. A memory button may be used to recall the last, maximum, minimum, and average readings. Compact size and light weight make for easy operation. Recommended use is for measuring rotation speeds by direct contact or by counting the speed of a reflective mark.

Limitations:

- Battery operated
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the tachometer recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within one-half of a scale division.

Low-Density Fluid U-Tube Manometer. The manometer is a simple, useful way to measure partial vacuum and pressure. In its simplest form, it consists of a U-shaped glass tube partially filled with liquid; a difference in height of the two fluid columns denotes a pressure difference in the two legs. Recommended uses include measuring pressure drops above 250 Pa across filters, coils, eliminators, fans, grilles, and duct sections; and measuring low manifold gas pressures.

Limitations:

- To ensure accuracy, manometer tubes must be chemically cleaned and filled with the correct fluid.
- U-tube manometers cannot be used for readings under 250 Pa.
- Reading accuracy depends on the user's ability to gage the level in each tube simultaneously; this is especially troublesome if surges occur in the flow being measured.

Diaphragm-Type Differential Pressure Gage. A dry diaphragm-operated differential pressure gage that uses a calibrated spring-loaded horseshoe magnet lever operated from the differential pressure on the diaphragm, causing rotation of a highly magnetic permeable helix that positions a pointer on the pressure scale. The pressure gage is operated by magnetic field linkage only, so it is extremely sensitive and accurate; its construction design makes it resistant to shock and vibration. The helix rotates on antishock-mounted sapphire bearings. A zero-calibration screw is located on the plastic cover. Common ranges are 0 to 125, 250, or 1250 Pa. There are approximately 30 available pressure ranges. The minimum accuracy of the instrument is ±2% of full dial range. Recommended for use with pitot tube or with static probe, or with specially constructed induction unit primary air total pressure measuring tip for primary air distribution balancing on high-pressure induction systems.

Limitations:

- Should not be used in preference to liquid or electronic manometer.
- Readings should be made in mid-scale of range.
- Should not be mounted on a vibrating surface.
- Should be held in same position as when zeroed
- Should be checked against a known pressure source with each use
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the pressure gage recalibrated by a qualified testing lab.

Smoke Devices. These devices are generally used in special studies of airflow and duct leakage. Candles are available in various sizes and durations of burning time. The chemical element in the smoke is zinc chloride.

Sticks are activated by crushing the end of the device, releasing a smoke stream approximately double that of a cigarette. **Guns** generally use a chemical that readily combines with atmospheric moisture. A **cartridge** produces 500 to 1000 puffs of smoke, or releases the same quantity in a steady stream. **Borazine guns** emit dense white clouds of smoke that tend to remain suspended in air for some time. A valve adjustment regulates the discharge.

Recommended uses include determining the direction and observing the velocity and pattern of airflow in room studies, hoods, filters, etc. Discharge patterns from exhaust systems, driers, hoods, and stacks can be identified.

Limitations:

- Some smoke devices may be toxic, and protective apparatus may be required. After extreme use, special removal efforts may be necessary.
- Smoke devices may activate fire and or smoke alarms in ductwork, computer rooms, or critical areas of the building; or cause panic if occupants are not notified.

Flow Capture Hoods. A conical or pyramid shaped hood may be used to collect the airflow from a terminal and guide it over a flow measuring system which reads directly in litres per second. The instrument can be a swinging vane anemometer, differential pressure air gage (diaphragm type), manometer, or thermal anemometer. The balancing cone should be tailored for the particular job. The large end of the cone should be sized to fit over the complete air inlet or outlet device and should have a seal to eliminate air leakage. The cone should terminate in a straight section with factory designed and calibrated pressure grids, straighteners, and instruments.

Recommended uses include proportionally balancing air distribution devices.

Limitations:

- Should not be used where discharge velocities exceed 10 m/s.
- Recognize that the device generally redirects the normal pattern of air discharge and that it contributes an artificially imposed pressure drop in the branch of the air terminal being measured. These may result in a decrease in the delivered airflow of the outlet.
- Contact the air inlet and outlet device manufacturer for details in using this instrument with their devices.
- The instrument must be calibrated for the intended use. For use with supply distribution devices, the instrument should have been calibrated in the supply mode. For use with return distribution devices, the instrument should have been calibrated in the return mode.
- Calibration is required. Flow-measuring instrument and hood assembly should be field checked with a velocity traverse. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the pressure gage recalibrated by a qualified testing lab.

Accuracy of field measurements. If the hood is properly shaped and positioned at the air terminal, accuracy of field measurements will be within the limitations of the flow reading instrument.

Micromanometer (Hook Gage). These instruments are designed to read small differences in air pressure accurately and usually have a wide scale range. Most scales read pressures of 0 to 1000 Pa, in hundredths of 10 Pa on the vertical scale, and thousandths of 1 Pa on a vernier scale.

Different versions of this instrument exist. The most common type contains two glass vials about 50 to 75 mm in diameter. A pointed needle or hook is positioned by a micrometer adjustment until the point dimples the water surface but does not break the surface tension. The difference in level is determined in micrometer readings.

Another variation of this instrument has a single vial or well and an inclined scale. The well is positioned by a micrometer or vernier adjustment. It is very important that all micromanometers, including the electronic units, be accurately leveled.

The solid-state electronic hook gage will measure positive, negative, or differential pressures to ±0.0625 Pa over a 0 to 500 Pa range. It can also be used with pitot tubes for accurate measurement of air velocities as low as 2.3 m/s. Recommended uses include readings at hoods, perforated ceilings, etc.; calibrating other instruments; and measurements of velocities between 2.3 and 3.0 m/s, when used with a standard pitot tube.

Limitations:

- Difficult to use with pulsating pressures.
- Stability and leveling requirements make the instrument difficult to use in the field.
- Generally not as sensitive as thermal anemometers below 3 m/s, when used with a standard pitot tube.

Double Reverse Tube. Other names for this device include impact reverse tube, combined reverse tube, and type S tube. It consists of two stainless steel tubes approximately 9.5 mm OD, permanently joined lengthwise. The tubes open facing opposite directions at the probe end with open ends at the base for connection to a manometer. (See Figure 1.) Recommended for use in dirty or wet airstreams where the amount of particulate matter in the airstream impairs the use of a pitot static tube. The instrument can be used to measure total pressure, static pressure, and obtain velocity pressure.

Limitations:

- Requires a large (19 mm) duct hole for insertion.
- The tube requires calibration and must be used in the same orientation as calibrated. The flow direction should be marked on the tube.
- The tube cannot be used to measure static pressure directly. It must be connected to two manometers and static pressure must be calculated.
- Tube ends must be kept smooth, clean, and free of burrs.

Accuracy of field measurements. Accuracy for field use of the combination of a double reverse tube with manometers is ±10%.

Clamp-On AC Power Meter (Wattmeter). The clamp-on type power meter has trigger-operated, clamp-on transformer jaws, like a voltammeter. This instrument measures true rms voltage and current, in addition to power in single phase or balanced three phase circuits. Compared with mean value measurement, true rms measurement is especially valuable for distorted waves, such as noise and multiplexed signals. Typical ranges are 20 to 600 V rms, 2 to 200 A rms, and 2 to 200 kW; or 20 to 600 V rms, 0.2 to 20 A rms, and 0.2 to 20 kW. Recommended uses include measurement of single, split-phase, and three-phase power sources. Given motor efficiency and power factor, power draw can be related to motor power on a fan or pump curve and the operating point determined.

Limitations:

- Caution is required, particularly when taking measurements under confined conditions.
- Readings below 10% of input range are not recommended.
- Batteries must be checked before use.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the pressure gage recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within ±1% of reading plus 0.5% of range

Recording Instruments. Recording instruments exist in wide variety, available to record any measurement taken by an instrument, such as dry-bulb temperature, wet-bulb temperature, relative humidity, and operating periods of cycling electrical equipment. The recording charts may be either continuous strip or circular, with chart rotation once every 24 h or 7 days. Some instruments are available with one or more remote bulbs. Recommended for obtaining round-the-clock data on the operation or performance of equipment. They are particularly useful for studying and diagnosing questionable operation in refrigerators, greenhouses, processing rooms, ovens, and comfort air conditioning systems.

Limitations. Some judgment must be used in the application of recording instruments. There are great differences in quality, accuracy, and cost. Care must be used to start the instrument at the correct time of day, and on the right day when a seven-day chart is used. Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the pressure gage recalibrated by a qualified testing lab.

Accuracy of field measurements. Carefully study the manufacturer catalog data for instrument accuracy. It is important to read and observe specific operating instructions to obtain the published accuracy from a given instrument.

Humidity-Measuring Devices. A number of instruments are available to measure the level of moisture in air, including

- Battery-powered hygrometer
- Powered dew point indicator
- Powered psychrometer with built in pump and fan
- Digital psychrometer with built-in reservoir and fan

Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the instrument recalibrated by a qualified testing lab.

Recommended use varies by type; hygrometers give direct, rapid relative humidity readings, and digital psychrometers provide dry- and wet-bulb depression within approximately 30 s.

Accuracy of field measurements. Hygrometers have an accuracy of ±2 to 3% rh in the 20 to 95% rh range. Psychrometer thermometer readings have an accuracy of ±0.3 K.

Barometer. A barometer measures atmospheric pressure, which is required to correct all airflow readings to standard conditions. A Bourdon tube type with accuracy of 1% of full scale should be used.

Barometric pressure information may also be obtained from weather radio stations or airports in the immediate vicinity. Actual pressure at local elevation must be used for air density calculations.

Fluid System Digital Electronic Differential Pressure Meter. This instrument measures the differential pressure across an element in a system when flow is present, providing digital readings in the range of 1 to 150 kPa. Some instruments include a temperature probe for a range of 0 to 120°C, hoses with snap-on fittings, and automatic air purging. A computer is available for calculating the flow in a range of 0.01 to 300 L/s and computing the hand wheel setting of compatible valves by proportional balancing procedures. Maximum working pressures can be up to 2060 kPa (gage).

Recommended uses include measurement of fluid flow, temperature, and differential pressure, as well as computing the setting of compatible valves by proportional balancing procedures.

Limitations:

- The computing feature is limited to compatible valves.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the instrument recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy of differential pressure within 3 kPa or 2% of valve readout (whichever is greater). This same accuracy is true for measurement of flow, done via the computing feature.

Electronic Differential Pressure Meter. This instrument is a portable device which measures differential pressure and gives a digital readout directly in pressure or velocity. Some instruments are also available with adapters and probes to measure flow and temperature. Typical ranges are 0 to 25 kPa for low-density fluids, and 0 to 600 kPa or 0 to 700 kPa for high-density fluids. Temperatures can be measured from –48 to 120°C. Recommended for use with a pitot tube, static probe, flow grid, orifice plate, or special balancing valve. Some instruments can also be combined with a flow-measuring hood. Many instruments have memories, averaging capabilities, and printers.

Limitations:

- When air velocities are below 3 m/s, a micromanometer or hook gage should be used. Some instruments of this type have micromanometer accuracies.
- These instruments are battery powered and require checking batteries and replacing or recharging them.
- Some instruments should not be stored below –10°C or operated below 0°C.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the instrument recalibrated by a qualified testing lab.

Accuracy of field measurements. Experience shows that qualified technicians can obtain measurements that range between ±5 and 10% accuracy under good field conditions. However, good field conditions do not always exist, and measurements can easily exceed ±10% error.

Ultrasonic Flowmeters. This is a device that determines flow through the use of acoustic signals, measured in design units (e.g., litres per second). The ultrasonic flow metering station is either an integral part of the piping system or a strap-on meter. In either case, there is no intrusion into the pipe or liquid flow that would generate a pressure drop. There are no moving parts in the flow to maintain or service. Two distinct types of ultrasonic flow meters exist: a transit-time device for HVAC or clear water measurement, and a

Doppler-effect device for flows containing a required volume of particulate in the liquid. Recommended use includes measurement of flow in full pipes; these devices are excellent when low or nonexistent pressure drop is a requirement. These are best for larger pipes, and most manufacturers' specifications are based on flows of 0.3 m/s or greater.

Limitations:

- For Doppler flow meters, liquid must contain particulate or gas bubbles.
- Transit-time flowmeters require liquid to be acoustically transparent (implies low particulate content [e.g., typical lake or river water or cleaner]).
- Portable (strap-on) flowmeters require that pipe details (e.g., diameter, wall thickness, material of construction) are known or determinable. Pipe must be acoustically transparent (both concrete and lined pipe are not).
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the instrument recalibrated by a qualified testing lab.

Accuracy of field measurements.

Doppler Flowmeters:

- Typically within 3 to 5% for strap-on transducers
- Typically within 2 to 3% for integral transducers

Transit-Time Flowmeters:

- Typically within 2 to 3% for strap-on transducers
- Typically within 1 to 2% for integral transducers
- Typically within 0.5 to 1% for integral transducers mounted to a calibrated flow tube

Turbine Flowmeter. This mechanical device uses a wheel placed in the path of the flow. Liquid causes the wheel to turn at speeds relative to the velocity, generating a signal and providing flow information directly in design units (e.g., litres per second) or a milliamp output. Recommended for measurement of flow in pipes with clean fluid flow.

Limitations:

- Care must be exercised to maintain the turbine flowmeter, because wear may affect the wheel bearings.
- Bearings may drag if impurities lodge in them.
- Debris can clog or break the wheel.
- Calibration is required. Readings must be verified with a recently calibrated instrument on each project. If the reading is not within ±2% of the recently calibrated instrument, have the instrument recalibrated by a qualified testing lab.

Accuracy of field measurements. Accuracy is within 2%.

Permanently Installed Airflow Measuring Stations. There are two main types of permanent airflow measuring stations. The **velocity pressure array** comprises a fixed array of velocity pressure measuring devices.

Recommended uses. These stations measure the fan total airflow and distribution of air in branch ducts. Other useful measurements include those of outdoor, return, and relief airflow.

Limitations:

- The required length of straight sections upstream and downstream of the measuring device depends on both velocity of airflow and the effects of the nearest obstruction. The location of the airflow measuring station must be in accordance with the manufacturer's recommendations.
- Inlet velocity magnitude, profile temperature, dust, moisture, and gas products may limit the use of airflow measuring stations.

Accuracy of field measurements. Under ideal conditions, a velocity pressure airflow measuring station should produce an accuracy of ±5% plus the error rate of the pressure sensor. Because of sensitivity to disturbances and duct conditions, the manufacturer's duct placement recommendations or *ASHRAE Handbook—Fundamentals* requirements for measurement with technologies based on velocity-pressure equalizing principles should be observed.

The **thermal dispersion array airflow measuring station** obtains velocity measurements directly using independent measurement points in a fixed array before averaging. Communications options allow technicians to download instantaneous point velocity and temperature data independently from the control system. A remote traverse without time lag between samples is possible either using an infrared reading device or over an RS-485 network using BACnet™ or Modbus® protocols. The independent nature of the sensor data allows for accurate duct area averaging.

Recommended uses:

- Direct measurement of outdoor airflow rates (low flow sensitivity and accuracy, wide operating velocity range, wide temperature range, fewer space restrictions)
- Maintaining fixed volumetric differentials for space pressurization control, using its high repeatability
- As a reference for other velocity and temperature instruments because of their stability and factory calibration (higher precision)
- Any conditioned air velocity, volume, or temperature averaging application that would benefit from highly repeatable measurement

Limitations:

- Performance depends on local conditions, velocity sensor density (number/unit area), and type of the nearest obstructions (upstream and downstream).
- Avoid placement downstream of modulating dampers or immediately upstream of a damper that may close completely.
- The discharge side of duct silencers can be problematic when the measuring station is within the absorption distance of a humidifier or wet coil face.

Accuracy of field measurements. Accuracy should be within ±3% of reading, when placement is within the manufacturer's guidelines.

Multifunction Portable Instruments. Digital electronic instruments are available with a wide selection of probes that can be fitted into the various channel ports of a single handheld meter with various uses, accuracies, and limitations. These uses can be singular (e.g., thermohygrometers for temperature and relative humidity) or many. Types of measurements include temperature of air, gas, and liquids with a wide choice of sensing elements, such as thermocouples or RTDs; pressure of air, gas, and liquids with manometers or pitot tubes; differential air pressure, static pressure, or barometric pressure; and differential water pressure or gage pressure. Amongst the specific tools used are wind vane, hot wire, or pitot tube anemometers; optical, inductive, and rotational tachometers; and water and air quality attachments for pH, conductivity, salinity, and mV, O_2, and ion concentration.

Some instruments have both battery and plug-in AC power; recording memory for downloading onto computers or transmission over RS-232 or RS-500 interface; hold, alternating, and averaging circuits for applications as traverses; relative humidity calibrating devices; and other features.

Individual manufacturers must be consulted for details of accuracy, limitations, usage, and response times of the individual measurements.

Instruments should be calibrated in accordance with ASHRAE *Standard* 111 to verify their accuracy and repeatability before use in the field.

5. AIR TESTING, ADJUSTING, AND BALANCING

This section sets forth requirements for system preparation, obtaining data, and system testing and adjusting. These requirements apply to both new and existing HVAC supply, return, and exhaust systems.

System Preparation

Before air system testing, adjusting, and balancing, obtain and verify the following:

- Obtain updated construction drawings, specifications, approved shop drawings and submittals, addenda, bulletins, and change orders related to air systems.
- Prepare field data forms to record testing and balancing process.
- Obtain system leakage rate data where duct leak testing is specified.
- Verify that fans are installed, rotating correctly with proper rpm, controlled to supply the required airflow rate, and that all installation, start-up, lubrication, and safety requirements have been met.
- Check for clean filters properly mounted and sealed.
- Fire, smoke, automatic, and volume control dampers are operable, accessible, and are in an open or normal position.
- Controls are installed, operable, and calibrated.
- Air terminal devices are installed, operable, and accessible.
- Air outlet and inlet devices are installed and accessible.
- Access doors are installed and secured.

Perform the following in accordance with design documents before beginning air system testing, adjusting, and balancing:

- Verify that all dampers are in an open position and all air terminal devices or automatic air volume control devices are in an acceptable mode.
- Verify that all air inlet or outlet deflectors are in the position indicated by the manufacturer when using A_k factors to determine airflow rate, and obtain correction factors for all velocity measuring instruments.
- Verify that all automatic controls in the system are set in the testing mode and all computer programs have been properly loaded (where applicable) and parameters set.

Air System Testing and Adjusting

Perform the following tests and adjustments before beginning the air system balancing:

- Record nameplate data on fan, motor, and air handling cabinet. Also, record sizes of sheaves, belts, and shafts.
- Test and record fan rate to confirm rated speed.
- Measure and record motor-running amperes and voltages.
- Set system in minimum outdoor air mode, then perform a pitot tube velocity traverse of main ducts and adjust fan speeds for total design supply and return airflow rates. Total design flow must include estimated duct leakage plus 5% of system total to allow for balancing effects. Minimum outdoor air quantities, established by pitot tube velocity traverse or other methods, must be maintained during all system modes.
- For special systems such as variable-air-volume or constant-volume pressure-independent air terminal devices, set system static pressure and proceed to test and balance all of the air terminal devices and their downstream air inlet or outlet devices, ensuring that air terminal device inlet pressure is in the correct range. Air terminal device adjustments must be done per manufacturer literature.

The following steps occur after all air terminal devices and related air inlet or outlet devices are balanced:

- Measure and record the static pressure resistance of the duct system and the static pressure drop across coils, filters, etc., in the cabinet or out in the duct system.
- Measure and record the pressures at fan suction and discharge per the pressure rating required, either static or total.
- After the system is balanced, test the system in the maximum outdoor air mode. If motor overloads or airflow rates are excessive, adjust manual dampers to obtain the same conditions as recorded with minimum outdoor air.
- Measure and record outdoor, return, and supply air temperatures with the system set at minimum outdoor air mode at design airflow or diversity and cooling or heating medium set for design flow. Verify coil capacities using the following formulas:

Sensible Heat

$$\text{Btu/h} = \text{cfm} \times 1.08 \times \Delta T$$

where

1.08 = constant, 60 min/h × 0.075 lb/ft^3 × 0.24 Btu/lb·°F
ΔT = dry-bulb temperature difference between air entering and air leaving the coil. In applications where cfm to conditioned space must be calculated, ΔT is the difference between supply air dry-bulb temperature and room dry-bulb temperature

Total Heat Air-Side

$$\text{Btu/h } t = \text{cfm} \times 4.5 \times \Delta h_{tot}$$

where

4.5 = conversion factor, 60 min/h × 0.075 lb/ft^3
Δh_{tot} = change in total heat content of supply air (enthalpy), in Btu/lb (from wet-bulb temperatures and psychrometric chart or table of properties of mixtures of air and saturated water vapor)

Total Heat Water-Side

$$\text{Btu/h} = \text{gpm} \times 500 \times \Delta T_w$$

where

500 = conversion factor, 60 min/h × 8.33 lbs/gallon × 1 Btu/lb·°F
ΔT_w = temperature difference between the entering and leaving water

Air System Balancing

Traverse Procedure. After the air system has been prepared, balance by the procedures set forth. *Note:* When system characteristics prevent design flow rates, balance the system components to equal percentages of design unless otherwise instructed by the design engineer.

Balancing Submain Air Ducts.

- Perform a pitot tube velocity traverse of each submain duct to determine flow rate through each.
- Adjust the main volume control dampers to provide the required flow through each submain air duct.

Balancing Branch Air Ducts. Balance the airflow in each branch duct by the following procedure:

- Beginning at the submain duct closest to the fan, or with the highest percentage of required flow, perform a pitot tube velocity traverse of each branch on that submain duct run.
- Proceeding from the branch with the highest percentage of required flow, adjust the branch volume control dampers to provide the required flow through each branch duct.
- Proceed to the submain duct with the next highest percentage of required flow, and traverse and adjust each branch per the preceding steps.

- Continue until all branches are balanced.

Balancing Air Terminal Device Flow Rates. After obtaining the required airflow rates in submain and branch ducts, balance each air terminal device by the following procedures:

- Starting at the air terminal device with the highest percentage of design flow and ending with the air terminal device having the lowest percentage of design flow, adjust the air terminal device volume control to provide an airflow rate within 10% of design. *Note:* If balanced properly without excess pressure, then at least one air terminal device on each branch should have the volume control damper fully open. Branch dampers may require readjustment.
- Continue until all air terminal devices are balanced to within 10% of design.

Final Adjusting and Balancing. Upon completion of the preceding steps, obtain final measurements as follows:

- Measure and record the final airflow rates at each air terminal device. If adjusting airflow rate through an air terminal device by 5% or less is required to achieve the final setting within 10% of design, it is not necessary to adjust nearby air terminal devices which have been final measured. Otherwise, nearby air terminal devices should be remeasured and adjusted as required.
- Secure, mark, seal, and record the final setting positions of all volume control dampers installed in submain or branch ducts.
- Measure and record the final airflow rates at velocity traverses in main, submain, and branch ducts. Do not adjust related volume control dampers.
- Measure and record the data, as outlined in Section 9.4 (b), (c), (f), and (g).
- Reset all controls for normal operations.

Air-Side Systems. In addition to the applicable procedures already detailed, the following air-side systems require additional balancing procedures as indicated. *Note:* For systems using fan volume controls, balance at less than 100% volume setting to allow for future pressure loss of wet coils, damper movement, or dirty filter, or simulate pressure losses with volume controls at 100%.

Single-Duct, Pressure-Dependent Systems:

- Operate all associated fans.
- Set the air terminal devices being testing on full cooling or for diversity and read all air outlet devices on the system.
- Take static pressures at all system components.
- Proportionally balance the air terminal devices. Start with the air terminal device with the highest percent of design airflow, and proportionally balance all VAV air terminal devices. This is done by setting the air terminal devices to full cooling (maximum airflow) and adjusting the manual volume damper in the inlet to the air terminal device. There must be adequate static pressure at all times in the primary air duct.
- Proportionally balance the air inlet or outlet devices.
- Measure and record the final total airflow rate by pitot tube traverse with system set for maximum airflow.
- Measure and record the data as detailed in Section 8.4 (b), (c), (f), (g), and (i), plus the duct static pressure sensed by the static pressure probe for automatic control of supply duct pressure existing when fan is at design flow rate.
- Reset all controls for normal operation.
- At the completion of balancing,
  - The inlet manual damper to at least one VAV air terminal device in the system will be fully open.
  - At least one damper in each branch duct will be fully open.
  - At least one air inlet or outlet device on each branch duct will be fully open.

Multizone Systems:

- Operate all fans (supply, return, and exhaust) associated with the system at or near design speeds.
- Take initial static pressure measurements at all system components.
- Take total air measurements. Determine total airflow quantity for each zone by pitot tube traverse unless impractical to do so. Take traverses as close to the unit as practical. Where the quantity cannot be obtained by pitot tube traverse, use the sum of the outlet quantities as the total airflow of the zones. Record this information on the report forms. If the system has diversity, determine the diversity ratio and keep the proportion of cooled air to total-volume constant during the balance by setting enough zones to full cooling to equal the design flow through the cooling coil. The remaining zones will be set to minimum flow.
- Check zone damper operation. Modulate the zone mixing dampers and measure the supply fan's motor amperage to ensure that motor overloading does not occur. Check amperage with the system in full cooling, full heating, and economizer modes to determine where maximum brake power occurs. Check that the unit's mixing dampers are operating correctly with minimal leakage. Depending on circumstances, this should be done visually by reading temperatures or using static pressure drops. Also verify that all zone mixing dampers are controlled by the proper space thermostat.
- Set zones being tested on full cooling or for diversity.
- Proportionally balance the zones. Using the data from the pitot tube traverses or reading the outlets, determine which zones are over or under design airflow. If any zone is especially low, investigate and correct for any blockages. To balance the zones, start with the highest zone and adjust each zone's manual balancing damper until the airflow is within 10% of the desired amount.
- To balance the branches, start with the highest branch and adjust the branch damper until the airflow is within 10% of the desired amount. Use the total of the air inlet or outlet devices on the branch or balance with the traverses. After the highest branch is adjusted to within 10% of desired flow, go to the next highest branch and adjust it accordingly. Continue adjusting each branch from the highest to the lowest. After all the branches have been adjusted, go back and recheck each branch, because there is usually some interaction between branches, and readjustment may be necessary.
- After all the branches are adjusted to within 10% of desired airflow, proceed with balancing the air inlet or outlet devices. Read all the air inlet or outlet devices and determine which air inlet or outlet devices have excessively great airflow and adjust them first, regardless of their location. Continue balancing until all the air inlet or outlet devices have been adjusted. Make one or more passes until an acceptable balance is obtained.
- As all the air inlet or outlet devices have been proportionally balanced to each other by branch, an adjustment at the branch damper will increase or decrease all the air inlet or outlet devices on that branch proportionally.
- Measure and record the final total airflow rate by pitot tube traverses in the heating and cooling mode with system set for maximum duct airflow.
- Measure and record the data required in Section 8.4 (b), (c), (f), (g), and (i), plus the duct static pressure sensed by the static pressure probe for automatic control of supply duct pressure existing when fan is at design flow rate.
- Reset all controls for normal operation.
- At the completion of balancing,
  - At least one air inlet or outlet device balancing damper will be fully open on every zone.
  - At least one zone balancing damper will be fully open.

- Reset the system to normal operating conditions.

Single-Duct, Fan-Powered Pressure- Systems:

Fan configurations vary among air terminal devices in fan-powered systems. The internal fan may be in series with the primary air for continuous airflow, or it may be in parallel with the primary air for intermittent airflow.

Airflow from these fans is controlled by various methods, such as multiple wiring for three-speed control, silicon-controlled rectifiers (SCR) for multiple-speed control, or manual dampers at the fan discharge. Consult the air terminal device manufacturer for the proper operation and setting of the flow control.

- Operate all associated fans.
- Set the air terminal devices being tested on full cooling or for diversity.
- Take static pressures at all system components.
- Proportionally balance all air terminal devices. Start with the air terminal device with the highest percent of design airflow, and proportionally balance all VAV air terminal devices. This is done by setting the air terminal devices to full cooling (maximum airflow) and adjusting the manual volume damper in the inlet to the air terminal device. There must be adequate static pressure at all times in the primary air duct.
- Proportionally balance all air outlet devices.
- Measure and record the final total airflow rate by pitot tube with system set for maximum duct airflow.
- Measure and record the data noted in Section 8.4 (b), (c), (f), (g), and (i) plus the duct static pressure sensed by the static pressure probe for automatic control of supply duct pressure existing when fan is at design flow rate.
- Reset all controls for normal operation.
- At the completion of balancing,
  - The inlet manual damper to at least one VAV air terminal device on each branch duct will be fully open.
  - At least one damper in each branch duct will be fully open.
  - Reset the system to normal operating conditions.

Single-Duct, Fan-Powered Pressure-Independent Systems:

Fan configurations and airflow control for these devices are the same as described in the Single-Duct, Fan-Powered Pressure-Dependent Systems section. Consult the terminal manufacturer for the proper operation and setting of the flow control.

- Operate all associated fans
- Set the air terminal devices being tested on full cooling or for diversity
- Take static pressures at all systemic components
- Proportionally balance all air terminal devices. Consider each air terminal device and associated downstream low-pressure ductwork as a separate, independent system. Verify the action of the thermostat (direct or reverse acting) and the volume damper position (normally closed or normally open). Verify the range of the damper motor as it responds to the velocity controller. Consult the air terminal device manufacturer's data for the required pressure drop range across the air terminal device. The total required inlet static pressure is this drop plus the downstream resistance. Take the static pressure drop across the air terminal device and the inlet static pressure. These readings should be within the required range. Verify that the air terminal device will operate at maximum flow when the inlet static pressure to the air terminal device is within the proper operating range by reading the downstream air outlet devices.
- Proportionally balance all air outlet devices.
- Test the VAV air terminal device for both maximum and minimum airflow as applicable. Consult the manufacturers' recommendations on the proper procedure for setting the velocity controllers if required. Include both quantities on the report.
- Measure and record the final total airflow rate by pitot tube traverses with system set for maximum duct airflow.
- Measure and record the data required in Section 8.4 (b), (c), (f), (g), and (i), plus the duct static pressure sensed by the static pressure probe for automatic control of supply duct pressure existing when fan is at design flow rate.
- Reset all controls for normal operation.
- At the completion of balancing,
  - The inlet manual damper to at least one VAV air terminal device on each branch duct will be fully open.
  - At least one damper in each branch duct will be fully open.
  - Reset the system to normal operating conditions.

Dual-Duct, Pressure-Independent Systems:

This type of system uses control schemes that supply a varying quantity of heated or cooled air to the space. The hot duct and cold duct each have their own volume controller.

- Operate all associated fans.
- Set the air terminal devices being tested on full cooling or for diversity.
- Take static pressures at all systemic components.
- If all of the air terminal devices are constant volume, set thermostats to obtain all the airflow through the cold ducts. Traverse the main ducts if more than 10% of the rated fan airflow is measured in the hot duct. During the balancing process, find and correct hot valve leakage or crossed box supplies.
- If the air terminal devices have a variable-volume feature, then adjust to full flow via thermostats so the sum total airflow rate of the air terminal devices equals the fan design flow rate during the balancing procedures.
- Test the inlet static pressure at several of the most difficult-to-supply air terminal devices and make system adjustments for adequate pressure at the air terminal device inlet (CV or VAV) to provide the required flow rate through the air terminal device and downstream ductwork.
- With the air terminal device set for 100% cold air delivery and with the hot-duct temperature at least 11 K warmer than the cold duct, test the air terminal device for hot-valve leakage. Measure the temperature of the cold inlet duct air and the supply air temperature at two air outlet devices. If the duct splits at the discharge, measure the temperature at an air outlet device on each branch. If the average supply air temperature at the air outlet device is higher than the cold inlet duct temperature by more than 5% of the difference between cold duct and hot duct temperatures, request the installer to correct the deficiency. Also test for, report, and correct any air mixing deficiencies that result in 1.6 K or more difference between air outlet device supply temperatures and those supplied by an air terminal device.
- Proportionally balance all air outlet devices. Consider each air terminal device and associated downstream low-pressure ductwork as a separate, independent system. Verify the action of the thermostat (direct or reverse acting) and the volume damper position (normally closed or normally open). Verify the range of the damper motor as it responds to the velocity controller. Consult the air terminal device manufacturer's data for the required pressure drop range across the air terminal device. The total required inlet static pressure is this drop plus the downstream resistance. Record the static pressure drop across the air terminal device and the inlet static pressure. These readings should be within the required range. Verify that the air terminal device will operate at maximum flow when the inlet static pressure to the air terminal device is within the proper operating range by reading out the downstream air outlet devices.
- Proportionally balance all air outlet devices.
- Test the VAV air terminal device for both maximum and minimum flow as applicable. Consult the manufacturer recommendations

on the proper procedure for setting velocity controllers if required. Include both quantities on the report.
- Measure and record the final total airflow rate that velocity traverses in the hot and cold ducts with system set for maximum cold duct airflow.
- Measure and record the data required in Section 8.4 (b), (c), (f), (g), and (i), plus the duct static pressure sensed by the static pressure probe for automatic control of supply duct pressure existing when fan is at design flow rate.
- Reset all controls for normal operation.
- At the completion of balancing,
  - The inlet manual damper to at least one VAV air terminal device on each branch duct will be fully open.
  - At least one damper in each branch duct will be fully open.
  - Reset the system
  - to normal operating conditions.

Laboratory Testing and Balancing:

The first three steps are written as for laboratories where room pressure is negative. The exhaust and supply airflow percentages will switch when the laboratories are designed to be positive pressure.

- For each fume hood, verify by pitot tube traverse that the airflow is between 100 and 110% of design. Design airflow is the volume of exhaust that produces the required face velocity at sash opening (i.e., face velocity × area).
- For each laboratory balance, the supply airflow should be between 90 and 100% of design. Avoid any direct velocity from the ceiling diffuser toward the fume hoods. Verify airflow measurements by establishing correction factors from pitot tube traverses.
- Balance the general exhaust system airflow to between 100 and 110% of design. When flow hoods are used to measure general exhaust airflow rates, care should be taken when reading multiple exhaust grilles that the flow hood does not add restriction, forcing the air to another exhaust grille.
- After the correct airflow for the hood has been established and all exhaust and supply air systems have been balanced, verify that the face velocities do not fall below the design face velocity as directed by the safety officer. Face velocities should be taken at equal areas as described in ASHRAE *Standard* 110.
- Make a sketch of the tested hood indicating each face velocity, the sash opening dimensions (height, width, and area), the position of the internal baffles, the traversed airflow rate, the laboratory room number, and exhaust system number. After the face velocities have been determined to be within the established limits, observe smoke flows into the hood to determine that no reverse flows are present.
- A sticker indicating the inspection test result should be placed on the side of the hood, at the maximum sash height measured, indicating (1) height of sash (in mm), (2) average velocity (m/s), (3) highest velocity (m/s), (4) lowest velocity (m/s, (5) person performing the test, and (6) date of test.

Note in the sketch that all face readings are for reference only. The flow is established by pitot tube traverse. At the present time, there is no way to take the average velocity multiplied by the face area to determine total flow. Each velocity-measuring instrument will require different correction factors, and these corrections are often different for different size hoods of the same type.

If the hood does not pass this requirement a caution tag must be placed on the sash. The caution tag should be a fluorescent orange tag stating that the hood does not meet specified flow requirements, with the date.

Tracking the laboratory control can be done in the following manner by establishing airflows for each air terminal device:

- All hood sashes open, minimum cooling.
- All hood sashes closed, minimum cooling.
- All hood sashes closed, maximum cooling.
- Note velocity at the door during the preceding steps.
- Identify the point at which the hood face velocity falls below its target velocity. (Any time a minimum airflow is set, the hood will track linearly until it reaches the minimum airflow point; face velocity will then increase).
- Indicate flows on a drawing of the laboratory at maximum and minimum conditions and velocities (to be posted at the door).
- Track the entire exhaust system from maximum to minimum flow by observing the static pressure entering the most remote hood exhaust air terminal device and the exhaust fan static pressure controller maintains set point.
- Track the entire supply system from maximum flow to minimum flow, observing the static pressure entering the most remote supply air terminal device. The supply air static pressure controller maintains set point.

Report Information

To be of value to the consulting engineer and owner's maintenance department, the air-handling report should consist of at least the following items:

1. *Design*
   - Air quantity to be delivered
   - Fan static pressure
   - Motor power installed or required
   - Percent of outdoor air under minimum conditions
   - Fan speed
   - Input power required to obtain this air quantity at design static pressure
2. *Installation*
   - Equipment manufacturer (indicate model and serial numbers)
   - Size of unit installed
   - Arrangement of air-handling unit
   - Nameplate power and voltage, phase, cycles, and full-load amperes of installed motor
3. *Field tests*
   - Fan speed
   - Power readings (voltage, amperes of all phases at motor terminals)
   - Total pressure differential across unit components
   - Fan suction and fan discharge static pressure (equals fan total pressure)
   - Plot of actual readings on manufacturer's fan performance curve to show the installed fan operating point
   - Measured airflow rate

   It is important to establish initial static pressures accurately for the air treatment equipment and duct system so that the variation in air quantity caused by filter loading can be calculated. It enables the designer to ensure that the total air quantity is never less than the minimum requirements. Because the design air quantity for peak loading of the filters has already been calculated, it also serves as a check of dirt loading in coils.
4. *Terminal Outlets*
   - Outlet by room designation and position
   - Manufacture and type
   - Size (using manufacturer's designation to ensure proper factor)
   - Manufacturer's outlet factor (where no factors are available, or field tests indicate listed factors are incorrect, a factor must be determined in the field by traverse of a duct leading to a single outlet); this also applies to capture hood readouts [see ASHRAE *Standard* 111])
   - Adjustment pattern for every air outlet

5. *Additional Information (if applicable)*
   - Air-handling units
     - Belt number and size
     - Drive and driven sheave size
     - Belt position on adjusted drive sheaves (bottom, middle, and top)
     - Motor speed under full load
     - Motor heater size
     - Filter type and static pressure at initial use and full load; time to replace
     - Variations of velocity at various points across face of coil
     - Existence of vortex or discharge dampers, or both
   - Distribution system
     - Unusual duct arrangements
     - Branch duct static readings in double-duct and induction system
     - Ceiling pressure readings where plenum ceiling distribution is used; tightness of ceiling
     - With wind conditions outdoor less than 2.2 m/s, relationship of building to outdoor pressure under both minimum and maximum outdoor air
     - Induction unit manufacturer and size (including required air quantity and plenum pressures for each unit) and test plenum pressure and resulting primary air delivery from manufacturer's listed curves
   - All equipment nameplates visible and easily readable

Many independent firms have developed detailed procedures suitable to their own operations and the area in which they function. These procedures are often available for information and evaluation on request.

6. BALANCING HYDRONIC SYSTEMS

Testing, adjusting, and balancing of hydronic systems has one core principle for functionality: conditioned water (fluid) must be provided to the heat transfer device (coil) so that at design conditions 97% of the coil heat transfer is achieved, while not allowing flow to have a larger tolerance than ±10% of design flow. It is at part load that the designer must take care to assure that a similar type of performance is attainable if desired. Many designers make the assumption that at part load a system will stay balanced. This implies proportionality, which is only ensured if all connected system terminals have the same head loss with respect to the pump. This can, and does, vary based on the type of device used to make adjustments. The condition also varies based on how other devices that affect system flow and head are operated; specifically, variable-speed pumping can have a major impact on how well fluid gets where it is intended by a distribution system at design and part load.

When other design options (e.g., diversity) are used, and where the pump (and possibly the piping system) are not sized to provide connected flow load as based on the required design flow rate for each connected terminal, the designer must analyze the system flow under varying load and control conditions and specify a sequence and methodology of test, with expected results, to ensure system operation. The evolution of system design criteria to incorporate higher Δt, reduce required flow rates, and incorporate advanced control strategies (e.g., variable-speed pumping) has increased the sensitivity of the system to slight variations from design. This necessitates additional calculation and analysis to achieve the comfort and energy efficiency conditions required, while protecting the system from potential hazards (e.g., mold growth) and that might in part be affected by a lack of performance in the system operation. This should not imply that there was or is anything wrong with the fundamentals of earlier system design and field adaptation. Those fundamentals provide the basis to apply design principles with modern knowledge, for efficient, well-operated systems. The relationship between flow and heat transfer is at the root of this understanding.

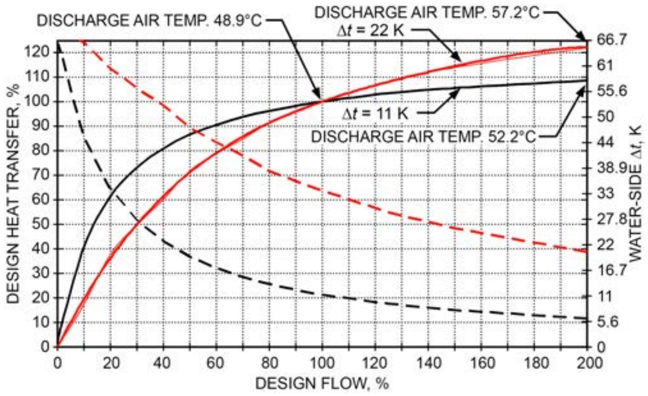

Fig. 1 Effects of Flow Variation on Heat Transfer from Hydronic Terminal

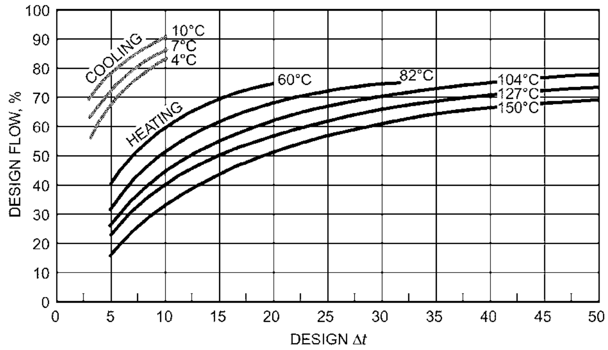

Fig. 2 Percent of Design Flow Versus Design Δt to Maintain 90% Terminal Heat Transfer for Various Supply Water Temperatures

Heat Transfer at Reduced Flow Rate

The traditional heating-only hydronic terminal (90°C, 11 K Δt) gradually reduces heat output as flow is reduced (Figure 1). Decreasing waterflow to 20% of design reduces heat transfer to 65% of that at full design flow. The control valve must reduce waterflow to 10% to reduce heat output to 50%. This relative insensitivity to changing flow rates is because the governing coefficient for heat transfer is the air-side coefficient; a change in internal or water-side coefficient with flow rate does not materially affect the overall heat transfer coefficient. This means (1) heat transfer for water-to-air terminals is established by the mean air-to-water temperature difference, (2) heat transfer is measurably changed, and (3) a change in mean water temperature requires a greater change in waterflow rate. Figure 1 shows the relationship between water-side design criteria and heat transfer.

The coil was selected for an entering water temperature of 82°C, and design water temperature drops Δt of 11 K and 33 K. The design exit air temperature of the coil is 50°C. Note that with waterflow twice that of design, there is a reasonable amount of temperature difference to indicate overflow. Acceptable industry practice has been to allow for only 10% overflow, and in that case a 20° Δt coil yields a negligible increase in heat transfer (101%) and an equally tough to measure 0.42 K change in departing air temperature. Similarly, the coil with 60° Δt has only 104% of design heat transfer with a 2° increase in leaving air temperature. The designer should not assume that a temperature control system will be able to adequately control any overflows based on sensing the increase in temperature. Though possible if great care is taken to match the control valve to the coil and tune the control loop for proper control, more often than not, this is rarely attained in implementation.

Tests of hydronic coil performance show that when flow is throttled to the coil, the water-side differential temperature of the coil increases with respect to design selection. This applies to both constant-volume and variable-volume air-handling units. In constantly circulated coils that control temperature by changing coil entering water temperature, decreasing source flow to the circuit decreases the water-side differential temperature.

A secondary concern applies to heating terminals. Hot water can be supplied at a wide range of temperatures. Inadequate heating capacity caused by actual conditions varying from design or insufficient flow can sometimes be overcome by raising supply water temperature. Designs below the 120°C limit (ASME *Boiler and Pressure Vessel Code*) often add enhanced flexibility to make this adjustment if there is adequate source capacity.

Figure 2 shows the flow variation when 90% terminal capacity is acceptable. Note that heating tolerance decreases with temperature and flow rates and that chilled-water terminals are much less tolerant of flow variation than hot-water terminals.

A third concern also needs to be considered when dual-temperature heating/cooling hydronic systems are employed. These systems are sometimes first started during the heating season. Adequate heating ability in the terminals may suggest that the system is balanced. However, when operated in cooling mode, capacity may vary greatly from that required. Figure 2 shows that 40% of design flow through the terminal provides 90% of design heating with 60°C supply water and a 5 K temperature drop. Increased supply water temperature establishes the same heat transfer at terminal flow rates of less than 40% design.

Sometimes, dual-temperature water systems have decreased flow during the cooling season because of chiller pressure drop; this could cause a flow reduction of 25%. For example, during the cooling season, a terminal that heated satisfactorily would only receive 30% of the design flow rate.

Although the example of reduced flow rate at Δt = 10 K only affects heat transfer by 10%, this reduced heat transfer rate may have the following negative effects:

- Object of the system is to deliver (or remove) heat where required. When flow is reduced from design rate, the system must supply heating or cooling for a longer period to maintain room temperature.
- As load reaches design conditions, the reduced flow rate is unable to maintain room design conditions.
- Control valves with average range ability (30:1) and reasonable authority (β = 0.5) may act as on/off controllers instead of throttling flows to the terminal. The resultant change in riser friction loss may cause overflow or underflow in other system terminals. Attempting to throttle may cause wear on the valve plug or seat because of higher velocities at the vena contracta of the valve. In extreme situations, cavitations may occur.

Table 1 Load Flow Variation

Load Type	% Design Flow at 90% Load	Other Load, Order of % Sensible	Total	Latent
Sensible	65	90	84	58
Total	75	95	90	65
Latent	90	98	95	90

Note: Dual-temperature systems are designed to chilled flow requirements and often operate on a 5 K temperature drop at full-load heating.

Terminals with lower water temperature drops have greater tolerance for unbalanced conditions. However, larger waterflows are necessary, requiring larger pipes, pumps, and pumping cost.

System balance becomes more important in terminals with a large temperature difference. Less waterflow is required, which reduces the size of pipes, valves, and pumps, as well as pumping costs. A more linear emission curve gives better system control. If flow varies by more than 5% at design flow conditions, heat transfer can fall off rapidly, ultimately causing poorer control of the wet-bulb temperature and potentially decreasing system air quality.

Heat Transfer at Excessive Flow

Increasing the flow rate above design in an effort to increase heat transfer requires careful consideration. Figures 1 and 3 both show that increasing the flow to 200% of design only increases heat transfer by 6 to 20%. However, the excess flow increases resistance or pressure drop four times and, more importantly, energy draw by a factor of eight using the cube of the original power (from the pump laws).

Generalized Chilled Water Terminal: Heat Transfer Versus Flow

Heat transfer for a typical chilled-water coil in an air duct versus waterflow rate is shown in Figure 4. The curves are based on AHRI rating points: 7.2°C inlet water at a 5.6 K rise with entering air at 26.7°C db and 19.4°C wb. The basic curve applies to catalog ratings for lower dry-bulb temperatures providing a consistent entering-air moisture content (e.g., 24°C db, 18°C wb). Changes in inlet water temperature, temperature rise, air velocity, and dry- and wet-bulb temperatures cause terminal performance to deviate from the curves. Figure 4 is only a general representation and does not apply to all chilled-water terminals. Comparing Figure 4 with Figure 1 indicates the similarity of nonlinear heat transfer and flow for both the heating and cooling terminals.

Table 1 shows that if the coil is selected for the load and flow is reduced to 90% of load, three flow variations can satisfy the reduced load at various sensible and latent combinations. Note that the reduction in flow will not maintain a chilled-water design differential when coil velocity drops below 0.5 m/s. This affects chiller loading and unloading.

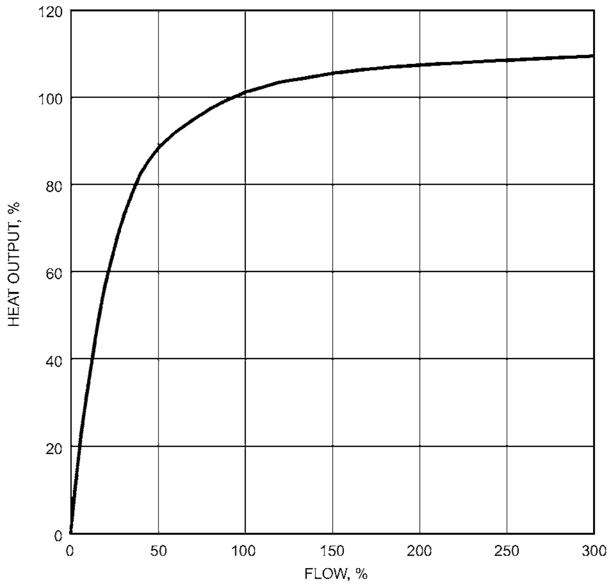

Fig. 3 Typical Heating-Coil Heat Transfer Versus Water Flow

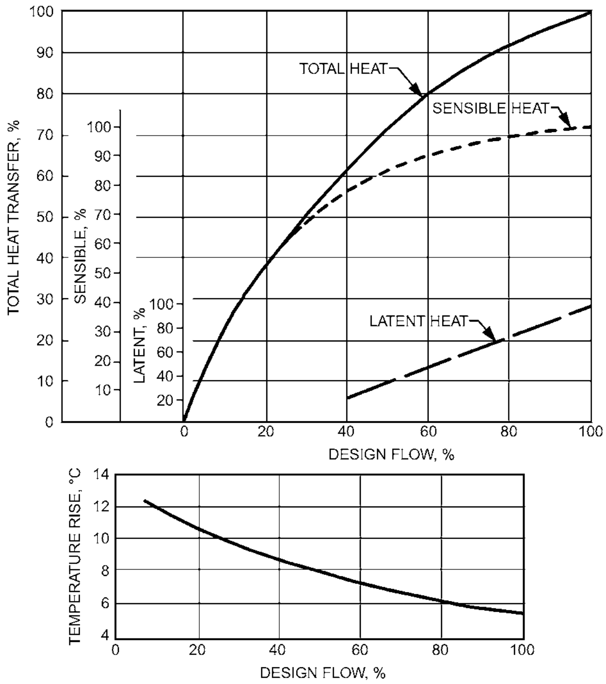

Fig. 4 Chilled Water Terminal Heat Transfer Versus Flow

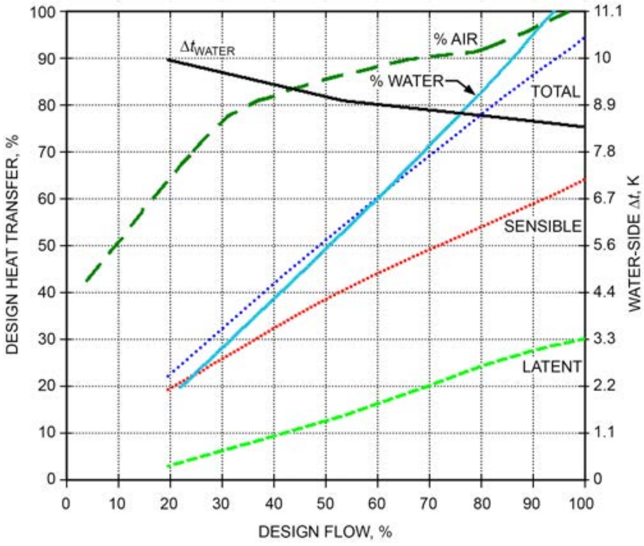

Fig. 5 Chilled Water Terminal Heat Transfer Versus Flow for VAV Unit with 20% Outdoor Air

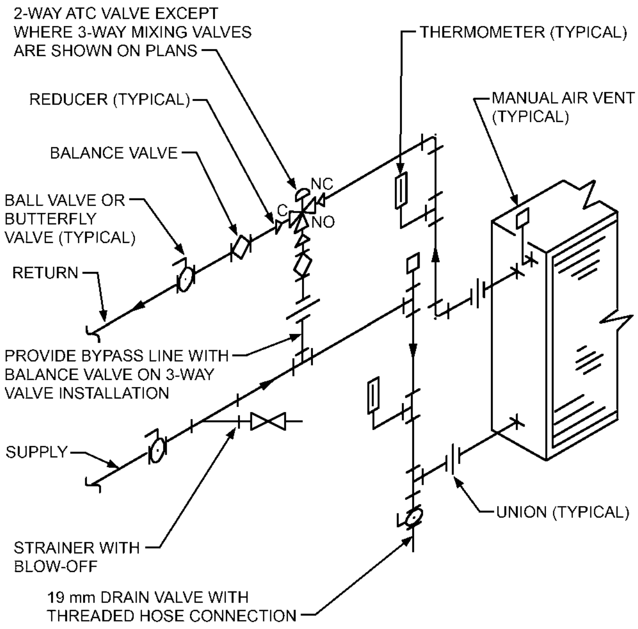

Fig. 6 Example of Coil Schematic

The coil characteristic shown in Figure 5 is for air that is always recirculated within a space, such as in a fan-coil. Another common (but nonstandard) approach in chilled-water systems is for airflow volume across the coil to vary according to load. Static pressure in the supply duct is controlled by VAV box dampers opening and closing, and some percentage of outdoor air is introduced at entering conditions. With these control modifications, the coil starts to appear more linear, depending on air turndown (determined by load) and variations in dry- and wet-bulb temperatures of the air being introduced. In some cases, as sensible design conditions are approached, reasonable variance in wet-bulb temperature can significantly change heat transfer across the coil. If enthalpy is the control set point, fluid flow may vary by 40% or more of design at the same entering dry-bulb temperature. These common characteristics make fluid flow measurement of a coil (rather than using surrogate indicators such as water-side Δ*t*) important in indicating the system balance.

Flow Tolerance and Balance Procedure

The design procedure rests on a design flow rate and an allowable flow tolerance. The designer must define both the terminal's flow rates and feasible flow tolerance, remembering that the cost of balancing rises with tightened flow tolerance. Any overflow increases pumping cost, and any flow decrease reduces the maximum heating or cooling at design conditions.

Water-Side Balancing

Minimum Design Requirements for Hydronic System Installation. Given the effect of flow on heat transfer, comfort, and energy efficiency, each coil must have some form of verifiable flow measurement to enable measurement and verification to properly verify system operation (even if no adjustments are planned). Traditionally, this function was performed by balancing valves, and the required performance was communicated in the written specification and in schematic drawings like the one shown in Figure 6.

The example is not meant to endorse any particular method of control or specification. For example, having thermometers entering and leaving the coil is a nice feature, especially when working on large coils and air-handling units. However, most terminal unit coils (e.g., fan-coils, terminal reheat coils) serving a small temperature control zone have flow rates of 0.03 to 0.63 L/s, and there are many coils. In that instance, the expense of thermometers is not justified. Alternatively, a measurement device could be installed that allows for the insertion and removal of a temperature sensor into the fluid stream to make a measurement. Note that many fittings and devices are shown. It is very common to find specialty devices installed as an alternative to the specification drawing at the request of the installer, with the object of providing functional performance while increasing the installation efficiency. Typically these are

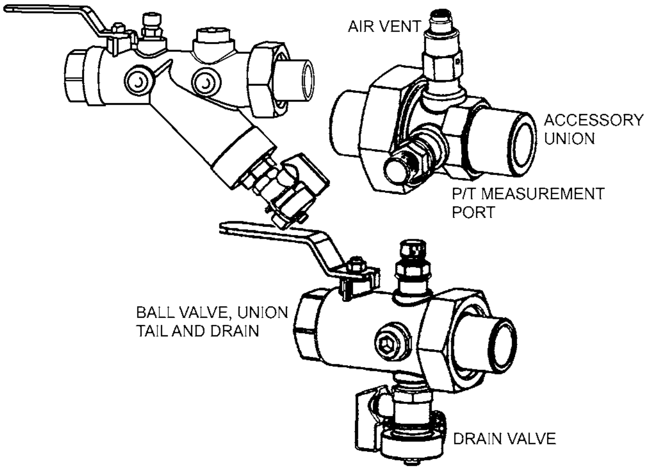

Fig. 7 Typical Coil Kit Components

called **hook-up kits** or **coil kits** and are installed with the TAB device and the control valve.

Figure 7 shows the three most common types of devices applied; note that the market can drive subtle variances of their design. There are a few things that are important in applying these devices:

- They should be described in detail in the written specification and shown on the drawings with the required features called out. These devices are not specifically covered by manufacturing standards such as MSS or ANSI standards as other valves and fittings are, and that leaves much open to interpretation.
- Note the required quantity and placement of pressure or temperature (P/T) measurement ports and the minimum required quantity of auxiliary mounting locations (e.g., the strainer valve, which has a P/T port installed, as well as a strainer blowdown and drain valve; in addition, it has a larger auxiliary port for assistance in piping the three-way valve bypass, as well as several alternative ports for relocation of the P/T, additional P/T ports, or other devices that might fit within the constraints of the thread size).
- The devices should specifically be checked for their specific application as a balance device. The devices shown in Figure 7 are all auxiliary piping devices. They provide the functions of shutoff valves, strainers, pressure, and temperature measurement locations or other functions, but they do not provide the calibration of a balancing device for flow measurement or if required adjustment. Balancing devices are distinct, and while the balancing device may serve the purpose of a shutoff valve for one side of the coil (based on code or performance requirements), the auxiliary device does not serve this purpose unless specifically designed to do so.

Balancing Devices. Traditional balancing valves are of two basic styles: static or dynamic. In addition, a simple flow measurement device such as an orifice or venturi could serve the same function, but these are often integrated into the balance valve

Static Balance Valves. Varieties exist for both operation and measurement. This valve is typically set to a position by a technician and does not self-adjust in operation. Typically, the simplest type of valve has a throttling device able to measure pressure entering and exiting the throttling orifice. Manufacturers publish the performance data associated with the valve using a standardized valve test, such as ISA *Standard* 75.02.01, with adjustment to compensate for the valve design and measurement points. In this manner, the balancing device uses a variable orifice for flow calculation based on the orifice flow coefficient c_V at the operating position. This device generally provides an acceptable flow measurement when wide open, but if care is not exercised to carefully match the differential pressure measurement device range to the flow coefficient of the valve, flow accuracy declines as the valve is closed.

A modified type of static valve uses a fixed orifice for flow calculation combined with a variable orifice for flow adjustment. The fixed orifice may be a simple orifice, venturi profile, or nozzle. Variable orifice measurement requires knowing where the device is set to calculate flow, which may require having to adjust a measurement device each reading. The fixed orifice, on the other hand, does not change each reading, thus giving a direct readout on flow if the measurement device incorporates this calculation and the measurement range is adequate for the measured flow. Remember the square relationship of flow to pressure drop: if 0.06 L/s is being measured at a pressure drop of 6.9 kPa, then reducing the flow to half gives a measured pressure drop of 1.7 kPa. These pressures can become quite small, and finding the proper range sensor is difficult unless care is taken in sizing and design to allow for enough pressure drop to calculate a reasonably accurate flow. Measuring at design flow is important and should be relatively easy to accomplish. However, if the intent is to check the system at part load, especially at flows less than 50% of design, this must be taken into account when selecting the design pressure drop for the measurement device, to make sure the signal is of enough magnitude as to be measurable by the available devices.

The built-in benefit of a static balancing valve is that, when properly field adjusted, all system flow paths have the same head loss (the same as the design head loss calculated for the selection of the pump). This system is therefore proportionally balanced; if flow is too great, all circuits have the same overflow, and if flow is too small, all circuits receive the same percentage of flow. This can be highly advantageous for some system designs. Note that in a system that is properly proportionally balanced, at least one of the balancing valves will be open, providing only the pressure drop required to provide an adequate differential pressure signal for flow calculation. There are no parasitic head losses in the system, because all paths have the same head loss, and maximum flow is limited, reducing flow to only that of design, thus saving pump motor power and energy.

Dynamic Devices (Automatic Flow Limiters). The process of adjusting the maximum flow in a circuit can be expensive or laborious, but there will be varying differential pressures at each branch that cause excessive flows at design, especially when control valves are selected with little care for required pressure drop at the point of system application. The dynamic device incorporates a system-powered regulator to either vary the open orifice area to keep no more than a specific set point flow, or control the differential pressure across a fixed orifice to accomplish the same function. Like all regulators, these devices rely on machined control areas and engineered springs to set a specific range of operation, and therefore exhibit proportional control of the regulator for the flow, but not proportional regulation of the controlled system (as does the static valve). Typically, these valves operate over a fixed range of differential pressure (e.g., 14 to 220, 14 to 415, or 35 to 415 kPa [differential]).

A drawback is that these valves do not definitively know the position, and thus the flow coefficient, where the regulator is operating. They also often do not allow for the correct pressures to establish flow. As a result, these devices cannot be used to measure flow at the design condition, and the manufacturer's statement of flow must be taken at face value. Performance is generally reasonable, but there are occasions when suspended construction material can obstruct the working apparatus, blocking flow and giving no indication that there is an issue. It is recommended that when these types of devices are installed, a properly sized fixed orifice device be installed to allow for positive flow measurement.

Pressure Regulators. Regulators are some of the earliest automatic control devices, using various materials and approaches to control specific processes. For example, the simple bimetallic element, which has two physically bonded strips of metal with different coefficients of expansion and contraction, is harnessed into the thermostat, so that when the element heats or cools, the corresponding physical movement of the element actuates a switch or provides control of air pressure to actuate a damper motor or valve. For TAB, system water pressure is directed to both sides of a diaphragm-operated actuator, to open or close a valve. Using a spring on the actuator, a specific pressure set point can be controlled for either a static or differential pressure; by adding other system-powered devices, this basic function can be turned into a flow regulator or other type of control element. Use of regulators on hydronic systems is returning to popularity, with widespread application of variable-speed pumping and designs that attempt to recreate proportional control. (The application of variable speed pumping will be handled separately.)

A differential pressure regulator is typically used, and it is applied either as an independent device across an individual branch, a temperature control valve, or a multiterminal branch. A subset of ΔP regulators is the pressure-independent control valve, which incorporates the ΔP regulator into the body of the temperature control valve to control the pressure drop across the control orifice. In that specific application, whenever system differential pressure at the point of the controlled valve exceeds the regulator pressure set point, the fixed ΔP set point is kept constant. This mimics the same conditions applied when a TC control valve is given the standard flow capacity test, and consequently the valve characteristic is maintained without deviation, because of system hydraulics.

The regulator ΔP is normally less than the pressure drop across the valve assembly as prescribed by the flow capacity test. Manufacturers normally state the controlled range of flow of the valve and the operating ΔP range, and often of the regulator. If the manufacturer states a specific flow coefficient A_v for the valve, this should imply the entire assembly's pressure drop per the standard test method. Whether these devices can be used for flow measurement or verification varies with manufacturer. In some cases, manufacturers provide the ability to measure pressure drop across some portion of the valve. It is common to designate three critical pressures: P1 (upstream pressure), P2 (regulator pressure), and P3 (downstream pressure). If only P1 and P3 are measurable, flow verification cannot be performed because the drop around the controlled orifice is unknown. If P2 and P3 are known and the flow coefficient for the applied position is known (published), it may be possible to verify flow. Some manufacturers incorporate fixed-flow orifices specifically for flow verification. Similar to automatic flow limiters, it is recommended that when these types of devices are installed, a properly sized fixed orifice device be installed (if not included in the valve assemblage) to allow positive flow measurement.

Normal Instrumentation for Field Measurement

Hydronic system measurement tools can be categorized by function: electrical (to deal with pumps), pressure and differential pressure (to establish system settings, pressure losses, and calculate flow rates), temperature (to establish performance levels), and direct-flow instruments (e.g., a strap-on instrument such as a doppler effect type of meter to measure flow directly). In addition, it is useful to apply thermal imagers and vibration analyzers when testing for improper operation and, if the TAB technician is designated to perform alignments, an alignment analyzer.

Electrical Measurements. As a result of the wide application of variable-speed drives to pumps, both a portable oscilloscope and a digital multimeter with required test probes and safety gear and procedures are required to take reasonable and repeatable measurements and establish power use. The oscilloscope is required to measure the voltage and current leaving the drive to the motor and entering the motor and check for imbalance. There are several other measurements that are useful but may not be part of the designated TAB technician's responsibility.

The majority of motors applied to large commercial systems are three-phase motors, and when attached to a speed drive, the frequency of the drive operation is too fast for a digital multimeter. In addition, both the scope and the digital multimeter (DMM) should incorporate a low-pass filter to filter out high frequencies associated with the drive. Note the instrument manufacturer, model, and whether the device includes a low-pass filter measurement documentation. If readings are taken by other technicians at a later time, using meters without the low-pass filter, there may be substantial difference in the reported measurement when no difference actually exists. Because of the function of the drive, voltage measurements can be significantly greater than the nominal 480 V assumed to being measured. Instruments should be rated for 750 to 1000 V to be safe. Analog meters are unacceptable for making these measurements because they lack the required electrical protections and capability to handle power transients. Note that power analyzers may not be substituted for oscilloscopes. Power analyzers are designed to measure supply power lines, but are incapable of measuring drive output power because of the frequencies encountered. The oscilloscope also allows for checking (1) drive setup for output versus load; (2) whether there are overvoltage reflections on the line, which could cause motor winding damage; (3) motor shaft voltages; (4) bearing currents, which can cause fluting of the bearing raceway leading to excess vibration and noise and ultimately leading to reduced motor life; and (5) if there is motor leakage current, which can interfere with control system data acquisition and communications. The digital multimeter is inadequate for many of these measurements, though there are other measurements for which it is very appropriate. Regardless, it too should have the low pass filter to deal with any high frequencies which could lead to errors in measurement.

Pressure Measurement. A broad variety of gages, transmitters, and digital meters exist for the purposes of pressure and differential pressure measurement. The use of the tube-filled manometers was the traditional standard of care, however the indicating fluid was mercury (now a banned substance), so these should never be seen in field application. Most commonly applied still would appear to be a basic mechanical, diaphragm separated dial gage, the device could also be liquid filled. In some cases these might be advantageous due to the inherent simplicity of the device, but what is important is carefully matching the gage range to the expected range of reading, and to ensuring that overpressurization does not influence or damage the gage. The most common problem of the field application of these types of devices is that a user will apply a gage with a reading of 0 to 300 kPa on a device providing a signal in the range of 0 to 2.5 kPa.

Digital manometers are also used. In these units, a semiconductor differential pressure sensor or matched pair of gage pressure sensors is used, with either electronic analog circuitry or an application-specific microprocessor to convert the electrical signal from the sensor into usable data by the technician. In many cases, the manufacturers will apply some user adaptability to enter field data that might display the differential pressure, and convert that sensed value to a calculated flow. In other cases, the applied microprocessor has a far greater set of operations, from device databases to instructional methods on making system adjustments. Most important to the balancing process is that an accurate, precise, and appropriate range sensor is applied to the measurement device, and that it is properly compensated for temperature of the working fluid. All sensing devices rely on some electrical interpretation of the physical movement of an object (e.g., diaphragm) in response to changing pressure. The same technologies that are applied to freestanding sensors used in the control process are also applied in the test instrumentation used by balancers. Digital manometers should minimally offer a capability of zeroing the sensor and electrical signal before measurement of the test specimen, and may also offer connection methods to the test specimen that balance the pressure across the device until reading to prevent sensor damage, and ensure that the physical connection device (e.g., tubes) are filled with liquid and vented of air. Test instruments should be regularly checked against a traceable reference standard; allow for regular calibration as required.

Temperature Measurement. Careful system design should always allow for a sensor to be placed directly into a fluid stream, not externally mounted to the pipe. There are a wide variety of mechanical temperature sensing methodologies, such as the traditional liquid-filled thermometer, and bimetallic or vapor-filled elements with a calibrated dial indicator or electronic sensing through RTD, thermistor, or other type of sensing element. Electronic sensing also implies semiconductor devices and implementations that can be quite small, allowing for the carrying or sheathing element to be equally small: the tube that carries the physical sensing device and wires can be diametrically as small as a hypodermic needle (1.5 mm diameter), or the more traditional instant-read type of dial indicator probe, which is slightly greater than 3.6 mm in diameter. Probe size should be checked to ensure that it can be injected into the fluid stream as far as possible (as this may be restricted by entry point). Temperature instruments should be regularly checked against a traceable reference standard, and allow for regular calibration as required and capable.

Less commonly applied, and appropriate for specific applications, are thermographic imagers, which may be handheld and have digital imaging. Though inappropriate for direct fluid temperature measurement, they are invaluable for extra measurements such as showing the face of a heat transfer coil or to indicate faulty points of insulation. On devices such as pumps, they can provide valuable data on motor and bearing operation.

Flow Sensing. The noninvasive flow sensor typically uses a form of ultrasonic detection to establish flow on the interior of a pipe. This is a nontraditional instrument in balancing for several reasons, including setup time and the data required to translate the signal into waterflow. However, in certain application instances, such as measuring main distribution piping, there can be value in spot checking flow rates.

In all of these device categories, there is a wide variety of other technologies which may be applied, especially when those applications are permanent to system operation. However, it is this permanence that makes them less applicable to field testing for TAB. A fluid flow turbine meter may be very good for getting a flow measurement, but adding and then removing the device to the fluid stream (aside from the piping complications) also substantively changes the system pressure drop and flow rate, making the overall readings and adjustments less accurate. This should be accounted for in design. If there are specific devices that the designer feels are more appropriate to the goals that they wish to accomplish, specific mechanical installation techniques and equipment should be incorporated into the design to accommodate those measurements. For example, a removable section of piping could allow for physical checking of the interior pipe surfaces to ensure accuracy for an ultrasonic device.

Expect sensing errors, and the associated error in rational units (e.g. ΔP into volume-per-unit-time flow). Expect that, when the accounting is complete, a gross reading at one point in the system will not be the same as all the individual unit flows when added. When attempting to establish the validity of the reported numbers, it may be necessary to recheck not only the installed devices but also the pipes and fittings. Expect problems, and provide simple logical points of measurement opportunity that allow the anomaly to be traced until satisfaction can be established with the data.

Anecdotal evidence supports the necessity of these precautions. In a 60 story office tower in Chicago, it was known for years that the chilled-water system did not seem to work right and that, in particular, the pumps did not develop the required system flow. After checking all of the installed devices, the building owners eventually installed extra measurement points that allowed enough data to be taken to track anomalies. Eventually, these measurements led to a specific section of pipe. The system was shut down for maintenance, drained, and the suspect pipe was cut open only to find it stuffed with tubes of conduit. Apparently the electrician thought it was a convenient storage spot during construction, and the pipefitters never recognized that it was a mistake, not some form of flow straightener in the pipe, welding it in. These types of errors can (and do) occur with regularity. Catching errors such as this is not the purpose of TAB, but the principles of TAB measurements can be used to address functional problems, as well as the normal system hydraulics.

System Calculation and Specification

Water-side balancing adjustments should be made with a thorough understanding of piping friction loss calculations and measured system pressure losses. It is good practice to show expected losses of pipes, fittings, and terminals, and expected pressures in operation on schematic system drawings (as recommended in ASHRAE *Standard* 111). Designers often use schematic drawings to provide functional representation of a system design, in addition to the dimensional piping plans associated with the building layout drawings. It is suggested that one of these schematics be drawn in a flat connection or ladder-type diagram, as shown in Figure 8. Conceptually, the schematic allows main distribution paths, branch connections, major devices, and the pump, without any piping lines crossing. The drawing serves several purposes: allowing all paths and various system interactions to be easily seen, evaluating opportunities for reverse or gravity flows, easily translating to a spreadsheet for sizing and analysis calculations, quickly and efficiently establishing the required balance adjustments and identifying differences between installed versus design differences (done by the TAB technician), and establishing and communicating more detailed sequences of operation for the control system.

The power of commonly available spreadsheets allows designers to create a straightforward calculation procedure that is easily verifiable by the firm using it. The spreadsheet approach also allows analysis to be performed while sticking to the basics of a system operating at the intersection of its pump and system curves. The accuracy of these methods is reasonably good, and the implementation complexity can be left to the designer of the spreadsheet. For example, to achieve a higher degree of precision in the calculations for fittings, the spreadsheet can account for the influences of geometric plane interaction (as shown by ASHRAE research and detailed in the 2017 *ASHRAE Handbook—Fundamentals*). However, if this is of less concern, the spreadsheet can implement something as simple as K factors or fitting TEL. Using Figure 8 as an example, a simple spreadsheet was established to provide design analysis, shown in Figure 9.

The spreadsheet allows calculation of the system flow coefficient (analogous to a valve flow coefficient C_V, and outlined in Chapter 47 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*) for showing how various branches will operate. In any pumped piping system, the system will operate at the intersection of the pump and system curve. The system curve is a composite of many system curves, which represent all of the individual paths of waterflow in the system. Each individual path flow coefficient is an indirect sum of the individual component (pipe, fittings, valves, coils, etc.) flow coefficients which may be either implied from calculation or tested under standard test procedures.

The math of the spreadsheet is expressed through algebraic rearrangement of the basic flow equation:

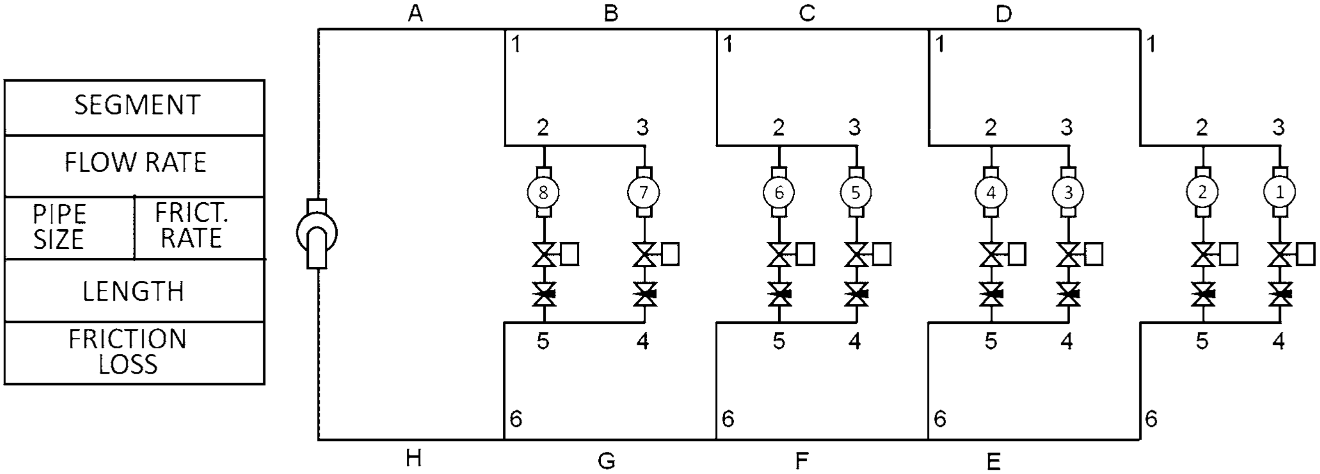

Fig. 8 Example of Flat System Schematic Drawing and Labeling for Devices

$$\frac{q}{\sqrt{\Delta P}} = C_v \quad \text{or} \quad \left(\frac{q}{C_v}\right)^2 = \Delta P \text{ and } \Delta P \text{ is } \Delta h \tag{1}$$

Given that the system head loss in a closed-loop hydronic system is the total of the single largest path's head loss of pipe, fittings, etc., the sum of the head losses can be rearranged into the requisite components of flow and flow coefficient as shown. As the flow is the same in all paths, the term drops out and an equation that can be solved for the system flow coefficient from the components is realized.

$$\left(\frac{q}{C_v}\right)^2_{Tot} = \left(\frac{q}{C_v}\right)^2_{Pipe} + \left(\frac{q}{C_v}\right)^2_{Coil} + \left(\frac{q}{C_v}\right)^2_{Elbows} + \left(\frac{q}{C_v}\right)^2_{Tees} + \left(\frac{q}{C_v}\right)^2_{Gate} + \left(\frac{q}{C_v}\right)^2_{Bal} \left(\frac{q}{C_v}\right)^2_{Cont}$$

$$\frac{1}{C^2_{V\text{-}Tot}} = \frac{1}{C^2_{V\text{-}Pipe}} + \frac{1}{C^2_{V\text{-}Coil}} + \frac{1}{C^2_{V\text{-}Elbow}} + \frac{1}{C^2_{V\text{-}Tee}} + \frac{1}{C^2_{V\text{-}Gate}} + \frac{1}{C^2_{V\text{-}Bal}} + \frac{1}{C^2_{V\text{-}Cont}} \tag{2}$$

$$\frac{1}{C^2_{V\text{-}Tot}} = \frac{1}{C^2_{V\text{-}1}} + \frac{1}{C^2_{V\text{-}2}} + \cdots + \frac{1}{C^2_{V\text{-}n}}$$

Each individual segment in a flow path will have a path flow rate equal to the design flow rate of the served heat transfer device, and the unique or shared head loss in a segment for that flow. For instance, Coil Path 3 has a flow rate of 100, but the distribution piping segment A-B has a design flow 800 for all eight circuits (only three are shown in Figure 9) and design head loss of 4.03. Using hydronic design principles, all paths see the bulk head loss, and the pump must provide enough energy to overcome these losses, so calculation of the path flow coefficient is as shown in the equation above. All that is being illustrated is the addition of the head losses in each flow path, but doing so as the *X* form of the equation, the flow divided by the flow coefficient squared.

Parallel-path flow coefficients are simply additive, and when used to develop a system curve, they can be plotted to a specific pump curve and the intersection point calculated. This allows for the requirements of the first pass of system adjustment to be determined.

Note that there will be differences in actual measured pressures and those calculated. In keeping with the Bernoulli principles, when fittings and devices are fitted to an installed system, they do not always behave in a perfectly theoretical way. Sometimes there are greater or fewer losses of a combined device, influenced by changes in velocity head and velocity head recovery and exhibited in things like the vicinity of a change in flow direction, and changes in the *X*, *Y*, and *Z* planes of the pipe. These losses can only be tested for, and examples of these influences are demonstrated in ASHRAE research project RP-968 (Rahmeyer 1998) (partially published in Tables 3, 4, and 5 and Figures 2 and 3 in Chapter 22 of the 2017 *ASHRAE Handbook—Fundamentals*). However, this should not be used as a reason not to calculate. The first step should always be to have a more rational quantitative approach by which to direct and decide.

One of the by-products of this type of analysis is the calculation of control valve authority, or the authority of any device used to throttle flow. Simply put, valve authority β is the ratio of control valve pressure drop to the maximum pressure drop of the system that it serves. For a constant-speed pump, Δ*P* maximum is the pump head, in a variable-speed pumping system, the pressure drop Δ*P* maximum is the controlled set-point pressure for the pump speed controller The indexing number offers a simple indication of how the valve will perform, but is fairly useless for calculating what the flow would be. However, treated as flow coefficients, the equivalent system flow coefficient is determined as follows.

$$\frac{C_{V\text{-}1} \times C_{V\text{-}2}}{\sqrt{(C_{V\text{-}2})^2 + (C_{V\text{-}1})^2}} = C_{V\text{-}SYST} \tag{3}$$

When the system flow coefficient is calculated for each valve position's flow coefficients, the deviation of a given valve's flow control characteristic may be graphically shown. Figure 10 shows the graphical result for a modified equal-percentage valve at various valve authorities. In the field there may be deviations from this, though the deviation has also been seen in operating systems. Through application of this method of analysis, the effects of balancing the system can be demonstrated for relative effect. It has been anecdotally maintained that application of balancing valves degrades control valve performance, and an example shows this to be partially true, with an unbalanced valve having 22% authority, compared to the same circuit balanced, which has 16%. If the control valve completely opens, under the applied pump differential of 200 kPa, that is higher than that required for the design flow.

Fig. 9 Example Spreadsheet

Though perfect for the most significant path that the pump was selected for, unbalanced and closer to the pump there will be about 15% overflow. This is shown in Figure 10, based on the example. This overflow is very likely not to be recognized by the valves temperature controller, and the beginning result is that there will be excess pump energy used until the controller is able to respond and reduce flow. For the controls technician, adjusting the proportional setting is harder. In the extreme, controller hunting will occur, continuously opening and closing the valve, over and underflowing. Balancing the poorly sized control valve at reduces the maximum opening overflow. Reduced flow at this condition saves pump energy. Tuning the control loop, however, can only be fixed by selecting the temperature control valve with a better valve authority, which means more design pressure drop, and indirectly increases the design pump head.

From the perspective of cost, reducing flow always saves operating expense (relatively). The use of a balancing device will generally save 10 to 15% (more for systems that have paid little or no attention to the hydronic system details, or that have pumps that provide more head than absolutely required) of the pump energy. Poor control valve authority has a larger energy penalty than balancing maximum flow, because the tuning that is possible leads to valves that generally react to disturbances sooner than the load requires (more flow at load), and at each valve position, more flow is delivered than would be indicated by the characteristic. Pumping costs can be significantly reduced by being able to maintain control valve characteristic (on the order of 50%) with even more energy when considering the operation cost of the source energy provider. In that regard, applying hydronic design options, such as properly zoned secondary pumping, zone differential pressure control, or pressure-independent control valves (PICV) for zone pressure control adds operating benefit.

Per CSI *Standard* 2305.93, TAB specification requires direct section implementation of equipment, procedures, and specialists. In addition, coordination should be noted in sections on controls, pumps, any installation sections, etc.

Hydronic systems should be tested by direct flow measurement. This method is accurate because it deals with system flow as a function of differential pressures, and avoids compounding errors introduced by temperature difference procedures. To achieve this, each circuit should have some form of inexpensive yet accurate producer of differential pressure related to flow, such as the previously outlined static balancing valve, or a small venturi or orifice measuring station. This requirement could also be a direct reading sensor (as these prices reach competitive levels, or the importance of the measured path requires). Measuring flow at each terminal enables verification of the system operation and, where required, proportional balancing. It also allows matching pump head and flow to actual system requirements and reducing excess flows by trimming the pump impeller or reducing pump speed. Often, reducing pump operating cost pays for the cost of water-side balancing.

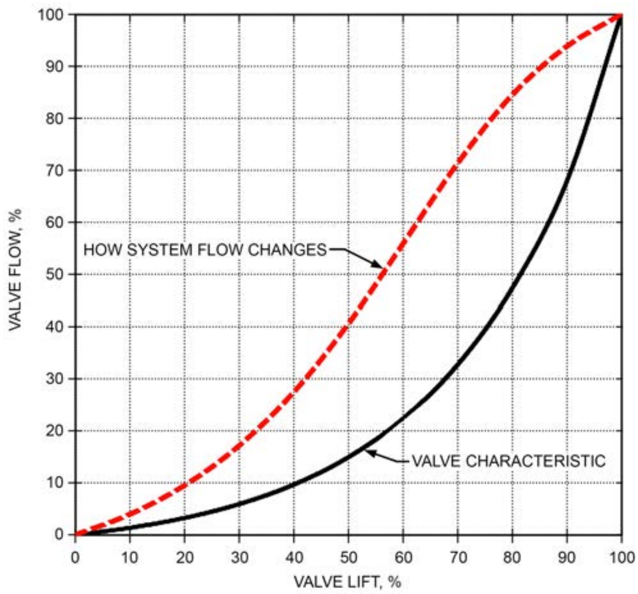

Fig. 10 System Flow and Valve Characteristics

Equipment

Proper equipment selection and preplanning are needed to successfully balance hydronic systems. Circumstances sometimes dictate that flow, temperature, and pressure be measured. The designer must specify the waterflow balancing devices and measurement points for installation during construction and use in testing during hydronic system measurement and adjustment. In addition, the designer is well served by specifying the minimum acceptable level for test equipment, which should include full-scale range and accuracy and required calibration. In so specifying, simplicity should be the order of the day. Temperature sensors should be able to fit into the specified measurement ports. Pressure and differential pressure sensing devices should be capable of providing accuracy that, when converted to system flow, falls within the specified tolerance for flow adjustment. Note that (as typical of all HVAC equipment) there is a broad range of implementation for specific instrumentation devices.

Record Keeping

Balancing requires accurate record keeping while making field measurements. Dated and signed field test reports help the designer or customer in work approval, and the owner has a valuable reference when documenting future changes.

Sizing Balancing Valves and Flow Measurement Devices

Flow measurement devices and balancing valves are placed in the system to measure flow and, where required, adjust waterflow to a terminal, branch, zone, riser, or main. These should be located on the leaving side of the hydronic branch, following the temperature control valve and prior to isolation or service valves. General branch layout is from takeoff to entering service valve and strainer, then to the coil, control valve, and balancing/service valve. Pressure is thereby left on the coil, helping keep dissolved air in solution and preventing false balance problems resulting from collected air and improper pressure references.

An improper but commonly applied sizing method is to select the valve or device for line size. These devices should be selected to pass design flows when near or at their fully open position with the differential pressure required to accurately represent flow for the measurement range desired. Although a small pressure drop may allow determination of design flow, it should be remembered that measurements will almost always be taken at reduced flows. The square relationship between flow and head will greatly reduce the available differential pressure for measurement. If a minimum differential pressure of 7 kPa is used for sizing, measurement at 50% design flow means measured ΔP will be 1.8 kPa; conversely, twice the flow will be a drop of 28 kPa. This factors into the practical and available instrumentation used in field measurement. If a manufacturer publishes a minimum accuracy of 0.5 kPa} and it was desired to read a flow of 0.06 L/s with an uncorrected valve flow coefficient of 1, then a 7 kPa drop would produce that reading at 0.02 L/s, or ±30%. If the designer is specifying a flow tolerance of ±10%, then sizing of devices and matching them to instrumentation become very important. A bare minimum 7 kPa pressure drop is suggested; more pressure drop for basic measurements is recommended. Many balancing valves and measuring meters give an accuracy of ±5% of range down to a pressure drop of 3 kPa with the balancing valve wide open. Too large a balancing valve pressure drop affects the performance and flow characteristic of the control valve. Too small a pressure drop affects its flow measurement accuracy as it is closed to balance the system. Equation (5) may be used to determine the flow coefficient A_v for a balancing valve or to size a control valve.

The flow coefficient A_v is defined as the number of cubic metres per second that flows through a wide-open valve with a pressure drop of 1 Pa. This is shown as

$$Q = A_v \sqrt{\rho / \Delta P} \qquad (4)$$

where

Q = design flow for terminal or valve, m^3/s
ρ = density of fluid, kg/m^3
SG = specific gravity of fluid
ΔP = pressure drop across valve, Pa

The inch-pound equivalent of A_v is C_v, measured in gallons per minute; C_v can be converted by the following factor:

$$A_v = 24 \times 10^{-6}\, C_v \qquad (5)$$

7. HYDRONIC BALANCING METHODS

Various techniques are used to balance hydronic systems. Balance by temperature difference and water balance by proportional method are the most common.

Preparation. Minimally, preparation before balancing should include collecting the following:

1. Pump submittal data; pump curves, motor data, etc.
2. Starter sizes and overload protection information
3. Control valve A_v ratings and temperature control diagrams
4. Chiller, boiler, and heat exchanger information; flow and head loss
5. Terminal unit information; flow and head loss data
6. Pressure relief and reducing valve setting
7. Flowmeter calibration curves
8. Other pertinent data

System Preparation for Static System

1. Examine piping system: Identify main pipes, risers, branches and terminals on as-built drawings. Check that flows for all balancing devices are indicated on drawings before beginning work. Check that design flows for each riser equal the sum of the design flows through the terminals.
2. Examine reducing valve
3. Examine pressure relief valves
4. Examine expansion tank
5. For pumps, confirm
   - Location and size
   - Vented volute
   - Alignment
   - Grouting
   - Motor and lubrication
   - Nameplate data
   - Pump rotational direction
6. For strainers, confirm
   - Location and size
   - Mesh size and cleanliness
7. Confirm location and size of terminal units
8. Control valves:
   - Confirm location and size
   - Confirm port locations and flow direction
   - Set all valves open to coil
   - Confirm actuator has required force to close valve under loaded conditions
9. Ensure calibration of all measuring instruments, and that all calibration data are known for balancing devices
10. Remove all air from piping; all high points should have air vents

Pump Start-Up

1. Start pump and confirm rotational direction; if rotation is incorrect, have corrected.
2. Read differential head and apply to pump curve to observe flow approximates design.

3. Slowly close pump (if pump is under 20 kW) throttle valve to shutoff. Read pump differential head from gages.
   - If shutoff head corresponds with published curve, the previously prepared velocity head correction curve can be used as a pump flow calibration curve.
   - A significant difference between observed and published shutoff head can be caused by an unvented volute, a partially plugged impeller, or by an impeller size different from that specified.

Confirmation of System Venting

1. Confirm tank location and size.
2. Shut off pump; record shutoff gage pressure at tank junction.
3. Start pump and record operating pressure at tank junction.
4. Compare operating to shutoff pressures at tank junction. If there is no pressure change, the system is air-free.
5. Eliminate free air.
   - No air separation: Shut off pump and revent. Retest and revent until tank junction pressure is stable.
   - Air separation: Operate system until free air has been separated out, indicated by stable tank junction pressure.

Balancing

For single-, multiple-, and parallel pump systems, after pump start-up and confirmation of system venting,

1. Adjust pump throttle until pump head differential corresponds to design.
2. Record pump motor voltage and amperage, and pump strainer head, at design flow.
3. Balance equipment room piping circuit so that pumped flow remains constant over alternative flow paths.
4. Record chiller and boiler circuits (for multiple-pump systems, requires a flowmeter installed between header piping).

For multiple-pump systems only,

5. Check for variable flow in source circuits when control valves are operated.
6. Confirm
   - Pump suction pressure remains above cavitations range for all operating conditions.
   - Pump flow rates remain constant.
   - Source working pressures are unaffected.

For parallel-pump systems, follow steps (1) to (4), then shut off pumps alternately and

7. Record head differential and flow rate through operating pump, and operating pump motor voltage and current.
8. Confirm that operational point is satisfactory (no overload, cavitation potential, etc.).

Balance by Temperature Difference

This common balancing procedure is based on measuring the water temperature difference between supply and return at the terminal. The designer selects the cooling and/or heating terminal for a calculated design load at full-load conditions. At less than full load, which is true for most operating hours, the temperature drop is proportionately less. Figure 11 demonstrates this relationship for a heating system at a design Δt of 10 K for outdoor design of –20°C and room design of 20°C.

For every outdoor temperature other than design, the balancing technician should construct a similar chart and read off the Δt for balancing. For example, at 50% load, or –1°C outdoor air, the Δt required is 5 K, or 50% of the design drop.

This method is a rough approximation and should not be used where great accuracy is required. It is not accurate enough for cooling systems.

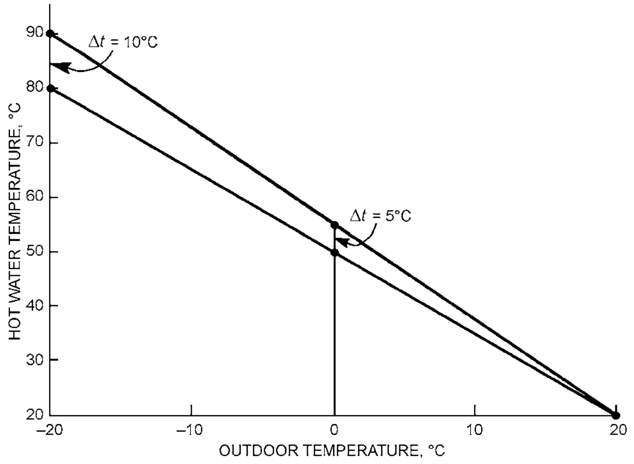

Fig. 11 Water Temperature Versus Outdoor Temperature Showing Approximate Temperature Difference

Water Balance by Proportional Method

Preset Method. A thorough understanding of the pressure drops in the system riser piping, branches, coils, control valves, and balancing valves is needed. Generally, several pipe and valve sizes are available for designing systems with high or low pressure drops. A flow-limiting or trim device will be required. Knowing system pressure losses in design allows the designer to select a balancing device to absorb excess system pressures in the branch, and to shift pressure drop (which might be absorbed by a balancing device nearly close to achieve balance) to the pipes, coils, and valves so the balancing device merely trims these components' performance at design flow. It may also indicate where high-head-loss circuits can exist for either relocation in the piping network, or hydraulic isolation through hybrid piping techniques. The installed balancing device should never be closed more than 40 to 50%; below this point flow reading accuracy falls to 20 to 30%. Knowing a starting point for setting the valve (preset) allows the designer to iterate system piping design. This may not always be practical in large systems, but minimizing head and flow saves energy over the life of the facility and allows for proper temperature control. In this method,

1. Analyze the piping network for the largest hydraulic loss based on design flow and pipe friction loss. The pump should be selected to provide the total of all terminal flows, and the head required to move water through the hydraulically greatest circuit. Balance devices in this circuit should be sized only for the loss required for flow measurement accuracy. Trimming is not required.
2. Analyze differences in pressure drop in the pumping circuit for each terminal without using a balancing device. The difference between each circuit and the pump head (which represents the drop in the farthest circuit) is the required drop for the balancing device.
3. Select a balancing device that will achieve this drop with minimum valve throttling. If greater than two pipe sizes smaller, shift design drop into control valve or coil (or both), equalizing pressure drop across the devices.
4. Monitor system elevations and pressure drops to ensure air management, minimizing pocket collections and false pressure references that could lead to phantom balancing problems.
5. Use proportional balancing methods as outlined for field testing and adjustment.

Proportional Balancing

Proportional water-side balancing may use design data, but relies most on as-built conditions and measurements and adapts well to design diversity factors. This method works well with multiple-riser systems. When several terminals are connected to the same circuit, any variation of differential pressure at the circuit inlet affects flows in all other units in the same proportion. Circuits are proportionally balanced to each other by a flow quotient:

$$\text{Flow quotient} = \frac{\text{Actual flow rate}}{\text{Design flow rate}} \qquad (6)$$

To balance a branch system proportionally,

1. Fully open the balancing and control valves in that circuit.
2. Adjust the main balancing valve for total pump flow of 100 to 110% of design flow.
3. Calculate each riser valve's quotient based on actual measurements. Record these values on the test form, and note the circuit with the lowest flow quotient.

Note: When all balancing devices are open, flow will be higher in some circuits than others. In some, flow may be so low that it cannot be accurately measured. The situation is complicated because an initial pressure drop in series with the pump is necessary to limit total flow to 100 to 110% of design; this decreases the available differential pressure for the distribution system. After all other risers are balanced, restart analysis of risers with unmeasurable flow at step (2).

Identify the riser with the highest flow ratio. Begin balancing with this riser, then continue to the next highest flow ratio, and so on. When selecting the branch with the highest flow ratio,

- Measure flow in all branches of the selected riser.
- In branches with flow higher than 150% of design, close the balancing valves to reduce flow to about 110% of design.
- Readjust total pump flow using the main valve.
- Start balancing in branches with a flow ratio greater than or equal to 1. Start with the branch with the highest flow ratio.

The reference circuit has the lowest quotient and the greatest pressure loss. Adjust all other balancing valves in that branch until they have the same quotient as the reference circuit (at least one valve in the branch should be fully open).

When a second valve is adjusted, the flow quotient in the reference valve also changes; continued adjustment is required to make their flow quotients equal. Once they are equal, they will remain equal or in proportional balance to each other while other valves in the branch are adjusted or until there is a change in pressure or flow.

When all balancing valves are adjusted to their branches' respective flow quotients, total system waterflow is adjusted to the design by setting the balancing valve at the pump discharge to a flow quotient of 1.

Pressure drop across the balancing valve at pump discharge is produced by the pump that is not required to provide design flow. This excess pressure can be removed by trimming the pump impeller or reducing pump speed. The pump discharge balancing valve must then be reopened fully to provide the design flow.

As in variable-speed pumping, diversity and flow changes are well accommodated by a system that has been proportionally balanced. Because the balancing valves have been balanced to each other at a particular flow (design), any changes in flow are proportionately distributed.

Balancing the water side in a system that uses diversity must be done at full flow. Because components are selected based on heat transfer at full flow, they must be balanced to this point. To accomplish full-flow proportional balance, shut off part of the system while balancing the remaining sections. When a section has been balanced, shut it off and open the section that was open originally to complete full balance of the system. When balancing, care should be taken if the building is occupied or if load is nearly full.

Variable-Speed Pumping. To achieve hydronic balance, full flow through the system is required during balancing, after which the system can be placed on automatic control and the pump speed allowed to change. After the full-flow condition is balanced and the system differential pressure set point is established, to control the variable-speed pumps, observe the flow on the circuit with the greatest resistance as the other circuits are closed one at a time. The flow in the observed circuit should remain equal to, or more than, the previously set flow. Waterflow may become laminar at less than 0.6 m/s, which may alter the heat transfer characteristics of the system.

Other Balancing Techniques

Flow Balancing by Rated Differential Procedure. This procedure depends on deriving a performance curve for the test coil, comparing water temperature difference Δt_w to entering water temperature t_{ew} minus entering air temperature t_{ea}. One point of the desired curve can be determined from manufacturer's ratings, which are published as $(t_{ew} - t_{ea})$. A second point is established by observing that the heat transfer from air to water is zero when $(t_{ew} - t_{ea})$ is zero (consequently, $\Delta t_w = 0$). With these two points, an approximate performance curve can be drawn (Figure 12). Then, for any other $(t_{ew} - t_{ea})$, this curve is used to determine the appropriate Δt_w. The basic curve applies to catalog ratings for lower dry-bulb temperatures, providing consistent entering air moisture content (e.g., 24°C db, 18°C wb). Changes in inlet water temperature, temperature rise, air velocity, and dry- and wet-bulb temperatures cause terminal performance to deviate from the curves. The curve may also be used for cooling coils for sensible transfer (dry coil).

Flow Balancing by Total Heat Transfer. This procedure determines waterflow by running an energy balance around the coil. From field measurements of airflow, wet- and dry-bulb temperatures up- and downstream of the coil, and the difference Δt_w between entering and leaving water temperatures, waterflow can be determined by the following equations:

$$Q_w = Q/4180\Delta t_w \qquad (7)$$

$$q_{cooling} = 1.20 Q_a (h_1 - h_2) \qquad (8)$$

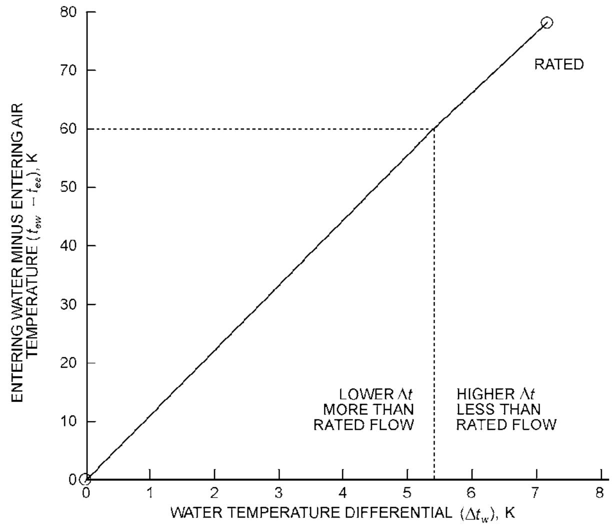

Fig. 12 Coil Performance Curve

$$q_{heating} = 1.23Q_a(t_1 - t_2) \quad (9)$$

where

Q_w = waterflow rate, L/s
q = load, W
$q_{cooling}$ = cooling load, W
$q_{heating}$ = heating load, W
Q_a = airflow rate, L/s
h = enthalpy, kJ/kg
t = temperature, °C

Example 1. Find the waterflow for a cooling system with the following characteristics:

Test data

t_{ewb} = entering wet-bulb temperature = 20.3°C
t_{lwb} = leaving wet-bulb temperature = 11.9°C
Q_a = airflow rate = 10 000 L/s
t_{lw} = leaving water temperature = 15.0°C
t_{ew} = entering water temperature = 8.6°C

From psychrometric chart

h_1 = 76.52 kJ/kg
h_2 = 52.01 kJ/kg

Solution: From Equations (5) and (6),

$$Q_w = \frac{1.20 \times 10\,000(76.52 - 52.01)}{4180(15.0 - 8.6)} = 11.0 \text{ L/s}$$

The desired waterflow is achieved by successive manual adjustments and recalculations. Note that these temperatures can be greatly influenced by the heat of compression, stratification, bypassing, and duct leakage.

General Balance Procedures

All the variations of balancing hydronic systems cannot be listed; however, the general method should balance the system and minimize operating cost. Excess pump pressure (operating power) can be eliminated by trimming the pump impeller. Allowing excess pressure to be absorbed by throttle valves adds a lifelong operating-cost penalty to the operation.

The following is a general procedure based on setting the balance valves on the site:

1. Develop a flow diagram if one is not included in the design drawings. Illustrate all balance instrumentation, and include any additional instrument requirements.
2. Compare pumps, primary heat exchangers, and specified terminal units, and determine whether a design diversity factor can be achieved.
3. Examine the control diagram and determine the control adjustments needed to obtain design flow conditions.

Balance Procedure: Primary and Secondary Circuits

1. Inspect the system completely to ensure that (1) it has been flushed out, it is clean, and all air is removed; (2) all manual valves are open or in operating position; (3) all automatic valves are in their proper positions and operative; and (4) the expansion tank is properly charged.
2. Place controls in position for design flow.
3. Examine flow diagram and piping for obvious short circuits; check flow and adjust the balance valve.
4. Take pump suction, discharge, and differential pressure readings at both full and no flow. For larger pumps, a no-flow condition may not be safe. In any event, valves should be closed slowly.
5. Read pump motor amperage and voltage, and determine approximate power.
6. Establish a pump curve, and determine approximate flow rate.
7. If a total flow station exists, determine the flow and compare with pump curve flow.
8. If possible, set total flow about 10% high using the total flow station first and the pump differential pressure second; then maintain pumped flow at a constant value as balance proceeds by adjusting the pump throttle valve.
9. Any branch main flow stations should be tested and set, starting by setting the shortest runs low as balancing proceeds to the longer branch runs.
10. With primary and secondary pumping circuits, a reasonable balance must be obtained in the primary loop before the secondary loop can be considered. The secondary pumps must be running and terminal units must be open to flow when the primary loop is being balanced, unless the secondary loop is decoupled.

8. FLUID FLOW MEASUREMENT

Flow Measurement Based on Manufacturer's Data

Any component (terminal, control valve, or chiller) that has an accurate, factory-certified flow/pressure drop relationship can be used as a flow-indicating device. The flow and pressure drop may be used to establish an equivalent flow coefficient as shown in Equation (3). According to the Bernoulli equation, pressure drop varies as the square of the velocity or flow rate, assuming density is constant:

$$Q_1^2/Q_2^2 = \Delta h_1/\Delta h_2 \quad (10)$$

For example, a chiller has a certified pressure drop of 80 kPa at 10 L/s. The calculated flow with a field-measured pressure drop of 90 kPa is

$$Q_2 = 10\sqrt{90/80} = 10.6 \text{ L/s} \quad (11)$$

Flow calculated in this manner is only an estimate. The accuracy of components used as flow indicators depends on the accuracy of (1) cataloged information concerning flow/pressure drop relationships and (2) pressure differential readings. As a rule, the component should be factory-certified flow tested if it is to be used as a flow indicator.

Pressure Differential Readout

Gages or digital differential pressure manometers are used to read differential pressures. Accurate readout is diminished when two separate devices are used, especially when the two are gages that are permanently mounted. When applying a single pressure gage for differential readout, follow the example of Figure 13. This gage should be alternately valved to the high- and low-pressure side to establish the differential. A single gage needs no static height correction, and excess coordinated errors caused by disparate gage calibration are eliminated.

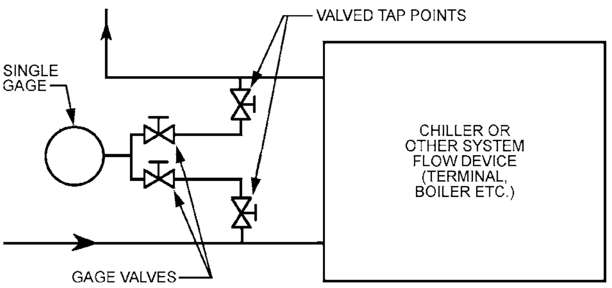

Fig. 13 Single Gage for Reading Differential Pressure

Differential pressure can also be read from differential gages, thus eliminating the need to subtract outlet from inlet pressures to establish differential pressure. Differential pressure gages are usually dual gages mechanically linked to read differential pressure.

Conversion of Differential Pressure to Head

Gages may be calibrated to metres of fluid head, which, historically, refers to the height of water above a point in the fluid circuit. Head is a function of density and is related to pressure by the hydrostatic law as

$$h = p/\rho g \quad (12)$$

where

h = fluid head, m
p = pressure, Pa
ρ = density, kg/m³
g = standard force of gravity = 9.806 65 N/kg

Because the calibration only applies at one density (typically at a standard temperature of 15°C), the reading of head may require correction when the gage is applied to high-temperature water with a significantly lower density. The relationship between head and pressure as a function of density is shown in Table 2.

Table 2 Differential Pressure Conversion to Head

Fluid Density, kg/m³	Approximate Corresponding Water Temperature, °C	Metre Fluid Head Equal to 1 kPa*
1500		0.680
1400		0.0728
1300		0.0784
1200		0.0850
1100		0.0927
1000	10	0.1020
980	65	0.104
960	95	0.106
940	125	0.108
920	150	0.111
900	170	0.113
800		0.127
700		0.146
600		0.170
500		0.204

*Differential kPa readout is multiplied by this number to obtain metres fluid head when gage is calibrated in kPa.

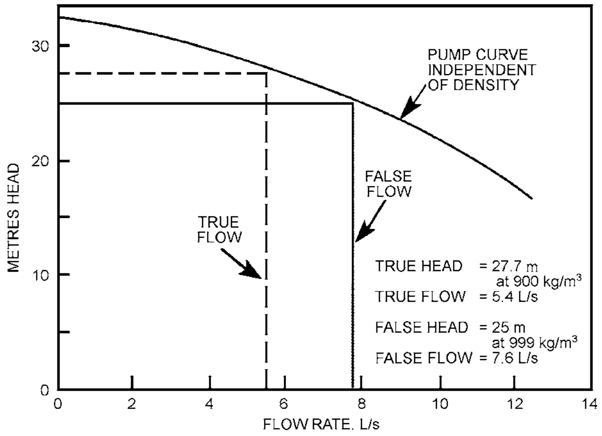

Fig. 14 Fluid Density Correction Chart for Pump Curves

For example, a manufacturer may test a boiler control valve with 40°C water. Differential pressures from another test made in the field at 120°C may be correlated with the manufacturer's data by using Equation (8) to account for the density differences of the two tests.

When differential heads are used to estimate flow, a density correction must be made because of the shape of the pump curve. For example, in Figure 15 the uncorrected differential reading for pumped water with a density of 900 kg/m³ is 25 m; the gage conversion was assumed to be for water with a density of 999 kg/m³. The uncorrected or false reading gives a 40% error in flow estimation.

Differential Head Readout with Manometers

Manometers are used for differential pressure readout, especially when very low differentials, great precision, or both, are required. But manometers must be handled with care; they should not be used for field testing because fluid could blow out into the water and rapidly deteriorate the components. A proposed manometer arrangement is shown in Figure 15.

Figure 15 and the following instructions provide accurate manometer readings with minimum risk of blowout.

1. Make sure that both legs of manometer are filled with water.
2. Open purge bypass valve.
3. Open valved connections to high and low pressure.
4. Open bypass vent valve slowly and purge air here.
5. Open manometer block vents and purge air at each point.
6. Close needle valves. The columns should zero in if the manometer is free of air. If not, vent again.
7. Open needle valves and begin throttling purge bypass valve slowly, watching the fluid columns. If the manometer has an adequate available fluid column, the valve can be closed and the differential reading taken. However, if the fluid column reaches the top of the manometer before the valve is completely closed, insufficient manometer height is indicated and further throttling will blow fluid into the blowout collector. A longer manometer or the single gage readout method should then be used.

An error is often introduced when converting millimetres of gage fluid to the pressure difference (in kilopascals) of test fluid. The conversion factor changes with test fluid temperature, density, or both. Conversion factors shown in Table 2 are to a water base, and the counterbalancing water height H (Figure 15) is at room temperature.

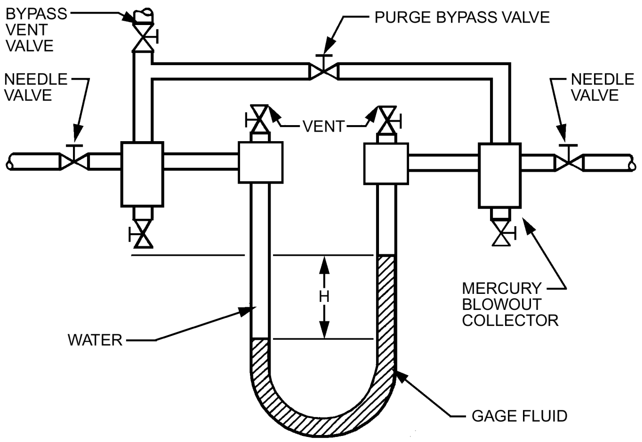

Fig. 15 Fluid Manometer Arrangement for Accurate Reading and Blowout

Orifice Plates, Venturi, and Flow Indicators

Manufacturers provide flow information for several devices used in hydronic system balance. In general, the devices can be classified as (1) orifice flowmeters, (2) venturi flowmeters, (3) velocity impact meters, (4) pitot-tube flowmeters, (5) bypass spring impact flowmeters, (6) calibrated balance valves, (7) turbine flowmeters, and (8) ultrasonic flowmeters.

The **orifice flowmeter** is widely used and is extremely accurate. The meter is calibrated and shows differential pressure versus flow. Accuracy generally increases as the pressure differential across the meter increases. The differential pressure readout instrument may be a manometer, differential gage, or single gage.

The **venturi flowmeter** has lower pressure loss than the orifice plate meter because a carefully formed flow path increases velocity head recovery. The venturi flowmeter is placed in a main flow line where it can be read continuously.

Velocity impact meters have precise construction and calibration. The meters are generally made of specially contoured glass or plastic, which allows observation of a flow float. As flow increases, the flow float rises in the calibrated tube to indicate flow rate. Velocity impact meters generally have high accuracy.

A special version of the velocity impact meter is applied to hydronic systems. This version operates on the velocity pressure difference between the pipe side wall and the pipe center, which causes fluid to flow through a small flowmeter. Accuracy depends on the location of the impact tube and on a velocity profile that corresponds to theory and the laboratory test calibration base. Generally, the accuracy of this **bypass flow impact** or differential velocity pressure flowmeter is less than a flow-through meter, which can operate without creating a pressure loss in the hydronic system.

The **pitot-tube flowmeter** is also used for pipe flow measurement. Manometers are generally used to measure velocity pressure differences because these differences are low.

The **bypass spring impact flowmeter** uses a defined piping pressure drop to cause a correlated bypass side branch flow. The side branch flow pushes against a spring that increases in length with increased flow. Each individual flowmeter is calibrated to relate extended spring length position to main flow. The bypass spring impact flowmeter has, as its principal merit, a direct readout. However, dirt on the spring reduces accuracy. The bypass is opened only when a reading is made. Flow readings can be taken at any time.

The **calibrated balance valve** is an adjustable orifice flowmeter. Balance valves can be calibrated so that a flow/pressure drop relationship can be obtained for each incremental setting of the valve. A ball, rotating plug, or butterfly valve may have its setting expressed in percent open or degree open; a globe valve, in percent open or number of turns. The calibrated balance valve must be manufactured with precision and care to ensure that each valve of a particular size has the same calibration characteristics.

The **turbine flowmeter** is a mechanical device. The velocity of the liquid spins a wheel in the meter, which generates a 4 to 20 mA output that may be calibrated in units of flow. The meter must be well maintained, because wear or water impurities on the bearing may slow the wheel, and debris may clog or break the wheel.

The **ultrasonic flowmeter** senses sound signals, which are calibrated in units of flow. The ultrasonic metering station may be installed as part of the piping, or it may be a strap-on meter. In either case, the meter has no moving parts to maintain, nor does it intrude into the pipe and cause a pressure drop. Two distinct types of ultrasonic meter are available: (1) the transit time meter for HVAC or clear-water systems and (2) the Doppler meter for systems handling sewage or large amounts of particulate matter.

If any of the above meters are to be useful, the minimum distance of straight pipe upstream and downstream, as recommended by the meter manufacturer and flow measurement handbooks, must be adhered to. Figure 16 presents minimum installation suggestions.

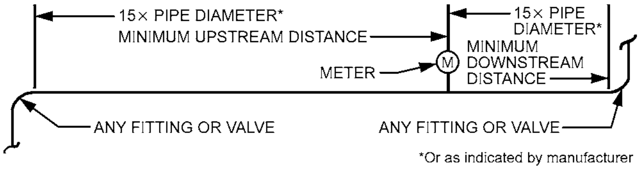

Fig. 16 Minimum Installation Dimensions for Flowmeter

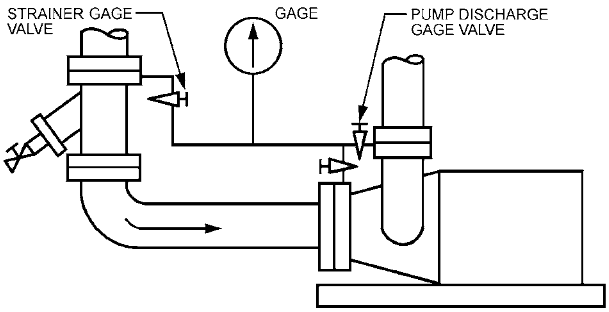

Fig. 17 Single Gage for Differential Readout Across Pump and Strainer

Using Pump as Indicator

Although the pump is not a meter, it can be used as an indicator of flow together with the other system components. Differential pressure readings across a pump can be correlated with the pump curve to establish the pump flow rate. Accuracy depends on (1) accuracy of readout, (2) pump curve shape, (3) actual conformance of the pump to its published curve, (4) pump operation without cavitation, (5) air-free operation, and (6) velocity pressure correction.

When a differential pressure reading must be taken, a single gage with manifold provides the greatest accuracy (Figure 17). The pump suction to discharge differential can be used to establish pump differential pressure and, consequently, pump flow rate. The single gage and manifold may also be used to check for strainer clogging by measuring the pressure differential across the strainer.

If the pump curve is based on fluid head, pressure differential, as obtained from the gage reading, needs to be converted to head, which is pressure divided by the density and gravity. The pump differential head is then used to determine pump flow rate (Figure 18). As long as the differential head used to enter the pump curve is expressed as head of the fluid being pumped, the pump curve shown by the manufacturer should be used as described. The pump curve may state that it was defined by test with 30°C water. This is unimportant, because the same curve applies from 15 to 120°C water, or to any fluid within a broad viscosity range.

Generally, pump-derived flow information, as established by the performance curve, is questionable unless the following precautions are observed:

1. The installed pump should be factory calibrated by a test to establish the actual flow/pressure relationship for that particular pump. Production pumps can vary from the cataloged curve because of minor changes in impeller diameter, interior casting tolerances, and machine fits.
2. When a calibration curve is not available for a centrifugal pump being tested, the discharge valve can be closed briefly to establish the no-flow shutoff pressure, which can be compared to the published curve. If the shutoff pressure differs from that

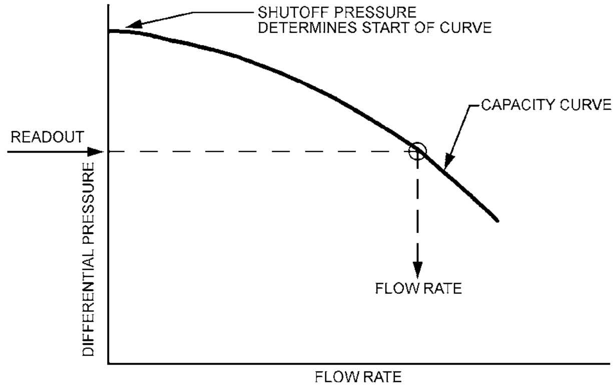

Fig. 18 Differential Pressure Used to Determine Pump Flow

published, draw a new curve parallel to the published curve. Though not exact, the new curve usually fits the actual pumping circumstance more accurately. Clearance between the impeller and casing minimizes the danger of damage to the pump during a no-flow test, but manufacturer verification is necessary.

3. Differential pressure should be determined as accurately as possible, especially for pumps with flat flow curves.
4. The pump should be operating air-free and without cavitation. A cavitating pump will not operate to its curve, and differential readings will provide false results.
5. Ensure that the pump is operating above the minimum net positive suction pressure.
6. Power readings can be used (1) as a check for the operating point when the pump curve is flat or (2) as a reference check when there is suspicion that the pump is cavitating or providing false readings because of air.
7. The flow determined by the pump curve should be compared to the flow measured at the flowmeters, flow measured by pressure drops through circuits, and flow measured by pressure drops through exchangers.
8. The pump flow derived from the pressure differential at the suction and discharge connections is only an indicator of the actual flow; it cannot be used to verify the test and balance measurements. If pump flow is to be used for balancing verification, it needs to be determined using the Hydraulic Institute procedure or by measuring the flow through a properly installed metering station 15 to 20 straight pipe diameters downstream from the pump discharge.

Power draw should be measured in watts. Ampere readings cannot be trusted because of voltage and power factor problems. If motor efficiency is known, the wattage drawn can be related to pump brake power (as described on the pump curve) and the operating point determined.

Central Plant Chilled-Water Systems

For existing installations, establishing accurate thermal load profiles is of prime importance because it establishes proper primary chilled-water supply temperature and flow. In new installations, actual load profiles can be compared with design load profiles to obtain valid operating data.

To perform proper testing and balancing, all interconnecting points between the primary and secondary systems must be designed with sufficient temperature, pressure, and flow connections so that adequate data may be indicated and/or recorded.

Water Flow Instruments

As indicated previously, proper location and use of instruments is vital to accurate balancing. Instruments for testing temperature and pressure at various locations are listed in Table 3. Flow-indicating devices should be placed in water systems as follows:

Table 3 Instruments for Monitoring a Water System

Point of Information	Manifold Gage	Single Gage	Thermometer	Test Well	Pressure Tap
Pump: Suction, discharge	x				
Strainer: In, out					x
Cooler: In, out		x	x		
Condensers: In, out		x	x		
Concentrator: In, out		x	x		
Absorber: In, out		x	x		
Tower cell: In, out				x	x
Heat exchanger: In, out	x		x		
Coil: In, out				x	x
Coil bank: In, out		x	x		
Booster coil: In, out					x
Cool panel: In, out					x
Heat panel: In, out				x	x
Unit heater: In, out					x
Induction: In, out					x
Fan-coil: In, out					x
Water boiler: In, out			x		
Three-way valve: All ports					x
Zone return main			x		
Bridge: In, out			x		
Water makeup		x			
Expansion tank		x			
Strainer pump					x
Strainer main	x				
Zone three-way: All ports				x	x

- At each major heating coil bank (0.6 L/s or more)
- At each major cooling coil bank (0.6 L/s or more)
- At each bridge in primary-secondary systems
- At each main pumping station
- At each water chiller evaporator
- At each water chiller condenser
- At each water boiler outlet
- At each floor takeoff to booster reheat coils, fan coil units, induction units, ceiling panels, and radiation (do not exceed 25 terminals off of any one zone meter probe)
- At each vertical riser to fan coil units, induction units, and radiation
- At the point of tie-in to existing systems

9. BALANCING STEAM DISTRIBUTION SYSTEMS

Procedures for Steam Balancing Variable Flow Systems

Steam distribution cannot be balanced by adjustable flow-regulating devices. Instead, fixed restrictions built into the piping in accordance with carefully designed pipe and orifice sizes are used to regulate flow.

It is important to have a balanced distribution of steam to all portions of the steam piping at all loads. This is best accomplished by properly designing the steam distribution piping, which includes carefully considering steam pressure, steam quantities required by each branch circuit, pressure drops, steam velocities, and pipe sizes. Just as other flow systems are balanced, steam distribution systems are balanced by ensuring that the pressure drops are equalized at design flow rates for all portions of the piping. Only marginal balancing can be done by pipe sizing. Therefore, additional steps must be taken to achieve a balanced performance.

Steam flow balance can be improved by using spring-type packless supply valves equipped with precalibrated orifices. The valves should have a tight shutoff between 80 to 400 kPa (gage). These valves have a nonrising stem, are available with a lockshield, and have a replaceable disk. Orifice flanges can also be used to regulate and measure steam flow at appropriate locations throughout the system. The orifice sizes are determined by the pressure drop required for a given flow rate at a given location. A schedule should be prepared showing (1) orifice sizes, (2) valve or pipe sizes, (3) required flow rates, and (4) corresponding pressure differentials for each flow rate. It may be useful to calculate pressure differentials for several flow rates for each orifice size. Such a schedule should be maintained for future reference.

After the appropriate regulating orifices are installed in the proper locations, the system should be tested for tightness by sealing all openings in the system and applying a vacuum of 35 kPa (absolute), held for 2 hours. Next, the system should be readied for warm-up and pressurizing with steam following the procedures outlined in Section VI of the ASME *Boiler and Pressure Vessel Code*. After the initial warm-up and system pressurization, evaluate system steam flow, and compare it to system requirements. The orifice schedule calculated earlier will now be of value should any of the orifices need to be changed.

Steam Flow Measuring Devices

Many devices are available for measuring flow in steam piping: (1) steam meters, (2) condensate meters, (3) orifice plates, (4) venturi fittings, (5) steam recorders, and (6) manometers for reading differential pressures across orifice plates and venturi fittings. Some of these devices are permanently affixed to the piping system to facilitate taking instantaneous readings that may be necessary for proper operation and control. A surface pyrometer used in conjunction with a pressure gage is a convenient way to determine steam saturation temperature and the degree of superheat at various locations in the system. This information can be used to evaluate performance characteristics.

Steam Pressure Regulation

Many large steam systems generate steam at higher pressures (for distribution efficiencies) than what is required by the building systems, and then modulate the pressure using pressure-reducing valves (PRVs). To aid in stable pressure control at low loads, many engineers install two PRVs sized for 1/3 and 2/3 of the design flow rate. To aid in stable pressure control during moderate loads, verify that the 2/3 PRV does not open until the 1/3 PRV is full open.

10. BALANCING COOLING TOWERS

Field-testing cooling towers is demanding and difficult. ASME *Standard* PTC 23 and CTI *Standard Specification* ATC-105 establish procedures for these tests. Certain general guidelines for testing cooling towers are as follows.

Waterflow from condenser to cooling tower should be the same flow. There may be basins and bypasses in the path that affect this pattern. Flow measurements should be made at both locations. For accurate flow measurements and good quality of flow, meters are required to be installed in the supply piping to each cooling tower and to each condenser. The condenser supply is from the cooling tower. This is a requirement even if there is more than one chiller or more than one cooling tower per system.

Measurements and Verification Process

1. Measure waterflow both into and out of the condenser.
2. Measure waterflow in the cooling tower and balance each cooling tower for design flow.
3. Measure flow of makeup water to each tower basin. Set overflow to zero during test so the evaporation rate can be determined. During test, isolate make up water.
4. Verify control valves are operating properly.
5. Verify the entire condenser water system is operating correctly by allowing the system to go to full cooling. Not all chillers need to run with adequate flow meters, but the controls must allow full flow through the condenser and cooling tower. Take final flow measurements and record for the final report.
6. Measure and record the temperatures on and off the cooling towers.
7. Measure and record outdoor wet-bulb temperature.
8. If the cooling tower has nozzles and pressure gages installed, take pressure measurements on each line to the nozzles at full flow and record.
9. Measure power usage including nameplate data. Include motor amperage, voltage, hertz, safety factor, overload protection, manufacturer, and rating. List nameplate motor power and actual brake power.
10. List cooling tower airflow from brake power and manufacturers' data.

Calculations and Verification

1. Calculate heat rejection of cooling tower as follows.

$$\text{Flow} \times \Delta t \times \text{factor/rate} = \text{heat rejection kilowatts}$$

Example:

$$63 \text{ L/s} \times 11.1\ \Delta t\ \text{K} \times 4.2/4.396 \text{ kW} = 668 \text{ kilowatts}$$

2. Verify and record data that each cooling tower is operating within manufacturers' design. Verify
   - Waterflow
   - Airflow
   - Power
   - Makeup water
   - Overflow water
   - Water treatment (with data from water treatment contractor)
3. If standby cooling towers and equipment are in the system, start up the standby units and shut down the tested units and repeat test.

11. VERIFICATION OF CONTROLS OPERATION

The performance of the HVAC system's automatic controls should be inspected and tested in each seasonal mode. In addition, the performance of all life safety devices and their interface with the HVAC systems should be verified and reported. In general, the TAB technician is responsible for verifying that the control system is operating as specified, and for reporting any installation problems discovered. Basically, this means (1) setting controls to a proper fixed mode to prevent changes during balancing, and (2) verifying proper operation. Actual adjusting, moving, or recalibrating controls is normally the responsibility of the control contractor. However, TAB technicians should work closely with the control contractor to ensure system operation within design limitations, identify and correct any problems, and ensure the safety of the system and its components, fulfilling the following steps:

1. Verify that controllers, including limiting controllers (e.g., fire stats and freeze stats), are calibrated and in control.
2. Verify that controller set points meet design intent.
3. Confirm that the sequences of operation for any control mode are in compliance with the approved drawings.
4. Check that the control terminations are in accordance with the approved drawings.
5. Verify the settings, operation, and adjustment of all end switches, mercury switches, solenoid valves, contractors, etc.
6. Check the operation of lockout or interlock systems.
7. Check the operation of all valve and damper actuators.
8. Determine that all controlled devices are properly connected.

9. Verify the operation of pilot positioners.
10. Confirm that all controlled devices are operated by the intended controller and note any overlap of controlled devices.
11. Prove that all controlled devices are in the position indicated by the controller (either open, closed, or modulating).
12. Determine the integrity of all controlled devices with regard to tightness of close-off and full-open positions. This includes dampers in multizone units, mixing boxes, and VAV air terminal devices.
13. Ensure that all controlled devices have free travel.
14. Verify that all controlled devices are properly installed in the distribution system with respect to direction of flow and location.
15. Confirm the proper operation of all controlled devices as applicable to normally open or normally closed.
16. Test the fail-safe modes of all controlled devices.
17. Examine the span of controls from a normally open position to a normally closed position, observing any dead bands, excessive pressures, and leading or lagging of simultaneously or sequentially controlled devices.
18. Check the location and installation of all sensors to determine if they will sense only the intended temperatures, humidities, or pressures.
19. Also check for potential erratic operation because of outdoor influences such as sunlight, drafts, outdoor walls, etc.

For pneumatic systems:

1. Check main supply air for proper pressures.
2. Observe the operation of the compressor and dryer.

For electronic systems:

1. Confirm that the control voltage is correct.
2. With the system in normal operation, test each control loop at both ends of its control range to verify that all control loops and their individual field points are responding correctly.
3. Check the calibration of all field sensors.
4. Verify the calibration and response time of all transducers.
5. Determine if the system has lightning protection and battery back-up.

For direct digital systems:

1. Confirm that the control voltage is correct.
2. With the system in normal operation, test each control loop at both ends of its control range to prove that all control loops and their individual field points are responding correctly.
3. Check the calibration of all field sensors.
4. Verify the calibration and response time of all transducers.
5. Determine if the system has lightning protection and battery back-up.
6. Confirm the application and accuracy of the software algorithms for each control loop.
7. Test the operation of the phone modem.

12. THERMAL PERFORMANCE VERIFICATION

After performing all preceding procedures, the system shall be set to simulate design conditions. Measure and record a complete set of dry-bulb and wet-bulb temperatures for air entering and leaving coils and heat exchangers, air leaving terminal devices (diffusers), and air in conditioned rooms or spaces. If conditions cannot be simulated and this affects verification, it should be documented in the testing and balancing report.

13. OUTDOOR AIR VENTILATION VERIFICATION

After completion of the balancing procedures, the system outdoor air rate should be verified. This is necessary to ensure that the design minimum outdoor air is being supplied to the occupied spaces. Obtain the minimum outdoor air rate and the appropriate balance conditions from the design documents. Determine the total system actual flow rate by traverse or other approved method and the return air rate by the same method. If adequate space is not available to perform a proper traverse, use the temperature ratio method if the outdoor temperature is at least 11 K above or below the return air temperature. Adjust the outdoor air rate to equal the required flow rate by balancing the return air system to allow sufficient outdoor air to enter the system. This setting should be locked in and marked as the minimum outdoor air setting. After setting the outdoor air rate, recheck the total system flow to make sure that it has not changed.

14. TEMPERATURE CONTROL VERIFICATION

The test and balance technician should work closely with the temperature control installer to ensure that the project is completed correctly. The balancing technician needs to verify proper operation of the control and communicate findings back to the agency responsible for ensuring that the controls have been installed correctly. This is usually the HVAC system designer, although others may be involved. Generally, the balancing technician does not adjust, relocate, or calibrate the controls. However, this is not always the case, and differences do occur with VAV terminal unit controllers. The balancing technician should be familiar with the specifications and design intent of the project so that all responsibilities are understood.

During the design and specification phase of the project, the designer should specify verification procedures for the controls and responsibilities for the contractor who installs the temperature controls. It is important that the designer specify the (1) degree of coordination between the installer of the control and the balancing technician and (2) testing responsibilities of each.

Verification of control operation starts with the balancing technician reviewing the submitted documents and shop drawings of the control system. In some cases, the controls technician should instruct the balancing technician in the operation of certain control elements, such as digital terminal unit controllers. This is followed by schedule coordination between the control and balancing technicians. In addition, the balancing and controls technicians need to work together when reviewing the operation of some sections of the HVAC system, particularly with VAV systems and the setting of the flow measurement parameters in digital terminal unit controllers.

Major mechanical systems should be verified after testing, adjusting, and balancing is completed. The control system should be operated in stages to prove it can match system capacity to varying load conditions. Mechanical subsystem controllers should be verified when balancing data are collected, considering that the entire system may not be completely functional at the time of verification. Testing and verification should account for seasonal variations; tests should be performed under varying outdoor loads to ensure operational performance. Retesting a random sample of terminal units may be desirable to verify the control technician's work.

Suggested Procedures

The following verification procedures may be used with either pneumatic or electrical controls:

1. Obtain design drawings and documentation, and become well acquainted with the design intent and specified responsibilities.
2. Obtain copies of approved control shop drawings.
3. Compare design to installed field equipment.
4. Obtain recommended operating and test procedures from manufacturers.
5. Verify with the control contractor that all controllers are calibrated and commissioned.

6. Check location of transmitters and controllers. Note adverse conditions that would affect control, and suggest relocation as necessary.
7. Note settings on controllers. Note discrepancies between set point for controller and actual measured variable.
8. Verify operation of all limiting controllers, positioners, and relays (e.g., high- and low-temperature thermostats, high- and low-differential pressure switches, etc.).
9. Activate controlled devices, checking for free travel and proper operation of stroke for both dampers and valves. Verify normally open (NO) or normally closed (NC) operation.
10. Verify sequence of operation of controlled devices. Note line pressures and controlled device positions. Correlate to air or waterflow measurements. Note speed of response to step change.
11. Confirm interaction of electrically operated switch transducers.
12. Confirm interaction of interlock and lockout systems.
13. Coordinate balancing and control technicians' schedules to avoid duplication of work and testing errors.

Pneumatic System Modifications

1. Verify main control supply air pressure and observe compressor and dryer operation.
2. For hybrid systems using electronic transducers for pneumatic actuation, modify procedures accordingly.

Electronic Systems Modifications

1. Monitor voltages of power supply and controller output. Determine whether the system operates on a grounded or nongrounded power supply, and check condition. Although electronic controls now have more robust electronic circuits, improper grounding can cause functional variation in controller and actuator performance from system to system.
2. Note operation of electric actuators using spring return. Generally, actuators should be under control and use springs only upon power failure to return to a fail-safe position.

Direct Digital Controllers

Direct digital control (DDC) offers nontraditional challenges to the balancing technician. Many control devices, such as sensors and actuators, are the same as those in electronic and pneumatic systems. Currently DDC is dominated by two types of controllers: fully programmable or application-specific. Fully programmable controllers offer a group of functions linked together in an applications program to control a system such as an air-handling unit. Application-specific controllers are functionally defined with the programming necessary to carry out the functions required for a system, but not all adjustments and settings are defined. Both types of controllers and their functions have some variations. One of the functions is adaptive control, which includes control algorithms that automatically adjust settings of various controller functions.

The balancing technician must understand controller functions so that they do not interfere with the test and balance functions. Literacy in computer programming is not necessary, although it does help. When testing the DDC,

1. Obtain controller application program. Discuss application of the designer's sequence with the control programmer.
2. Coordinate testing and adjustment of controlled systems with mechanical systems testing. Avoid duplication of efforts between technicians.
3. Coordinate storage (e.g., saving to central DDC database and controller memory) of all required system adjustments with control technician.

In cases where the balancing agency is required to test discrete points in the control system,

1. Establish criteria for test with the designer.
2. Use reference standards that test the end device through the entire controller chain (e.g., device, wiring, controller, communications, and operator monitoring device). An example would be using a dry block temperature calibrator (a testing device that allows a temperature to be set, monitored, and maintained in a small chamber) to test a space temperature sensor. The sensor is installed with extra wire so that it may be removed from the wall and placed in the calibrator chamber. After the system is thermally stabilized, the temperature is read at the controller and the central monitor, if installed.
3. Report findings of reference and all points of reading.

Refer to ASHRAE *Standard* 111 for further details on HVAC TAB.

15. TESTING FOR SOUND AND VIBRATION

Testing for sound and vibration ensures that equipment is operating satisfactorily and that no objectionable noise and vibration are transmitted to the building structure and occupied space. Although sound and vibration are specialized fields that require expertise not normally developed by the HVAC engineer, the procedures to test HVAC are relatively simple and can be performed with a minimum of equipment by following the steps outlined in this section. Although this section provides useful information for resolving common noise and vibration problems, consult Chapter 49 for details on problem solving or the design of HVAC.

Testing for Sound

Present technology does not test whether equipment is operating within rated sound levels; field tests can only determine sound pressure levels, and equipment ratings are almost always in terms of sound power levels. Until new techniques are developed, the testing engineer can only determine (1) whether sound pressure levels are within desired limits and (2) which equipment, systems, or components are the source of excessive or disturbing transmission.

Sound-Measuring Instruments. Although an experienced listener can often determine whether systems are operating in an acceptably quiet manner, sound-measuring instruments are necessary to determine whether system noise levels are in compliance with specified criteria, and if not, to obtain and report detailed information to evaluate the cause of noncompliance. Instruments normally used in field testing are as follows.

The **precision sound level meter** is used to measure sound pressure level. The most basic sound level meters measure overall sound pressure level and have up to three weighted scales that provide limited filtering capability. The instrument is useful in assessing outdoor noise levels in certain situations and can provide limited information on the low-frequency content of overall noise levels, but it provides insufficient information for problem diagnosis and solution. Its usefulness in evaluating indoor HVAC sound sources is thus limited.

Proper evaluation of HVAC sound sources requires a sound level meter capable of filtering overall sound levels into frequency increments of one octave or less.

Sound analyzers provide detailed information about sound pressure levels at various frequencies through filtering networks. The most popular sound analyzers are the octave band and one third octave band center frequency analyzers, which break the sound into the eight octave bands or twenty-four third octave bands of audible sound. Octave band or narrower sound analyzers are required where specifications are based on noise criteria (NC) and room criteria (RC) curves or similar frequency criteria and for problem jobs where knowledge of frequency is necessary to determine proper corrective action.

Personal computers are a versatile sound-measuring tool. Software used on portable computers has all the functional capabilities described previously, plus many that previously required a fully equipped acoustical laboratory. This type of sound-measuring system is many times faster and much more versatile than conventional sound level meters. With suitable accessories, it can also be used to evaluate vibration levels. Accuracy and calibration to applicable standards are of concern for software.

Regardless of which sound-measuring system is used, it should be calibrated before each use. Some systems have built-in calibration, while others use external calibrators. Much information is available on the proper application and use of sound-measuring instruments.

Air noise, caused by air flowing at a velocity of over 5 m/s or by winds over 19 km/h, can cause substantial error in sound measurements because of wind effect on the microphone. For outdoor measurements or in drafty places, either a wind screen for the microphone or a special microphone is required. When in doubt, use a wind screen on standard microphones.

Sound Level Criteria. Without specified values, the testing engineer must determine whether sound levels are within acceptable limits (Table 1 in Chapter 49 Note that a complete absence of noise is seldom a design criterion, except for certain critical locations such as sound and recording studios. In most locations, a certain amount of noise is desirable to mask other noises and provide speech privacy; it also provides an acoustically pleasing environment, because few people can function effectively in extreme quiet. Table 1 in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals* lists typical sound pressure levels. Most field sound-measuring instruments and techniques yield an accuracy of ±3 dB, the smallest difference in sound pressure level that the average person can discern. A reasonable tolerance for sound criteria is 5 dB.

The measured sound level of any location is a combination of all sound sources present, including sound generated by HVAC equipment, as well as sound from other sources such as plumbing systems and fixtures, elevators, light ballasts, and outdoor noises. In testing for sound, all sources from other than HVAC equipment are considered background or ambient noise.

Background sound measurements generally have to be made (1) when the specification requires that the sound levels from HVAC equipment only, as opposed to the sound level in a space, not exceed a certain specified level; (2) when the sound level in the space exceeds a desirable level, in which case the noise contributed by the HVAC system must be determined; and (3) in residential locations where little significant background noise is generated during the evening hours and where generally low allowable noise levels are specified or desired. Because background noise from outdoor sources such as vehicular traffic can fluctuate widely, sound measurements for residential locations are best made in the normally quiet evening hours. Procedures for residential sound measurements can be found in ASTM *Standard* E1574, Measurement of Sound in Residential Spaces.

Sound Testing. Ideally, a building should be completed and ready for occupancy before sound level tests are taken. All spaces in which readings will be taken should be furnished with whatever drapes, carpeting, and furniture are typical because these affect the room absorption, which can affect sound levels and the subjective quality of the sound. In actual practice, because most tests must be conducted before the space is completely finished and furnished for final occupancy, the testing engineer must make some allowances. Because furnishings increase the absorption coefficient and reduce by about 4 dB the sound pressure level that can be expected between most live and dead spaces, the following guidelines should suffice for measurements made in unfurnished spaces. If the sound pressure level is 5 dB or more over the specified or desired criterion, it can be assumed that the criterion will not be met, even with the increased absorption provided by furnishings. If the sound pressure level is under 4 dB greater than the specified or desired criterion, recheck when the room is furnished to determine compliance.

Follow this general procedure:

1. Obtain a complete set of accurate, as-built drawings and specifications, including duct and piping details. Review specifications to determine sound and vibration criteria and any special instructions for testing.
2. Visually check for noncompliance with plans and specifications, obvious errors, and poor workmanship. Turn system on for aural check. Listen for noise and vibration (especially duct leaks and loose fittings).
3. Adjust and balance equipment, as described in other sections, so that final acoustical tests are made with the HVAC system operating as designed. It is desirable to perform acoustical tests for both summer and winter operation, but where this is not practical, make tests for the summer operating mode, as it usually has the potential for higher sound levels. Tests must be made for all mechanical equipment and systems, including standby.
4. Check calibration of instruments.
5. Measure sound levels in all areas as required, combining measurements if equipment or systems must be operated separately. Before final measurements are made in any particular area, survey the area using an A-weighted scale reading (dBA) to determine the location of the highest sound pressure level. Indicate this location on a testing form, and use it for test measurements. Restrict the preliminary survey to determine location of test measurements to areas that can be occupied by standing or sitting personnel. For example, measurements would not be made directly below a diffuser located in the ceiling, but would be made as close to the diffuser as standing or sitting personnel might be situated. In the absence of specified sound criteria, the testing engineer should measure sound pressure levels in all occupied spaces to determine compliance with criteria indicated in Table 1 in Chapter 49 and to locate any sources of excessive or disturbing noise. With octave band sound level measurements, overall NC and RC values can be determined using measurements in the 125 Hz to 8000 Hz range.
6. Determine whether background noise measurements must be made.
   - If specification requires determining sound level from HVAC equipment only, background noise readings must be taken with HVAC equipment turned off.
   - If specification requires compliance with a specific noise level or criterion (e.g., sound levels in office areas not to exceed 35 dBA), ambient noise measurements must be made only if the noise level in any area exceeds the specified value.
   - For residential locations and areas requiring very low noise, such as sound recording studios and locations used during the normally quieter evening hours, it is usually desirable to take sound measurements in the evening and/or take ambient noise measurements.
7. For outdoor noise measurements to determine noise radiated by outdoor or roof-mounted equipment such as cooling towers and condensing units, the section on Sound Control for Outdoor Equipment in Chapter 49, which presents proper procedure and necessary calculations, should be consulted.

Noise Transmission Problems. Regardless of precautions taken by the specifying engineer and installing contractors, situations can occur where the sound level exceeds specified or desired levels, and there will be occasional complaints of noise in completed installations. A thorough understanding of Chapter 49 and the section on Testing for Vibration in this chapter is desirable before attempting to resolve any noise and vibration transmission problems. The following is intended as an overall guide rather than a detailed problem-solving procedure.

All noise transmission problems can be evaluated in terms of the source-path-receiver concept. Objectionable transmission can be resolved by (1) reducing noise at the source by replacing defective equipment, repairing improper operation, proper balancing and adjusting, and replacing with quieter equipment; (2) attenuating paths of transmission with silencers, vibration isolators, and wall treatment to increase transmission loss; and (3) reducing or masking objectionable noise at the receiver by increasing room absorption or introducing a nonobjectionable masking sound. The following discussion includes ways to identify actual noise sources using simple instruments or no instruments and possible corrections.

When troubleshooting in the field, the engineer should listen to the offending sound. The best instruments are no substitute for careful listening, because the human ear has the remarkable ability to identify certain familiar sounds such as bearing squeak or duct leaks and can discern small changes in frequency or sound character that might not be apparent from meter readings only. The ear is also a good direction and range finder; noise generally gets louder as one approaches the source, and direction can often be determined by turning the head. Hands can also identify noise sources. Air jets from duct leaks can often be felt, and the sound of rattling or vibrating panels or parts often changes or stops when these parts are touched.

In trying to locate noise sources and transmission paths, the engineer should consider the location of the affected area. In areas remote from equipment rooms containing significant noise producers but adjacent to shafts, noise is usually the result of structure-borne transmission through pipe and duct supports and anchors. In areas adjoining, above, or below equipment rooms, noise is usually caused by openings (acoustical leaks) in the separating floor or wall or by improper, ineffective, or maladjusted vibration isolation systems.

Unless the noise source or path of transmission is quite obvious, the best way to identify it is by eliminating all sources systematically as follows:

1. Turn off all equipment to make sure that the objectionable noise is caused by the HVAC. If the noise stops, the HVAC components (compressors, fans, and pumps) must be operated separately to determine which are contributing to the objectionable noise. Where one source of disturbing noise predominates, the test can be performed starting with all equipment in operation and turning off components or systems until the disturbing noise is eliminated. Tests can also be performed starting with all equipment turned off and operating various component equipment singularly, which permits evaluation of noise from each individual component.

   Any equipment can be termed a predominant noise source if, when the equipment is shut off, the sound level drops 3 dBA or if, when measurements are taken with equipment operating individually, the sound level is within 3 dBA of the overall objectionable measurement.

   When a sound level meter is not used, it is best to start with all equipment operating and shut off components one at a time because the ear can reliably detect differences and changes in noise but not absolute levels.
2. When some part of the HVAC system is established as the source of objectionable noise, try to further isolate the source. By walking around the room, determine whether the noise is coming through air outlets or returns, hung ceiling, or floors or walls.
3. If the noise is coming through the hung ceiling, check that ducts and pipes are isolated properly and not touching the hung ceiling supports or electrical fixtures, which would provide large noise radiating surfaces. If ducts and pipes are the source of noise and are isolated properly, possible remedies to reduce noise include changing flow conditions, installing silencers, and/or wrapping the duct or pipe with an acoustical barrier or lagging such as a lead blanket or other materials suitable for the location (see Chapter 49).
4. If noise is coming through the walls, ceiling, or floor, check for any openings to adjoining shafts or equipment rooms, and check vibration isolation systems to ensure that there is no structure-borne transmission from nearby equipment rooms or shafts.
5. Noise traced to air outlets or returns usually requires careful evaluation by an engineer or acoustical consultant to determine the source and proper corrective action (see Chapter 49). In general, air outlets can be selected to meet any acoustical design goal by keeping the velocity sufficiently low. For any given outlet, sound level increases with an increase in airflow velocity and doubling the velocity can increase this the sound level by 12 to 15 dB. Approach conditions caused by improperly located control dampers or improperly sized diffuser necks can increase these sound levels by 10 to 20 dB. Using variable-frequency drive (VFD) speed controllers on air-handling units can help evaluate air velocity concerns. Dampers used to limit airflow typically increase these sound levels.

   A simple, effective instrument that aids in locating noise sources is a microphone mounted on a pole. It can be used to localize noises in hard-to-reach places, such as hung ceilings and behind heavy furniture.
6. If noise is traced to an air outlet, measure the A-weighted sound level close to it but with no air blowing against the microphone. Then, remove the inner assembly or core of the air outlet and repeat the reading with the meter and the observer in exactly the same position as before. If the second reading is more than 3 dB below the first, a significant amount of noise is caused by airflow over the vanes of the diffuser or grille. In this case, check whether the system is balanced properly. As little as 10% too much air increases the sound generated by an air outlet by 2 dB. As a last resort, a larger air outlet could be substituted to obtain lower air velocities and hence less turbulence for the same air quality. Before this is considered, however, the air approach to the outlet should be checked.

   Noise far exceeding the normal rating of a diffuser or grille is generated when a throttled damper is installed close to it. Air jets impinge on the vanes or cones of the outlet and produce **edge tones** similar to the hiss heard when blowing against the edge of a ruler. The material of the vanes has no effect on this noise, although loose vanes may cause additional noise from vibration.

   When balancing air outlets with integral volume dampers, consider the static pressure drop across the damper, as well as the air quantity. Separate volume dampers should be installed sufficiently upstream from the outlet so that there is no jet impingement. Plenum inlets should be brought in from the side, so that jets do not impinge on the outlet vanes.
7. If air outlets are eliminated as sources of excessive noise, inspect the fan room. If possible, change fan speed by about 10%. If resonance is involved, this small change can make a significant difference.
8. Sometimes fans are poorly matched to the system. If a belt-driven fan delivers air at a higher static pressure than is needed to move the design air quantity through the system, reduce fan speed by changing sheaves. If the fan does not deliver enough air, consider increasing fan speed only after checking the duct system for leakage. Turbulence in the air approach to the fan inlet increases fan sound generation and decreases its air capacity. Other parts that may cause excessive turbulence are dampers, duct bends, and sudden enlargements or contractions of the duct. When investigating fan noise, seek assistance from the fan supplier or manufacturer.
9. If additional acoustical treatment is to be installed in the ductwork, obtain a frequency analysis. This involves the use of an octave-band analyzer and should generally be left to a trained engineer or acoustic consultant.

Testing for Vibration

Vibration testing is necessary to ensure that (1) equipment is operating within satisfactory vibration levels and (2) objectionable vibration and noise are not transmitted to the building structure. Although these two factors are interrelated, they are not necessarily interdependent. A different solution is required for each, and it is essential to test both the isolation and vibration levels of equipment. When measured routinely at the same location, vibration can be used for predictive maintenance.

General Procedure.

1. Verify final system balancing is complete.
2. Make a visual check of all equipment for obvious errors that must be corrected immediately.
3. Make sure all isolation is free-floating and not short-circuited by obstruction between equipment or equipment base and building structure.
4. Conduct bump test to determine the natural frequency.
5. Energize the system for an aural check of any obviously rough operation. Checking bearings with vibration measurement instrumentation is especially important because bearings can become defective in transit and/or if equipment was not properly stored, installed, or maintained. Defective bearings should be replaced immediately to avoid damage to the shaft and other components.
6. Set or drive equipment and systems so that final vibration tests are made on equipment as it will actually be operating.
7. Test equipment vibration.

Instruments. Although instruments are not required to test vibration isolation systems, they are essential to test equipment vibration properly.

Sound-level meters and **computer-driven sound-measuring systems** are the most useful instruments for measuring and evaluating vibration. Usually, they are fitted with accelerometers or vibration pickups for a full range of vibration measurement and analysis. Other instruments used for testing vibration in the field are described as follows.

Reed vibrometers are relatively inexpensive and are often used for testing vibration, but their relative inaccuracy limits their usefulness.

Vibrometers are moderately priced and measure vibration amplitude by means of a light beam projected on a graduated scale.

Vibrographs are moderately priced mechanical instruments that measure both amplitude and frequency. They provide a chart recording amplitude, frequency, and actual wave form of vibration. They can be used for simple, accurate determination of the natural frequency of shafts, components, and systems by a **bump test**.

Reed vibrometers, vibrometers, and vibrographs have largely been supplanted by electronic meters that are more accurate and have become much more affordable.

Vibration meters are moderately priced, relatively simple-to-use modern electronic instruments that measure the vibration amplitude. They provide a single broadband (summation of all frequencies) number identifying the magnitude of the vibration level. Both analog and digital readouts are common.

Vibration analyzers are relatively expensive electronic instruments that measure amplitude and frequency, usually incorporating a variable filter.

Strobe lights are often used with many of the other instruments for analyzing and balancing rotating equipment.

Stethoscopes are available as inexpensive mechanic's type (basically, a standard stethoscope with a probe attachment), relatively inexpensive models incorporating a tunable filter, and moderately priced powered types that electronically amplify sound and provide some type of meter and/or chart recording.

The choice of instruments depends on the test. Vibrometers and vibration meters can be used to measure vibration amplitude as an acceptance check. Because they cannot measure frequency, they cannot be used for analysis and primarily function as a go/no-go instrument. The best acceptance criteria consider both amplitude and frequency. Anyone seriously concerned with vibration testing should use an instrument that can determine frequency as well as amplitude, such as a vibrograph or vibration analyzer.

Vibration measurement instruments (both meters and analyzers) made specifically for measuring machinery vibration typically use **moving coil velocity transducers**, which are sizable and rugged. These are typically limited to a lower frequency of 500 cycles per minute (cpm) [8.33 Hz] with normal calibration. If measuring very-low-speed machinery such as large fans, cooling towers, or compressors operating below this limit, use an adjustment factor provided by the instrument manufacturer or use an instrument with a lower low-frequency limit, which typically uses a smaller accelerometer as the vibration pickup transducer.

Testing Vibration Isolation.

1. Ensure that equipment is **free-floating** by applying an unbalanced load, which should cause the equipment to move freely and easily. On floor-mounted equipment, check that there are no obstructions between the base or foundation and the building structure that would cause transmission while still permitting equipment to rock relatively free because of the application of an unbalanced force (Figure 19). On suspended equipment, check that hanger rods are not touching the hanger. Rigid connections such as pipes and ducts can prohibit mounts from functioning properly and from providing a transmission path. Note that the fact that the equipment is free floating does not mean that the isolators are functioning properly. For example, a 500 revolutions per minute (rpm) fan on isolators with a natural frequency of 500 cpm (8.33 Hz) could be free-floating but would actually be in resonance, resulting in transmission to the building and excessive movement.
2. Determine whether isolators are adjusted properly and providing desired isolation efficiency. All isolators supporting a piece of equipment should have approximately the same deflection (i.e., they should be compressed the same under the equipment). If not, they have been improperly adjusted, installed, or selected; this should be corrected immediately. Note that isolation efficiency cannot be checked by comparing vibration amplitude on equipment to amplitude on the structure (Figure 20).

   The only accurate check of isolation efficiencies is to compare vibration measurements of equipment operating with isolators to measurements of equipment operating without isolators. Because this is usually impractical, it is better to check whether the isolator's deflection is as specified and whether the specified or desired isolation efficiency is being provided. Figure 21 shows natural frequency of isolators as a function of deflection and indicates the theoretical isolation efficiencies for various frequencies at which the equipment operates.

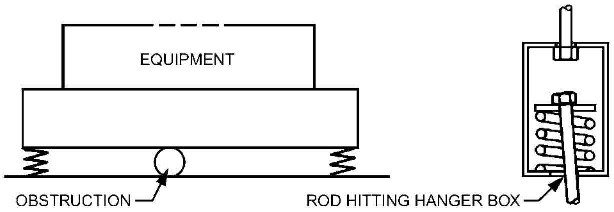

Fig. 19 Obstructed Isolation Systems

Although it is easy to determine the deflection of spring mounts by measuring the difference between the free heights with a ruler (information as shown on submittal drawings or available from a manufacturer), these measurements are difficult with most pad or rubber mounts. Further, most pad and rubber mounts do not lend themselves to accurate determination of natural frequency as a function of deflection. For these mounts, the most practical approach is to check that there is no excessive vibration of the base and no noticeable or objectionable vibration transmission to the building structure.

If isolators are in the 90% efficiency range and there is transmission to the building structure, either the equipment is operating roughly or there is a flanking path of transmission, such as connecting piping or obstruction, under the base.

Testing Equipment Vibration. Testing equipment vibration is necessary as an acceptance check to determine whether equipment is functioning properly and to ensure that objectionable vibration and noise are not transmitted. Although a person familiar with equipment can determine when it is operating roughly, instruments are usually required to determine accurately whether vibration levels are satisfactory.

Vibration Tolerances. Vibration tolerance criteria are listed in Table 45 of Chapter 49. These criteria are based on equipment installed on vibration isolators and can be met by any reasonably smoothly running equipment. Note that values in Chapter 49 are based on root-mean-square (RMS) values; other sources often use peak-to-peak or peak values, especially for displacements. For sinusoid responses, it is simple to obtain peak from RMS values, but in application the relationship may not be so straightforward. The main advantage of RMS is that the same instrumentation can be used for both sound and vibration measurements by simply changing the transducer. Also, there is only one recognized reference level for the decibel used for sound-pressure levels, but for vibration levels there are several recognized ones but no single standard. A common mistake in interpreting vibration data is misunderstanding the reference level and whether the vibration data are RMS, peak-to-peak, or peak values. Use great care in publishing and interpreting vibration data and converting to and from linear absolute values and levels in decibels.

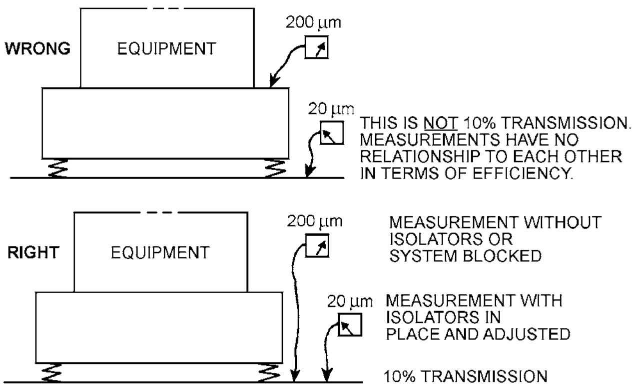

Fig. 20 Testing Isolation Efficiency

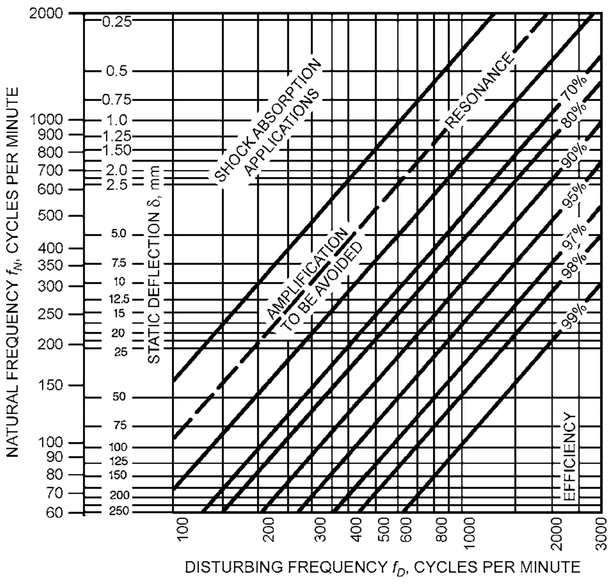

Fig. 21 Isolator Natural Frequencies and Efficiencies

Procedure for Testing Equipment Vibration.

1. Determine operating speeds of equipment from nameplates, drawings, or a speed-measuring device such as a tachometer or strobe, and indicate them on the test form. For any equipment where the driving speed (motor) is different from the driven speed (e.g., fan wheel, rotor, impeller) because of belt drive or gear reducers, indicate both driving and driven speeds.
2. Determine acceptance criteria from specifications, and indicate them on the test form. If specifications do not provide criteria, use those shown in Chapter 49.
3. Ensure that the vibration isolation system is functioning properly (see the section on Testing Vibration Isolation).
4. Conduct bump test to determine the natural frequency. This can be accomplished by placing the accelerometer and taping or bumping the bearing or motor with a rubber hammer.
5. Energize equipment and make visual and aural checks for any apparent rough operation. Any defective bearings, misalignment, or obvious rough operation should be corrected before proceeding further. If not corrected, equipment should be considered unacceptable.
6. Measure and record vibration at bearings of driving and driven components in horizontal, vertical, and, if possible, axial directions. At least one axial measurement should be made for each rotating component (fan motor, pump motor).
7. Evaluate measurements.

Evaluating Vibration Measurements.

Amplitude Measurement. When specification for acceptable equipment vibration is based on amplitude measurements only, measurements can be made with an instrument that measures only amplitude (e.g., a vibration meter or vibrometer),

- No measurement should exceed specified values or values shown in Tables 45 or 46 of Chapter 49, taking into consideration reduced values for equipment installed on inertia blocks
- No measurement should exceed values shown in Tables 45 or 46 of Chapter 49 for driving and driven speeds, taking into consideration reduced values for equipment installed on inertia blocks. For example, with a belt-driven fan operating at 800 rpm and having an 1800 rpm driving motor, amplitude measurements at fan bearings must be in accordance with values shown for 800 cpm (13.3 Hz), and measurements at motor bearings must be in accordance with values shown for 1800 cpm (30 Hz). If measurements at motor bearings exceed specified values, take measurements of the motor only with belts removed to determine whether there is feedback vibration from the fan.
- No axial vibration measurement should exceed maximum radial (vertical or horizontal) vibration at the same location.

Amplitude and Frequency Measurement. When specification for acceptable equipment vibration is based on both amplitude and fre-

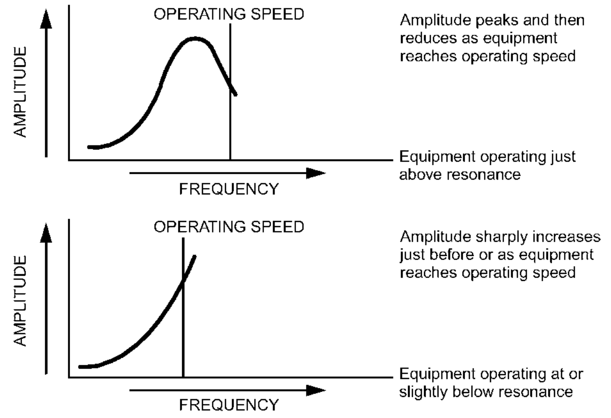

Fig. 22 Vibration from Resonant Condition

quency measurements must be made with instruments that measure both amplitude and frequency (e.g., a vibrograph or vibration analyzer),

- Amplitude measurements at driving and driven speeds should not exceed specified values or values shown in Tables 45 or 46 of Chapter 49, taking into consideration reduced values for equipment installed on inertia blocks. Measurements that exceed acceptable amounts may be evaluated as explained in the section on Vibration Analysis.
- Axial vibration measurements should not exceed maximum radial (vertical or horizontal) vibration at the same location.
- The presence of any vibration at frequencies other than driving or driven speeds is generally reason to rate operation unacceptable; this vibration should be analyzed as explained in the section on Vibration Analysis.

Vibration Analysis. The following guide covers most vibration problems that may be encountered.

Axial Vibration Exceeds Radial Vibration. When the amplitude of axial vibration (parallel with shaft) at any bearing exceeds radial vibration (perpendicular to shaft, vertical or horizontal), it usually indicates misalignment, most common on direct-driven equipment because flexible couplings accommodate parallel and angular misalignment of shafts. This misalignment can generate forces that cause axial vibration, which can cause premature bearing failure, so misalignment should be checked carefully and corrected promptly. Other possible causes of large-amplitude axial vibration are resonance, defective bearings, insufficient rigidity of bearing supports or equipment, and loose hold-down bolts.

Vibration Amplitude Exceeds Allowable Tolerance at Rotational Speed. The allowable vibration limits established by Table 41 of Chapter 49 are based on vibration caused by rotor imbalance, which results in vibration at rotational frequency. Although vibration caused by imbalance must be at the frequency at which the part is rotating, a vibration at rotational frequency does not have to be caused by imbalance. An unbalanced rotating part develops centrifugal force, which causes it to vibrate at rotational frequency. Vibration at rotational frequency can also result from other conditions such as a bent shaft, an eccentric sheave, misalignment, and resonance. If vibration amplitude exceeds allowable tolerance at rotational frequency, the following steps should be taken before performing field balancing of rotating parts:

1. Check vibration amplitude as equipment goes up to operating speed and as it coasts to a stop. Any significant peaks at or near operating speed, as shown in Figure 22, indicate probable resonance (i.e., some part having a natural frequency close to the operating speed, resulting in greatly amplified levels of vibration).

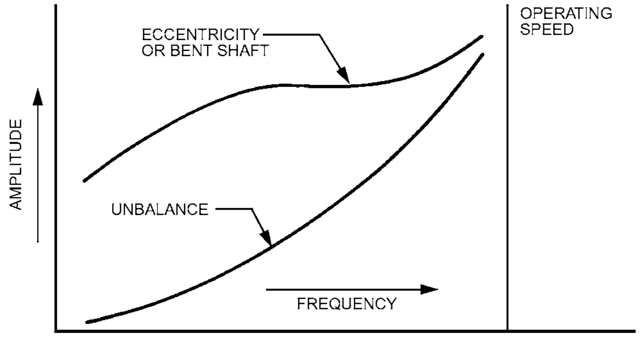

Fig. 23 Vibration Caused by Eccentricity

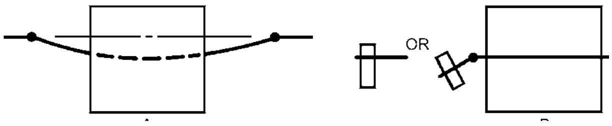

Fig. 24 Bent Shafts

A bent shaft or eccentricity usually causes imbalance that results in significantly higher vibration amplitude at lower speeds, as shown in Figure 23 whereas vibration caused by imbalance generally increases as speed increases.

If a bent shaft or eccentricity is suspected, check the dial indicator. A bent shaft or eccentricity between bearings as shown in Figure 24A can usually be compensated for by field balancing, although some axial vibration might remain. Field balancing cannot correct vibration caused by a bent shaft on direct-connected equipment, on belt-driven equipment where the shaft is bent at the location of sheave, or if the sheave is eccentric (Figure 24B). This is because the center-to-center distance of the sheaves fluctuates, each revolution resulting in vibration.

2. For belt- or gear-driven equipment where vibration is at motor driving frequency rather than driven speed, it is best to disconnect the drive to perform tests. If the vibration amplitude of the motor operating by itself does not exceed specified or allowable values, excessive vibration (when the drive is connected) is probably a function of bent shaft, misalignment, eccentricity, resonance, or loose hold down bolts.
3. Vibration caused by imbalance can be corrected in the field by firms specializing in this service or by testing personnel if they have appropriate equipment and experience.

Vibration at Other than Rotational Frequency. Vibration at frequencies other than driving and driven speeds is generally considered unacceptable. Table 4 shows some common conditions that can cause vibration at other than rotational frequency.

Resonance. If resonance is suspected, determine which part of the system is in resonance.

Isolation Mounts. The natural frequency of the most commonly used spring mounts is a function of spring deflection, as shown in Figure 25, and it is relatively easy to calculate by determining the difference between the free and operating height of the mount, as explained in the section on Testing Vibration Isolation. This technique cannot be applied to rubber, pad, or fiberglass mounts, which have a natural frequency in the 300 to 3000 cpm (5 to 50 Hz) range. Natural frequency for such mounts is determined by a bump test. Any resonance with isolators should be immediately corrected because it results in excessive movement of equipment and more

Table 4 Common Causes of Vibration Other than Unbalance at Rotation Frequency

Frequency	Source
0.5 × rpm	Vibration at approximately 0.5 rpm can result from improperly loaded sleeve bearings. This vibration will usually disappear suddenly as equipment coasts down from operating speed.
2 × rpm	Equipment is not tightly secured or bolted down.
2 × rpm	Misalignment of couplings or shafts usually results in vibration at twice rotational frequency and generally a relatively high axial vibration.
Many × rpm	Defective antifriction (ball, roller) bearings usually result in low-amplitude, high-frequency, erratic vibration. Because defective bearings usually produce noise rather than any significantly measurable vibration, it is best to check all bearings with a listening device.

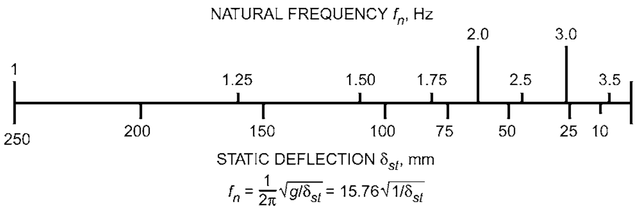

Fig. 25 Natural Frequency of Vibration Isolators

transmission to the building structure than if equipment were attached solidly to the building (installed without isolators).

Components. Resonance can occur with any shaft, structural base, casing, and connected piping. The easiest way to determine natural frequency is to perform a bump test with a vibration spectrum analyzer.

Checking for Vibration Transmission. The source of vibration transmission can be checked by determining frequency with a vibration analyzer and tracing back to equipment operating at this speed. However, the easiest and usually best method (even if test equipment is being used) is to shut off components one at a time until the source of transmission is located. Most transmission problems cause disturbing noise; listening is the most practical approach to determine a noise source because the ear is usually better than instruments at distinguishing small differences and changes in character and amount of noise. Where disturbing transmission consists solely of vibration, an instrument will probably be helpful, unless vibration is significantly above the sensory level of perception. Vibration below sensory perception is generally not objectionable.

If equipment is located near the affected area, check isolation mounts and equipment vibration. If vibration is not being transmitted through the base, or if the area is remote from equipment, the probable cause is transmission through connected piping and/or ducts. Ducts can usually be isolated by isolation hangers. However, transmission through connected piping is very common and presents many problems that should be understood before attempting to correct them (see the following section).

Vibration and Noise Transmission in Piping. Vibration and noise in connected piping can be generated by either equipment (e.g., pump or compressor) or flow (velocity). Mechanical vibration from equipment can be transmitted through the walls of pipes or by a water column. Flexible pipe connectors, which provide system flexibility to permit isolators to function properly and protect equipment from stress caused by misalignment and thermal expansion, can be useful in attenuating mechanical vibration transmitted through a pipe wall. However, they rarely suppress flow vibration

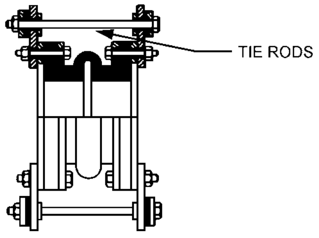

Fig. 26 Typical Tie Rod Assembly

and noise and only slightly attenuate mechanical vibration as transmitted through a water column.

Tie rods are often used with flexible rubber hose and rubber expansion joints (Figure 26). Although they accommodate thermal movements, they hinder vibration and noise isolation. This is because pressure in the system causes the hose or joint to expand until resilient washers under tie rods are virtually rigid. To isolate noise adequately with a flexible rubber connector, tie rods and anchor piping should not be used. However, this technique generally cannot be used with pumps on spring mounts, which would still permit the hose to elongate. Flexible metal hose can be used with spring-isolated pumps because wire braid serves as tie rods; metal hose controls vibration but not noise.

Problems of transmission through connected piping are best resolved by changes in the system to reduce noise (improve flow characteristics, reduce impeller size) or by completely isolating piping from the building structure. Note, however, that it is almost impossible to isolate piping completely from the structure, because the required resiliency is inconsistent with rigidity requirements of pipe anchors and guides. Chapter 49 contains information on flexible pipe connectors and resilient pipe supports, anchors, and guides, which should help resolve any piping noise transmission problems.

16. FIELD SURVEY FOR ENERGY AUDIT

An energy audit is an organized survey of a specific building to identify and measure all energy uses, determine probable sources of energy losses, and list energy conservation opportunities. This is usually performed as a team effort under the direction of a qualified energy engineer. The field data can be gathered by firms employing technicians trained in testing, adjusting, and balancing. Procedures for energy audits can be found in ASHRAE (2011).

Instruments

To determine a building's energy use characteristics, existing conditions must be accurately measured with proper instruments. Accurate measurements point out opportunities to reduce waste and provide a record of the actual conditions in the building before energy conservation measures were taken. They provide a compilation of installed equipment data and a record of equipment performance before changes. Judgments will be made based on the information gathered during the field survey; that which is not accurately measured cannot be properly evaluated.

Generally, instruments used for testing, adjusting, and balancing are sufficient for energy conservation surveying. Possible additional instruments include a power factor meter, light meter, combustion testing equipment, refrigeration gages, and equipment for recording temperatures, fluid flow rates, and energy use over time. Only high-quality instruments should be used.

Observation of system operation and any information the technician can obtain from the operating personnel pertaining to the operation should be included in the report.

Data Recording

Organized record keeping is extremely important. A camera is also helpful. Photographs of building components and mechanical and electrical equipment can be reviewed later when the data are analyzed.

Data sheets for energy conservation field surveys contain different and, in some cases, more comprehensive information than those used for testing, adjusting, and balancing. Generally, the energy engineer determines the degree of fieldwork to be performed; data sheets should be compatible with the instructions received.

Building Systems

The most effective way to reduce building energy waste is to identify, define, and tabulate the energy load by building system. For this purpose, load is defined as the quantity of energy used in a building, or by one of its subsystems, for a given period. By following this procedure, the most effective energy conservation opportunities can be achieved more quickly because high priorities can be assigned to systems that consume the most energy.

A building can be divided into nonenergized and energized systems. Nonenergized systems do not require external energy sources such as electricity and fuel. Energized systems (e.g., mechanical and electrical systems) require external energy. Energized and nonenergized systems can be divided into subsystems defined by function.

Nonenergized Systems. Nonenergized subsystems include building site, envelope, and interior; building use; and building operation.

Building Site, Envelope, and Interior. These subsystems should be surveyed to determine how they can be modified to reduce the building load that the mechanical and electrical systems must meet (without adversely affecting the building's appearance). It is important to compare actual conditions with conditions assumed by the designer, so that mechanical and electrical systems can be adjusted to balance their capacities to satisfy actual needs.

Building Use. These loads can be classified as people occupancy or operation loads. People occupancy loads are related to schedule, density, and mixing of occupancy types (e.g., process and office). People operation loads are varied and include operation of manual window shading devices; setting of room thermostats; and conservation-related habits such as turning off lights, closing doors and windows, turning off energized equipment when not in use, and not wasting domestic hot or chilled water.

Building Operation. This subsystem consists of the operation and maintenance of all the building subsystems. The load on the building operation subsystem is affected by factors such as the time at which janitorial services are performed, janitorial crew size and time required to clean, amount of lighting used to perform janitorial functions, quality of equipment maintenance program, system operational practices, and equipment efficiencies.

Energized Systems. Energized subsystems of a building generally include plumbing, heating, ventilating, cooling, space conditioning, control, electrical, and food service. Although these systems are interrelated and often use common components, logical organization of data requires evaluating the energy use of each subsystem as independently as possible. In this way, proper energy conservation measures for each subsystem can be developed.

Process Loads

In addition to building subsystem loads, the process load in most buildings must be evaluated by the energy field auditor. Most tasks not only require energy for performance, but also affect the energy consumption of other building subsystems. For example, if a process releases large amounts of heat to the space, the process consumes energy and also imposes a large load on the cooling system.

Guidelines for Developing Field Study Form

The following checklist outlines requirements for a field study form, needed to conduct an energy audit.

Inspection and Observation of All Systems. Record physical and mechanical condition of the following:

- Fan blades, fan scroll, drives, belt tightness, and alignment
- Filters, coils, and housing tightness
- Ductwork (equipment room and space, where possible)
- Strainers
- Insulation ducts and piping
- Makeup water treatment and cooling tower

Interview of Physical Plant Supervisor. Record answers to the following survey questions:

- Is the system operating as designed? If not, what changes have been made to ensure its performance?
- Have there been modifications or additions to the system?
- If the system has had a problem, list problems by frequency of occurrence.
- Are any systems cycled? If so, which systems, when, and would building load allow cycling systems?

Recording System Information. Record the following system/equipment identification:

- *Type of system.* Single-zone, multizone, dual-duct, low- or high-velocity, reheat, variable-volume, or other
- *System arrangement.* Fixed minimum outdoor air, no relief, gravity or power relief, economizer gravity relief, exhaust return, or other
- *Air-handling equipment.* (Supply, return, and exhaust) manufacturer, model, size, type, and class of fans; dampers (vortex, scroll, or discharge); motors manufacturer, power requirement, full-load amperes, voltage, phase, and service factor
- *Chilled- and hot-water coils.* Area, tubes on face, fin spacing, and number of rows (coil data necessary when shop drawings are not available)
- *Terminals.* High-pressure mixing box manufacturer, model, and type (reheat, constant-volume, variable-volume, induction); grilles, registers, and diffusers manufacturer, model, style, and correction factor to convert field-measured velocity to flow rate
- *Main heating and cooling pumps, over 3.5 kW.* Manufacturer, pump service and identification, model, size, impeller diameter, speed, flow rate, head at full flow, and head at no flow; motor data (power, speed, voltage, amperes, and service factor)
- *Refrigeration equipment.* Chiller manufacturer, type, model, serial number, nominal tons, input power, total heat rejection, motor (kilowatts, amperes, volts), chiller pressure drop, entering and leaving chilled water temperatures, condenser pressure drop, condenser entering and leaving water temperatures, running amperes and volts, no-load running amperes and volts
- *Cooling tower.* Manufacturer, size, type, nominal cooling capacity, range, flow rate, and entering wet-bulb temperature
- *Heating equipment.* Boiler (small through medium) manufacturer, fuel, energy input (rated), and heat output (rated)

Recording Test Data. Record the following test data:

- *Systems in normal mode of operation (if possible).* Fan motor running amperes and volts and power factor (over 3.5 kW; fan speed, total air (pitot tube traverse where possible), and static pressure (discharge static minus inlet total); static profile drawing (static pressure across filters, heating coil, cooling coil, and dampers); static pressure at ends of runs of the system (identifying locations).
- *Cooling coils.* Entering and leaving dry- and wet-bulb temperatures, entering and leaving water temperatures, coil pressure drop (where pressure taps permit and manufacturer's ratings can be

obtained), flow rate of coil (when other than fan), outdoor wet and dry bulb, time of day, and conditions (sunny or cloudy).

- *Heating coils.* Entering and leaving dry-bulb temperatures, entering and leaving water temperatures, coil pressure drop (where pressure taps permit and manufacturer's ratings can be obtained), and flow rate through coil (when other than fan).
- *Pumps.* No-flow head, full-flow discharge pressure, full-flow suction pressure, full-flow differential pressure, motor running amperes and volts, and power factor (over 3.5 kW).
- *Chiller (under cooling load conditions).* Chiller pressure drop, entering and leaving chilled water temperatures, condenser pressure drop, entering and leaving condenser water temperatures, running amperes and volts, no-load running amperes and volts, chilled water on and off, and condenser water on and off.
- *Cooling tower.* Waterflow rate in tower, entering and leaving water temperatures, entering and leaving wet bulb, fan motor (amperes, volts, power factor [over 3.5 kW], and ambient wet bulb).
- *Boiler (full fire).* Input energy (if possible), percent CO_2, stack temperature, efficiency, and complete Orsat test on large boilers.
- *Boiler controls.* Description of operation.
- *Temperature controls.* Operating and set-point temperatures for mixed air controller, leaving air controller, hot-deck controller, cold-deck controller, outdoor reset, interlock controls, and damper controls; description of complete control system and any malfunctions.
- Outdoor air intake versus exhaust air. Total airflow measured by pitot tube traverses of both outdoor air intake and exhaust air systems, where possible. Determine whether an imbalance in the exhaust system causes infiltration. Observe exterior walls to determine whether outdoor air can infiltrate return air (record outdoor air, return air, and return air plenum dry- and wet-bulb temperatures). The greater the differential between outdoor and return air, the more evident the problem will be.

17. TAB REPORTS

This section sets forth an outline for the procedures and forms which make up the final report of operating conditions.

Supervising personnel should use a logical approach in preparing forms and recording data. This section will list form titles and entries commonly used, allowing for design suited to each particular job. All entries will not be required in every situation. Many excellent forms have been developed by various associations but are available for use by their members only.

Accuracy in preparing the final report forms is important for several reasons:

- They provide a permanent record of system operating conditions after the last adjustments have been made.
- They confirm that prescribed procedures have been followed.
- They will serve as a reference that can be used by the owner for maintenance.
- They provide the designer with a system operational check and could serve as an aid in diagnosing problems.

All forms shall include identification of project, system/unit, location, date, technician, page number, and remarks.

General Items

The report should contain the following, as applicable:

Title page:

- Name and address of TAB firm
- Project name
- Location
- Architect
- Engineer
- Contractor
- Report date
- Signature of TAB firm person who approved report

Summary of comments:

- Design versus final performance
- Notable characteristics of system
- Description of systems operation sequence
- Summary of outdoor and exhaust flows to indicate amount of building pressurization

Nomenclature sheet:

- Codes for boxes, reheat coils, terminals, etc. (with data on manufacturer, type, size, fittings, etc.)
- Notes that explain in detail why certain final data in the body of the report deviate from design values

Test conditions (to be stated on the fan or pump performance form):

- Setting of outdoor, return, and exhaust dampers
- Condition of filters
- Cooling coil wet or dry
- Face and bypass damper setting at coil
- Fan drive setting (indicate setting
- percentage of maximum pitch diameter)
- Set points of variable flow controller
- Setting of supply air static pressure controller
- Other systems operating which affect performances

System Diagram

A single line diagram for schematic layout of air distribution systems and hydronic systems is highly recommended to ensure systematic and efficient procedures. Quantities of outdoor air, return air, relief air; sizes and airflow rates for main ducts; sizes and airflow rates for all air terminal devices, dampers, and other regulating devices should be shown. All air terminals should be numbered before filling out the air terminal device report. Though diagrams are suggested, the use of this form is not mandatory.

Air Apparatus Test Report

The performance of air handling apparatus with coils is to be reported. Motor voltage and amperage for three-phase motors should be reported for all three legs (T1, T2, and T3). If the design engineer did not specify a design quantity for any item in the test data section, place an X in the space for the design quantity and record the actual quantity. If available, include equipment manufacturer ratings in the design columns when design quantity is unknown. If motor ratings differ from design, provide an explanation at the bottom of the page. If there are split coils, record data for each airstream.

Unit Data

- Make/type
- Model number/size
- Serial number
- Arrangement/class
- Discharge
- Sheave make
- Sheave size/bore
- Number of belts/make/size
- Number of filters/type/size
- Make/frame
- W/Rad/s
- Volts/phase/hertz
- Full load amps/service factor
- Sheave make
- Cooling coil differential static pressure
- Heating coil differential static pressure
- Outdoor airflow rate
- Return airflow rate

- Outdoor air damper position
- Return air damper position
- Vortex damper position

Motor Data

- Sheave size/bore
- Sheave adjustment

Test Data (list design and actual for each)

- Total airflow rate
- Total system static pressure
- Fan Hz
- Motor volts, T1-T2, T2-T3, T3-T1
- Motor amps, A1, A2, A3
- Discharge static pressure
- Filter differential static pressure
- Preheat coil differential static pressure

Apparatus Coil Test Report:

The performance of chilled water, hot water, steam, or DX coils, and for runaround heat recovery systems is to be reported.

Coil Data:

- System number
- Location
- Coil type
- Number of rows/fins
- Make/model
- Face area
- Tube size
- Tube/fin material
- Circuiting

Test Data: (list design and actual for each)

- Airflow rate
- Air velocity
- Air pressure drop
- Entering/leaving air (db/wb)
- Waterflow rate
- Water pressure differential
- Entering/leaving water temperature
- Exp. valve/refrigeration
- Refrigeration suction pressure
- Refrigeration suction temperature
- Inlet steam pressure

Gas/Oil Fired Heat Apparatus Test Report

Data for gas- or oil-fired devices, (e.g., unit heaters, duct furnaces, etc.) will be recorded. This report is not intended to be used in lieu of a factory startup equipment report, but could be used as a supplement. All available design data should be reported. Some information could apply to the burner motor, burner fan motor, unit air fan motor, etc., depending on the application or equipment. Therefore, designate the motor of the recorded data.

Unit Data:

- System number
- Location
- Make/type
- Model number/size
- Serial number
- Type fuel/input
- Output/W
- Ignition type
- Burner control
- Volts/phase/hertz
- W/Rad/s
- Full load amps/service factor
- Sheave data

Test Data: (list design and actual for each)

- Airflow rate
- Entering/leaving air temperature
- Entering/leaving air pressure
- Low fire input
- High fire input
- Manifold pressure/CFH
- High limit setting
- Operating set point
- Voltage, T1-T2, T2-T3, T3-T1
- Amps, A1, A2, A3
- Heating value of fuel

Electric Coil/Duct Heater Test Report

Data for electric furnaces or for electric coils installed in built-up units or ducts will be recorded. “Minimum air velocity” is as recommended by manufacturers.

Unit Data:

- System/location
- Coil number
- kW
- Stages
- Volts/phase/Hertz
- Amps
- Airflow rate
- Face area
- Minimum air velocity

Test Data: (list design and actual for each)

- kW
- Air velocity
- Airflow rate
- Entering air temperature
- Leaving air temperature
- Voltage, T1-T2, T2-T3, T3-T1
- Amps, A1, A2, A3
-

Fan Test Report

The performance of all supply, return, and exhaust fans should be recorded.

Fan Data:

- System number
- Location
- Make/type
- Model number/size
- Serial number
- Arrangement/class
- Sheave make
- Sheave size/bore

Motor Data:

- Make/frame
- W/Rad/s
- Volts/phase/Hertz
- Full load amps
- Service factor
- Sheave make
- Sheave size/bore
- Number of belts/make/size
- Sheave centerline distance and adjustment
-

Test Data: (list design and actual for each)

- Airflow rate
- Total system static pressure
- Fan Hz
- Discharge static pressure
- Suction static pressure
- Voltage, T1 T2, T2 T3, T3 T1
- Amps, Al, A2, A3

Duct Traverse Report

The results of a pitot tube traverse in all rectangular, round, and oval ducts shall be recorded. For rectangular duct traverses, make a grid representing the duct cross section with a box for each test point and its distance from sides of duct. It is recommended that the velocity pressures be recorded in one half of each box provided and then converted to velocities in the other half of the box at a later time. The velocities should be averaged, but do not average the velocity pressures. For round duct traverses, make a circle representing the duct cross section. Make columns with a number for each test point, along with its distance from sides of duct, and for velocity pressures or velocities taken at points across three diameters at a 60° angles to each other. For oval duct traverses, make columns with a number for each test point, its dimension along the major and minor axis, and velocity pressures or velocities taken at points across the two axes of the duct, or show on a traverse sheet the horizontal reading.

Data Reported:

- System/unit number
- Location/zone
- Traverse air temperature
- Duct static pressure

- Duct size
- Duct area
- Design velocity
- Design flow rate
- Actual average velocity
- Actual flow rate
- Barometric pressure

Air Terminal Device Report

The flow rate of all air terminal devices should be recorded. If the final adjusted flow rate of any air terminal device deviates from design by more than ±10%, a note indicating the amount of variance shall be recorded in the "remarks" section of the report to provide known or potential reasons for such deviation. All correction factors should be shown in the remarks column for all velocity measurement instruments.

Data Reported:

- System/unit number
- Location/zone
- Test apparatus
- Area served
- Air terminal device number (from system diagram)
- Air terminal device type/ model
- Air terminal device size
- Design flow rate
- Design velocity
- Preliminary velocity (as needed)
- Make preliminary flow rate (as needed)
- Final velocity
- Final volume
- A_k/effective area

System Coil Report

The performance of reheat coils or the water coil on terminal units should be recorded.

Equipment Data:

- System/unit number
- Location/zone
- Room number/riser number
- Coil make
- Model/size
- Design flow rate
- Design water supply temperature
- Flow meter type/size

Test Data:

- Flow meter reading (if available)
- Design pressure drop
- Entering water pressure
- Leaving water pressure
- Actual pressure drop
- Design water temperature drop
- Entering/leaving water temperature
- Actual water temperature drop
- Design air pressure drop
- Entering/leaving air static pressure
- Actual air static pressure drop
- Design air temperature drop (cooling coil [db, wb] heating coil [db])
- Entering/leaving air temperature
- Actual air temperature drop

Packaged Chiller Test Report

The control settings and the entering and leaving conditions at the chiller should be recorded. This data should be substantially completed and verified by the manufacturers' representatives and/or the equipment owner or installing contractor before the HVAC distribution systems are balanced. Temperature and pressure differential readings of the chiller unit evaporator and condenser should be recorded during the TAB procedures. Describe the flow measuring device when used.

(List design and actual quantities where appropriate.)

Unit Data:

- Make/type
- Model number/size
- Serial number
- Capacity refrigerant
- Refrigerant
- Starter
- Heater size

Condenser Data:

- Condenser pressure/temperature
- Entering/leaving water pressure
- Water pressure drop
- Entering/leaving water temperature
- Entering/leaving air temperature
- Actual air temperature drop
- Water temperature drop

Evaporator Data:

- Evaporator pressure/temperature
- Entering/leaving water pressure
- Water pressure drop
- Entering/leaving water temperature
- Water temperature drop
- Waterflow rate

Compressor Data:

- Make/model
- Serial number
- Suction pressure/temperature
- Discharge pressure/ temperature
- Oil pressure/temperature
- Voltage, T1-T2, T2-T3, T3-T1
- Amps, A1, A2, A3
- Kilowatt input
- Crankcase heater amps
- Chilled-water control setting
- Cond. water control setting
- Low-pressure cutout setting
- High-pressure cutout setting

Refrigeration Data:

- Oil level checked
- Oil failure sw. diff.
- Refrigeration level checked
- Relief valve setting
- Unloader set points
- Percent cylinders unloaded
- Purge operation checked
- Bearing temperature
- Vane position
- Demand limit
- Low-temperature cutout setting

Package Rooftop/Heat Pump A/C Unit Test Report

Test data from package units of all types shall be recorded. If the unit has components other than the evaporator fan, DX coil, and compressor and condenser fan(s), use the appropriate report forms for: water or steam coils, direct fired heaters, electric coils, or return air fans.

Unit Data:

- Make/model number
- Type/size
- Serial number
- Filter type/size
- Fan sheave make
- Fans sheave diameter/bore
- Number, make, and size of belts
- Type of heating section (use other appropriate form)

Motor Data:

- Make/frame
- W/Rad/s
- Volts/phase/hertz
- Full-load amps/SF
- Sheave make
- Sheave diameter/bore
- Sheave centerline distance and adjustment

Evaporator Test Data: (list design and actual)

- Total airflow rate
- Total static pressure
- Discharge static pressure
- Suction static pressure
- Outdoor airflow rate
- Outdoor air db/wb

- Return airflow rate
- Return airflow db/wb
- Entering air db/wb
- Leaving air db/wb
- Fan rpm
- Voltage, T1-T2, T2-T3, T3-T1
- Amps, A1, A2, A3

Condenser Test Data: (list design and actual)

- Refrigerant mass
- Compressor manufacturer/ number
- Compressor model/serial number
- Low ambient control
- Suction pressure/temperature
- Condenser pressure/ temperature
- Crankcase motor amps
- Compressor volts, T1-T2, T2-T3, T3-T1
- Compressor amps, A1, A2, A3
- Low-/high-pressure cutout setting
- Number of fans/rpm
- Condenser fan power/airflow rate
- Condenser fan volts/amps/phase

Compressor and/or Condenser Test Report

Control settings, as well as entering and leaving conditions at the compressor and/or condenser, should be recorded. Because the balancing firm is not necessarily responsible for startup or the proper operation of the machine, this form does not attempt to indicate the performance or efficiency of the machine except as may be determined by the design engineer from the data contained therein.

These data should be substantially completed and verified by the manufacturers' representatives and/or the equipment owner or installing contractor before the HVAC distribution systems are balanced. Temperature and pressure differential readings of the unit should be recorded during the TAB procedures.

This report may also be used to record data for the refrigerant side of unitary systems, bare compressors, separate air-cooled condensers, or separate water-cooled condensers.

Unit Data:

- Unit make
- Unit model/serial number
- Compressor make
- Compressor model/serial number
- Refrigerant mass
- Low ambient control

Test Data: (list design and actual for each)

- Duct inlet/outlet static pressure
- Entering/leaving air db
- Cond. water temperature in/out
- Cond. water pressure in/out
- Control setting
- Unloader set points
- Low-/high-pressure cutout setting
- Suction pressure/temperature
- Cond. pressure temperature
- Oil pressure/temperature
- Voltage, T1 T2, T2 T3, T3 T1
- Amps, A1, A2, A3
- Kilowatt input
- Crankcase heater amps
- Number of fans/fan rpm/airflow rate
- Fan motor make/frame/power
- Fan motor volts/amps

Cooling Tower or Condenser Test Report

This data should be substantially completed and verified before the system is balanced. The pump data section is to be used for the recirculating pump in evaporative condensers, not the system used with cooling towers.

Unit Data:

- Make/type
- Model number/size
- Serial number
- Nominal capacity
- Refrigerant
- Water treatment

Pump Data:

- Make/model
- Pump serial number
- Motor make/frame
- Motor W/Rad/s
- Volts/phase/hertz
- Waterflow rate

Fan Data:

- Number of fan motors
- Motor make/frame
- Motor W/Rad/s
- Volts/phase/hertz
- Motor sheave diameter/bore
- Fan sheave diameter/bore
- Sheave centerline distance
- Number of belts/make/size

Air Data: (list design and actual for each)

- Duct airflow rate
- Duct inlet static pressure
- Duct outlet static pressure
- Average entering/leaving wb
- Ambient wb

Water Data: (list design and actual for each)

- Entering/leaving water pressure
- Water pressure drop
- Entering/leaving water temperature
- Water temperature drop
- Water flow rate
- Bleed waterflow rate

Heat Exchanger/Converter Test Report

The record final conditions for steam or hot water heat exchangers should be recorded.

Unit Data:

- Location
- Service
- Make/type
- Model number/size
- Serial number
- Rating

Steam Test Data: (list design and actual for each)

- Pressure
- Flow rate

Primary Test Data: (list design and actual for each)

- Entering/leaving temperature
- Temperature drop
- Entering/leaving pressure
- Pressure drop
- Waterflow rate

Secondary Test Data: (list design and actual for each)

- Entering/leaving temperatures
- Temperature differential
- Entering/leaving pressure
- Pressure differential
- Waterflow rate
- Control set point
- Circuiting type

Pump Test Report

The final data on each pump is to be recorded. The actual impeller diameter entry is that indicated by plotting the head curve based on a no-flow head test or by actual field measurement where possible.

Net positive suction head (NPSH) is important for pumps in open circuits and for pumps handling fluids at elevated temperatures.

Design Data:

- Service/location
- Make
- Model number
- Serial number
- Waterflow rate/head
- Required NPSH
- Pump rpm
- Impeller diameter
- Motor make/frame
- Motor W/Rad/s

- Volts/phase/hertz
- Seal type
- Full-load amps/SF

Actual Test Data:

- Number of flow heads
- Full open head
- Final discharge pressure
- Final head
- Voltage, T1-T2, T-T3, T3-T1
- Actual impeller diameter
- Full open flow rate
- Final suction pressure
- Final flow rate
- Amps, A1, A2, A3

Boiler Test Report

The control settings and the entering and leaving conditions at the boiler should be recorded. Because the balancing firm is not necessarily responsible for start-up or the proper operation of the machine, these data do not attempt to indicate the performance or efficiency of the boiler except as may be determined by the design engineer from the data contained therein.

This report should be substantially completed and verified by the manufacturers' representatives and/or the installing contractor before the HVAC distribution systems are balanced. Temperature and/or pressure readings of the boiler should be entered during TAB procedures.

A flue gas analysis normally is not in the scope of TAB procedures, but data could be added in a commentary section if available and required by the engineer/owner.

Unit Data:

- Location/service
- Model number/size
- Fuel/input
- Ignition type
- Volts/phase/hertz
- Make/type
- Serial number
- Number of passes
- Burner control

Test Data: (list design and actual for each)

- Operating pressure/temperature
- Number of safety valves/size
- High limit setting
- High fire set point
- Voltage, T1-T2, T2-T3, T3-T1
- Draft fan volts/amps
- Safety controls check
- Entering/leaving temperature
- Safety valve settings
- Operating control setting
- Low fire set point
- Amps, A1, A2, A3
- Manifold pressure

Instrument Calibration Report

This report is to document the application and date of the most recent calibration test or calibration for each instrument used in the testing, adjusting, and balancing work.

Data Reported:

- Instrument/make
- Application
- Date(s) of calibration
- Serial number
- Dates of use

Component Failure Report

This report is intended to provide sufficient information to determine cause of failure and provide feedback to the manufacturer, designer, or installer. This report should be used as soon as a problem has occurred, and its inclusion in the final report is at the discretion of the balancer. It should be noted on the report, if appropriate, that the analysis and recommendations are not to be considered final or expert.

Data Reported:

- Project
- Component
- System
- Manufacturer
- Serial number
- Date
- Contractor
- Description and problem
- Probable cause
- Model number
- Architect/engineer
- Submittal data
- Field test results
- Recommendations

Reports should comply with ASHRAE *Standard* 111, be complete, and include the location of test drawings. An instrument list including serial numbers and current and future calibration dates should also be provided.

CHAPTER 40

OPERATION AND MAINTENANCE MANAGEMENT

Operation and Maintenance as Part of Life-Cycle Costs 40.1
Operating a Facility for Optimal Performance 40.2
Maintenance Strategies for Optimal Performance 40.3
Documentation 40.7
Staffing 40.8
Managing Changes in Buildings 40.10

OPERATING a building, like operating any piece of machinery, entails dynamic assessment of when to turn systems on and what the set points of those systems should be. Examples include determining what level of lighting is needed for particular spaces and times, or how much ventilation air is necessary in certain rooms. Building operations also include deciding whether and when to turn those systems off or to a reduced level of output if they are no longer needed. Building maintenance involves performing any tasks designed to ensure that building systems are functionally available at acceptable levels when needed. Both operation and maintenance impact building performance, which is the building's ability to fulfill its design intent.

As buildings age, their performance (particularly energy performance) drifts from design. Even new buildings can experience degradation in the first few years of operation due to errors in design or construction, manufacturing defects in equipment, or human activity (e.g., adjusting thermostat set points, adding plug loads, leaving things on when not in use). A Lawrence Berkeley National Laboratory study (Mills 2009) found that retro- or recommissioning activities that reset operating parameters to meet current facility requirements can improve existing building performance by 7 to 29%. Given the unavoidability of building system wear and performance drift, it is clear that active management of both the operation and maintenance is necessary to maintain the desired levels of building performance.

Managing operation and maintenance (O&M) includes planning, implementing, and evaluating the outcomes of both operation and maintenance activities. More specifically, this consists of setting performance goals; developing strategies to achieve the established performance goals; communicating both the goals and the results to the building managers, operators, and users; and then providing direction to building operators and maintenance staff, coordinating their efforts based on available resources, and supervising their work. This is all done with the end of achieving and maintaining the established building performance targets. Buildings may have several performance goals, including condition, availability, functionality, system reliability, water use, and indoor environmental quality. Energy use and energy cost are also two key parameters by which the performance of many buildings is measured. This chapter presents a general discussion of how buildings may be operated to minimize these. It also outlines various approaches to maintenance, as well as strategies, tools, and required documentation for both operations and maintenance management programs.

1. OPERATION AND MAINTENANCE AS PART OF LIFE-CYCLE COSTS

Building life-cycle cost is the sum total of costs associated with owning and operating a building over its lifetime. Chapter 38 offers a detailed discussion of life-cycle costs specific to operating and maintaining buildings. Figure 1 identifies the major categories of building life-cycle cost as acquisition, operation, maintenance, and decommissioning.

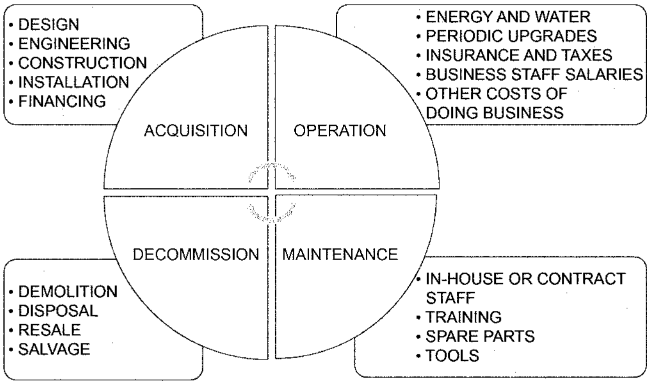

Fig. 1 Typical Building Life-Cycle Cost Categories

The costs involved with each of these components depend on many factors, such as the nature, size, location, and management of the facility. However, several studies have found that, although the costs of operations and maintenance tend to be dwarfed by the costs of beneficial use and staff salaries, they exceed the costs of design and construction many times over. For example, Romm (1994) found that, over a 30-year period, operations and maintenance costs are about three times the cost of design and construction, and Yates (2001) found that operational costs are approximately five times construction costs over a 60-year building life. Results of the Building Owners and Management Association (BOMA) 2008 *Experience Exchange Report* indicate that, specifically for office buildings, operation and maintenance costs are approximately 11 times that of initial design and construction costs. Figure 2 shows the results of BOMA's 2017 analysis of office buildings: utilities, maintenance, and repair accounted for more than 50% of typical operating expenditures, further underscoring the need to prioritize building operations and maintenance management. Although the weight of cost elements clearly varies depending on the time period of study, type of facility, and other factors, it is generally understood that utility, maintenance, and repair costs are significant contributors to building life-cycle costs and that building performance cannot be optimized without also optimizing these principal factors.

2. OPERATING A FACILITY FOR OPTIMAL PERFORMANCE

In essence, there are as many ways to operate a facility as there are facilities to be operated. During planning phases, the building design team develops the building attributes (e.g., operating set points, schedules, sequences) to meet the owner's project requirements

The preparation of this chapter is assigned to TC 7.3, Operation and Maintenance Management.

Table 1 Examples of General Operating Principles in Practice

Operating Principle	HVAC (Building System)	Lighting (Building System)	Domestic Hot Water (Building System)
Turn systems on only when needed	Heat and cool spaces no more than needed to maintain set points. Start morning warm-up/cool-down as late as possible while meeting IEQ set points upon occupancy.	Turn lighting on only when spaces are occupied.	Lower storage temperatures when building is unoccupied for extended periods.
Turn systems on only to extent needed and optimize system output with available free sources	Use economizers to offset need for mechanical cooling. Use recovered heat for preheating. Ventilate spaces based on demand. Reset working chilled- and heating-water temperatures based on outdoor air conditions. Use set-point setback and setups during unoccupied hours.	Use multilevel general lighting and task lighting. Coordinate lighting power with available daylighting	Use lowest storage temperature such that delivery temperature to farthest faucet matches design temperature. Use recovered heat to preheat hot water.
Turn systems off when no longer needed	When spaces are unoccupied for extended periods, reset cooling set points to maximal values and reset heating and ventilation set points to minimal values. As early as possible, allow system to coast to unoccupied set points, while maintaining IEQ set points during occupancy.	Turn lighting off when spaces are unoccupied.	Lower storage temperatures when building is unoccupied for extended periods.

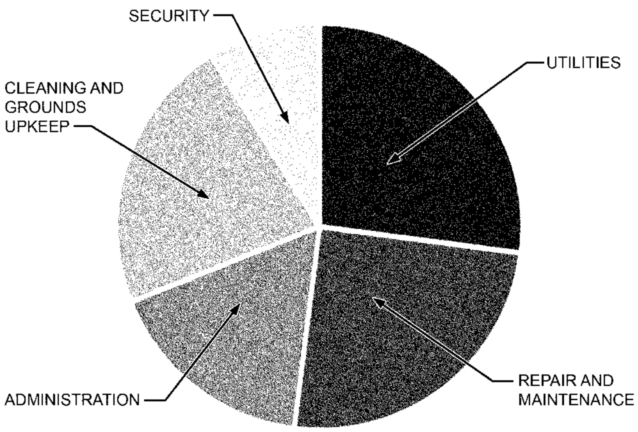

Fig. 2 Facility Operating Expenditures for Typical Office Building
(Adapted from the 2017 EER [BOMA])

(OPR), including those for energy performance. Thus, buildings should generally be operated in accordance with their design. However, over the course of time, building uses may evolve. Likewise, so do standards of thermal comfort and indoor environmental quality. Frequently, building operation schemes do not reflect current building needs or the current state of technological advancement. Research has shown that many buildings have the potential to reduce energy consumption by 10 to 40% by modifying outdated operation strategies (Landsberg et al. 2009).

In general, there are three guiding principles to optimize facility operation for energy performance: (1) only turn systems on when needed, (2) only turn systems on to the extent needed, and (3) turn systems off or to minimum acceptable output levels when acceptable. These three operating principles can be applied to all building systems that consume energy, including those for occupant conveyance and service water. Table 1 provides examples of the principles in practical applications. Often these principles are instituted with the aid of existing control algorithms, though sometimes additional equipment is also required.

Implementation of these principles varies with specific spaces. For example, consider two enclosed offices, one on the perimeter and one on the interior of a building. Both offices require an average illuminance level of 430 lx when occupied. However, whereas the interior office will likely always require the entire amount of installed lighting power to achieve the required illuminance level, there will likely be times when artificial lighting in the perimeter office can (and should) be offset by natural daylight to reduce energy consumption. There may even be times when the perimeter office needs no artificial lighting. Any electric lighting used during such times would constitute wasted energy and degrade building performance.

Similar guidance applies to HVAC systems; spaces should be cooled, heated, and ventilated only when necessary; cooled just to the maximum acceptable temperature; and heated to the coolest acceptable temperature. Additionally, cooling, heating, and ventilation should be coordinated with occupancy needs, outdoor conditions, and the availability of non-energy-consuming alternatives, such as economizer air to offset mechanical cooling. As an illustration, consider a space-heating boiler designed to provide 175 MW with 82°C water on a design day of –18°C. On winter days when the outdoor temperature is –4°C, the facility will still require heating, but it will not require the full 175 MW. An older way of modulating boiler output is to simply periodically fire the boiler and allow it to deliver 82°C water to the radiators. With this approach, the space may experience wide and uncomfortable temperature swings. Additionally, off-design-day system losses would be similar to design-day losses (i.e., they would be maximal). A more efficient method of modulation is to reduce the boiler output, lowering the hot-water temperature as the outdoor temperature rises. This advanced operating method limits temperature swings and further improves system performance by reducing stack and distribution losses.

ASHRAE *Guideline* 36 provides more comprehensive guidance on operating facilities in a manner that improves building performance. It includes a list of detailed standardized sequences of operation specific to HVAC systems, which can be used to reduce energy consumption while improving indoor air quality. The sequences are also designed to elevate fault detection from lagging to real-time, which can help reduce downtime.

3. MAINTENANCE STRATEGIES FOR OPTIMAL PERFORMANCE

Maintenance tasks can include inspecting, adjusting, lubricating, cleaning, nondestructively testing, and repairing or replacing components. These activities are designed to minimize the risk of failures and to preserve the performance of building assets, thus enabling them to be used effectively to meet owner and occupant requirements for thermal comfort, indoor environmental quality, and energy efficiency. They also allow for the evaluation of conditions that can indicate the probability of acceptable future performance. These **condition indicators** can be evaluated by observation, as with fan belt wear, or by measurement, as with compressor amperage draw. As soon as condition indicators suggest unacceptable future performance, remedial actions should be expedited to avoid failures or excessive repair costs. Thus, to ensure acceptable building performance, condition indicators should be monitored and reviewed regularly.

The time interval between successive assessments of a particular condition indicator defines the maintenance **task frequency**. Tasks may be performed once per shift, daily, weekly, monthly, quarterly, semiannually, annually, or at other intervals. For example, ASHRAE *Standard* 180 recommends that variable-speed drives on air handlers be checked for proper operation every six months and corrected if necessary. Task frequencies are typically derived from manufacturers' recommendations, which are based on failure mode effect analyses, average time between failures, and other reliability data. However, these frequencies can (and should) be adjusted based on actual field conditions and data. For example, if acceptable condition indicators are found on three successive inspections of heat exchanger tubes, the interval between tube inspections can be extended. Similarly, if unacceptable conditions are found in two successive inspections, the interval should be shortened, and in this case, depending on the criticality of the component, a systematic root cause analysis may need to be undertaken to identify and remedy the cause of unacceptable performance.

Condition indicators, maintenance tasks, and task frequencies are developed based on the building **performance objectives,** which are the desired outcomes measured in terms of equipment and system deliverables. Primary deliverables are typically occupant thermal comfort, building energy consumption, and indoor environmental quality. Other deliverables may include system uptime, mean time between failures, mean time to repair, and normalized cost data. Building performance objectives should be quantitative, and efforts should be made to define any qualitative objectives in quantitative terms that can be more easily and objectively measured.

Maintenance activities can be planned or unplanned, active or reactive but in general, there are three basic maintenance strategies that define when maintenance activities are performed. In **run-to-failure maintenance**, minimal or no resources are invested in maintenance until equipment or systems break down. Once breakdown occurs, the equipment is repaired or replaced. This strategy is most often used when the cost of maintenance or repair exceeds the costs of replacement and acceptable losses in the event of a failure. The equipment may or may not be monitored for proper operation, depending on the consequences of a loss of beneficial use. For example, instead of repairing a vibrating window air conditioner, it may be operated until failure, then replaced with a new unit. Other types of equipment for which this strategy might be suitable are light bulbs; batteries; baseboard, wall, and other types of electric heaters; some valves; and fractional power recirculating pumps. Run-to-failure maintenance can be planned or unplanned. If unplanned, replacements are treated reactively with levels of urgency that depend on the criticality of the equipment and the system it supports. If planned, spare parts, components, or equipment

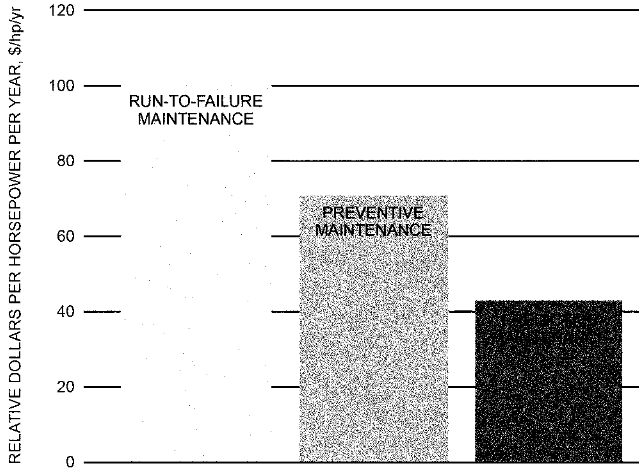

Fig. 3 Relative Maintenance Cost for General Industrial Rotating Equipment
(Adapted from Hudacheck and Dodd 1976)

are on hand to replace failed units so that interruptions of service are minimized.

Preventive maintenance is planned and scheduled, either by equipment run time or by calendar. In this strategy, maintenance tasks are performed at frequencies recommended by the manufacturer, industry standard, or as adapted to field conditions. This proactive strategy is typically used for essential building equipment such as pumps, air handlers, boilers, ductwork, elevators, and transformers. One of the disadvantages of preventive maintenance is that it can lead to excessive maintenance costs because tasks are performed on schedule regardless of whether the equipment requires them. Thus, though preventive maintenance is currently the most common maintenance strategy, strategies specifically designed to optimize maintenance intervals continue to grow in popularity.

Predictive maintenance uses measurements of the condition and/or performance quality of equipment and systems to guide maintenance activities. Current conditions and performance can be compared to benchmarks determined by industry standards or facility historical performance. Rates and types of component wear and/or performance degradation are used to predict when failure is likely to occur. Corrective maintenance action can then be planned and scheduled to take place, just in time before failure or loss of beneficial use. By basing maintenance actions on analysis of actual field data, both excessive and too infrequent maintenance can be avoided, thereby minimizing downtime and maintenance costs, maximizing maintenance personnel productivity, and optimizing plant reliability. As shown in Figure 3, Hudacheck and Dodd (1976) found that using a predictive maintenance strategy for general industrial rotating machinery can reduce maintenance costs by almost 60%.

An evolving subcategory of predictive maintenance strategies referred to under various names (e.g., condition-based maintenance, reliability-centered maintenance, benefit-based maintenance) is also in use. Each iteration focuses on a particular performance index to determine when and what maintenance should be performed. All forms of predictive maintenance, however, rely on nondestructive testing and observation to obtain the data on which future performance is predicted. Future failure predictions can be based on nearly any indicator of performance degradation that changes gradually over time. Typical nondestructive diagnostics include tools and techniques such as (1) thermal infrared imaging of electrical connections to determine whether mechanical joints are tight; (2) electrical current analysis to diagnose motor winding faults; (3) vibration analysis to identify imbalances, bearing wear, and misalignment in rotating

Table 2 Basic Maintenance Strategies

	Basic Maintenance Strategy		
	Run-to-Failure	**Preventive**	**Predictive**
Principal objective	Minimize maintenance tasks and expenses	Minimize failure and maintain durability, reliability, efficiency, and safety	Cost-effectively minimize failure and maintain durability, reliability, efficiency, and safety
Key advantages	Minimal staff requirements Minimal planning	Extends asset life Maintains energy efficiency Reduces unplanned downtime	All preventive strategy benefits Prevents unnecessary maintenance Optimizes maintenance costs Optimizes building performance Optimizes staff productivity Enhances ability to troubleshoot and identify root causes
Key disadvantages	Downtime costs Inability to plan Increased capital spending High inventory costs to minimize downtime	Does not consider asset wear, which can lead to unnecessary maintenance expense	Requires highly skilled staff to interpret data Requires monitoring and diagnostic equipment

equipment; (4) chemical analysis of oil and grease for contamination; (5) measurement of pressure differentials across filter banks and heat exchangers to determine optimum change or cleaning frequency; (6) measurement of temperature differentials to indicate proper performance of chillers and air-handling equipment; (7) sonic testing to measure material thickness at critical wear points in piping; (8) dye testing to identify cracks in components; (9) eddy current testing to evaluate the integrity of chiller heat exchanger tubes; and (10) visual inspection of fan belts to identify and characterize wear.

Condition and performance measurements can be completed either continuously or periodically. Periodic measurements tend to be performed manually by operators on routine patrols or while performing other tasks. For example, the condition of water or glycol in hydronic loops can be checked by sampling fluids while cleaning strainer baskets and changing filters. Visually checking fan belts for wear or using ultrasonic microphones to detect leaks in steam or compressed air systems or to detect dry motor bearings can easily be incorporated into regular patrols.

Although using manual patrols to detect faults does alert maintenance staff to the presence of some issues that require attention (e.g., burned-out lamps), there may be a lag between the fault occurrence and its detection. Depending on the equipment and its criticality, this lag could have a significant impact on performance. Additionally, there are some faults (e.g., failed outdoor air dampers) that are not easily discovered by patrol. Continuous monitoring provides more information and enables identification of failures as they occur. Advancements in this area, coupled with building automation systems (BAS) and controls, have given rise to **automated fault detection and diagnosis (AFDD).** This software-based tool can keep operations and maintenance staff better apprised of the conditions of HVAC&R equipment and systems and can help manage both equipment-level and system-level maintenance activities. With AFDD, system performance indicators are automatically monitored, measured, and compared to expected values. The expected values may be input into the AFDD tool manually, or they may be extracted from a building information model (BIM), a computer-based tool increasingly used during building design and construction. Discrepancies are identified and analyzed for root causes using algorithms based on engineering principles and empirical data, and a list of facility-specific recommended corrective action is generated.

AFDD greatly improves the operating energy efficiency of commercial HVAC systems, and its benefits have been validated in part by studies that document a wide variety of detected operating faults in common HVAC equipment (Breuker and Braun 1998; Breuker et al. 2000; Comstock et al. 2002; House et al. 2001, 2003; Jacobs et al. 2003; Katipamula et al. 1999; Proctor 2004; Rossi 2004; Seem et al. 1999). The immense value of AFDD lies principally in its ability to identify unwanted operating conditions that waste energy and that are not easily discoverable by cursory observation. This is particularly true for equipment that may be installed in locations without easy access (e.g., on roofs, above ceilings, in walls) that are inspected infrequently. Examples of detected faults include economizers in packaged air conditioners and heat pumps not operating properly; low or high (depending on the season) refrigerant charges; condenser and filter fouling; faulty sensors and controls; electrical problems; and air-handling units with too little or too much outdoor-air ventilation, poor economizer control, failed outdoor-air dampers, and other problems. For a detailed explanation of AFDD, see Chapter 63.

Choosing the Best Combination of Maintenance Strategies

The ideal maintenance program preserves the required asset reliability and availability at the lowest cost by identifying and implementing actions that reduce the probability of failure to an acceptable level. It is unlikely that a single strategy will satisfy the availability, reliability, performance, and economic criteria for all assets in a facility. Thus, optimal maintenance programs generally incorporate all three basic strategies selectively. For example, a program might use a run-to-failure replacement strategy for lighting, windows, and door weatherstripping; a preventive strategy for water heaters; and a predictive strategy for chillers and air handlers. Each basic strategy has advantages, disadvantages, and cost implications that should be considered when defining a maintenance program. Table 2 provides a simple characterization of the basic strategies.

When developing a maintenance program, the needs of each asset class or system should be considered separately. For each asset, an economic analysis weighing the costs and benefits of the three basic strategies should be performed. Because maintenance takes place over the life of an asset, the economic analysis will need to determine the net present values of costs and benefits. For details on performing net present value calculations, see Chapter 38.

The economic evaluation may include many factors; however, those that are essential to strategy selection include

- Owner and occupant requirements for availability and performance of the asset
- Criticality of the asset function, both stand-alone and within any applicable systems
- Cost to purchase the asset
- Cost to replace the asset
- Life-cycle labor costs for maintenance associated with the asset
- Effects and consequences of failure

- Cost of downtime resulting from asset failure
- Safety issues related to asset failure
- Cost of required staff training to maintain the asset
- Cost of required instrumentation and diagnostic tools to maintain the asset

Other factors may include benefits, such as productivity improvements, improved indoor environmental quality, and enhanced occupant comfort and satisfaction. Qualitative benefits such as these do not have simple monetary values and will need to be assigned monetary worth. To reduce subjectivity, it is recommended that formulas be developed for valuing non-monetary benefits. Once the costs and benefits have been determined and summed, they can be compared to determine which of the three strategies has the greatest benefits, or the least cost. This information can then be used to more objectively select the optimal maintenance strategy for each asset, asset class, or system.

Elements of Effective Operations and Maintenance Programs

Simply put, building operation is the engaging, disengaging, and modulation of building systems, and building maintenance is the series of activities performed to keep those building systems in acceptable working order. Often, the function of many building systems is largely automated, though building operators are still tasked with ensuring that those systems function correctly as intended. Additionally, all building maintenance activities are performed by people. Thus, building operations and maintenance management is essentially management of the people who operate and maintain buildings. A general definition of management is the planning, organizing, and control of a process or activity to achieve a certain outcome. A successful O&M management program can, therefore, be defined as one that manages the activities of the people who operate and maintain buildings, achieving effective use and preservation of assets.

Organization

Whether for a single building or a facility complex of buildings, operations and maintenance management is a team effort. It demands the participation of the building owner, occupants, facility manager, and various other staff. A successful program requires (at least)

- Senior management’s commitment, in both form and action, to support the program
- A shared understanding and appreciation of both the quantitative and qualitative benefits of operations and maintenance activities
- A written program with clear objectives, methods, and targets that are directly tied to owner and occupant requirements and to business objectives
- Development and integration of long- and short-term performance goals, objectives, and plans along with the tactical, day-to-day operational activities
- Sufficiently budgeted resources (including people, training, and tools) to fulfill duties
- Regular evaluation of performance, progress and outcomes with course corrections implemented as necessary
- A well-organized system for maintaining records

The importance of senior management’s commitment to operation and maintenance cannot be overstated. Senior management provides direction and leadership, and sets the course for the organization on every front. Without management support, operation and maintenance initiatives will lack adequate resource allocation and fail. Demonstrated support necessarily takes several forms, including

- Establishing a policy statement that aligns facility performance with business performance
- Assigning an accountable O&M advocate
- Establishing a team to track facility performance that includes representatives from finance and human resources departments as well as the operations and maintenance functional group
- Budgeting resources to support the program
- Measuring and reviewing performance on a regular basis, recognizing and rewarding success.

Ultimately, the implementation team will be responsible for performing the operation and maintenance tasks. The challenge for management personnel is to harmonize the two functions of operations and maintenance to deliver an effective and cohesive program.

Communication is also critical to success and best achieved through documentation of the program. The level of detail should allow each team member to comprehend his/her individual role, responsibilities, and objectives, as well as how his/her contributions complement those of others. This helps ensure that everyone is working toward a common end and facilitates continuity when members leave or join the team.

An essential aspect of the written program is specifying the relationship between asset and building performance and the organization’s productivity. Communicating how the facility’s performance fits into the organization’s mission and success makes it easier for business managers to make budget and resource allocation decisions that support facility operation and maintenance objectives.

Like a building, the O&M management program is dynamic; it should be considered a living document. Over the life of a building, performance objectives are likely to change, as for example, when building tenants change or building systems are upgraded. At regular intervals and most especially at times of significant change, the O&M management program should be re-evaluated and updated to ensure that it continues to be aligned with building owner and occupant objectives.

O&M Goals and Targets

Setting goals is a process that begins with the end in mind and bridges the gap between the desired outcome and the point of origin. **Objectives** are broad statements describing fundamental desired outcomes, and **goals** are statements that describe the intermediate steps or achievements necessary to support the larger objective. For example, an organization’s senior management might establish an objective of being recognized amongst its peers for sustainability. To support this objective, several operations-related goals might be established, such as reducing water consumption by 2% annually, reducing energy waste by 15% by the end of the year, or achieving a total energy utilization index (EUI) of 1760 MJ/($m^2 \cdot$yr) in two years. The measurable parts of the goals are the **targets**. To be effective, all goals must have targets. Targets should be clearly defined and specifically linked to building systems and equipment performance parameters. They should also be attainable by the equipment and systems to which they pertain; be results oriented and relevant to the overall objective; and establish a time frame to create an appropriate sense of urgency.

Many facility goals will be related to the operation and performance of the building as a whole or to certain building systems. However, the maintenance program is generally established to mitigate the degradation and failure of specific assets while enabling assets to deliver the required performance. Therefore, the maintenance program also needs goals and targets specific to maintaining equipment **reliability**: the probability that equipment or a system will perform its intended function for a specified period of time when used under specific conditions and environment. A related concept is **durability,** or the average expected service life. Manufacturers quantify durability as design life, which is the average number of hours or years of operation before failure, extrapolated from accelerated life tests and from stressing critical components to economic destruction. Chapter 38 tabulates median years of equipment service life for many typical pieces of HVAC equipment. A common goal for a maintenance program is to have equipment attain or exceed its design life.

Another common reliability-related maintenance goal focuses on **uptime**, the percentage of time the equipment is operable when needed. For example, the reliability of data centers is often defined, in part, by uptime, with target values ranging from 99.671% uptime (an allowable downtime of 28.8 h per year) to 99.995% uptime (an allowable downtime of 26 min per year). Other related concepts that are more qualitative include **capability**, the ability of a system to satisfactorily provide the required level of service; and **maintainability**, which is a singular, calculated value representing the ease, accuracy, safety, and economy of performing maintenance.

The term **sustainability** is also increasingly used in relation to operation and maintenance programs. In recent years, the term has been used generally to mean providing for the needs of the present while not compromising the ability of future generations to meet their own needs. However, when applied to operation and maintenance practices, its historical definition (able to be maintained at a certain level) is more useful. ASHRAE *Guideline* 32 suggests using the term to indicate that the performance level of operation and maintenance practices can be upheld and that they can keep building systems operating at their intended levels of performance.

By adding a measurable target to any of these reliability-related concepts, they can be converted into a goal suitable for the maintenance group. When establishing maintenance goals, consideration must also be given to available financial and human resources, the age of equipment and systems, and capital projects planned for the near future. Additionally, maintenance goals must balance the criteria of building operating plans and the criticality of equipment and systems. For example, in systems for which continuous operation is a critical requirement, procedures must be established to perform maintenance while equipment is operating, or redundant capacity may be needed to allow for off-line maintenance without interruption of operation of the equipment or system.

Reviewing Performance Data

Equipment- and system-level data should be reviewed regularly to ensure that all equipment is operating as intended. These data reviews can be thought of as an extension of the maintenance inspections. The frequency of the review should be such that any necessary adjustments to the equipment or system can be made within a reasonable time after discovery to minimize energy waste. In a facility equipped with a building automation system (BAS), it is important that operation and maintenance staff spend time each day looking at the system's alarm history and analyzing the data it presents. Dillenbeck and Sheppard (2018) suggest conducting the alarm review during a daily meeting, during which the operator's log from the previous shift is reviewed line by line. The log should include the entry date and item number, location and description of the fault, action taken, and follow-up action recommended or requested. The log should also include a space for system specialists to indicate their notes, additional findings, actions taken or planned, and whether any additional follow-up by the operator is required. Automated fault detection and diagnosis (AFDD) software can be a valuable tool here because some fault conditions are not individually alarmed. For example, consider an outdoor air damper that has failed in the open position. A BAS may not alarm this specific condition, but the fault can be inferred by knowledgeable and attentive operators from the unusually low (or high, depending on the season) temperature in the mixed air stream as compared to return and supply air temperatures.

In reviewing the daily log, pay special attention to any parameters that are not within allowable tolerances, because this can help to identify system correction or improvement opportunities. Regardless of the nature of the poor performance, a thorough analysis should be conducted to ensure that the root causes of any problems have been identified. Only then can proper solutions be devised and implemented. There are a variety of analysis methodologies that may be used to pinpoint sources of poor performance. In selecting a problem-solving approach, care must be taken that the rigor of the analysis be commensurate with the scale and scope of the problem.

Although daily logs are an important tool for the operations and maintenance team, they should not be viewed in isolation. Data trends are equally important. Trended data can help predict future performance in advance of potentially unwanted conditions, and this advance notice can often help to save energy as well.

Commissioning Before, During, and After Turnover

Commissioning is a quality assurance strategy that goes far beyond equipment check/test/start procedures or the testing and balancing of distribution systems. It is a formal process for integrating all project requirements throughout all the phases of building development. Commissioning verifies and documents that the facility and its systems are planned, designed, constructed and/or installed, tested, operated, and able to be maintained in order to meet the owner's project requirements. It includes the development and documentation of the **owner's project requirements** (OPR), the required function of the facility and how its success will be determined, and regular reviews to ensure the OPRs are continuously met as the project progresses. Chapter 44 provides an overview of commissioning for HVAC systems. ASHRAE *Standard* 202 and *Guideline* 0 offer guidance and define the standard of care that should be taken in delivering a commissioning project with all the major systems typical of a complete facility.

Ideally, the systems and equipment of every new construction, addition, and alteration project should be commissioned before turning over the facility to the operations and maintenance team. This helps to ensure that a fully functioning and high-quality facility is delivered and that the facility management team is adequately trained and prepared to operate and maintain it. Commissioning facility projects also helps to enhance communication and reduce misunderstandings, reduce the number of change orders, reduce the total cost of project delivery, and improve the delivered quality and value for the building owner and occupants.

Commissioning activities take place through the project delivery process, and a well-written commissioning specification will include provisions for the **commissioning authority (CxA)**, the entity contracted to manage the commissioning process, to provide quality assurance services through the warranty period or first year of occupancy. In addition to ensuring that systems continue to function without issue, involvement of the CxA through the initial occupancy period ensures that the building operators and maintenance team are adequately prepared to fulfill their duties as planned. The commissioning authority's continued participation also helps to identify and address deficiencies in operator or maintenance personnel training. With the growing introduction of building controls and the fast pace of technological advancement, this benefit cannot be overestimated.

Periodically, existing buildings may need to be commissioned. Over time, equipment performance may drift from design or building function may change. Both **recommissioning** systems that were previously commissioned and **retrocommissioning** systems that have not previously undergone commissioning largely follow the same process as the commissioning of a new facility. However, there are some key differences. For example, in commissioning, the OPR are provided to the commissioning authority as part of the design documents that establish acceptable performance levels. However, in retro or recommissioning, the commissioning authority must develop and define the current facility requirements in conjunction with the building owner and occupants. Guidance for facility retrocommissioning and recommissioning is provided in ASHRAE *Guideline* 0.2

Both recommissioning and retrocommissioning have a high potential to reset system performance to near original levels. However, drift from initial performance is a naturally occurring eventuality. To better ensure that building systems remain optimal throughout the facility service life, a policy of **ongoing commissioning (OCx)** should be considered. Ongoing commissioning is a continuation of the commissioning process throughout the service life of the building. With ongoing commissioning, the original owner's project requirements are dynamically updated as they change. These updated requirements are referred to as the **current facility requirements (CFR)**. Ongoing commissioning is cyclical and activities are repeated at intervals appropriate for the facility, its use, and its management team. Guidance for ongoing commissioning is also provided in ASHRAE *Guideline* 0.2

4. DOCUMENTATION

Information on the facilities, systems, and equipment is essential for appropriate and informed operation and maintenance. It also aids in staff training; troubleshooting; updating program elements such as schedules and operating strategies; updating maintenance approaches; budgeting; assessing and communicating performance; and managing facility upgrade and retrofit projects. ASHRAE *Guidelines* 0 and 4 provide detailed guidance on preparing accurate, relevant operation and maintenance documentation that is easy to use and update. Additionally, ASHRAE *Standard* 90.1 includes documentation requirements for specific systems, such as building envelope, lighting, power, HVAC, service hot water, conveyance, and others. The design and commissioning team should ensure that a comprehensive systems manual (as outlined in these guidelines) is provided to the owner.

For new construction, the design team should establish operation and maintenance documentation requirements as part of the owner's project requirements. Deliverables should support the expected maintenance strategy, skills of the maintenance and operations staff, and anticipated resources to be committed to performing operations and maintenance tasks. The requirements for operation and maintenance programs developed for existing facilities are the same, but the O&M staff may play a larger role in developing the documents (rather than the design team).

O&M Documents

For projects involving new equipment, it is critical that all information required to operate and maintain the systems and equipment be compiled before project turnover to the owner's staff. Moreover, it is essential that the information be made available to the entire facilities department so that everyone responsible and accountable for operating and/or maintaining equipment has sufficient information to successfully perform their role. Whether operation and maintenance documentation is being assembled by the design team or by the facilities team, it is a good practice to compile the information into a series of interrelated manuals as it becomes available. In addition to being used by the facilities team to operate and maintain the building, this information can be used to support design and construction activities, commissioning, initial training of O&M staff, and facility start-up.

A complete operation and maintenance library includes a document directory, an emergency information and procedures manual, a facility operating manual with operating procedures and as-built construction documents for all major systems, and a facility maintenance manual with detailed maintenance procedures and commissioning test reports for all major systems and equipment. Recommended contents for each manual are provided in Table 3.

The O&M library will serve the facility for the building's lifespan. It contains many documents and manuals that will likely evolve and grow in number over time. During this time, staff turnover may also occur any number of times. An **operation and maintenance document directory** lists and identifies the location of all the information and documents held by the facilities team. A directory that is well organized and current facilitates quick reference by both existing and new technicians and operators.

Additionally, regardless of building type, function, or size, it is imperative that **emergency information** be directly distributed to emergency response personnel. Including this critical information in the operation and maintenance library ensures that it is immediately available when needed by nontechnical persons (e.g., security and medical responders), as well as by technical persons (e.g., building operators, utility personnel, firefighters).

Documentation Methods

There are two basic methods for collecting and archiving operation and maintenance documents: (1) hard-copy paper documents and (2) soft-copy, electronic documents maintained in a computer database. The chosen method should be aligned with maintenance program complexity and scope, as well as the accessibility needs of facility management and the skill level of maintenance staff. Both methods allow staff to enter, archive, update, and evaluate information on building systems and assets efficiently and effectively. However, with advances in communications technology and the prevalence of computers and other smart devices, many staff members find it easier to maintain, access, and update documents electronically and, at times, remotely. Nevertheless, in general, operators of small, single, and simple buildings still tend to rely on paper documents whereas operators of large, complex buildings and facilities are more inclined to use computer-based documentation methods. Regardless of which method is used, it is important that O&M staff be provided adequate time to regularly collect and document the required performance information. Otherwise, the data collected may not be of the quality or accuracy needed to support effective decision making.

A computerized maintenance management system (CMMS) is a software tool to

- Plan, schedule, and track maintenance activities
- Store maintenance histories and asset inventory information
- Communicate building operation and maintenance information
- Generate reports to quantify maintenance productivity.

It can be used by facility managers, maintenance technicians, third-party maintenance service providers, and asset managers to track the status, asset condition, and cost of day-to-day maintenance activities. The number and type of modules used in a CMMS are specified by the facility management team, depending on the facility's needs and the management team's goals. Typical CMMS modules include provisions for requesting, generating, and tracking the progress of work orders; inventory control; maintenance planning; equipment histories; maintenance contracts; and key performance indicator (KPI) tracking, analyzing, and reporting.

Although a CMMS is not required to manage maintenance activities, they are becoming more commonly used (Sapp 2016). When implementing a CMMS in a new or existing facility or upgrading an existing CMMS, the requirements of the tool, as well as communication protocols and interfaces, must be carefully planned. Although using a CMMS has the potential to increase the facility management team's efficiency and serve as a historical maintenance archive, more than 50% of CMMS implementations fail (Berger 2009). One reason for failure is inadequate data population. To overcome this challenge, especially when new buildings and major renovations are designed

Table 3 Recommended Tables of Contents for Manuals Forming O&M Documentation Library

Operating Manual	Safety Manual	Maintenance Manual
• General information - Building function - Building description with as-built construction documents - Energy budget - Operating standards with sequences of operation, set points, and acceptable ranges of values - Operating logs - Communication requirements: (1) performance, progress, and status reporting to management, and (2) advising occupants of seasonal changes and other alterations • Technical information - System descriptions, including as-built drawings - Seasonal start-up and shut-down procedures - Operating routines and procedures - Seasonal shutdown procedures - Emergency procedures - Other special procedures, for example operation during extreme weather - Basic troubleshooting • Required testing - List of systems requiring testing, along with required test frequencies and procedures (e.g., fire protection system, boilers and pressure vessels, etc.) - Log of test dates and results - Contact information for contractors providing third-party testing	• Communication protocols • Objectives • Key performance indicators (KPIs) • Regulations • Responsibilities and accountabilities • Building and building maintenance related hazards • Training requirements for emergency topics, type, and frequency • Required safety measures - Safe work practices - Engineering controls - Administrative controls - PPE • What to do in the event of an emergency, including the following, as applicable - - Fire - Security breach - Flood - Gas - Power outage - Plumbing overflow - Elevator - HVAC - Refrigerant release - Chemical spill	• Equipment inventory - Equipment description, function, and associated system - Data sheets (approved submittals) with operating and nameplate data - Purchase date and warranty information - Equipment location • Maintenance program and procedure information - Maintenance plan with KPIs - Manufacturer installation, operation, and maintenance (IOM) instructions - Spare parts information (may be in the IOMs) - Corrective and planned maintenance task lists with frequencies, as applicable - Health and safety plan (HASP) - Required personal protective equipment (PPE) - Emergency procedures - Reports for air and water distribution systems testing, adjusting, and balancing (TAB); systems commissioning; factory tests; etc. - Repair histories

and constructed using building information modeling (BIM), open information exchanges should be used. A supplement in the ASHRAE Handbook Online version of this chapter provides a brief overview of what open information exchange standards are, followed by a descriptive list of current and developing open information exchange standards. Selecting the right software does not guarantee that using a CMMS will improve maintenance productivity, so it is important to evaluate, document, and align facility management processes with how the CMMS will be used. When implementing or upgrading a CMMS, adequate time should be allocated to design new processes and develop a set of system requirements, using a participatory approach that includes all stakeholders (Berger 2009).

5. STAFFING

In addition to maintaining building assets in acceptable working order, it is important for maintenance staff to be able to provide good customer service. This means responding effectively to service requests and complaints from building occupants. The level of customer service provided, and how that service is perceived, are both determinants of success and continued support for the maintenance organization. Thus, determining quantity and necessary skills of staff is critical. Questions that every operation and maintenance department must answer include

- How many persons are needed to operate the facility? How many are needed to maintain the facility?
- What skills must the operations and maintenance teams possess?
- Should the facility operation and/or the facility maintenance be self-performed or contracted with a service provider?

One of the first steps in estimating staff size requirements is to translate the maintenance plan into a series of tasks and then to estimate the time necessary to perform each task, considering the number and frequency of all tasks, as well as when they can or need to be completed. The size of the staff should be such that work loads are appropriate and that personnel can perform their assigned maintenance tasks and duties both safely and within acceptable time limits. References, such as APPA (2011), provide standard labor units for maintenance tasks to help develop projections of time requirements.

Facility operating hours also affect staff sizing. For example, hospital maintenance staff need to be on site around the clock to ensure building systems and other critical systems are functioning properly and to address any operational issues that may arise. Other considerations for staff sizing include available funding, staff sourcing, labor agreement provisions, vacations, sick days, when maintenance is likely to be required, and business imperatives.

As with other organizational departments, the maintenance department should be staffed by people with a variety of talents. The nature of the job tasks dictates the required levels of skill staff members must possess to perform the work. For example, facilities with large central heating plants may require stationary operating engineers, and industrial facilities with large centrifugal chillers requiring a compressor teardown to inspect bearings every five years require a different level of skilled maintenance than a facility served by a single residential-style furnace or small packaged rooftop unit. Factors to consider when defining needed skill sets include the complexity and criticality of the equipment and systems to be maintained, the rigor of the maintenance program, the actual maintenance tasks that must be performed, and whether any special skills or certifications are required to perform them.

In addition to tradespeople and regardless of facility size, equipment type, or system complexity, there are certain roles that every

Table 4 Common Roles Within Operations and Maintenance Department

Role or Job Function	Key Responsibilities:
Shift Operator	• Provide patrols and respond to emergent issues, including BAS alarms • Document condition indicators as required • Document conditions and issues requiring resolution or further attention • Attend each day's roundup meeting
Equipment or system specialist	• Triage reports from operators • Determine skills, tools, etc. required to resolve outstanding issues • Prioritize work • Ensure that corrective work is not dropped, waylaid, or misinterpreted • Work with site trades • Manage service contracts • Manage special system requirements (such as water treatment) for performance and safety
BAS and controls programmers and technicians	• Diagnose and resolve issues with the BAS instruments, electronic components, and computer code
Planner/scheduler	• Review operator and system reports • Issue work requests • Plan and schedule work • Review and update task descriptions
Project leader	• Work with stakeholders to develop project scopes • Maintain a prioritized list of proposed projects • Develop and execute capital funded projects • Assist in bidding work and securing contractors • Work with the contractors to execute the work
Project comptroller	• Track operating, maintenance, and capital project costs • Prepare regular reports for business management
Facility manager, head of section, or department head	• Oversee the BAS/HVAC section. • Provide guidance and direction to the department staff • Mange operating and capital budgets • Communicate facility and departmental needs and performance to senior management

operation and maintenance department needs to fulfill. In large organizations, the roles may be discrete; in small organizations, individual staff members may need to take on multiple responsibilities. Exact titles vary depending on the preference of the defining organization, but the essential functions, adapted from Dillenbeck and Sheppard (2018), include operators, specialists, planners, project leaders and department heads. Table 3 provides a summary of each role.

Training

To be effective and efficient, operation and maintenance management staff must have both technical and managerial skills. Managerial skills include providing direction, guidance, correction, and coaching to the personnel who operate and maintain the facility. Facility management responsibilities may include developing operation and maintenance strategies; determining program goals and objectives; and administering contracts with tenants, service providers, and labor unions. Even when specialized contract maintenance companies provide certain services, the facility manager needs to be skilled in these areas to be a smart consumer of services.

Technical skills include the ability to understand how mechanical and electrical systems operate and how equipment maintenance is performed, as well as the analytical problem solving expertise of a physical plant engineer. Additionally, because the interest in sustainable, high-performance buildings continues to grow, it is also suggested that staff be trained in how to recommission and/or retrocommission systems. Doing so will help ensure continued efficient system operation, minimal operation and maintenance costs, and occupant satisfaction.

The training program should be established with a written training plan. Ideally, the training plan would originate in the predesign phase of a construction project and be incorporated into the project commissioning plan and construction documents. However, the training plan can be a stand-alone document and can be initiated at any time in the life of the facility. The plan should identify the knowledge and skills necessary for everyone with a stake in the facility. This includes the owner, facility managers, building operators, and occupants. However, all stakeholders will not require the same degree or amount of training. Facility managers and operators will require in-depth systems and equipment training, whereas the training requirements for occupants will be more cursory and simply provide a general awareness of how occupant behavior can impact facility performance. The plan will necessarily evolve over time. It should always be reviewed annually and define

- The skills, knowledge, and performance expected to meet the key responsibilities of each job (refer to Table 4 for key responsibilities for some technical jobs)
- Who needs to be trained, what current knowledge and skill levels are, and the budget and other resources allocated for training
- The training schedule and how it fits into the larger project
- The duration of initial training and requirements for refresher courses and/or continuous education
- Specifications for trainers as well as training materials, delivery methods, and archives of reference materials
- Specifications for documentation, verification, and records of training efforts and accomplishments

For construction projects, training should incorporate the owner's project requirements; for existing facilities, it should integrate the current facility requirements. Training for the facility management team should cover all the building systems and equipment, including mechanical, electrical, plumbing, controls, conveyance, and any special or unique systems (e.g., those for laboratories and cleanrooms) in the facility. As appropriate to specific job duties, training should cover the OPR and/or current facility requirements, as well as routine operation and maintenance. It should also include simple and major repairs, overhauls, failure modes, system interactions, and emergency operations and procedures. ASHRAE *Guideline* 1.3-2018 provides additional guidance for development and implementation of training programs that support acceptable building performance.

Self-Performance Versus Contract

For most enterprises with large facilities, maintenance organizations are not usually part of the core business, and economic considerations become an important factor in determining whether maintenance will be self-performed or provided by a contractor. For self-performance, another cost factor to consider is the cost of training for development and training for various credentials. Wage structures, the available labor pool, staff skills, and ability to perform specialized tasks are among the other factors considered when deciding to self-perform or contract facility O&M.

Often, owners of (one or even several) small buildings cannot justify the expense of employing in-house maintenance personnel. Thus, they may decide to contract out all operations and maintenance work. In these cases, it is important that the contract specifies that the work to be carried out is consistent with the recommendations in this chapter as well as industry standards and guidelines such as ASHRAE *Standards* 180 and 100 and ASHRAE *Guidelines* 4 and 36. The contract should also specify periodic operational checks of equipment operating schedules, set points, and indoor air quality. There should also be provisions to protect key building owner intellectual property and ensure it is available for continued use beyond the service provider’s contract. Such intellectual property includes

- Equipment tagging database and equipment tags installed in the field
- Preventive maintenance task list and schedule for each piece of equipment
- Operator’s log books and electronic logs
- Records of inspections and preventive and corrective maintenance performed
- End-of-life and capital upgrade plans
- BAS and other programmable system hardware and software, including all passwords and access permissions

When the owner employs in-house operations and maintenance staff, responsibilities should include operation checks and maintenance duties (as needed and within staff capabilities), in addition to responding to occupant complaints and overseeing corrective actions. At minimum, it is reasonable to expect changing filters, belts, and motors; lubricating bearings; and similar routine maintenance. In many buildings, particularly larger ones or campuses, in-house maintenance staff may include specialized expertise, reducing the need to retain contractors. However, whenever the operator cannot service and repair the systems or components installed, the owner should ensure that qualified contractors and technicians perform the work. Additionally, when there are regulatory or certification requirements to perform specialized work, the owner’s in-house staff must either possess the certification, or the work must be contracted out to someone who does possess the required certification.

Commonly, a mix of the two approaches is used: routine performance checks and inspection tasks are self-performed, and repairs to major equipment are contracted to factory-authorized service providers. This approach can reduce expenses associated with the tools and training necessary for infrequently needed maintenance activities.

Often, with the mixed approach, cost-plus service agreements (in which the service provider is paid for all allowed expenses, plus a fee for profit) are used because they make it easy to begin work when only a partial scope of required work is known, especially in cases where costs can unexpectedly increase, such as with emergency repairs. Where maintenance programs are well defined, and thus conducive to firm, fixed-price contracts, alternative contracting methods can be used. These agreements may have some form of indefinite-quantity, indefinite-delivery provisions to cover unplanned maintenance or repair requirements. Recently, performance incentives such as savings sharing, extending the contract term, and award fees have been provided to contractors.

6. MANAGING CHANGES IN BUILDINGS

For building projects, the owner should always work with the design team to clearly define facility requirements. Even so, some of those requirements will likely evolve during the facility’s life. Existing building systems and equipment are based on the technology available to planners and designers at the time of preparation, construction, and installation. Data from the Energy Information Agency’s 2012 *Commercial Building Energy Consumption Survey* suggest that, in the United States, the median age of commercial buildings in use is over 40 years. In 2009, new buildings represented only about 2% of construction costs across the United States (Holness 2009). Thus, even though operation and maintenance programs for targeted building performance may be followed, new technologies (e.g., high-efficiency equipment, better control systems, sustainability advances) with the potential to increase overall building performance are likely to become available. Additionally, ownership, occupants, or building function may change, or the building footprint may be expanded. Satisfactory performance may even be redefined. Undoubtedly, such changes will also impact operation and maintenance programs.

Managing such changes is key to continued acceptable building performance. Operation, maintenance, and maintainability of all building systems for the service life of the building should be considered during the initial design. A facility with adequate space to inspect, repair, and replace components and equipment should be part of the owner’s project requirements. The owner and designer must agree on the criticality of each system and establish criteria for access, redundancy, and component isolation. This work helps prepare for future replacements, upgrades, and renovations.

Many renovation and retrofit projects will necessarily occur while the facilities are still operation. Construction projects in occupied buildings require a higher level of planning. Operation during construction can impact system design and create challenges for project scheduling. Often, this necessitates a phased installation. In these cases, it is generally helpful to select the construction team before design completion. This allows the expertise of all parties to contribute to discussions of constructability, maintainability, budget consequences, and other concerns before the design is finalized. See Chapter 60 for information on integrated teams.

In all projects in existing buildings, but especially those retrofit projects that involve major conversions to new technologies, the value of the project should be assessed in terms of life-cycle costs. In addition to life-cycle factors of acquisition, operating, and maintenance costs, other important considerations include (1) indirect costs of conversion, including potential revenue losses from associated downtime; (2) service life of the retrofitted equipment or system; and (3) remaining service life of the building and whether it will be extended by the new system.

After the renovation or retrofit project has been implemented, the new equipment and all building systems affected by it should be commissioned in accordance with ASHRAE *Guideline* 0. This quality assurance strategy helps ensure that all is operating as intended and delivering the expected results. Following the recommended commissioning process also ensures that the documentation library is updated to reflect the most current operating protocols, parameter set points, and safety and maintenance requirements and procedures. If a CMMS is in place, its database should also be updated to reflect the current equipment inventory. If BIM was used in the original facility design, the building information housed in its database should also be updated.

Properly commissioning a retrofit or renovation project also involves providing training to facility operations and maintenance personnel so that they know how to efficiently operate and effectively maintain the new equipment. This helps to preserve its benefits for enhanced building performance throughout the service life. As with new construction projects, much of the training material will be derived from the installing contractor's submittals, as-built record drawings, and test records. Training materials for HVAC systems should be prepared in accordance with ASHRAE *Guideline* 1.3. Training materials for other building systems may follow the principles detailed in *Guideline* 1.3 but should align with the system manufacturer recommendations and fulfill the facility operating and maintenance staff knowledge needs.

ASHRAE Resources for BAS System Design 41.10

COMPUTERS are used in a wide variety of applications in the HVAC industry. Rapid technological advances and the decreasing cost of computing power, memory, and secondary storage have changed many aspects of the HVAC industry. New HVAC design tools allow optimal solutions to be found in engineering applications. Building operations benefit from low-cost networking to achieve multivendor control system interoperability. Consulting engineers can search manufacturers' equipment and specifications online. Designers can collaborate from remote locations. More powerful applications that are also easier to use are now affordable by a wider segment of the industry; many HVAC calculations, such as heating and cooling loads, can be performed easily and automatically.

Business applications and infrastructure have also positively affected the HVAC industry. Open communications standards and internetworking allow fast, efficient communications throughout company and industry circles. HVAC design, manufacture, installation, and maintenance functions benefit as businesses build computing infrastructure through corporate information services (IS) or information technology (IT). Many cloud computing advances in the business community have been adopted by the HVAC industry as de facto standard practice.

1. INTRODUCTION TO COMPUTING TECHNOLOGIES

Because of rapid advances in computer technology, computers offer tremendous power at very low cost. However, the total cost of ownership of a personal computer is not limited to the cost of the computer hardware. Software, network connectivity, support, and maintenance expenses quickly surpass the initial cost of hardware.

Selecting a computer platform includes a wide variety of issues, such as

- Analysis of application needs
- Corporate computer support architecture and standards
- Vendor support, including guaranteed response time
- Central processing unit (CPU) power, random-access memory (RAM), graphics processing units (GPUs), and secondary or hard disk storage capacity
- System compatibility and interoperability between vendors
- Ease of use and required training
- Data back-up strategy: how will the data on the computer be restored in the event of a system failure?
- Security issues: what data will be accessible, and how will data be protected from unauthorized access?
- Network communications capability and compatibility
- Technical support live and/or online, including driver update support
- Information system infrastructure/interoperability requirements
- Technology reliability and obsolescence
- Total cost of ownership

Virtually all personal computers and laptop computers now have more than enough speed for basic business applications such as word processing and spreadsheets. Personal computers differ in their ability to handle multimedia graphics and sound, which are useful in advanced software applications. More recently, cloud computing solutions with subscription models have become common in the industry for agile development and deployment of software applications and business services.

An information system comprised of computer networks depends on the ability of computers to communicate with each other in a standard architecture. Technological advances have resulted in computer systems becoming obsolete in less than five years. Therefore, it is important to plan for compatibility with future business computer requirements. Software and hardware must match the needs of the user, and be consistent with the business system architecture.

System architecture standards from organizations such as the Institute of Electrical and Electronics Engineers (IEEE), the American National Standards Institute (ANSI), and the International Organization for Standardization (ISO) have resulted in well-defined standards such as Ethernet, TCP/IP, and HTTP. The combination of popular standards has resulted in network and Internet accessibility from local computers, and the adoption of cloud computing using remote computer resources.

1.1 SOFTWARE AVAILABILITY

Software can be **purchased** from manufacturers, distributors, representatives, discount stores, and computer specialty stores. Software price, support, return policies, and distribution vary from vendor to vendor. During installation, most software displays a detailed software license granting *use* rather than *ownership* of the software program. This license gives specific restrictions on how the software is to be used. Most high-volume software does not offer direct support, but many software companies offer pay-per-incident and other fee arrangements if desired. Many applications have online discussion groups or message boards, where solutions to problems may be found. With the advent of cloud computing, software subscription services are becoming more common, allowing users to purchase access to software for a period of time rather than purchase a physical product. Besides proprietary software tools, HVAC applications are widely available as open source software. Following are some of the open source licensing types.

The preparation of this chapter is assigned to TC 1.5, Computer Applications.

Freeware is copyrighted software that is free. The user can run the software, but must obey the copyright restrictions.

Public domain software is available to the public for little or no charge. Public domain software, which is not copyrighted, is often confused with freeware, which is copyrighted. Public domain software can be used without the restrictions associated with copyrighted software.

Shareware is software available for users to try before buying it; after the trial period, users are expected to register or stop using the application. There is usually a nominal registration fee.

1.2 CUSTOM PROGRAMMING

Using an existing software package is usually preferable to designing a custom application, which is much more expensive and potentially riskier. This is especially true for large, mission-critical software such as client-server applications. If, after careful evaluation, prepackaged software will not suffice, the choice must be made between in-house and outside development. Custom software can be (1) contracted out to a specialized firm, (2) developed solely by internal staff, or (3) developed by internal staff with consultation help by an outside firm.

Contracting to an outside firm involves hiring a specialized outside party to define, estimate, schedule, and create the software. Funds should be budgeted for the outside organization to support modifications or enhancements not specifically covered in the contract. Contracting outside is suitable for an organization that does not have the resources or expertise to accomplish the project. Disadvantages of this approach include the expense and lack of control over the program. Licensing and ownership issues must be defined in the contract.

Developing the program internally is viable only if the skills and resources are available. Internal projects are easier to control because the people involved are co-located.

Consultation help from an outside firm involves a skilled outside party assisting internal staff, who may have insufficient skill in the area on their own. Outside firms can provide expertise to get a project going quickly. Long-term support and maintenance of the software are done in-house.

Specifications are key to the success of a software project. Calculations, human interface, reports, user documents, and testing procedures should be carefully detailed and agreed on by all parties before development begins. Software testing should be specified at the beginning of the project to avoid the common problem of low quality resulting from hasty and inadequate testing. Design testing should address the human interface, a wide range of input values including improper input, the various functions, and output to screen, disk, or other media. Field tests should include conditions experienced by the final users of the software.

With any development approach, good, understandable documentation is required. If for any reason the software cannot be adequately supported, the program will have to be replaced at substantial cost.

1.3 PROGRAMMING LANGUAGES

HVAC application software is written in a variety of computer languages. Most commercial software is written in C++, C#, or C, to allow fast speed and efficient use of resources. In addition, there are several programming and scripting languages such as Python, JavaScript, Ruby, Perl, and Swift used for web and mobile computing and customized software applications. The choice of programming language depends on several factors, including the programming paradigm (e.g., compiled versus interpreted, procedural versus functional versus object oriented), operating system, memory requirements, development environment, and user-interface features. The targeted deployment platform (e.g., stand-alone desktop, web-based application, a combination of both) often determines the programming language used. It is also more common to see several programming languages used to develop independent components of a software application and then integrated to deliver an end-user software tool. For example, energy simulation software tools use a procedural programming language to perform the calculations but use a different programming language for multiplatform user-interface development.

In addition, there are special application programming languages, such as MATLAB and R, used for mathematical programming and analysis of large amounts of data.

2. BIG DATA

The term "big data" is often used to reference related concepts, such as business intelligence and data mining, but differs in that it refers to data sets that are so voluminous and complex that traditional data processing application software is inadequate to deal with them. Big data challenges include capturing data, storage, analysis, search, sharing, transfer, visualization, querying, updating, and information privacy. There are four recognized dimensions of big data: velocity, volume, variety, and veracity (Figure 1).

Data sets grow rapidly, in part because they are increasingly gathered by cheap and numerous information-sensing Internet of things (IoT) devices, such as mobile devices, aerial (remote sensing) devices, software logs, cameras, microphones, radio-frequency identification (RFID) readers, and wireless sensor networks. The world's technological per-capita capacity to store information has roughly doubled every 40 months since the 1980s; as of 2012, 2.5 exabytes (2.5×10^{18}) of data are generated each day. By 2025, market intelligence advisors predict data will exceed 160 zettabytes (10^{21}). One question for large enterprises is who should own big data initiatives that affect the entire organization.

Relational database management systems, desktop statistics software, and visualization packages often have difficulty handling big data. The work may require massively parallel software running on tens, hundreds, or even thousands of servers. What counts as big data varies depending on the capabilities of the users and their tools. Expanding data collection capabilities and maturing software tools make big data a moving target.

Big data entails a shift of analytical focus, from descriptive analytics to predictive and prescriptive analytics. Descriptive analytics handle questions about what happened in the past, typically in the form of reporting; predictive analytics tend to address what might happen next, and prescriptive analytics attempt to develop a response.

The main benefits of big data analytics are to (1) draw insight from data, (2) make better decisions based on that insight, and (3) automate those decisions and formulate them into a process. A big data solution may address a particular problem; it is valuable that a given solution

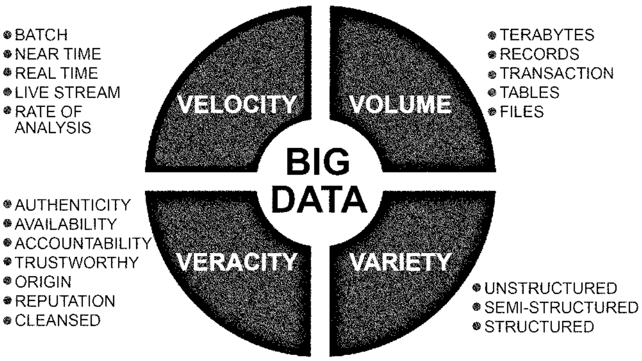

Fig. 1 Four Vs of Big Data
(Courtesy of Ennovision, ennovision.co.uk/)

is rooted in the original problem. For example, user churn prediction should reduce user churn and therefore avert a decline in revenue from subscriptions. Building a business case for big data analytics starts with a defined problem, not with data or technology.

2.1 HVAC APPLICATIONS

In the context of HVAC&R, big data tends to refer to the use of predictive analytics, user behavior analytics, sentiment analytics, operational analytics, or certain other advanced data analytics methods that extract value from data. Analysis of data sets can find new correlations to spot use trends, equipment interoperability problems, and so on.

With the explosive growth of the IoT, there are more connected devices offering more information than ever before. The ability to analyze this data has also vastly improved. Intelligent analytics tools have meant that data sets that previously would have been far too large to analyze for traditional methodologies are now a valuable source of insight into how to improve systems and behaviors. For instance, facility managers are now able to gather information from thousands of data points in a building. The installation of a vast array of information-gathering and intelligence/analytical technologies (e.g., smart sensors, smart meters, smart breakers) to inform operational decisions can be crucial to operator oversight of a facility.

Using data analytics, large volumes of building data can be transformed into actionable information that targets underlying problems and creates opportunities for energy savings. This type of management can save up to 20% annually on maintenance and energy costs by refining service programs and achieving optimal building performance and cost effectiveness. For example, with smart HVAC systems and the right sensors, a building manager can be made aware of system leakages where cool air may be migrating from the building, causing energy loss overnight.

Sustainability

This same technology can simultaneously assist in driving environmental sustainability. For example, by checking carbon dioxide levels to see if people are in the room, a building management system (BMS) can manage the HVAC systems to respond to presence appropriately, saving energy where possible. If someone is detected, a BMS may turn on ventilation to bring in fresh air, turn more lights on, and adjust the temperature out of a power-conserving deep setback. When people leave, everything goes back to an energy-saving state. Major drivers for investment in technology and building design are commonly a combination of saving operational cost, the need for innovation, increased productivity, and talent attraction/retention.

Economic Benefits

There are maintenance-cost benefits to getting equipment management right with big data and analytics. Smart systems offer embedded analytics, including automated fault detection and diagnostics (FDD). By automating detection and diagnosis of equipment health, FDD can help organizations better predict the timing of costly equipment failure. This allows them to make informed decisions when it comes to addressing problems and repairing equipment before critical failure. Problems such as unnecessary equipment operation, suboptimal strategies, faulty equipment, or poorly tuned loops that are undiagnosed and creating energy wastage and comfort issues, can be addressed by these analytical techniques.

For facility managers, the return on investment (ROI) of a project is often of primary concern. Though one-off investments in infrastructure may appear to be simple solutions, their long-term ROI is often uncertain. A new solar panel may promise a reduced energy bill; however, without proper analysis, it may not properly address a facility's underlying energy inefficiency issues. When decisions are made without proper guidance by data and intelligence, those investments may prove troublesome or expensive.

Guided by experience and insight, the optimal use of an investment can be identified. When choices range from repairing/replacing existing and outdated infrastructure to analyzing and resolving system inefficiencies and/or recommending new infrastructure where necessary, the best ROI will be found by someone with extensive training and knowledge of the latest trends and technologies.

3. CLOUD COMPUTING

Since 2010, cloud computing has become a very common, cost-effective solution to access high-performance computing infrastructure and services on an as-needed basis. The National Institute of Science and Technology (NIST) defines cloud computing as "a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction."

Essential Characteristics

- On-demand self-service: provision computing capabilities such as servers, network storage, and databases
- Broad network access: accessibility of cloud resources from mobile devices, laptops, workstations, etc.
- Resource pooling: pooling resources to serve multiple customers independent of location of the physical resource
- Rapid elasticity: rapidly and elastically provide the computing resources automatically as needed
- Measured service: monitor, control, and report resource usage with a metering capability

Service Models

- Software as a service (SaaS): application software running on a cloud infrastructure, accessible over Internet
- Platform as a service (PaaS): tools for consumers to develop and deploy application software
- Infrastructure as a service (IaaS): capability provided to consumer for computer servers, storage, and resources

Deployment Models

- Private cloud: provided for exclusive use by a single organization comprising multiple users
- Community cloud: provided for exclusive use by a specific community, either on or off site
- Public cloud: provided for open use by general public
- Hybrid cloud: a composition of two or more of the preceding models that remain unique entities, but work together

Several leading cloud service providers have developed multiple data centers that provide a full range of cloud computing resources and infrastructure to support all these deployment models. HVAC industry applications have begun to adopt cloud computing for most aspects of design, documentation, data storage, and mobile device access to all building design and operational data. Big data and cloud computing together have enabled collection and analysis of BAS data for improving building operations and automation of fault detection and diagnosis.

4. MOBILE COMPUTING

There are two distinct, common types of mobile applications: web-based and native. Web-based means, as the name implies, that a web site has been designed to be functional and visually appealing on a smaller (mobile) screen such as a cell phone or tablet. For this reason, these applications require Internet access via Wi-Fi or cellular data because they are just a user interface for the full web site. Native mobile applications, though still designed to operate and be user friendly on a smaller screen, operate via a device's operating system, so Internet access is not required to use the application. There are benefits and drawbacks to each type of mobile application.

Web-based applications are most common: examples include apps on a phone (e.g., navigation, social media). These are easy to use and easy to maintain. Computing does not require as much memory or computing space, and these applications typically work across all operating systems. This allows owners of the app to maintain updates more easily; updates can be sent out to all users at one time.

However, with any web-based application, users are at a higher security and privacy risk because all data is being sent out through the web. Some of these risks can be mitigated with privacy settings, but these could limit the application's full operating abilities. Even common privacy settings, such as limiting access to location or photos and data, can prevent the application from functioning at its full capability.

Native applications are typically purchased or sold alongside another product and operate using a mobile device's operating system. These are typically designed to work on one type of operating system. These apps rely on a device's operating system, so they may not require Internet access (i.e., can operate at all times), and data is typically more secure. These applications are typically designed by industry experts (including but not limited to HVAC), so the user can be confident in the data/results provided.

However, because the data uses a phone's operating system, backing up data can be challenging. Users must also be cautious in using these applications, because apps can be written in any language or for any operating system. In the case of HVAC design, if a designer is using more than one company to design a system (e.g., chillers and cooling towers), this potentially forces the user to design one subsystem at a time. This limits the designer to subsystem efficiencies, a disadvantage. Some of this can be avoided if the user is aware of the operating systems up front.

Companies that design mobile applications and mobile application platform software have also created **hybrid mobile applications**. Hybrid mobile applications are designed at a variety of levels that take the best of each application type. To choose the right application, various questions need to be addressed. As with any technology, those of greater capability also require more time and cost to develop and involve more difficult maintenance.

Important questions to ask are

- What is the budget?
- What is the (or the customer's) required security level?
- How much time is available to implement a solution?
- How much does the end user know about mobile applications?
- What is the end user's operating device capability?
- How user friendly/easily accessible should the mobile application be?
- How many end users will there be?

Many applications today are designed to have a combination of both web-based and native application traits. Some companies even have a mobile application platform advanced enough to take multiple native applications and provide a means of operating all applications at once. Once the selection questions are answered for a given project, the appropriate route can be taken. For those in HVAC looking to add mobile app development to a business, there are a couple of options. As with most business concepts, solutions can either be developed in house or outsourced to an expert. This depends on the complexity of the project and the software development capability at a given company.

If outsourcing, there are various companies that provide enterprise mobile application solutions (i.e., mobile applications designed for more complex projects that are typically associated with enterprise-size projects, with the complexity determined by the answers to the questions previously listed). Complexity increases with the number of users, or more back-end data analysis (native application capabilities) is needed. Lack of time for a solution or a high first-cost, more user-friendly application both increase complexity.

When outsourcing, look for products/platforms that can

- Allow a designer to build a mobile application
- Design multiple levels of hybrid native/web-based mobile applications
- Combine mobile apps that a company already has available

The best option is not the same for every company or project, and it is up to the project lead or company managers to determine the best course of action. However, a clearly defined goal and project specifications help optimize use of mobile applications.

4.1 MOBILE APPLICATIONS IN THE HVAC INDUSTRY

HVAC companies often develop their own mobile application platform for their employees. However, to provide HVAC industry members with tools necessary to the industry, ASHRAE has supported development of several mobile applications. The applications are intended provide members with tools that can be used quickly in the field to check compliance with ASHRAE standards and equipment performance. The following is a brief introduction into some of the most commonly used ASHRAE supported applications.

Psychrometric App. The ASHRAE HVAC Psychrometric App is designed for users to easily view a psychrometric map while out in the field. This app allows users to plot points and processes on a fully customizable psychrometric map. Then, if necessary, results from the points can be shared via e-mail for later use. Figure 2 shows the standard home page of an example psychrometric chart. Cross hairs enable the user to know exactly where the cursor is pointing on the map. To plot, users double-tap on a point in point mode.

Because it is only available on iPad® or iPhone®, this application is intended for users who are in the field or in a conversation with a customer when full use of their tools is not available. For this reason, both individual point processes and a PDF of a psychrometric chart can be e-mailed using the e-mail icon.

Duct Fitting Database. This application, based on ASHRAE's desktop *Duct Fitting Database* tool, allows users to produce pressure loss calculations for the more than 240 ASHRAE duct fittings from the field. Calculations can be in SI or I-P units and can easily be shared via e-mail for further use or analysis.

90.1 Energy Cost Budget Application. This ASHRAE-sponsored tool enables users to model compliance with ASHRAE *Standard* 90.1-2010. This application follows the energy cost budget form in the *User's Manual* (ASHRAE 2016a) and allows users to enter all available site details and then export the data into the energy cost budget report in Excel®. This application is web based, and the data can be accessed via any device that has Internet access.

HVAC ASHRAE 62.1. This application allows users to perform calculations from the 2007 and 2013 versions of ASHRAE *Standard* 62.1,Ventilation for Acceptable Indoor Air Quality. It loosely follows the 62MZCalc.xls Excel® spreadsheet from the ASHRAE (2016b) *62.1 User's Manual* for each project; however, as with most applications, the capabilities exceed that of manual entry documents. Users can create an unlimited number of projects. Each project can be created quickly, and calculation results can be shared via e-mail for a detailed analysis when the user is no longer in the field.

HVAC PT Chart Application. This application makes quick calculations of refrigerant properties in the field. Users can choose the refrigerant and units they are interested in to obtain refrigerant pressure or temperature.

HVAC Duct Sizer Mobile Application. This application is simple compared to some of the others described here, which involve more intricate calculations. However, it is still useful for easy field calculations: it allows users to size ducts based on airflow and or dimension. To get to these calculations, the user simply follows the appropriate prompt.

5. CYBERSECURITY

Computer security requires sound planning and continuous maintenance and monitoring. Mail servers can scan for viruses before users open e-mail, and individual virus software loaded on individual machines serves as a second layer of protection. Always save attached files to a safe directory and scan with antivirus software before using. Typically, information services (IS) and information technology (IT) staff have a dedicated support person and strategy to maintain security.

Traditional cybersecurity involves protecting computer systems, their contents, and their communications from harm, including theft, undesired access, or undesired modifications. Often, cybersecurity attacks involve malware (malicious software). Cybersecurity related to control systems has greater significance because its failure can negatively impact the physical world in ways that range from minor inconvenience, to damaged equipment, or even physical harm to people. As with other types of security, to be effective it must be multilayered and constantly evolving to respond to new threats. All users of computer systems need to be aware (to some degree) of cybersecurity.

Industry guidelines for cybersecurity exist for computer system administrators and for network administrators. These guidelines are relevant to the network portion of networked HVAC systems. The latest versions of these guidelines can be found online. One source, NIST *Standard* SP 800-82, Guide to Industrial Control Systems (ICS) Security, contains guidance that is more relevant to HVAC systems and is based on NIST *Standard* SP 800-53, Security and Privacy Controls for Federal Information Systems and Organizations.

More information can be obtained from the Department of Homeland Security's Industrial Control Systems—Computer Emergency Response Team (ICS-CERT), whose mission it is to reduce the risk of systemic cybersecurity and communications challenges in cyber defense and incident response. ICS-CERT, aligned under the National Cybersecurity and Communications Integration Center (NCCIC), offers a free tool that provides a systematic approach for evaluating a system's security posture using the selected security controls listed in NIST *Standard* SP 800-53. The Cyber Security Evaluation Tool (CSET) is a desktop software tool that guides owners and operators through a step-by-step process to evaluate their system security practices.

Physical building security measures are discussed in Chapter 61. ASHRAE *Guideline* 13 also has guidance on physical and cybersecurity measures.

5.1 BASIC CYBERSECURITY PRACTICES

Keeping devices that support HVAC control systems secure requires some basic security practices and procedures. These procedures can be used for company-owned devices but are also applicable for personally owned devices.

The best practices for all electronic devices (e.g., PCs, laptops, tablets, phones) are very similar. Listed here are some tips to improve the security posture of these devices.

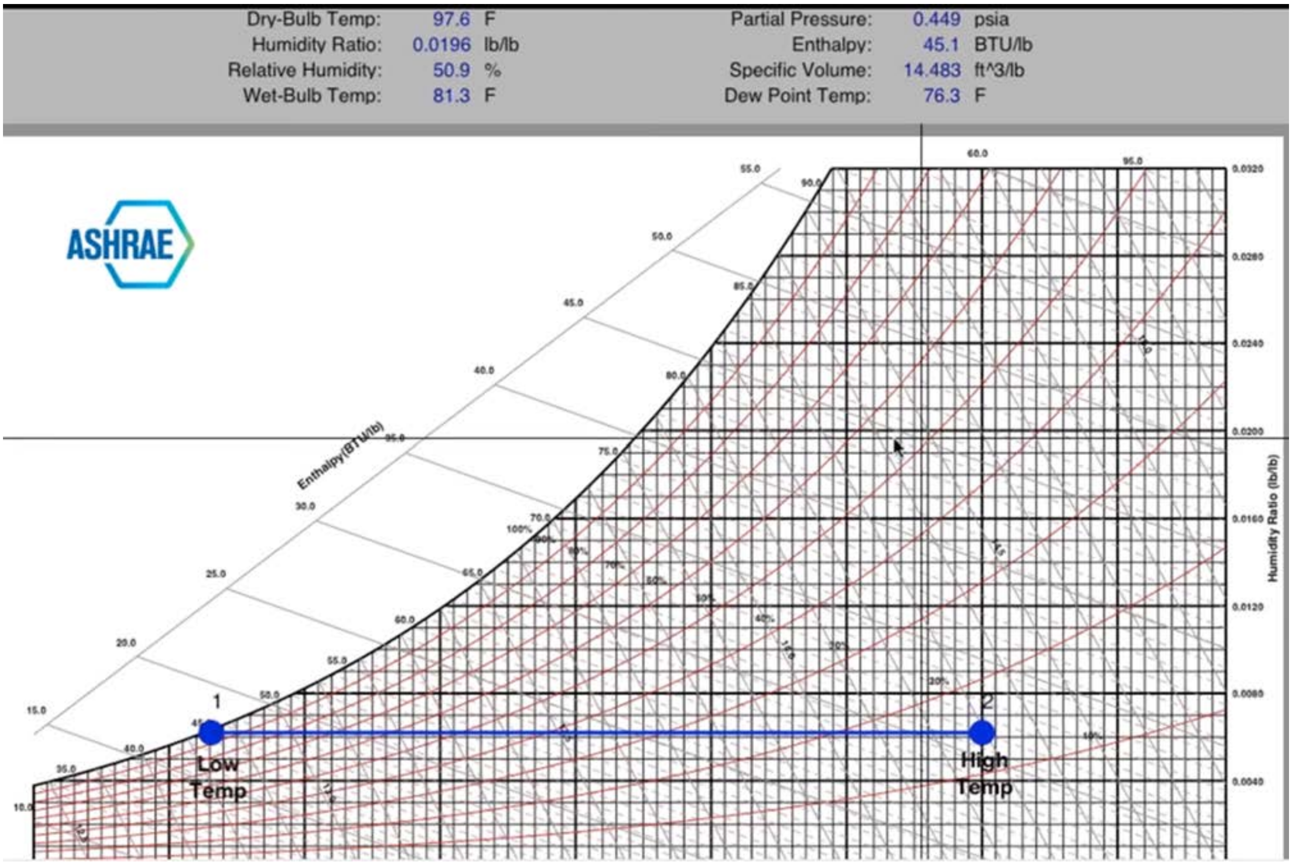

Fig. 2 Psychrometric Chart Example

Users should not connect to untrusted networks or systems. Many control systems have been connected to the Internet to provide convenient, 24/7 operation and maintenance support, remote monitoring capabilities, and data collection for analysis. However, most control systems have not been designed to operate in the cyber-contested environments that have had negative effects on critical infrastructures throughout the world. Until control systems have robust security measures integrated throughout the equipment stack, it is recommended that these systems remain in an isolated network environment that connects only to trusted, secure networks.

If circumstances do not allow isolation, then remote connections or any other connections from or into the control system network to other networks should be through a protected communications channel such as a **virtual private network (VPN)**.

It is important to use an appropriate account. Everyday web browsing does not require administrative privileges. Using an account with security privileges that are too high creates greater vulnerability.

Only dedicated devices should be used for control systems. To save money, many devices are used for multiple purposes and are connected across multiple networks. However, this introduces inherent risk that can propagate viruses, ransomware, and other malware across multiple systems. Due to the lack of cybersecurity resilience, it is recommended that users avoid this practice to minimize potential contamination of the control system environment.

Users can take the following steps to increase security:

- A strong password is crucial.
- Use a screen lock (password, fingerprint, facial recognition) on smartphones. A simple password is better than no password.
- The strength of a password is determined by both the length and range of characters used. A short password, with a few lowercase letters, is very weak. A long password, with 9 or more characters, including numbers, uppercase letters, and symbols would be strong. Length is the more important factor: it would be better to have a long password with only a few numbers or symbols, than a short password with many. A short phrase may be easier to remember than a long password, and more difficult for an attacker to break. Generally, the longer the password the better.
- If it is in the dictionary, do not put it in a password. Except in a long passphrase, dictionary words should be modified by replacing characters with numbers/symbols or by inserting numbers/symbols in the word. Avoid any use of common words like "password" or sequences like "123" or "qwerty". If replacing letters with symbols, do not use a predictable substitution, such as @ for a.
- Do not use any personally identifiable information, such as birthday, social security number, address, etc., as part of a password.
- Do not use the same password for different important web sites, such as e-mail and financial services.
- Consider using a password manager. These are applications that can generate secure passwords for you, and use them to help you log in to web sites. Users then only need to remember one password.

For detailed guidance, consult the NIST *Standard* SP 800-63-3, Digital Identity Guidelines.

Software updates are important to install. They are usually provided to fix problems with a current version of the software that may lead to poor performance or put the device at risk. If a device is company owned, there should be guidelines or policy governing updates. If a program is no longer supported and is not being updated, it should be removed from the device.

System updates update the software that runs a device. Devices may be configured to tell users when these are available, if connected to the Internet (not recommended practice). *Application updates* update a specific application or suite of applications. Many applications inform users of available updates, but some may require periodic checks if connected to the Internet (again, not recommended practice).

Only software from known sources should be installed. Random apps should not be installed, because they may disguise malware. Programs or apps to be installed should also be approved by IT personnel. It is essential to have antivirus software installed (often for little to no cost).

Back-up is also critical; in the event of a ransomware attack (wherein files are encrypted and a price demanded to regain owner access), it is the best method to recover files. Only dedicated devices and software services for control system operations should be used. Avoid software services such as e-mail and personal web browsing. These two services are the primary attack vectors into private systems such as control system networks. Removing these two services will greatly enhance the security of the system.

If web browsing or e-mail cannot be disabled, precautions are recommended.

Web Browser Security

The functionality of web browsers can be increased by installing extensions, which are small add-ons that often act like a utility program; they may help with bookmarks, tabs, or security. This section discusses some types of extension that improve security. Note that, although most web sites are safe, caution is always advised.

Ad Blocker. One common method for malware distribution is malicious links hidden in online advertising. Some methods only require the user to move their mouse cursor over an advertisement. Ad blocker extensions stop or limit the downloading of advertisements and are highly recommended.

JavaScript Blocker. JavaScript is a computer language used to add functionality to web pages. As with any tool, it is also often misused. A JavaScript blocker extension allows users to specify which web sites are allowed to run JavaScript on the browser. This can be selective, with the JavaScript required to display a page allowed and the type of JavaScript that downloads blocked. This type of extension is highly recommended. Other types of extensions include privacy, which are designed to keep personal information controlled, and security, which provide antivirus or VPN capabilities.

Safe Browsing. It is important to be wary when following links, especially those found in chatrooms or search results. Malware distributors post links in chatrooms, or design pages to match common searches.

Use of encrypted pages allows greater security. Almost every web site allows users to request an encrypted version by changing the "http" in the address to "https." This is important if the page contains forms with personal data. Many web sites now use https by default. Browser extensions can also be installed to enforce use of https.

E-mail Security

Various types of cybersecurity threats are delivered through e-mail, including scams, malicious links, and phishing. Phishing involves an attempt to steal personal information through impersonation. Any e-mail requesting personal or business information should be treated with suspicion. Other flags include an unknown sender address, links that appear strange, and grammar or spelling errors.

There are other resources available on control systems cybersecurity that can provide specific, detailed guidance for implementing cybersecurity in HVAC systems. The International Society of Automation's ISA/IEC *Standard* 62443 addresses cybersecurity standards for industrial control systems.

6. SOFTWARE APPLICATIONS

Computer software applications have revolutionized work processes and practices in the building industry. From drafting tables, to HVAC load calculations, to duct fabrication, software applications have transformed the tasks performed by designers, construction managers, and building operators from manual to automated ways of working. Computerization of work processes promises improved productivity and quality along with decreased cost and time. Computerization also brings learning curves, disruption of time-honored practices, and its own set of issues to be resolved.

This section discusses a range of software applications currently in use in the buildings industry, as well as some emerging trends. It is not meant to be an exhaustive listing of applications, nor a comprehensive discussion of their use. Rather, this is meant as a broad introduction to the variety of software applications currently available, and as a starting point to further reading and exploration.

6.1 EXAMPLE SOFTWARE APPLICATIONS

Numerous software applications are currently used in the cycle of building/facility design, construction, and operations and maintenance. These software applications are tools that support practitioners in their work processes in each of these stages. The extent to which these tools are adopted is based on industry segment, company/firm, and individual practitioner methods. However, the overall trend is toward increased use and more rapid change both in individual tools and in industry practices.

Design

Architectural Design (Massing, Space Layout, Rendering). Simplified energy simulation tools can provide easy and quick performance analysis at early stages of design, thus assisting designers and architects in making decisions. Simple tools do not require much detailed information as inputs, instead using standard defaults and modeling processes in place of building specifications that might not be available at the early design stage (e.g., schedules, internal loads). Simple tools can be very useful for preliminary energy performance prediction and for informing early design decisions.

MEP Design (HVAC Sizing, Selection, Layout; Electrical, Plumbing). There are several mechanical, electrical, and plumbing (MEP) design software solutions that can integrate building information models (BIM) and calculations in an intelligent computer-aided design (CAD) environment. These can help engineers design, detail, estimate, fabricate, and install MEP building systems more quickly and accurately. Software can either have an integrated BIM capability or provide a capability to import BIM models created by other tools, by reading the file itself or through a Green Building XML (gbXML; www.gbxml.org) import.

These tools can read the physical properties of the BIM objects to calculate the HVAC loads space by space. They can also help define air duct and piping networks, taking into consideration flow rates, pressure drops, and other parameters and provide the ability to develop piping/ducting networks in two and three dimensions. Some tools even provide complete documentation, including detailed calculation sheets, technical reports, bill of materials, bids, and more.

Energy Simulation. Whole-building energy simulation tools are used for characterizing energy flows and analyzing the impact of building characteristics, thermal loads, and system performance on building energy consumption, thermal comfort of occupants, etc. A building energy simulation tool allows a user to provide inputs for local weather; building geometry; building envelope characteristics; internal heat gains from lighting, people, and plug loads; heating, ventilation, and cooling (HVAC) system specifications; operation schedules; and control strategies. The simulation engine then calculates the building energy performance using complex physics-based models to determine thermal load, resulting energy use, and related metrics such as occupant thermal comfort and carbon emissions.

Code Compliance. Numerous jurisdictions (within the United States and elsewhere) require energy code compliance of building designs prior to issuing building permits. Many code compliance software applications have been developed to assist in the process of testing and documenting energy code compliance. Some of these applications focus on so-called prescriptive approaches to compliance that provide rules for various aspects of a building design, such as minimum window performance characteristics and window-area-to-floor-area ratios. More sophisticated performance-based approaches rely on energy performance simulation to test and document code compliance. In all instances, each jurisdiction will provide a list of approved code compliance software applications.

Construction

Construction Document Production. The use of architectural and MEP design applications during the design phase can greatly aid the production of construction document (CD) packages. This has been true since the development of two-dimensional design tools, but has become even more common and productive since the development and adoption of three-dimensional and BIM-based design applications. These models, if created following best-practice standardized techniques, can easily generate CD packages for hand-off to construction planners and managers.

Construction Planning and Execution. BIM and 3D building models created during design that include MEP systems details and physical layout and architectural features (e.g., walls, floors, rooms) can be used for applications beyond that of CD production.

Automated clash detection is one such application, in which piping, ducts, and electrical runs that interfere spatially (either with each other or with architectural features) can be detected and brought to the attention of designers and contractors for resolution before actual construction.

Even more sophisticated applications, such as four-dimensional construction planning, also are possible with well-developed three-dimensional/BIM building models. Four-dimensional construction planning involves applications that add the dimension of time to a model, supporting construction sequencing for complex projects where trade coordination and materials delivery are critical.

Facility Handover. The true benefit of BIM is the capture of accurate building information that can be more easily updated throughout design and construction to create up-to-date as-built building models, which can be handed over to building owners and facility managers and operators for use in the longest phase of the building life cycle: occupancy. These building models, if kept accurate, can be used for a variety of applications, including occupancy space planning, space rent assessment, asset (e.g., furniture, moveable equipment, fixed equipment) management, maintenance scheduling, work order tracking, and more.

Energy Simulation. Value engineering often occurs during the construction phase. This process, along with change orders and redesign, can significantly impact the eventual energy and occupant comfort performance of the constructed building. Energy simulation applications can be used during these processes to assess the performance impact of changes from the original design and provide important feedback to ensure desired whole-building performance.

Operations and Maintenance

Software applications to be used during the operations and maintenance (O&M) phase of a building life cycle are generally less abundant than those for other phases. This may be due to the less computationally intensive nature of O&M work processes, but the computerization of these work processes promises substantial and longer-lasting benefits due to the duration of the O&M phase. Much of the application of software to this phase revolves around information management tasks such as asset (equipment) management, space and change management, occupant comfort (hot and cold calls), and maintenance work order management. However, newer applications such as fault detection and diagnostics, energy demand management, and continuous commissioning, along with the periodic use of energy simulation for HVAC system optimization and building audits and renovation (design and code compliance), presents many further opportunities for computerization.

Building Automation Systems. Building automation systems (BASs) provide both manual and automatic centralized control of a building's HVAC, lighting, and other systems, using a network of sensors and activators accessed and programmed through the BAS. The objectives of building automation include improved occupant comfort, efficient operation of building systems, and reduction in energy consumption and operating costs.

Computerized Maintenance and Management Systems. Computerized maintenance and management systems (CMMS) (also called facility management, enterprise asset management, or computer-aided facility management) are software tools that maintain a database of information about a building/facility and provide work order scheduling, asset and space tracking, and other capabilities to support O&M activities in buildings. These tools also often provide dashboards (high-level display of information in an organized format) and more sophisticated report generation capabilities.

Continuous Commissioning, Fault Detection, and Diagnostics. Building automation systems can also support enhanced analytics that use the continuously collected building system data to perform continuous commissioning and detect and diagnose faulty system operation. These analytics can lead to alarm notifications that allow building operators to identify energy- and cost-saving opportunities, occupant comfort issues, and mechanical system failures or inefficient operation.

Demand Management and Response. BASs also provide access to the real-time building energy use data and building system control, as well as access to outside information regarding utility grid energy use, required to perform active demand management and demand response control operations.

Energy Simulation. Energy simulation tools can also be used for a number of applications during the O&M phase of a building. This includes prediction of savings from building-audit-identified energy efficiency measures, design optimization and code compliance during renovation, ongoing HVAC system optimization, fault detection and diagnostics, and demand management and response.

6.2 BIM AND DATA INTEROPERABILITY

As evidenced by the (incomplete) list of software applications provided, ASHRAE members and other professionals in the buildings industry use a wide variety of computer software applications. Historically, these applications have generally been stand-alone desktop tools, using unique custom, and often proprietary, data models to describe the information they require. Moving from one application to another (e.g., between architectural and mechanical design and energy simulation) has required manual recreation of often similar building information in different formats. This process consumes considerable time and effort and invites error in the different models of the same building.

BIM technologies and procedures have been developed over the past several decades to address this problem. The benefits of automated data exchange between disparate software tools, often referred to as **data interoperability**, have been recognized for years, but such exchange has still not reached a level of wide adoption. However, BIM has recently been gaining traction, especially in the design and construction stages of the building life cycle.

ASHRAE resources on BIM and data interoperability include the following:

- Multidisciplinary Task Group (MTG) BIM: Building Information Modeling
- *An Introduction to Building Information Modeling (BIM): A Guide for ASHRAE Members* (ASHRAE 2009; cms.ashrae.biz/bim/pdf/BIMGuide_Rev_110309.pdf)
- *Guideline* 20
- Standards Project Committee (SPC) 205: Standard Representation of Performance Simulation Data for HVAC&R and Other Facility Equipment (spc205.ashraepcs.org)
- SPC 224: Standard for the Application of Building Information Modeling

7. BUILDING AUTOMATION AND CONTROL

Controls systems perform functions such as monitoring sensors, controlling equipment, scheduling, alarm reporting, energy use monitoring, and trend logging. Systems may use pneumatic or electronic control systems to perform some of these functions, but most modern systems use computers or controllers in direct digital controls (DDC).

Common types of DDC systems and their functions include the following:

- Building automation system (BAS): automating monitoring and control
- Energy monitoring and control system (EMCS): conserving energy by both automatic and manual control with the aid of energy monitoring
- Energy management system (EMS): conserving energy by specific automatic control programs
- Facility management system (FMS): HVAC control of a subset of multiple subsystems or buildings, including fire, security, elevator, or manufacturing systems

BAS has become the most popular term for description of a computerized control system that may provide one or more of these functions and is the term adopted by ASHRAE *Guideline* 13.

7.1 APPLICATION AND PURPOSE

BASs can be applied to achieve several different goals and outcomes, often simultaneously. Example applications include

- Control for energy efficiency/optimization
- Occupancy conditions and comfort, such as outlined in ASHRAE *Standard* 55
- Equipment and ventilation scheduling
- Lighting control
- Security
- Life safety
- Code compliance
- Utility-based demand load shedding
- Fault detection and diagnostics for preservation of capital and utility expenses
- Trending of building and building equipment conditions and operation
- Remote access

7.2 NETWORK ARCHITECTURE AND COMPONENTS

BAS components are usually arranged and interconnected in a hierarchical structure that can be described in four tiers (Figure 3).

Tier 1 comprises enterprise and site connectivity devices, which includes web servers, user interfaces, trend databases, time schedules, analytics, demand response, load shed protocols, IP Backbone, VLAN, and the Web. This tier is often the point of connection for remote access and for data sharing with external optimization services. This is also the point that represents a cybersecurity risk from outside the network and requires coordination with building

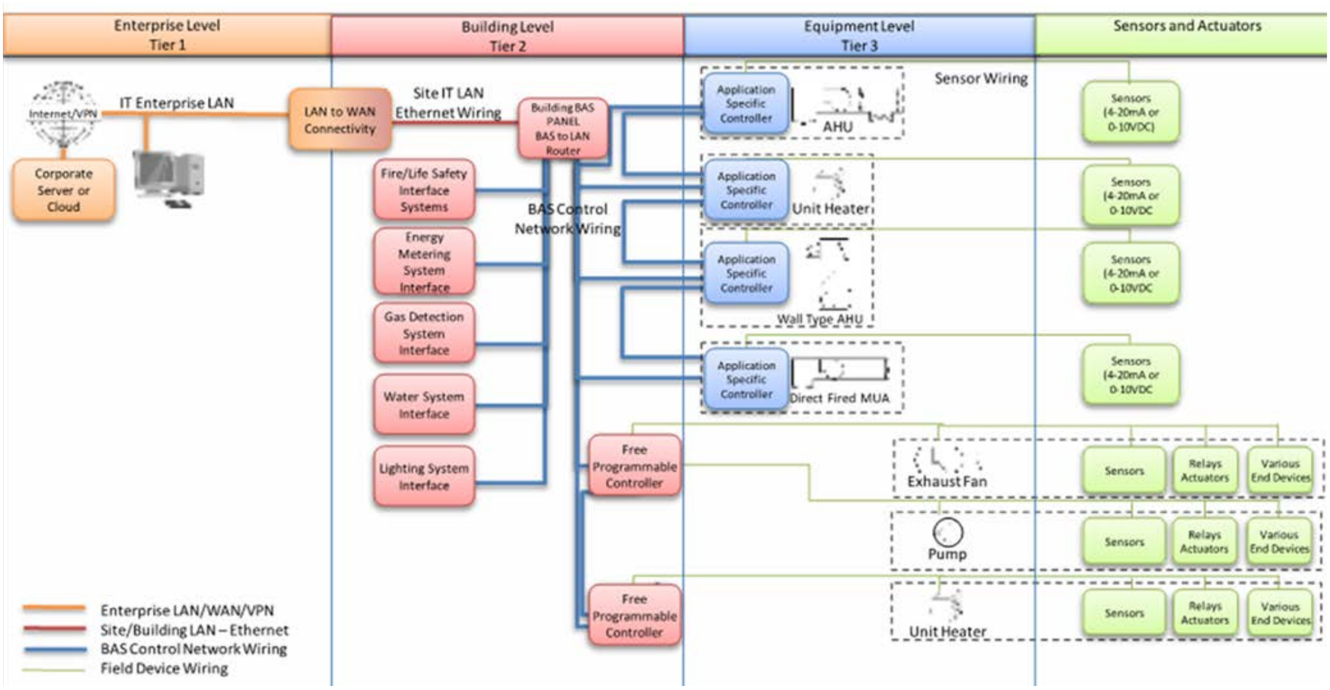

Fig. 3 Tiers of BAS
(ASHRAE *Guideline* 13)

network personnel to maintain security while allowing the necessary connectivity.

Tier 2 is the building infrastructure and includes components that bridge Tiers 1 and 2. This may include routers that interconnect building systems such as HVAC and lighting for access to Tier 1. This tier is usually IP based and may also contain network controllers that operate equipment directly, such as a variable speed drive or programmable controllers. This is also the tier where open building control protocols such as BACnet™ or LonWorks® originate to connect subsystem components.

Tier 3 contains application-specific controllers (ASCs) that control equipment or subsystems. ASCs can interconnect to other system components through the building control network but are generally used as the main controller of equipment and may include the point of connectivity to system sensors.

The last tier contains sensors and end devices such as relays and actuators. In general, components on this level do not contain any control logic and are either input or output devices. The advent of network sensors and other devices may alter the structure whereby the devices connect from the last tier directly to Tier 2.

7.3 CONTROL COMMUNICATION PROTOCOLS

In the past, because all major HVAC equipment required some type of control system, control points were duplicated. Adoption of communication standards has greatly reduced total control costs and increased functionality by providing information (e.g., part-load performance criteria) to users that was previously only available from manufacturer testing. As the functionality of component control increases and associated cost decreases, component-level interaction makes building-wide system integration less critical.

HVAC manufacturers use DDC microprocessors to create powerful, low-cost controls and feature-rich equipment. In the past, many control devices were proprietary and information was not shared between manufacturers. With standard communication protocols, diverse applications such as HVAC, energy, security, lighting, and fire controls in large buildings can use a single integrated control system.

Standard protocols allow application-specific component control systems designed for particular HVAC equipment to be included in building-wide strategies. For example, low-cost componentized DDCs provide operation, safety, maintenance, and even self-diagnostic information and control functions. Making a chiller or a variable-speed drive controller a part of a cohesive, building-wide control system is now possible because of standard protocols.

Standard communication protocols are developed in committee by professional societies, *open* protocols are created by manufacturers but available for all to use, and *proprietary* protocols are developed by manufacturers but not freely distributed. User needs should be determined before selecting a particular protocol for a given application. There are two major standard protocols used in HVAC building automation today: BACnet™ and LonWorks®.

BACnet is the ASHRAE *Standard* 135 Building Automation and Control Networks Protocol. It provides mechanisms by which computerized equipment for a variety of building control functions may exchange information, regardless of the particular building service it performs. As a result, the BACnet protocol may be used by head-end computers, general-purpose direct digital controllers, and application-specific or unitary controllers. Working groups represented in BACnet include lighting, life safety, elevators, smart grid, security, network security, utility integration, wireless networking, and XML applications. BACnet is based on a four-layer collapsed architecture that corresponds to the physical, data link, network, and application layers of the ISO/OSI (International Organization for Standardization Open Systems Interconnection) model. The application layer and a simple network layer are defined in the BACnet standard.

The **physical layer** provides a means of connecting devices and transmitting the electronic signals that convey the data. BACnet devices often use Ethernet networking, and can coexist with PCs on the same network.

The **data link layer** organizes the data into frames or packets, regulates access to the medium, provides addressing, and handles some error recovery and flow control.

Functions provided by the **network layer** include translation of global addresses to local addresses, routing messages through one or more networks, accommodating differences in network types and in the maximum message size permitted by those networks, sequencing, flow control, error control, and multiplexing. BACnet is designed so that there is only one logical path between devices, thus eliminating the need for optimal path routing algorithms.

The **presentation layer** provides a way for communicating partners to negotiate the transfer syntax used to conduct the communication. This transfer syntax is a translation from the abstract user view of data at the application layer to sequences of octets treated as data at the lower layers.

The **application layer** of the protocol provides the communication services required by the applications to perform their functions, in this case monitoring and control of the HVAC&R and other building functions.

LonWorks defines a protocol for interoperability between control and automation devices. Task groups represented in LonMark include HVAC, fire, industrial, lighting, vertical transportation (elevators), automated food service equipment, home/utility, network tools, refrigeration, router, security, semiconductor, sunblinds, system integration, and transportation. Building automation system networks are local area networks, even though some applications must exchange information with devices in a very distant building.

7.4 BAS SECURITY

BAS designs have many vectors for manipulation by unauthorized personal. These include physical access to equipment and controls and access through the BAS control networks. Security measures must be weighed against the risk associated with unauthorized manipulation. Physical building security measures are discussed in Chapter 61. ASHRAE *Guideline* 13 also has guidance on physical and cybersecurity measures.

7.5 ASHRAE RESOURCES FOR BAS SYSTEM DESIGN

- Chapter 7 of the 2017 *ASHRAE Handbook—Fundamentals* focuses on automatic control system concepts and common devices.
- Chapter 48 of this volume focuses on the application of controls systems of specific HVAC systems (air handlers, chillers, boilers, etc.).
- Chapter 65 of this volume addresses occupant-centric controls.
- ASHRAE *Guideline* 13 provides guidance for the designer to prepare a specification of a BAS for bidding to installation contractors based on the CSI specification format. The guideline includes discussion of system designs, integration of different systems, common sequences of operation, security measures, and a sample specification.
- ASHRAE *Guideline* 36 establishes a set of standardized sequences of operation intended to offer energy efficiency and ease of implementation for BAS designers, programmers, and operators.

CHAPTER 42

BUILDING ENERGY AND WATER MONITORING

Reasons for Energy or Water Monitoring 42.1
Small Projects 42.3
Protocols for Performance Monitoring 42.4
Common Monitoring Issues 42.6
Steps for Project Design and Implementation 42.7

BUILDING energy monitoring was conducted on a large scale in the 1980s and 1990s. Project requirements were often not addressed adequately in these projects, and this chapter was developed to address these and capture new insights. The intent of monitoring projects is to provide realistic, empirical information from field data to enhance understanding of actual building energy performance and help quantify changes in performance over time. Although different building energy monitoring projects can have different objectives and scopes, all have several commonalities that allow methodologies and procedures (monitoring protocols) to be standardized.

This chapter provides guidelines for developing building monitoring projects that provide the necessary measured data at acceptable cost. The intended audience includes building owners, building energy monitoring practitioners, and data end users such as energy and energy service suppliers, energy end users, building system designers, public and private research organizations, utility program managers and evaluators, equipment manufacturers, and officials who regulate residential and commercial building energy systems. The scope of this chapter has been expanded to include water, water monitoring, and associated water efficiency project measurement and verification. A section on small projects is also included, to show how the methodology can be simplified.

Monitoring projects can be **uninstrumented** (i.e., no additional instrumentation beyond the utility meter) or **instrumented** (i.e., billing data supplemented by additional sources, such as an installed instrumentation package, portable data loggers, or building automation system [BAS]). Uninstrumented approaches are generally simpler and less costly, but they can be subject to more uncertainty in interpretation, especially when changes made to the building represent a small fraction of total energy or water use. It is important to determine the accuracy needed to meet objectives, the type of monitoring needed to provide the desired accuracy, and whether the such accuracy justifies the cost of an instrumented approach.

Instrumented field monitoring projects generally involve a data acquisition system (DAS), which is typically comprised of sensors and data-recording devices (e.g., data loggers) or a suitably equipped BAS. Projects may involve a single building or hundreds of buildings and may be carried out over periods ranging from weeks to years. Most monitoring projects involve the following activities:

- Project planning
- Site installation and calibration of data acquisition equipment (if required)
- Ongoing data collection and verification
- Data analysis and reporting

These activities often require support by several professional disciplines (e.g., engineering, data analysis, management) and construction trades (e.g., electricians, controls technicians, pipe fitters).

Useful building energy performance data cover whole buildings, lighting, HVAC equipment, water heating, meter readings, utility demand and load factors, excess capacity, controller actuation, and building and component lifetimes. Useful building water performance data cover whole buildings and end use component breakdowns, potable fixtures, HVAC equipment (makeup water), water heating (boiler feed water), meter readings, utility demand and load factors, excess capacity, controller actuation, and building and component lifetimes. Current monitoring practices vary considerably. For example, a utility load research project may characterize the average performance of buildings with relatively few data points per building, whereas a test of new technology performance may involve monitoring hundreds of parameters in a single facility. Monitoring projects range from broad research studies to very specific, contractually required savings verifications carried out by performance contractors. Auditing examines energy performance using observations and measured data, which are detailed in ASHRAE (2011). BSR/ASHRAE/ACCA *Standard* 211-2018 specifies minimum requirements for such audits.

All practitioners should use accepted standards and protocols of monitoring practices to communicate results. Key elements in this monitoring process are (1) classifying the types of project monitoring and (2) developing consensus on the purposes, approaches, and problems associated with each type (Haberl et al. 1990; Misuriello 1987). For example, energy or water savings from energy service performance contracts can be specified on either a whole-building or component basis. Monitoring requirements for each approach vary widely and must be carefully matched to the specific project. Procedures in ASHRAE *Guideline* 14-2014 and the IPMVP (2014) can be used to determine monitoring requirements. Performance measurement protocols for commercial buildings (new or retrofit construction), including energy, water, and indoor environmental quality, are presented in ASHRAE (2010). Best practices for performance measurement are given in ASHRAE (2012).

1. REASONS FOR ENERGY OR WATER MONITORING

Monitoring projects can be broadly categorized by their goals, objectives, experimental approach, level of monitoring detail, and uses (Table 1). Other factors, such as resources available, data validation and analysis procedures, duration and frequency of data collection, and instrumentation, are common to most, if not all, projects.

Energy or Water End Use Assessment

Energy or water end use assessment projects typically focus on individual energy or water systems in a particular market sector or building type. Monitoring usually requires separate meters or data collection channels for each end use, and analysts must account for all factors that may affect energy or water use. Examples of this approach include detailed utility load research efforts, energy or water audits, evaluation of utility incentive programs, and end use calibration of computer simulations. Depending on the project objectives, the frequency of data collection may range from one-time measurements of full-load operation to continuous time-series measurements.

The preparation of this chapter is assigned to TC 7.6, Building Energy Performance.

Table 1 Characteristics of Major Monitoring Project Types

Project Type	Goals and Objectives	General Approach	Level of Detail	Uses
Energy or water end use assessment	Determine characteristics of specific energy or water end uses in building.	Often uses large, statistically designed sample. Monitor energy or water demand or use profile of each end use of interest.	Detailed data on end uses metered. Collect building and operating data that affect end use.	Load forecasting by end use. Energy or water audit to identify and confirm energy or water conservation or demand-side management opportunities. Simulation calculations. Rate design.
Specific technology assessment	Measure field performance of building system technology or retrofit measure in individual buildings.	Characterize individual building or technology, occupant behavior, and operation. Account and correct for variations.	Uses detailed audit, submetering, indoor temperature, on-site weather, and occupant surveys. May use weekly, hourly, or short-term data.	Technology evaluation. Retrofit performance. Validate models and predictions.
Energy or water savings measurement and verification	Estimate the impact of retrofit, commissioning, or other building alteration to serve as basis for payments or benefits calculation.	Pre-retrofit consumption is used to create baseline model. Post-retrofit consumption is measured; the difference between the two is savings.	Varies substantially, including verification of potential to provide savings, retrofit isolation, or whole-building or calibrated simulation.	Focused on specific campus, building, component, or system. Amount and frequency of data varies widely between projects.
Building operation and diagnostics	Solve problems. Measure physical or operating parameters that affect energy or water use or that are needed to model building or system performance.	Typically uses one-time and/or short-term measurement with special methods, such as infrared imaging, flue gas analysis, blower door, or flow measurement.	Focused on specific building component or system. Amount and frequency of data vary widely between projects.	Energy or water audit. Identify and solve operation and maintenance, indoor air quality, or system problems. Provide input for models. Building commissioning.

Specific Technology Assessment

Specific technology assessment projects monitor field performance of particular equipment or technologies that affect building energy or water use, such as envelope retrofit measures, major end use system loads or savings from retrofits (e.g., lighting, plumbing fixtures), or retrofits to, or performance of, mechanical equipment.

The typical goal of retrofit performance monitoring projects is to estimate savings resulting from the retrofit despite potentially significant variation in indoor/outdoor conditions, building characteristics, and occupant behavior unrelated to the retrofit. The frequency and complexity of data collection depend on project objectives and site-specific conditions. Projects in this category assess variations in performance between different buildings or for the same building before and after the retrofit.

Field tests of end use equipment are often characterized by detailed monitoring of all critical performance parameters and operational modes. In evaluating equipment performance or improvements to energy/water efficiency, it is preferable to measure in situ performance. Although manufacturers and laboratory performance measurements can provide excellent data for sizing and selecting equipment, installed performance can differ significantly from that at design conditions. The project scope may include reliability, maintenance, design, energy or water efficiency, sizing, and environmental effects (Phelan et al. 1997a, 1997b).

Savings Measurement and Verification (M&V)

Accountability is increasingly necessary in energy and water performance retrofits, whether they are performed as part of energy savings performance contracting (ESPC) or directly by the owner. In either case, savings measurement and verification (M&V) is an important part of the project. Because the actual energy or water savings cannot be measured directly, the appropriate role of energy or water monitoring methodology is to

- Ensure that appropriate data are available, including pre-retrofit data if retrofits are installed
- Accurately define baseline conditions and assumptions
- Confirm that proper equipment and systems were installed and have the potential to generate the predicted energy or water savings
- Take post-retrofit measurements
- Estimate the savings achieved

Proper assessment of a retrofit involves comparing before and after energy or water use, and adjusting for all non-retrofit changes that affected that use. Weather and occupancy are examples of factors that often change. To assess the effectiveness of the retrofit alone, the influence of these other complicating factors must be removed as best possible. To do so, relationships must be found between and these factors and energy or water use. These relationships are usually determined through data analysis, not textbook equations. Because data analysis can be conducted in an infinite number of ways, there can be no absolute certainty about a given relationship. The need for accuracy must be carefully balanced with measurement and analysis costs, recognizing that absolute certainty is not achievable. Among the numerous sources of uncertainty are instrumentation or measurement error, normalization or model error, sampling error, and errors of assumption. Each source can be minimized (to varying degrees) by using more sophisticated measurement equipment, analysis methods, sample sizes, and assumptions. However, more certain savings determinations generally follow the law of diminishing returns, where further increases in certainty come at progressively greater expense. Total certainty is seldom achievable, and even less frequently cost-effective (ASHRAE *Guideline* 14).

Other resources are also available. One of the widest known is the *International Performance Measurement and Verification Protocol* (IPMVP 2014). The IPMVP is more general than ASHRAE *Guideline* 14-2014 but provides important background for understanding the larger context of M&V efforts.

Building Operation and Diagnostics

Diagnostic projects measure physical and operating parameters that determine the energy or water use of buildings and systems. Usually, the project goal is to determine the cause of problems, model or improve energy or water performance of a building or system(s), or isolate effects of components. Diagnostic tests frequently involve one-time measurements or short-term monitoring. To give insight, the frequency of measurement must be several times faster than the rate of change of the effect being monitored. Some diagnostic tests require intermittent, ongoing data collection.

The most basic energy or water diagnostic for buildings is determining rate of use or demand for a specific period, ranging from a single point in time to a few weeks. The scope of measurement may include the whole building or only one component. The purpose can range from measurement system parameter estimation to verification of nameplate information. Daily or weekly profiles may also be of interest.

A large number of diagnostic procedures are used for energy and water measurements in residential (particularly single-family) buildings. Typical measurements for single-family residences include (1) flue gas and other analysis procedures to determine steady-state furnace combustion efficiency and the efficiency of other end uses, such as air conditioners, refrigerators, and water heaters; (2) fan pressurization tests to measure and locate building envelope air leakage (ASTM *Standard* E779) and tests to measure airtightness of air distribution systems (Modera 1989; Robison and Lambert 1989); (3) infrared thermography to locate thermal defects in the building envelope and other methods to determine overall building envelope parameters (Subbarao 1988); and (4) faucet and shower flow meter bags.

Energy and water systems in multifamily buildings can be much more complex than those in single-family homes, but the types of diagnostics are similar: combustion equipment diagnostics, air leakage measurements, flow meter bags, and infrared thermography to identify thermal defects or moisture problems (DeCicco et al. 1995). Some techniques are designed to determine the operating efficiency of steam and hot-water boilers, identify plumbing leaks, and measure air leakage between apartments.

Diagnostic techniques have also been created to measure the overall airtightness of office building envelopes and the thermal performance of walls (Armstrong et al. 2001; Persily et al. 1988; Sellers et al. 2004). Practicing engineers also use a host of monitoring techniques to aid in diagnostics and analysis of equipment energy performance. Portable data loggers are often used to collect time-synchronized distributed data, allowing multiple data sets (e.g., chiller performance and ambient conditions) to be collected and quickly analyzed. Similar short-term monitoring procedures are used to provide more detailed and complete commercial building system commissioning. Short-term, in situ tests have also been developed for pumps, fans, and chillers (Phelan et al. 1997a, 1997b).

Diagnostics are also well suited to support development and implementation of building energy or water management programs (see Chapter 37). Long-term diagnostic measurements support improvements (Liu et al. 1994). Diagnostic measurement projects can generally be designed using procedures adapted to specific project requirements (see the section on Steps for Project Design and Implementation).

Equipment for diagnostic measurement may be installed temporarily or permanently to aid energy and water management efforts. Designers should consider providing permanent or portable check metering of major electrical loads and plumbing fixtures in new building designs. Building automation systems also can be used to collect the data required for diagnostics. The same concept can be extended to fuel and thermal energy use.

2. SMALL PROJECTS

Most metering projects are done on a small scale, and the project steps described in this chapter are simplified and compacted. This section briefly describes how to apply the information in this chapter to a small project.

Small projects are potentially impacted by the issues described here, but if only a small group of people are involved, they can choose what to address and how to handle the project requirements. Table 2 relates small-project approaches to the material in this chapter.

Table 2 Comparison of Small Projects to Overall Methodology

Project Characteristic	Small Project Approach	Overall Methodology Coverage
Project problem areas	• Project goals and resources are iteratively evaluated in short time. Only one to possibly a few people involved. Small group allows more informal procedures and high interaction as needed. • Data products loosely defined. Data collection starts. Initial and ongoing analysis indicates any data management or quality control issues. • Data products refined over time as needed, based on analysis. • Accuracy evaluated on the fly as data are collected. • Commitment is to finish the work. • Advice still sought where needed.	Project goals, project costs and resources, data products, data management, data quality control, commitment, accuracy requirements, advice.
Building and occupant characteristics	Typically, only one to a few buildings included; work is reasonably local. Characteristic data collected on site, at convenience of project person(s), depending on project location. Return trips likely needed for simplified data collection approach; supporting data can be collected on return trips.	Fairly extensive data structure (e.g., a characteristic database) and definition of levels of detail may be needed to handle possibly many buildings and improve ability to report results. With many buildings, only one trip per building may be acceptable.
Project design	Project personnel usually know what they want to measure and report, and may not want to be confused by complex approach in this chapter. Knowledge of experimental approaches may also be understood minimally but still applied successfully, without specific declaration, to small project.	Three higher-level general approaches: (1) fewer buildings or systems with more detailed measurements, (2) many buildings or systems with less detailed measurements, or (3) many buildings or systems with more detailed measurements. Six major experimental design approaches: on/off, before/after, test/reference, simulated occupancy, nonexperimental reference, engineering field test.
Reporting	Reporting is informal to somewhat formal (more like straightforward engineering project than research project). Reported results are often minimal but provide key information.	Research project report is likely required, possibly hundreds of pages long, with multiple appendices. Extensive databases likely generated and must be quality checked and corrected for use by others. Data user access procedures may have to be developed. Databases must be maintained over years in many cases and must be well documented. Extensive research results may have been generated and should be reported. For example, Fracastoro and Lyberg (1983) discussion of guiding principles for residential projects is 300 pages long.

How to Use This Chapter for Small Projects

1. Skim through the chapter and make a few notes on items that may apply for the project in question.
2. Generate a brief project plan to ensure major issues that could cause problems are not overlooked.
3. Generate a brief checklist from the item notes for final check-off during or at the end of project.
4. Clarify what building or site characteristics data may be needed, and be sure to collect those data.
5. Analyze data from the start, to make sure there are no quality or data issues.
6. Consider whether any data should be made available to others at the end of the project, and if so, develop a data format for exchange.
7. Skim through the chapter again when the report is being prepared to gather ideas about what to include in the report.

3. PROTOCOLS FOR PERFORMANCE MONITORING

ASHRAE (2010) gives protocols for performance monitoring of commercial buildings (energy, water, thermal comfort, indoor air quality, lighting, and acoustics) at three levels (basic, intermediate, and advanced). These protocols apply to both retrofit and new building projects and identify what to measure, how to measure (instrumentation and spatial resolution), and how often to measure. Implementation of these protocols for the same six elements, at three levels (basic evaluation, diagnostic measurement, and advanced analysis) is discussed in ASHRAE (2012). Examples of procedures (protocols) for evaluating **energy or water savings** for projects involving retrofit of existing building systems are presented here. These protocols should also be useful to those interested in more general building energy or water monitoring.

Building monitoring has been significantly simplified and made more professional in recent years by the development of these fairly standardized monitoring protocols. Although there may be no way to define a protocol to encompass all types of monitoring applications, repeatable and understandable methods of measuring and verifying retrofit savings are needed. However, following a protocol does not replace adequate project planning and careful assessment of project objectives and constraints.

Residential Retrofit Monitoring

Protocols for monitoring residential building retrofit performance can answer specific questions associated with actual measured performance. For example, Ternes (1986) developed a single-family retrofit monitoring protocol, a data specification guideline that identifies important parameters to be measured. Both one-time and time-sequential data parameters are covered, and parameters are defined carefully to ensure consistency and comparability between experiments. Discrepancies between predicted and actual performance, as measured by the energy or water bills, are common. This protocol improves on billing data methods in two ways: (1) internal temperature is monitored, which eliminates a major unknown variable in data interpretation; and (2) data are taken more frequently than monthly, which potentially shortens monitoring duration. Utility bill analysis generally requires a full season of pre- and post-retrofit data. The single-family retrofit protocol may require only a single season.

Ternes (1986) identified both a minimum set of data, which must be collected in all field studies that use the protocol, and optional extensions that can be used to study additional issues. See Table 3 for details. Szydlowski and Diamond (1989) developed a similar method for multifamily buildings.

The single-family retrofit monitoring protocol recommends a before/after experimental design, and the minimum data set allows performance to be measured on a normalized basis with weekly time-series data (some researchers recommend daily). The protocol also allows hourly recording intervals for time-integrated parameters, an extension of the basic data requirements in the minimum data set. The minimum data set may also be extended through optional data parameter sets for users seeking more information.

Table 3 Data Parameters for Residential Retrofit Monitoring

	Recording Period	
	Minimum	**Optional**
Basic Parameters		
House description	Once	
Space-conditioning system description	Once	
Entrance interview information	Once	
Exit interview information	Once	
Pre- and post-retrofit infiltration rates	Once	
Metered space-conditioning system performance	Once	
Retrofit installation quality verification	Once	
Heating and cooling equipment energy consumption	Weekly	Hourly
Weather station climatic information	Weekly	Hourly
Indoor temperature	Weekly	Hourly
House gas or oil consumption	Weekly	Hourly
House electricity consumption	Weekly	Hourly
Wood heating use	—	Hourly
Domestic hot water energy consumption	Weekly	Hourly
Optional Parameters		
Occupant behavior		
Additional indoor temperatures	Weekly	Hourly
Heating thermostat set point	—	Hourly
Cooling thermostat set point	—	Hourly
Indoor humidity	Weekly	—
Microclimate		
Outdoor temperature	Weekly	Hourly
Solar radiation	Weekly	Hourly
Outdoor humidity	Weekly	Hourly
Wind speed	Weekly	Hourly
Wind direction	Weekly	Hourly
Shading	Once	
Shielding	Once	
Distribution system		
Evaluation of ductwork infiltration	Once	

Source: Ternes (1986).

Data parameters in this protocol have been grouped into four data sets: basic parameters, occupant behavior, microclimate, and distribution system (Table 3). The minimum data set consists of a weekly option of the basic data parameter set. Time-sequential measurements are monitored continuously during the field study. These are all time-integrated parameters (i.e., appropriate average values of a parameter over the recording period, rather than instantaneous values).

This protocol also addresses instrumentation installation, accuracy, measurement frequency, and expected ranges for all time-sequential parameters (Table 4). The minimum data set (weekly option of the basic data) must always be collected. At the user's discretion, hourly data may be collected, which allows two optional parameters to be monitored. Parameters from the optional data sets may be chosen, or other data not described in the protocol added, to arrive at the final data set.

This protocol standardizes experimental design and data collection specifications, enabling independent researchers to compare project results more readily. Moreover, including both minimum and optional data sets and two recording intervals accommodates projects of varying financial resources.

Commercial Retrofit Monitoring

Several related guidelines have been created for evaluating **retrofit savings (measurement and verification [M&V])**.

Table 4 Time-Sequential Parameters for Residential Retrofit Monitoring

Data Parameter	Accuracy[a]	Range	Stored Value per Recording Period	Scan Rate[b] Option 1	Option 2
Basic Parameters					
Heating/cooling equipment energy consumption	3%		Total consumption	15 s	15 s
Indoor temperature	0.5 K	10 to 35°C	Average temperature	1 h	1 min
House gas or oil consumption	3%		Total consumption	15 s	15 s
House electricity consumption	3%		Total consumption	15 s	15 s
Wood heating use	0.5 K	10 to 450°C	Average surface temperature or total use time		1 min
Domestic hot water	3%		Total consumption	15 s	15 s
Optional Data Parameter Sets					
Occupant behavior					
Additional indoor temperatures	0.5 K	10 to 35°C	Average temperature	1 h	1 min
Heating thermostat set point	0.5 K	10 to 35°C	Average set point		1 min
Cooling thermostat set point	0.5 K	10 to 35°C	Average set point		1 min
Indoor humidity	5% rh	10 to 95% rh	Average humidity	1 h	
Microclimate					
Outdoor temperature	0.5 K	–40 to 50°C	Average temperature	1 h	1 min
Solar radiation	30 W/m²	0 to 1100 W/m²	Total horizontal radiation	1 min	1 min
Outdoor humidity	5% rh	10 to 95% rh	Average humidity	1 h	1 min
Wind speed	0.2 m/s	0 to 10 m/s	Average speed	1 min	1 min
Wind direction	5°	0 to 360°	Average direction	1 min	1 min

ASHRAE *Guideline* 14-2014 provides methods for effectively and reliably measuring the energy, water and demand savings due to building improvement projects. The guideline defines a minimum acceptable level of performance in measuring energy, water, and demand savings from conservation measures in residential, commercial, or industrial buildings. These measurements can serve as the basis for commercial transactions between energy services providers and customers who rely on measured energy or water savings as the basis for financing payments. Three approaches are discussed: whole building, retrofit isolation, and calibrated simulation. The guideline includes an extensive resource on physical measurement, uncertainty, and regression techniques. Example M&V plans are also provided.

The *International Performance Measurement and Verification Protocol* (IPMVP 2014) provides guidance to buyers, sellers, and financiers of energy projects on quantifying energy savings performance of energy retrofits. The Federal Energy Management Program has produced guidelines specific to federal projects, which include many procedures applicable to calculating retrofit savings in nonfederal buildings (FEMP 2015).

On a more detailed level, ASHRAE research project RP-827 resulted in separate guidelines for in situ testing of chillers, fans, and pumps to evaluate installed energy efficiency (Phelan et al. 1996, 1997a, 1997b). The guidelines specify the physical characteristics to be measured; number, range, and accuracy of data points required; methods of artificial loading; and calculation equations with a rigorous uncertainty analysis.

In addition to these specialized protocols for particular monitoring applications, a number of specific laboratory and field measurement standards exist, and many monitoring source books are in circulation.

Finally, MacDonald et al. (1989) developed a protocol for field monitoring studies of energy improvements (retrofits) for commercial buildings. Similar to the residential protocol, it addresses data requirements for monitoring studies. Commercial buildings are more complex, with a diverse array of potential efficiency improvements. Consequently, the approach to specifying measurement procedures, describing buildings, and determining the range of analysis must differ.

The strategy used for this protocol is to specify data requirements, analysis, performance data with optional extensions, and a building core data set that describes the field performance of efficiency improvements. This protocol requires a description of the approach used for analyzing building energy or water performance. The necessary performance data, including identification of a minimum data set, are outlined in Table 5.

Commercial New Construction Monitoring

New building construction offers the potential for monitoring building subsystem energy consumption at a reasonable cost. Information obtained by monitoring operating hours or direct energy consumption can benefit building owners and managers by

- Verifying design intent
- Highlighting inefficient or improper operation of equipment
- Providing data that can be useful in determining benefits of alternative operating strategies or replacement equipment
- Evaluating costs of operation for extending occupancy hours for special conditions or event
- Demonstrating effects of poor maintenance or identifying when maintenance procedures are not followed
- Diagnosing and fixing comfort and other space condition problems
- Diagnosing power quality problems
- Submetering tenants
- Verifying/improving savings of a performance contract
- Maintaining persistence of energy or water savings

To provide data necessary to improve building systems operation, monitoring should be considered for boilers, chillers, cooling towers, heat pumps, air-handling unit fans, large fan-coil units, major exhaust fans, major pumps, comfort cooling compressors, lighting panels, electric heaters, receptacle panels, substations, motor control centers, major feeders, service water heaters, plumbing systems, process loads, and computer rooms.

Guidance on energy monitoring to determine energy savings for new construction design modifications is available in IPMVP (2014). Construction documents may include provisions for various meters to monitor equipment and system operation. Some equipment can be specified to have factory-installed hour meters that record actual operating hours of the equipment. Hour meters can also be easily field-installed on any electrical motor.

More sophisticated power-monitoring systems, with electrical switchgear, substations, switchboards, and motor control centers, can be specified. These systems can monitor energy demand, energy consumption, power factor, neutral current, etc., and can be linked to

Table 5 Performance Data Requirements of Commercial Retrofit Protocol

Projects with Submetering			
	Before Retrofit	**After Retrofit**	
Utility billing data (for each fuel)	12 month minimum	3 month minimum (12 months if weather normalization required)	
Submetered data (for all recording intervals)	All data for each major end use, up to 12 months	All data for each major end use, up to 12 months	
	Type	**Recording Interval**	**Period Length**
Temperature data (daily maximum and minimum must be provided for any periods without integrated averages)	Maximum and minimum —or— Integrated averages	Daily —or— Same as for submetered data but not longer than daily	Same as billing data length —or— Length of submetering
Projects Without Submetering			
	Before Retrofit	**After Retrofit**	
Utility billing data (for each fuel)	12 month minimum	12 month minimum	
	Type	**Recording Interval**	**Period Length**
Temperature data	Maximum and minimum —or— Integrated averages	Daily	Same as billing data length

a computer. These same systems can be installed on circuits to existing or retrofit fans, chillers, lighting panels, etc. Some equipment commonly used for improving system efficiency, such as variable-frequency drives, can be provided with capability to monitor kilowatt output, kilowatt-hours consumed, and other variables.

Using direct digital control (DDC) or BAS for monitoring is particularly appropriate in new construction. These systems can monitor, calculate, and record system status, water use, energy use at the main meter or of particular end-use systems, demand, and hours of operation; as well as start and stop building systems, control lighting, and report alarms when systems do not operate within specified limits. Initial specification of the new control system should include specific requirements for sensors, calculations, and trend logging and reporting functions. Special issues related to sensors and monitoring approaches can be found in Piette et al. (2000).

4. COMMON MONITORING ISSUES

Field monitoring projects require effective management of various professional skills. Project staff must understand the building systems being examined, quality control of data, data management, data acquisition, and sensor technology. In addition to data collection, processing, and analysis, the logistics of field monitoring projects require coordinating equipment procurement, delivery, and installation.

Key issues include the **accuracy** and **reliability** of collected data. Projects have been compromised by inaccurate or missing data, which could have been avoided by periodic sensor calibration and ongoing data verification.

Planning

Many common problems in monitoring projects can be avoided by effective and comprehensive planning.

Project Goals. Project goals and data requirements should be established before hardware is selected. Unfortunately, projects are often driven by hardware selection rather than by project objectives, either because monitoring hardware must be ordered several months before data collection begins or because project initiation procedures are lacking. As a result, the hardware may be inappropriate for the particular monitoring task, or critical data points may be overlooked.

Project Costs and Resources. After goal setting, the feasibility of the anticipated project should be reviewed in light of available resources. Projects to which significant resources can be devoted usually involve approaches different from those with more limited resources. This issue should be addressed early on and reviewed throughout the course of the project. Although it is difficult at an early stage to assess with certainty the cost of an anticipated project, rough estimates can be quite helpful.

Data Products. It is important to establish the type and format of the final results calculated from data before selecting data points. Failure to plan these data products may lead to failure to answer critical questions.

Data Management. Failure to anticipate the typically large amounts of data collected can lead to major difficulties. The computer and personnel resources needed to verify, retrieve, analyze, and archive data can be estimated based on experience with previous projects.

Data Quality Control. It is also important to validate the quality and plausibility of data before use. Failure to use some type of quality control often results in data errors and invalid results.

Commitment. Many projects require long-term commitment of personnel and resources. Project success depends on long-term, daily attention to detail and staff continuity.

Accuracy Requirements. The required accuracy of data products and accuracy of the final data and experimental design needed to meet these requirements should be determined early on. After the required accuracy is specified, the sample size (number of buildings, control buildings, or pieces of equipment) must be chosen, and the required measurement precision (including error propagation into final data products) must be determined. Because trade-offs must usually be made between cost and accuracy, this process is often iterative. It is further complicated by a large number of independent variables (e.g., occupants, operating modes) and the stochastic nature of many variables (e.g., weather).

Advice. Expert advice should be sought from others who have experience with the type of monitoring envisioned.

Implementation and Data Management

The following steps can facilitate smooth project implementation and data management:

- Calibrate sensors before installation. Spot-check calibration on site. During long-term monitoring projects, recalibrate sensors periodically. Appropriate procedures and standards should be used in all calibration procedures (see ASHRAE *Guideline* 14-2014 and IPMVP [2014]).
- Track sensor performance regularly. Quick detection of sensor failure or calibration problems is essential. Ideally, this should be an automated or a daily task. The value of data is high, because they may be difficult or impossible to reconstruct.

- Generate and review data on a timely, periodic basis. Problems that often occur in developing final data products include missing data from failed sensors, data points not installed because of planning oversights, and anomalous data for which there are no explanatory records. If data products are specified as part of general project planning and produced periodically, production problems can be identified and resolved as they occur. Automating the process of checking data reliability and accuracy can be invaluable in keeping the project on track and in preventing sensor failure and data loss.
- Occupancy surveys are generally used as subjective measures to assess indoor environmental quality (thermal comfort, IAQ, lighting, acoustics). Surveys such as those of the Center for the Built Environment at the University of California at Berkeley (CBE 2008), can be administered in paper or electronic form, and provide comparison of sampled results with those of peer buildings. These measurements can be taken over time to determine any changes in occupant satisfaction.

Data Analysis and Reporting

For most projects, the collected data must be analyzed and reported. Because the objective of the project is to translate these data into information, and ultimately into knowledge and action, the importance of this step cannot be overemphasized. Clear, convenient, and informative formats should be devised in the planning stages and adhered to throughout the project.

Data analysis should be carefully defined before the project begins. Close attention must be paid to resource allocation to ensure that adequate resources are dedicated to verification, management, and analysis of data and to ongoing maintenance of monitoring equipment. As a quality control procedure and to make data analysis more manageable, these activities should be ongoing.

5. STEPS FOR PROJECT DESIGN AND IMPLEMENTATION

This section describes methodology for designing effective field monitoring projects that meet desired goals with available project resources. The task components and relationships among the nine activities constituting this methodology are identified in Figure 1. The activities fall into four categories: project management, project development, resolution and feedback, and production quality and data transfer. Field monitoring projects vary in terms of resources, goals and objectives, data product requirements, and other variables, affecting how methodology should be applied. Nonetheless, the methodology provides a proper framework for advance planning, which helps minimize or prevent implementation problems.

An iterative approach to planning activities is best. The scope, accuracy, and techniques can be adjusted based on cost estimates and resource assessments. The initial design should be performed simply and quickly to estimate cost and evaluate resources. If costs are out of line with resources, such as when desired levels of instrumentation exceed the resources available, adjustments are needed. Planning should identify and resolve any trade-offs necessary to execute the project in a given budget. Examples include reducing the scope of the project versus relaxing instrumentation specifications or accuracy requirements. These decisions often depend on what questions the project must answer and which questions can be eliminated, simplified, or narrowed.

One frequent oversight in project planning is failing to reserve sufficient time and resources for later analysis and reporting of data. Unanticipated additional costs associated with data collection and problem resolution should not jeopardize these resources.

Documenting the results of project planning should cover all nine parts of the process. This report can be a useful part of an overall project plan that may document other important project information, such as resources to be used, schedule, etc.

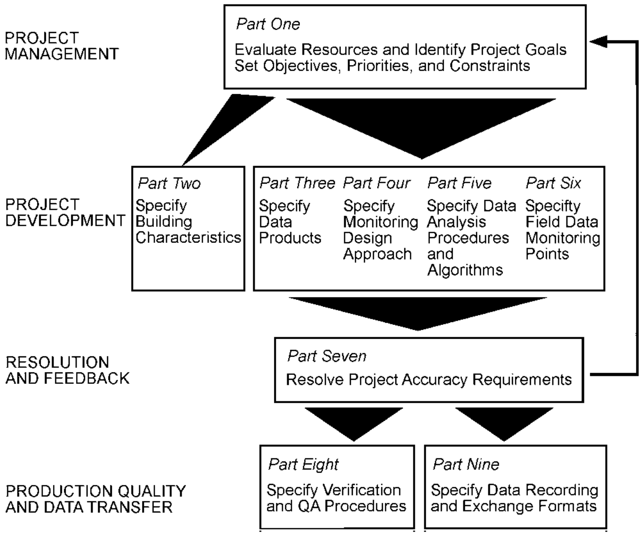

Fig. 1 Methodology for Designing Field Monitoring Projects

Part One: Identify Project Objectives, Resources, and Constraints

Start with a clear understanding of the decision or action that the project will inform. The goals and objectives statement determines the overall direction and scope of the data collection and analysis effort. The statement should also list questions to be answered by empirical data, noting the error or uncertainty associated with the desired result. Realistic assessment of error is needed because requiring too small an uncertainty leads to an overly complex and expensive project. It is important in monitoring projects that a data acquisition plan be developed and followed with a clear idea of the **research questions** to be answered.

Resource requirements for equipment, personnel, and other items must feed into budget estimates to determine expected funding needed for different project objectives. Scheduling requirements must also be considered, and project constraints defined and considered. Trade-offs on budget and objectives require that priorities be established.

Even if a project is not research-oriented, it is attempting to obtain information, which can be expressed in the form of questions. Research questions can have varying scopes and levels of detail, addressing entire systems or specific components. Examples of research questions include

- **Measurement and verification:** Have contractors fulfilled their responsibilities of installing equipment and improving systems to achieve the agreed-upon energy or water savings?
- **Classes of buildings:** How much energy or water has been saved by using the building construction/performance standard mandated in the jurisdiction?
- **Particular buildings:** Has a lapse in building maintenance caused energy or water performance to degrade?
- **Particular components:** What is the average reduction in demand charges during summer peak periods because of the installation of an ice storage system in this building?

Research questions vary widely in technical complexity, generally taking one of the following three forms:

- How does the building/component perform?
- Why does the building/component perform as it does?

- Which building/component should be targeted to achieve optimal cost effectiveness?

The first form of question can sometimes be answered generically for a class of typical buildings without detailed monitoring and analysis, although planning and thorough analysis are still required. The second and third forms usually require detailed monitoring and analysis and, thus, detailed planning.

In general, more detailed and precise goal statements are better. They ensure that the project is constrained in scope and developed to meet specific accuracy and reliability requirements. Usually, projects attempt to answer more than one research question, and often consider both primary and secondary questions. All data collected should have a purpose of helping to answer a project question; the more specific the questions, the easier it becomes to identify required data.

Part Two: Specify Building and Occupant Characteristics

Measured energy or water data will not be meaningful to people who were not involved in the project unless the characteristics of the building being monitored, and its use, have been documented. To meet this need, a data structure (e.g., a characteristic database) can be developed to describe the buildings.

Building characteristics can be collected at many levels of detail, depending on the type of monitoring project and the parameters that affect results. For projects that determine whole-building performance, it is important to provide at least enough detail to document the following:

- General building type, use, configuration, and envelope (particularly energy-related aspects)
- Building occupant information (number, occupancy schedule, activities)
- Internal loads
- HVAC system descriptive information characterizing key parameters affecting HVAC system performance
- Type and quantity of other energy-using systems, especially lighting
- Type and quantity of potable water fixtures
- Any building changes that occur during the monitoring project
- Entrance interview information focusing on energy or water-related behavior of building occupants before monitoring
- Exit interview information documenting physical or lifestyle changes at the test site that may affect data analysis

The minimum level of detail is known as **summary characteristics** data. **Simulation-level characteristics (**detailed information collected for hourly simulation model input) may be desirable for some buildings. Regardless of the level of detail, the data should provide a context for analysts, who may not be familiar with the project, to understand the building and its energy use.

Part Three: Specify Data Products and Project Output

The objective of a monitoring project is not to merely produce data, but to answer a question. However, the data must be of high quality and must be presented to key decision makers and analysts in a convenient, informative format. The specific **data products** (scope, format, and content of data needed to meet project goals and objectives) must be identified and evaluated for feasibility and usefulness in answering project questions identified in Part One. Final data products must be clearly specified, together with the minimum acceptable data requirements for the project. It is important to clearly define an **analysis path** showing what will be calculated and what data are necessary to achieve desired results; assurance should be given that the resources needed to analyze the data, once collected, are available. Clear communication is critical to ensure that project requirements are satisfied and factors contributing to monitoring costs are understood.

Evaluation results can be presented in many forms, often as interim and final reports (possibly by heating and/or cooling season), technical notes, or technical papers. These documents must convey specific results of the field monitoring clearly and concisely. They should also contain estimates of the accuracy of the results.

The composition of data presentations and analysis summaries should be determined early to ensure that all critical parameters are identified (Hough et al. 1987). For instance, mock-ups of data tables, charts, and graphs can be used to identify requirements. Previously reported results can be used to provide examples of useful output. Data products should also be prioritized to accommodate possible cost trade-offs or revisions resulting from other steps in the process such as error analysis (see Part Seven).

Although requirements for the minimum acceptable data results can often be specified during planning, data analysis typically reveals further requirements. Thus, budget plans should include allowances and optional data product specifications to handle additional or unique project output requirements uncovered during data analysis.

Longer-term goals and future information needs should be anticipated and explained to project personnel. For example, a project may have short- and long-term data needs (e.g., demonstrating reductions in peak electrical demand versus demonstrating cost effectiveness or reliability to a target audience). Initial results on demand reduction may not be the ultimate goal, but rather a step toward later presentations on cost reductions achieved. Thus, it is prudent to consider long-term and potential future data needs so that additional supporting information, such as photographs or testimonials, may be identified and obtained.

Part Four: Specify Design of Monitoring

A general monitoring design must be developed that defines three interacting factors: the number of buildings in the study, the monitoring approach (or experimental design), and the level of detail in the data being measured. A less detailed or precise approach can be considered if the number of buildings is increased, and vice versa. If the goal is related to a specific product, the monitoring design must isolate the effects of that product. Haberl et al. (1990) discuss monitoring designs. For example, for retrofit M&V, protocols have been written allowing a range of monitoring methods, from retrofit verification to retrofit isolation (ASHRAE *Guideline* 14-2014; FEMP 2015; IPMVP 2014). Some monitoring approaches are better suited than others to larger numbers of buildings.

Specifying the approach is particularly important because total building performance is a complex function of several variables, changes in which are difficult to monitor and to translate into performance. Unless care is taken with measurement organization and accuracy, uncertainties, errors (noise), and other variations (e.g., weather) can make it difficult to detect performance changes of less than 20% (Fracastoro and Lyberg 1983).

In some cases, judgment may be required in selecting the number of buildings involved in the project. If an owner seeks information about a particular building, the number of buildings in the experiment is fixed at one. However, for other monitoring applications, such as drawing conclusions about effects in a sample population of buildings, some selection is involved. Generally, error in the derived conclusions decreases as the square root of the number of buildings increases (Box 1978). A specific project may be directed at

- Fewer buildings or systems with more detailed measurements
- Many buildings or systems with less detailed measurements
- Many buildings or systems with more detailed measurements

For projects of the first type, accuracy requirements are usually resolved initially by determining expected variations of measured quantities (dependent variables) about their average values in response to expected variations of independent variables. For buildings, a typical concern is the response of heating and cooling loads to changes in temperature or other weather variables. The response of lighting energy use to daylighting is another example of the relationship between dependent and independent variables. Fluctuations in response are caused by (1) outside influences not quantified by measured energy use data and (2) limitations and uncertainties associated with measurement equipment and procedures. Thus, accuracy must often be determined using statistical methods to describe mean tendencies of dependent variables.

For projects of the second and third types, the increased number of buildings improves confidence in the mean tendencies of the dependent response(s) of interest. Larger sample sizes are also needed for experimental designs with control groups, which adjust for some outside influences. For more information, see Box (1978), Fracastoro and Lyberg (1983), and Hirst and Reed (1991). Projects can also use more complex, multilevel measurement and modeling approaches to handle an array of technologies or to improve confidence in results (Hughes and Shonder 1998).

Most monitoring procedures use one or more of the following general experimental approaches:

Before/After. Building, system, or component energy consumption is monitored before and after a new component or retrofit improvement is installed. Changes in factors not related to the retrofit, such as the weather and building operation, must be accounted for, often requiring a model-based analysis (Fels 1986; Hirst et al. 1983; Kissock et al. 1992; Robison and Lambert 1989; Sharp and MacDonald 1990). This experimental design is the primary concern of most current building energy monitoring documents (ASHRAE *Guideline* 14-2014; FEMP 2015; IPMVP 2014).

Test/Reference. The building energy consumption data of two "identical" buildings, one with the product or retrofit being investigated, are compared. Because buildings cannot be absolutely identical (e.g., different air leakage distributions, insulation effectiveness, temperature settings, and solar exposure), measurements should be taken before installation as well, to allow calibration. Once the product or retrofit is installed, any deviation from the calibration relationship can be attributed to the product or retrofit (Fracastoro and Lyberg 1983; Levins and Karnitz 1986).

On/Off. If the retrofit or product can be activated or deactivated at will, energy consumption can be measured in a number of repeated on/off cycles. On-period consumption is then compared to off-period consumption (Cohen et al. 1987; Woller 1989).

Simulated Occupancy. In some cases, the desire to reduce noise can lead the experimenter to postulate certain standard profiles for temperature set points, internal gains, moisture release, or window manipulation and to introduce this profile into the building by computer-controlled devices. The reference is often given by the test/reference design. In this case, both occupant and weather variations are held constant in the comparison (Levins and Karnitz 1986).

Nonexperimental Reference. A reference for assessing the performance of a building can be derived nonexperimentally using (1) a normalized, stratified performance database, such as energy use per unit area classified by building type (MacDonald and Wasserman 1989) or (2) a representative standard (peer) building, simulated by a calculated hourly or bin-method calibrated building energy performance model subject to the same weather, equipment type, and occupancy as the monitored building.

This design, also called **calibrated simulation**, is a secondary concern of current building energy monitoring documents (ASHRAE *Guideline* 14-2014; FEMP 2015; IPMVP 2014).

Engineering Field Test. When an experiment focuses on testing a particular piece of equipment, actual (in situ) performance in a building is often of interest. The building provides a realistic environment for testing the equipment for reliability, maintenance requirements, and comfort and noise levels, as well as energy or water usage. Because energy consumption of mechanical equipment is significantly affected by the system control strategy testing procedures should be designed to incorporate the control strategy of the equipment and its system (Phelan et al. 1997a, 1997b). This type of monitoring and testing can also be used to calibrate computer simulation models of as-built and as-operated buildings, which can then be used to evaluate whole-building energy consumption. The equipment may be extensively instrumented.

Some of the general advantages and disadvantages of these approaches are listed in Table 6 (Fracastoro and Lyberg 1983). Combining monitoring design choices can been successful (e.g., the before/after and test/reference approaches).

Table 6 Advantages and Disadvantages of Common Experimental Approaches

Mode	Advantages	Disadvantages
Before/after	No reference building required. Same occupants implies smaller occupant variations. Modeling processes are mostly identical before/after.	Weather different before/after. More than one heating/cooling season may be needed. Model is required to account for weather and other changes.
Test/reference	One season of data may be adequate. Small climate difference between buildings.	Reference building required. Calibration phase required (may extend testing to two seasons). Occupants in either or both buildings can change behavior.
On/off	No reference building required. One season may be adequate. Modeling processes are mostly identical before/after. Most occupancy changes are small.	Requires reversible product. Cycle may be too long if time constants are large. Model is required to account for weather differences in cycles. Dynamic model accounting for transients may be needed.
Simulated occupancy	Noise from occupancy is eliminated. A variety of standard schedules can be studied.	Not "real" occupants. Expensive apparatus required. Extra cost of keeping building unoccupied.
Nonexperimental reference	Cost of actual reference building eliminated. With simulation, weather variation is eliminated.	Database may be lacking in strata entries. Simulation errors and definition of reference problematic. With database, weather changes usually not possible.
Engineering field test	Information focused on product of interest. Minimal number of buildings required. Same occupants during test.	Extensive instrumentation of product processes required. Models required to extrapolate to other buildings and climates. Occupancy effects not determined.

Source: Partially based on Fracastoro and Lyberg (1983).

Questions to be considered in choosing a monitoring approach include the following:

- Can the building alteration being investigated be turned on and off at will?
- Are occupancy and occupant behavior critical? Changes in building tenants, use schedules, internal gains, temperature set points, and natural or forced ventilation practices should be considered because any one of these variables can ruin an experiment if not held constant or accounted for.
- Are critical baseline energy or water performance data available? In before/after designs, time must be allotted to characterize the before case as precisely as the after case. For instances in which heating and cooling systems are evaluated, data may be required for a wide range of anticipated ambient conditions.
- Is it a test of an individual technology, or are multiple technologies installed as a package being tested? If the effects of individual technologies are sought, detailed component data and careful model-based analyses are required.
- Does the technology have a single mode or multiple modes of operation? Can the modes be controlled to suit the experiment? If many modes are involved, it is necessary to test over a variety of conditions and conduct model-based analysis (Phelan et al. 1997a, 1997b).

Part Five: Specify Data Analysis Procedures and Algorithms

Data are useless unless they are distilled into meaningful products that allow conclusions to be drawn. Too often, data are collected and never analyzed. This planning step focuses on specifying the minimum acceptable data analysis procedures and algorithms and detailing how collected data will be processed to produce desired data products. In this step, monitoring practitioners should

- Determine the independent variables and analysis constants to be measured in the field (e.g., fan power, lighting and receptacle power, indoor air temperature).
- Develop engineering calculations and equations (algorithms) necessary to convert field data to end products: this may include use of statistical methods and simulation modeling.
- Specify detailed items, such as the frequency of data collection, the required range of independent variables to be captured in the data set, and the reasons certain data must be obtained at different intervals. For example, 15 min interval demand data may be assembled into hourly data streams to match utility billing data.

Determine proper National Institute of Standards and Technology (NIST)-traceable calibration standards for each sensor type to be used. For details, see the references in ASHRAE *Guideline* 14-2014 and IPMVP (2014) for specific types of sensors. However, it is often impractical to implement standards in the field. For example, maintaining the length of straight ductwork required for an airflow sensor is usually difficult, requiring compromise.

Algorithm inputs can be assumed values (e.g., energy value of a unit volume of natural gas), one-time measurements (e.g., leakage area of a house), or time-series measurements (e.g., fuel consumption and outdoor and indoor temperatures at the site). The algorithms may pertain to (1) utility level aggregates of buildings, (2) whole-building performance of particular buildings, or (3) performance of instrumented components.

Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals* contains a lengthy discussion on modeling procedures, and readers should consult this material for more information on modeling. In this chapter, the discussion is categorized differently, with a view toward procedures and issues related to field energy monitoring projects.

Table 7 provides a guide to selecting an analysis method. The error quotations are rough estimates for a single-building scenario.

Empirical Methods. Although analysis methods based on measured data are the simplest, they can have large uncertainty and may generate little or no information for small sample sizes. The simplest empirical methods are based on annual consumption values, tracking annual numbers and looking for degradation. Questions about building performance relative to other buildings are based on comparing certain performance indices between the building and an appropriate (peer) reference. The ENERGY STAR tools (www.energystar.gov) are probably the best-known performance comparison tools. The ASHRAE Building Energy Quotient (Building EQ) tool has also been developed to not just provide performance comparison (benchmarking), but also streamline the energy audit process to include improvement measures in the report generated from Building EQ.

For commercial buildings, the most common comparison index is the **energy utilization index (EUI)**, which is annual consumption, either by fuel type or summed over all fuel types, divided by the gross floor area (see MacDonald and Wasserman [1989] for a discussion of indices). Comparison is often made only on the basis of general building type, which can ignore potentially large variations in how much floor area is heated or cooled, climate, number of workers in a building, number and type of computers in a building, and HVAC systems. Variations can be accommodated somewhat by stratifying the database from which the reference EUI is chosen. Computer simulations are often used to set reasonable comparison values.

The Commercial Buildings Energy Consumption Survey (CBECS) database (summarized in Chapter 37) has been used to develop ENERGY STAR and Building EQ energy use benchmarking methods for several building types in the United States. Many of the building tools use 2003 data and are updating to the 2012 CBECS survey data Building types covered as of June 2009 include

- Offices (general offices, financial centers, bank branches, and courthouses)

Table 7 Whole-Building Analysis Guidelines

	Class of Method		
Project Goal	**Empirical (Billing Data)***	**Time-Integrated Model***	**Dynamic Model**
Building evaluation	Yes, but expect monthly fluctuations in 20 to 30% range.	Yes, extra care needed beyond 15% uncertainty.	Yes, extra care needed beyond 10% uncertainty.
Building retrofit evaluation	Not generally applicable using monthly data, unless large samples are used. Requires daily data and various normalization techniques for reasonable accuracy.	Yes, but difficult beyond 15% uncertainty. Method cannot distinguish multiple retrofit effects.	Yes, can resolve 5% change with short-term tests. Can estimate multiple retrofit effects.
Component evaluation	Not applicable.	Not applicable unless submetering is done to supplement.	Yes, about 5% accuracy, but best with submetering.

Note: Error figures are approximate for total energy use in a single building. All methods improve with selection of more buildings.

*Accuracy can be improved by decreasing time step to weekly or daily. These methods are of little use when outdoor temperature approaches balance temperature.

- K-12 schools
- Supermarkets/grocery stores
- Hospitals (acute care and children's)
- Medical offices and clinics
- Hotels/motels
- Residence halls/dormitories
- Retail stores
- Warehouses (refrigerated and nonrefrigerated)

For some of these building types, some secondary spaces are allowed:

- Computer data centers
- Garages and parking lots
- Swimming pools

Initial work in this area covered only electricity use for office buildings (Sharp 1996), but the methods have been extended to cover all fuels for the listed building types and water. Results show that electricity use of office buildings is most significantly explained by the number of workers in the building, number of computers, whether the building is owner-occupied, and number of operating hours each week. Only a subset of these parameters might be used to determine a benchmark within a specific census division. ENERGY STAR documentation on current tools and the performance normalization factors for a range of building types can be found at www.energystar.gov/buildings.

Simple empirical methods applied to retrofit applications should include at least some periods of data on daily energy or water use and average daily temperature (recorded locally) to account for variations in occupancy and building schedules. Monthly EUI or billing data provide more information for empirical analysis and can be used for extended analysis of energy impacts of retrofit applications, for example, in **conditional demand analysis** (Hirst and Reed 1991). Monthly data can also be used to detect billing errors, improper equipment operation during unoccupied hours, and seasonal space condition problems (Haberl and Komor 1990a, 1990b). Daily data are often used in these analyses, and raw hourly total building consumption data, when available, provide more detailed information on occupied versus unoccupied performance. Hourly, daily, monthly, and annual EUI across buildings can be directly compared when reduced to average power per unit area (power density). To avoid false correlations, the method of analysis should have statistical significance that can be traced to realistic parameters (Haberl et al. 1996). ASHRAE (2012) gives best-practice protocols for measurements at different time periods.

Model-Based Methods. These techniques allow a wide range of additional data normalization to potentially improve the accuracy of comparisons and provide estimates of cause-and-effect relations. The analyst must carefully define the system and postulate a useful form of the governing energy balance/system performance equation or system of equations, as often embodied in hour-by-hour simulation programs. Explicit terms are retained for equipment or processes of particular interest. As part of the data analysis, whole-building data (driving forces and thermal or energy response) are used to determine the model's significant parameters. The parameters themselves can provide insight, although parameter interpretation can be difficult, particularly with time-integrated billing data methods. The model can then be used for normalization as well as future diagnostic and control applications. Two general classes of models are used in analysis methods: time-integrated methods and dynamic techniques (Balcomb et al. 1993). Simulation modeling results used for design of new buildings may not cover all energy used in a building and thus could be difficult to compare with empirical data.

Time-Integrated Methods. Based on algebraic calculation of the building energy balance, time-integrated methods are often used before data comparison to correct annual consumption for variations in outdoor temperature, internal gains, and internal temperature (ASHRAE 2002; Fels 1986; Haberl and Claridge 1987). This type of calibrated model is essential for most retrofit applications.

Time-integrated methods can be used with whole-building energy consumption data (billing data) or with submetered end-use data. For example, standard time-integrated methods are often used to separately analyze end-use consumption data on heating, cooling (Ternes and Wilkes 1993), domestic water heating, and others for comparison and analysis. Time-integrated methods are generally reliable, as long as the following three conditions are accounted for:

- *Appropriate time step.* Generally, the time step should be as long as or longer than the response time of the building or building system for which energy use is being integrated. For example, the response of daylighting controls to natural illumination levels can be rapid, allowing short time steps for data integration. In contrast, the response of cooling system energy use to changes in cooling load can be comparatively slow. In this instance, either a time step long enough to average over these slow variations or a dynamic model should be used. In general, an appropriate time step should account for the physical behavior of the energy system(s) and the expression of this behavior in model parameters.
- *Linearity of model results.* Generally, time-integrated models should not be applied to data used to estimate nonlinear effects. Air infiltration, for example, is nonlinear when estimated using wind speed and indoor/outdoor temperature difference data in certain models. Estimation errors result if these parameters are independently time-integrated and then used to calculate air infiltration. These nonlinear effects should be modeled at each time step (each hour, for example).
- *End-use uniformity within data set.* End-use data sets should be uniform (i.e., should not inadvertently contain observations with measurements of end uses other than those intended). During mild weather, for example, HVAC systems may provide both heating and cooling over the course of a day, creating data observations of both heating and cooling measurements. In a time-integrated model of heating energy use, these cooling energy observations lead to error. These observations should be identified or otherwise flagged by their true end use.

For whole-building energy consumption data (billing data), reasonable results can be expected from heating analysis models when the building is dominantly responsive to indoor/outdoor temperature differences. Billing data analysis yields little of interest when internal gains are large compared to envelope loads, as in large commercial buildings and industrial applications. Daily, weekly, and monthly whole-building heating season consumption integration steps can been used (Claridge et al. 1991; Fels 1986; Sharp and MacDonald 1990; Ternes 1986). Cooling analysis results have been less reliable because cooling load is not strictly proportional to variable-base cooling degree-days (Fels 1986; Haberl et al. 1996; Kissock et al. 1992). Problems also arise when solar gains are dominant and vary by season.

Dynamic Techniques. Dynamic models, both **macrodynamic** (whole-building) or **microdynamic** (component-specific), offer great promise for reducing monitoring duration and increasing conclusion accuracy. Furthermore, individual effects from multiple measures and system interactions can be examined explicitly. Dynamic whole-building analysis is generally accompanied by detailed instrumentation of specific technologies.

Dynamic techniques create a dynamic physical model for the building, adjusting model parameters to fit experimental data (Duffy et al. 1988; Subbarao 1988). In residential applications, computer-controlled electric heaters can be used to maintain a steady interior temperature overnight, extracting from these data an experimental value for the building steady-state load coefficient. A cooldown period can also be used to extract information on internal building mass thermal storage. Daytime data can be used to renormalize the building response (computed from a microdynamic model) to solar radiation, which is particularly appropriate for buildings with glazing areas over 10% of the building floor area (Subbarao et al. 1986). Once the data with electric heaters have been taken, the building can be used as a dynamic calorimeter to assess the performance of auxiliary heating and cooling systems.

Similar techniques have been applied to commercial buildings (Burch et al. 1990; Norford et al. 1985). In these cases, delivered energy from the HVAC system must be monitored directly in lieu of using electric heaters. Because ventilation is a major variable in the building energy balance, outdoor airflow rate should also be monitored directly. Simultaneous heating and cooling (common in large buildings) requires a multizone treatment, which has not been adequately tested in any of the dynamic techniques.

Equipment-specific monitoring guidelines using dynamic modeling have been successfully tested in a variety of applications. For fans and pumps, relatively simple regression techniques from short-term monitoring provided accurate estimates of annual energy consumption when combined with an annual equipment load profile. For chillers, a thermodynamic model used with short-term monitoring captured the most important operating parameters for estimating annual chiller energy performance. In all cases, the key to accurate model results was capturing a wide enough range of the independent load variable in monitored data to reflect annual operating characteristics (Phelan et al. 1997a, 1997b).

Part Six: Specify Field Data Monitoring Points

Careful specification of field monitoring points is critical to identifying variables that need to be measured to produce required data. The analysis method determines the data to be measured. The simplest methods require no on-site instrumentation. As methods become more complex, data channels increase. For engineering field tests conducted with dynamic techniques, up to 100 data channels may be required.

Because metering projects are often conducted in buildings with changing conditions, special consideration must be given to identifying and monitoring significant changes in climate, systems, and operation during the monitoring period. Additional monitoring points may be required to measure variables that are assumed to be constant, insignificant, or related to other measured variables to draw sound conclusions from the measurements. Because the necessary data may be obtained in several ways, data analysts, equipment installers, and data acquisition system engineers should work together to develop tactics that best suit the project requirements. It is important to anticipate the need for supplemental measurements in response to project needs that may not become apparent until equipment is installed.

The cost of data collection is a nonlinear function of the number, accuracy, and duration of measurements considered while planning within budget constraints. Costs per data point typically decrease as the number of points increases, but increase with accuracy requirements. Duration of monitoring can have many different effects. If the extent of data applications is unknown, such as in research projects, the value of other concurrent measurements should be considered, because the incremental cost of additional analyses may be small.

For any project involving large amounts of data, data quality verification (see Part Eight) should be automated (Lopez and Haberl 1992). Although this may require adding monitoring points to facilitate energy balances or redundancy checks, the added costs are likely to be offset by savings in data verification.

If multiple sites are to be monitored, common protocols for selecting and describing all field monitoring points should be established so data can be more readily verified, normalized, compared, and averaged. Protocols, such as those recommended in ASHRAE (2010), also add consistency in selecting monitoring points. Pilot installations should be conducted to provide data for a test of the system and to ensure that the necessary data points have been properly specified and described.

Monitoring Equipment. General considerations in selecting monitoring equipment include

- Evaluating equipment thoroughly under actual test conditions before committing to large-scale procurement. Particular attention should be paid to any sensitivity to power outages and to protection against power surges and lightning.
- Considering local setup and testing of complex data acquisition systems that are to be installed in the field.
- Avoiding unproven data acquisition equipment (Sparks et al. 1992). Untested equipment, even if donated, may not be a good value.
- Considering costs and benefits of remote data interrogation and programming.
- Evaluating quality and reliability of data loggers and instrumentation; these issues may be more important than cost, particularly when data acquisition sites are distant.
- Verifying vendor claims by calling references or obtaining performance guarantees.
- Considering portable battery-powered data loggers in lieu of hard-wired loggers if the monitoring budget is limited and the length of the monitoring period is less than a few months.
- Ensure that monitoring equipment and installation methods are consistent with prevailing laws, building codes, and standards of good practice.

Using a building energy management system or direct digital control systems for data acquisition may decrease costs. This should be considered only when the sensors and their accuracy and limitations (scan rate, etc.) are thoroughly understood. When merging data from two data acquisition systems, problems may arise such as differing reliability and low data resolution (e.g., 1 kW resolution of a circuit that draws 10 kW fully loaded). These problems can often be avoided, however, by adding appropriate sensors and setting up custom logging or calculations with point, memory, and programming capacity.

Once the required field data monitoring points are specified, these requirements should be clearly communicated to all members of the project team to ensure that the actual monitoring points are accurately described. This can be accomplished by publishing handbooks for measurement plan development and equipment installation and by outlining procedures for diagnostic tests and technology assessments.

Because hardware needs vary considerably by project, specific selection guidelines are not provided here. However, general characteristics of data acquisition hardware components are shown in Table 8. Some typical concerns for selecting data acquisition hardware are outlined in Table 9. In general, data logger and instrumentation hardware should be standardized, with replacements available in the event of failure. Also consider redundant measurements for critical data components that are likely to fail, such as modems, flowmeters, shunt resistors on current transformers, and devices with moving parts (O'Neal et al. 1993). Some measurements that are more difficult to obtain accurately because of instrumentation limitations are summarized in Table 10.

Safety must be considered in equipment selection and installation. Installation teams of two or more individuals reduce risks. When contemplating thermal metering, the presence of asbestos insulation on water piping should be determined. Properly licensed trades personnel, such as an electrician or welder, should be a fundamental part of any team installing electrical monitoring equipment.

To prevent inadvertent tampering, occupants and maintenance personnel should be carefully briefed on what is being done and the

Table 8 General Characteristics of Data Acquisition System (DAS)

Types of DAS	Typical Use	Typical Data Retrieval	Comments
Manual readings	Total energy or water use	Monthly or daily written logs	Human factors may affect accuracy and reading period. Data must be manually entered for computer analysis.
Pulse counter, solid state (1, 4, or 8 channels)	Total energy or water use (some end use)	Polled by telephone to mainframe or minicomputer	Computer hardware and software are needed for transfer and conversion of pulse data. Can be expensive. Can handle large numbers of sites. User-friendly.
Stick-on battery powered logger (1 to 8 channels)	Diagnostics, technology assessment, end use	Monthly manual download to PC	Very useful for remote sites. Can record pulse counts, temperature, etc., up to thousands of records.
Plug-in A/D boards for PCs	Diagnostics, technology assessment, control	On-site real-time collection and storage	Usually small-quantity, unique applications. PC programming capability needed to set up data software and configure boards.
Simple field DAS (usually 16 to 32 channels)	Technology assessment, residential end use (some diagnostics)	Phone retrieval to host computer for primary storage (usually daily to weekly)	Can use PCs as hosts for data retrieval. Good A/D conversion available. Low cost per channel. Requires programming skills to set up field unit and configure communications for data transfer.
Advanced field DAS (usually >40 channels/ units)	Diagnostics, energy control systems, commercial end use	On-site real-time collection and data storage, or phone retrieval	Usually designed for single buildings. Can be PC-based or stand-alone unit. Can run applications/diagnostic programs. User-friendly.
Direct digital control or building automation system	On-site diagnostics, energy measurement and verification	Proprietary data collection procedures, manual or automated export to spreadsheet.	Requires significant coordination with building operation personnel. Sensor accuracy, calibration, and installation require confirmation. Good for projects with limited instrumentation budget.

Table 9 Practical Concerns for Selecting and Using Data Acquisition Hardware

Components	Field Application Concerns
Data logger unit and peripherals	• Select equipment for field application. Flexible or adaptable input capabilities desirable. • Equipment should store data electronically for easy transfer to a computer. • Remote programming capability should be available to minimize on-site software modifications. • Avoid equipment with cooling fans. • Use high-quality, reliable communication devices or methods. • Make sure logger/computer and communication reset after power outage.
Cabling and interconnection hardware	• Use only signal-grade cable: shielded, twisted-pair with drain wire for analog signals. • Mitigate sources of common mode and normal mode signal noise.
Sensors	• Use rugged, reliable sensors rated for field application. • Use a signal splitter if sharing existing sensors or signals with other recorders or energy management control system (EMCS). • Select ranges so sensors operate at 50 to 75% of full scale. • Choose sensors that do not require special signal conditioning or power supply, if possible. • Calibrate sensors and recalibrate periodically. • When possible, use redundant channels to cross-check critical channels that can drift.

purpose of sensors and equipment. Data loggers should have a dedicated (non-occupant-switchable), hard-wired power supply to prevent accidental power loss.

Sensors. Sensors should be selected to obtain each measurement on the field data list. Next, conversion and proportion constants should be specified for each sensor type, and the accuracy, resolution, and repeatability of each sensor should be noted. Sensors should be calibrated before they are installed, preferably with a NIST-traceable calibration procedure. They should be checked periodically for drift, recalibrated, and then post-calibrated at the conclusion of the experiment (Haberl et al. 1996). Instrument calibration is particularly important for flow and power measurement.

Table 10 Instrumentation Accuracy and Reliability

Instrument	Problems
Hygrometers	Drift, saturation, and accuracy over time; need for calibration to remove temperature dependence; aspirated systems need to be cleaned periodically. Chilled-mirror systems require frequent maintenance.
Flowmeters	Need for calibration, reliability (especially for steam flow). Moving parts prone to failure. Pipe size must be verified before calibration or installation.
Heatflow meters	60 Hz noise from surroundings, calibration.
Single-ended voltage	Grounding problems, spurious line voltages, 60 Hz noise.
Outdoor air temperature sensor	Must be properly shielded from solar radiation. Aspiration may reduce solar radiation effects but decrease long-term reliability.
RTD sensors	Signal wire length affects readings.
Power meters	Polarity of current transducers (CTs) often marked incorrectly, problems with shunt resistors and CT output. Devices should be checked before installation.

Particular attention must be paid to sensor location. For example, if the method requires an average indoor temperature, examine the potential for internal temperature variation; data from several temperature sensors must often be averaged. Alternatively, temperature sensors adjacent to HVAC thermostats detect the temperature to which the HVAC equipment reacts. For temperature or pitot tube flow measurements the location must be sufficiently downstream of louvers, filters, and pipe turns to obtain accurate results.

Scanning and Recording Intervals. Measurement frequency and data storage can affect the accuracy of results. Scanning differs from storage in that data channels may be read (scanned) many times per second, for example, whereas average data may be recorded and stored every 15 min. Most data loggers maintain temporary storage registers, accumulating an integrated average of channel readings from each scan. The average is then recorded at the specified interval.

After the channel list is compiled and sensor accuracy requirements established, scan rates should be assigned. Some sensors, such as indoor and outdoor temperature sensors, may require low scan rates (once every 5 min). Others, such as total electric sensors, may contain high-frequency transients that require rapid sampling (many times per second). The scan rate must be fast enough to ensure that all significant effects are monitored.

The maximum sampling rate is usually programmed into the logger, and averages are stored at a specified time step (e.g., hourly). Some loggers can scan different channels at different rates. The logger's interrupt capability can also be used for rapid, infrequent transients. Interrupt channels signal the data logger to start monitoring an event only once it begins. In some cases, online computation of derived quantities must be considered. For example, if heating or cooling flow in an air duct is required, it can be computed from a differential temperature measurement multiplied by an air mass flow rate determined from a one-time measurement. However, it should be computed and totaled only when the fan is operating.

Part Seven: Resolve Project Data Accuracies

Data collected by monitoring equipment are usually used for the following purposes:

- Direct reporting of primary measurement data
- Reporting of secondary or deduced quantities (e.g., thermal energy consumed by a building, found by multiplying mass flow rate and temperature difference)
- Subsequent interpretation and analyses (e.g., to develop a statistical model of energy used by a building versus outdoor dry-bulb temperature)

In all three cases, the value of the measurements is dramatically increased if the associated uncertainty can be quantified.

Basic Concepts. Uncertainty can be better understood in terms of confidence limits, which define the range of values that can be expected to include the true value with a stated probability (ASHRAE *Guideline* 2). Thus, a statement that the 95% confidence limits are 5.1 to 8.2 implies that the true value is between 5.1 and 8.2 in 19 out of 20 observations or, more loosely, that we are 95% confident that the true value lies between 5.1 and 8.2. For a given set of n observations with normal (Gaussian) error distribution, the total variance about the mean predicted value X' provides a direct indication of the confidence limits. Thus the "true" mean value X' of the random variable is bounded as follows:

$$\overline{X'} \pm (t_{\alpha/2,\,n-1}\sqrt{\sigma^2/n}) \qquad (1)$$

where

α = level of significance
$\overline{X'}$ = mean predicted value of random variable X
$t_{\alpha/2,n-1}$ = t-statistic with probability of $1 - \alpha/2$ and $n - 1$ degrees of freedom (tabulated in most statistical textbooks)
n = number of observations, with Gaussian error distribution
σ^2 = estimated measurement variance

The terms **accuracy** and **precision** are often used to distinguish between bias errors and random errors. A set of measurements with small bias errors is said to have high accuracy, and a set of measurements with small random errors is said to have high precision. In repeated measurements of a given sample by the same technique (single-sample data), each measurement has the same bias. Bias errors include those that are (1) known and can be removed by calibration, (2) negligible and are ignored, and (3) estimated and are included in the uncertainty analysis. It is usually difficult to estimate bias limits, and this effect is often overlooked. However, a proper error analysis should include bias error, which is usually written as a plus-minus error. ASME *Standard* PTC 19.1 has a more complete discussion.

Because bias errors b_m and random errors ε_m are usually uncorrelated, measurement variance σ^2 can be expressed as

$$\sigma^2_{meas}(b_m, \varepsilon_m) = \sigma^2(b_m) + \sigma^2(\varepsilon_m) \qquad (2)$$

For further information on uncertainty, see Chapter 37 of the 2017 *ASHRAE Handbook—Fundamentals*. For more information on uncertainty calculation methods related specifically to building energy savings monitoring, see ASHRAE *Guideline* 14-2014, Annex B.

Primary Measurement Uncertainty. Sensor and measuring equipment manufacturers usually specify measurement variances; frequent recalibration minimizes bias errors. As indicated by Equation (1), increasing the number of measurements n reduces the uncertainty bounds.

Uncertainty in Derived Quantities. Once a specific algorithm or equation for obtaining final data from physical measurements has been established, standard techniques can be used to incorporate primary measurement uncertainties into the final data product. For random errors, the Kline and McClintock (1953) error propagation method, based on a first-order Taylor series expansion, is widely used to determine measurement uncertainties in derived variables in single-sample experiments. Bias errors are difficult to account for; the usual practice is to remove them through calibration and exclude them from the uncertainty analysis.

Uncertainty in Statistical Regression Models. Statistical regression models developed from measured data are usually used for predictive purposes. Measurement errors are much smaller than model errors, which arise because the regression model is imperfect; that is, it is unable to explain the entire variation in the regression variable (Box 1978). Measurement error is inherently included in the identified model, so total prediction variance is simply given by the model prediction uncertainty.

Determining prediction errors from regression models is subject to different types of problems. The sources of error can be classified into three categories (Reddy et al. 1998):

- Model *misspecification* errors occur because the functional form of the regression model is usually an approximation of the true driving function of the response variable.
- Model *prediction* errors occur because a model is never perfect.
- Model *extrapolation* errors occur when a model is used for prediction outside the region covered by the data from which the model was developed. Models developed from short data sets, which do not satisfactorily represent the annual behavior of the system, are subject to this error. This error cannot be quantified in statistical terms alone, but certain experimental conditions are likely to lead to accurate predictive models. This falls under the purview of experimental design (Box 1978).

Misspecification and extrapolation errors are likely to introduce bias and random error. If ordinary least-squares regression is used for parameter estimation, and if the model is subsequently used for prediction, model prediction will be purely random. Thus, models identified from short data sets and used to predict seasonal or annual energy use are affected by misspecification and extrapolation errors.

The least-squares method of calculating linear regression coefficients cannot produce unbiased estimators of slope and intercept if there are errors associated with measuring the predictor variable. The uncertainty analysis methodology developed for in situ equipment testing uses standard linear regression practices to find the functional relationship and then estimates the increased uncertainty in the regression prediction because of random and bias errors in both variable measurements (Phelan et al. 1996).

Experimental Design. Errors can also be estimated based on historical experience (e.g., using results from previous similar projects). Alternatively, a pilot study can obtain an estimate of potential errors in a proposed analysis. Some estimate of potential error must be available to determine whether project goals and objectives are reasonable.

Estimating data uncertainty is one part of the iterative procedure associated with proper experimental design. If the final data product uncertainty determined using the given evaluation procedure is unacceptable, uncertainty can be reduced in one or more of the following ways:

- Reducing overall measurement uncertainty (improving sensor precision)
- Increasing the duration of monitoring to average out stochastic variations
- Increasing the number of buildings tested (sample size)

On the other hand, if simulations or estimates indicate that the expected bias in the final data product is unacceptable, the bias may be reduced by one or more of the following steps:

- Adding sensors to get an unbiased measurement of the quantity
- Using more detailed models and analysis procedures
- Increasing data acquisition frequency, combined with a more detailed model, to address biases from sensor or system nonlinearities.

Accuracy Versus Cost. The need for accuracy must be carefully balanced against measurement and analysis costs. Accuracy loss can stem from instrumentation or measurement error, normalization or model error, sampling or statistical error, and errors in assumptions. Each of these sources can be controlled to varying degrees. However, in general, more accurate methods follow the law of diminishing returns, in which further reductions in error come at progressively greater expense.

Because of this trade-off, the optimal measurement solution is usually found by an iterative approach, where incremental improvements in accuracy are assessed relative to the increase in measurement cost. Such optimization requires that a value be placed on increasing levels of accuracy. One method of evaluating the uncertainty of a proposed method is to calculate results using the highest and lowest values in the confidence interval. The difference between these values can be translated into a monetary amount that is at risk. The question that must be answered is whether further measurement investment is warranted to reduce this risk.

Part Eight: Specify Verification and Quality Assurance Procedures

Establishing and using data quality assurance (QA) procedures can be very important to the success of a field monitoring project. The amount and importance of the data to be collected help determine the extent and formality of QA procedures. For most projects, the entire data path, from sensor installation to procedures that generate results for the final report, should be considered for verification tests. In addition, the data flow path should be checked routinely for failure of sensors or test equipment, as well as unexpected or unauthorized modifications to equipment.

QA often requires complex data handling. Building energy monitoring projects collect data from sensors and manipulate those data into results. Data handling in a project with only a few sensors and required readings can consist of a relatively simple data flow on paper. Computers, which are generally used in one or more stages of the process, require a different level of process documentation because much of what occurs has no direct paper trail.

Computers facilitate collection of large data sets and increase project complexity. To maximize automation, computers require development of specific software. Often, separate computers are involved in each step, so passing information from one computer to another must be automated in large projects. To move data as smoothly as possible, an automated **data pipeline** should be developed; this minimizes the delay from data collection to results production and maximizes the cost-effectiveness of the entire project.

Because collected data are valuable, data back-up procedures must also be part of QA. At a minimum, the basic data, either raw or first-level processed, should be stored in at least one, and preferably two, different back-up locations, apart from the main data storage location, to allow data recovery in case of hardware failure, fire, vandalism, etc. Back-ups should occur at regular intervals, probably not less than weekly for larger projects.

Frequent data acquisition (preferably automated), with a quality control review of summarized and plotted data, is essential to ensure that reliable data are collected. Verification procedures should be performed at frequent intervals (daily or weekly), depending on the importance of missing data. This minimizes data loss due to equipment failure and/or changes at a building site. It also allows processed information to be applied quickly.

The following QA actions should take place:

- Calibrate hardware and establish a good control procedure for collection of data. Use NIST-traceable calibration methods.
- Verify data, check for reasonableness, and prepare a summary report to ensure data quality after collection.
- Perform initial analysis of data. Significant findings may lead to changes in procedures for checking data quality.
- Thoroughly document and control procedures applied to remedy problems. These procedures may entail changes in hardware or collected data (such as data reconstruction), which can have a fundamental effect on the results reported.
- Archive raw data obtained from the site to ensure project integrity.

Three aspects of a monitoring project that require QA are shown in Table 11: hardware, engineering data, and characteristics data.

Table 11 Quality Assurance Elements

Time Frame	Hardware	Engineering Data	Characteristics Data
Initial start-up	Bench calibration (1) Field calibration (1) Installation verification (1)	Installation verification (1) Collection verification (1, 2) Processing verification (1, 2) Result production (1, 2)	Field verification (1) Completeness check (1) Reasonableness check (1, 2) Result production (1, 2)
Ongoing	Functional testing (1) Failure mode diagnosis (3) Repair/maintenance (4) Change control (1)	Quality checking (2) Reasonableness checking (2) Failure mode diagnosis (3) Data reconstruction (4) Change control (1)	Problem diagnosis (3) Data reconstruction (4) Change control (1)
Periodic	Preventive maintenance (1) Calibration (1)	Summary report preparation and review (2)	Scheduled updates/resurveys (1) Summary report preparation and review (2)

(1) Actions to ensure good data. (2) Actions to check data quality. (3) Actions to diagnose problems. (4) Actions to repair problems.

Three QA reviews are necessary for each aspect: (1) initial QA confirms that the project starts correctly; (2) ongoing QA confirms that information collected by the project continues to satisfy quality requirements; and (3) periodic QA involves additional checks, established at the beginning of the project, to ensure acceptable performance quality.

Information about data quality and the QA process should be readily available to data users. Otherwise, significant analytical resources may be expended to determine data quality, or the analyses may never be performed because of uncertainties.

Part Nine: Specify Recording and Data Exchange Formats

This step specifies the formats in which data are supplied to the end user or other data analysts. Both raw and processed (adjusted for missing data or anomalous readings) data formats should be specified. In addition, if supplemental analyses are planned, the medium and format to be used (type of storage, possibly magnetic tape type, spreadsheet, character encoding standard) should be specified. These requirements can be determined by analyzing the software data format specifications. Common formats for raw data are comma- and blank-delimited American Standard Code for Information Exchange (ASCII), which do not require data conversion.

Data documentation is essential for all monitoring projects, especially when several organizations are involved. Data usability is improved by specifying and adhering to data recording and exchange formats. Most data transfer problems are related to inadequate documentation. Other problems include hardware or software incompatibility, errors in electronic storage media, errors or inconsistencies in the data, and transmittal of the wrong data set. The following precautions can prevent some of these problems:

- Provide documentation to accompany the data transfer (Table 12). Because these guidelines apply to general data, models, programs, and other types of information, items listed in Table 12 may not apply to every case.
- Provide documentation of transfer media, including the computer operating system, software used to create the files, media format (e.g., ASCII, application-specific), and media characteristics (note that many CD-ROM formats exist, some of which are proprietary and not widely used, so care should be taken to use commonly available methods).
- Provide procedures to check the accuracy and completeness of data transfer, including statistics or frequency counts for variables and hard-copy versions of the file. Test input data and corresponding output results for models on other programs.
- Keep all raw data, including erroneous records.
- Convert and correct data; save routines for later use.
- Limit equipment access to authorized individuals.
- Check incoming data soon after they are collected, using simple time-series and x-y inspection plots.
- Automate as many routines as possible to avoid operator error.

Table 12 Documentation Included with Computer Data to Be Transferred

1. Title and/or acronym
2. Contact person (name, address, phone number)
3. Description of file (file format, number of records, geographic coverage, spatial resolution, time period covered, temporal resolution, sampling methods, uncertainty/reliability)
4. Definition of data values (variable names, units, codes, missing value representation, location, method of measurement, variable derivation, variable formats)
5. Original uses of file
6. Size of file (number of records, bytes)
7. Original source (person, agency, citation)
8. Pertinent references (complete citation) on materials providing additional information
9. Appropriate reference citation for the file
10. Credit line (for use in acknowledgments)
11. Restrictions on use of data/program
12. Disclaimer, such as
    - Unverified data; use at your own risk.
    - Draft data; use with caution.
    - Clean data to the best of our knowledge. Please let us know of any possible errors or questionable values.
    - Program under development.
    - Program tested under the following conditions (conditions specified by author).

Control Strategies for Air-Handling Units 43.43
Control Strategies for Building Zones 43.44

COMPUTERIZED building and energy management and control systems provide a variety of effective ways to reduce utility costs and energy consumption associated with maintaining environmental conditions and thermal comfort in buildings. These systems can incorporate advanced control strategies that respond to inputs including changing weather, building conditions, occupancy levels and utility rates to minimize operating costs, energy consumption and greenhouse gas emissions while also enhancing occupant comfort. This chapter focuses on the opportunities and control strategies associated with using supervisory control strategies and optimization methods applied to cooling systems, heating systems, air handling units and zone equipment.

HVAC and other building energy systems are typically controlled using a hierarchical control structure where two or more levels of control, from local through to supervisory level, are combined to form a sophisticated control system designed to achieve particular high-level functions or objectives, such as maintaining temperature within a space. With this control philosophy, controller intelligence increases from lower to higher levels within the hierarchy. The lowest control level typically exists only to provide **local-loop control** of a single set point through manipulation of one or more actuators. For example, the supply air temperature discharged from a cooling coil is controlled by adjusting the opening of a valve that provides chilled water to the coil, or by adjusting mixing dampers and the coil valve. The upper control level, typically called **supervisory control**, specifies the set points and other modes of operation that are time dependent. System performance monitoring capabilities may also be provided at this level. Ideally, the supervisory control level would determine optimal set points and operating modes that minimize operating cost and/or energy consumption, maximize comfort, and may also identify potential faults or alarms in the control system. Distributed control structures have also been applied to building energy systems, although further research is required to determine their efficacy and the benefits they may provide over more traditional and well-understood control systems.

Performance of large, commercial HVAC systems can be improved through better local-loop and supervisory control. Proper tuning of local-loop controllers can enhance comfort, reduce energy use, and increase component life. Systems that are properly commissioned or tuned, such as through a recommissioning process or the use of automated fault detection and diagnostics software, ensure that theoretical performance gains from supervisory control strategies are realized. Set points and operating modes for cooling or heating plant equipment can be adjusted by supervisory control strategies or static optimization to maximize overall operating efficiency. Dynamic optimization strategies for ice or chilled-water storage systems can significantly reduce on-peak electrical energy and demand costs to minimize total utility costs. Similarly, thermal storage inherent in a building's structure can be dynamically controlled to minimize utility costs, for example, with the use of **thermally activated building systems (TABS)**. In general, strategies that take advantage of thermal storage work best when dynamic optimization is applied using forecasts of future energy requirements.

Significant increases in computational power and communications capabilities mean that both supervisory and distributed control systems are now able to incorporate many new data streams and simultaneously co-optimize a number of performance metrics. Rather than simply regulating temperature, the supervisory control system may manage thermal comfort while minimizing utility cost, energy consumption, and greenhouse gas emissions. Ubiquitous consumer electronics, such as smart phones, tablets, and laptops, mean that direct feedback of occupant preferences may be obtained rather than relying on inferred statistical models. Building thermal response and internal gain forecast models (e.g., learned by the controller) allow optimal start-up, night-purge, and economy modes as well as potential participation in utility demand response programs and cost reductions in demand and capacity charges.

Where resources are constrained by equipment sizing, maintenance, or imposed through energy targets or demand charges, a coordinated approach to resource allocation is required to ensure an equitable balance of comfort for all building occupants. This is increasingly likely to be an important control scheme design consideration with increased focus on energy efficiency, demand response, and the uptake of intermittent renewable generation, requiring energy users to respond to resource variability. New energy pricing models will substantially reward users who have this flexibility, but may also adversely impact those without the capability to dynamically manage loads.

1. TERMINOLOGY

Air distribution system: includes terminal units (variable-air-volume [VAV] boxes, etc.), air-handling units (AHUs), ducts, and controls. In each AHU, ventilation air is mixed with return air from the zones and fed to the cooling/heating coil.

The preparation of this chapter is assigned to TC 7.5, Smart Building Systems.

Air-side economizer control: used to select between minimum and maximum ventilation air, depending on the condition of the outdoor air relative to the conditions of return air. Under certain outdoor air conditions, AHU dampers may be modulated to provide a mixed air condition that can satisfy the cooling load without the need for mechanical cooling.

Building thermal mass storage: storing energy in the form of sensible heat in building materials, interior equipment, and furnishings.

Capacity: heating or cooling output at design or rating condition or, in certain contexts, at current operating condition.

CAV systems: air-handling systems that have fixed-speed fans and provide no feedback control of airflow to the zones. Zone temperature is controlled to a set point using a feedback controller that regulates the amount of local reheat applied to the air entering each zone.

Charging: storing cooling capacity by removing heat from a cool storage device; or storing heating capacity by adding heat to a heat storage device.

Chilled-/hot-water/steam loop: consists of pumps, pipes, valves, and controls. Two different types of pumping systems are considered in this chapter: primary and primary/secondary. With a **primary pumping** system, a single piping loop is used and water that flows through the chiller or boiler also flows through the cooling or heating coils. When steam is used, a steam piping loop sends steam to a hot-water converter, returning hot condensate back to the boiler. Another piping loop then carries hot water through the heating coils. Often, fixed-speed pumps are used with their control dedicated to chiller or boiler control. **Dedicated control** means that each pump is cycled on and off with the chiller or boiler that it serves. Systems with fixed-speed pumps and two-way cooling or heating coil valves often incorporate a **water bypass valve** to maintain relatively constant flow rates and reduce system pressure drop and pumping costs at low loads. The valve is typically controlled to maintain a fixed pressure difference between the main supply and return lines. This set point is termed the **chilled-** or **hot-water loop differential pressure**. Sometimes, primary systems use one or more variable-speed pumps to further reduce pumping costs at low loads. In this case, water bypass is not used and pumps are controlled directly to maintain a water loop differential pressure set point.

Chiller or boiler plant: one or more chillers or boilers, typically arranged in parallel with dedicated pumps, provide the primary source of cooling or heating for the system. Individual feedback controllers adjust the capacity of each chiller or boiler to maintain a specified supply water temperature (or steam header pressure for steam boilers). Additional control variables include the number of chillers or boilers operating and the relative loading for each. For a given total cooling or heating requirement, individual chiller or boiler loads can be controlled by using different water supply set points for constant individual flow or by adjusting individual flows for identical set points.

Chiller priority: control strategy for partial storage systems that uses the chiller to directly meet as much of the load as possible, normally by operating at full capacity most of the time. Thermal storage is used to supplement chiller operation only when the load exceeds the chiller capacity.

Condenser water loop: consists of cooling towers, pumps, piping, and controls. Cooling towers reject heat to the environment through heat transfer and possibly evaporation (for wet towers) to the ambient air. Typically, large towers incorporate multiple cells sharing a common sump, with individual fans having two or more speed settings. Often, a feedback controller adjusts tower fan speeds to maintain a temperature set point for water leaving the cooling tower, termed the **condenser water supply temperature**. Typically, condenser water pumps are dedicated to individual chillers (i.e., each pump is cycled on and off with the chiller it serves).

COP: heating or cooling output divided by electrical power input; may include chilled-water (CW) pump and tower fan as well as compressor power (see also **System COP**).

Demand limiting: a partial storage operating strategy that limits the capacity of the cooling system during the on-peak period. The cooling system capacity may be limited based on its cooling capacity, its electric demand, or the facility demand.

Discharge capacity: maximum rate at which cooling can be supplied from a cool storage device.

Discharging: using stored cooling capacity by adding thermal energy to a cool storage device or removing thermal energy from a heat storage device.

Ice storage: types of ice storage systems include the following. An **ice harvester** is a machine that cyclically forms a layer of ice on a smooth cooling surface, utilizing the refrigerant inside the heat exchanger, then delivers it to a storage container by heating the surface of the cooling plate, normally by reversing the refrigeration process and delivering hot gases inside the heat exchanger. In **ice-on-coil-external melt**, tubes or pipes (coil) are immersed in water and ice is formed on the outside of the tubes or pipes by circulating colder secondary medium or refrigerant inside the tubing or pipes, and is melted externally by circulation the unfrozen water outside the tubes or pipes to the load. **Ice-on-coil-internal melt** is similar, except the ice is melted internally by circulating the same secondary coolant or refrigerant to the load.

Load leveling: a partial storage sizing strategy that minimizes storage equipment size and storage capacity. The system operates with the refrigeration equipment running at full capacity for 24 h to meet the normal cooling minimum load profile and, when the load is less than the chiller output, the excess cooling is stored. When the load exceeds the chiller capacity, the additional cooling requirement is obtained from the thermal storage system.

Load profile: compilation of instantaneous thermal loads over a period of time, normally 24 hours.

Nominal chiller capacity: (1) chiller capacity at standard ARI (*Standard* 550/590) rating conditions, or (2) chiller capacity at a given operating condition selected for the purpose of quick chiller sizing selections.

Partial storage: a cool storage sizing strategy in which only a portion of the on-peak cooling load is met from thermal storage, with the remainder of the load being met by operating the chilling equipment.

Precooling: a thermal energy storage (TES) strategy that allows a properly designed chiller system to operate more efficiently with lower condensing temperatures (low night ambient temperature) higher evaporating temperatures (15 to 20°C chilled water) and at or near its most efficient part-load point. Precooling can be applied to the conditioned space, or directly to mass by passing chilled air or water through building elements such as concrete floor decks.

Primary/secondary chilled- or hot-water systems: systems designed specifically for variable-speed pumping. In the primary loop, fixed-speed pumps provide a relatively constant flow of water to the chillers or boilers. This design ensures good chiller or boiler performance and, for chilled-water systems, reduces the risk of freezing on evaporator tubes. The secondary loop incorporates one or more variable-speed pumps that are controlled to maintain a water loop differential pressure set point. The primary and secondary loops may be separated by a heat exchanger. However, it is more common to use direct coupling with a common pipe.

Storage capacity: the maximum amount of cooling (or heating) that can be achieved by the stored medium in the thermal storage device. **Nominal storage capacity** is a theoretical capacity of the thermal storage device. In many cases, this may be greater than usable storage capacity. This measure should not be used to compare usable capacities of alternative storage systems.

Storage cycle: a period (usually one day) in which a substantial charge and discharge of a thermal storage device has occurred, beginning and ending at the same state or same time of day.

Storage efficiency: the ratio of useful heating or cooling extracted during the discharge cycle to that imparted to storage during the charging cycle. One may also define an exergic efficiency that accounts for mixing and thermal destratification as well as conduction losses.

Storage inventory: the amount of usable heating or cooling capacity remaining in a thermal storage device.

Storage priority: a control strategy that uses stored cooling to meet as much of the load as possible. Chillers are operated only if the load exceeds the storage system's available cooling capacity.

Supply air temperature: temperature of air leaving an AHU or package unit. The temperature supplied to the zones may differ from the supply air temperature because of heat transfer in the ductwork and local reheat. A local-loop controller adjusts the flow of water through the air handler cooling/heating coil using a two- or three-way valve to maintain a specified set-point temperature for the air downstream of the cooling/heating coil. The value of the supply air temperature set-point will affect energy consumption and can be adjusted by the supervisory control system.

System capacity: maximum amount of cooling that can be supplied by the entire cooling system, which may include the chillers and the thermal storage. **Usable storage capacity** is the total amount of beneficial cooling able to be discharged from a thermal storage device. (This may be less than the nominal storage capacity, because the distribution header piping may not allow discharging the entire cooling capacity of the thermal storage device.)

System COP: ratio of cooling rate ($kW_{thermal}$) to system input power ($kW_{electric}$) required to operate all distribution fans and pumps as well as compressors and condenser or cooling tower fans and pumps.

Temperature set point: zone temperature set points are typically fixed values within the comfort zone during the occupied time, and zone humidity is allowed to "float" within a range dictated by the system design and choice of the supply air set-point temperature. **Night setup** is often used in summer to raise the zone temperature set points during unoccupied times and reduce the cooling requirements. Similarly, **night setback** is often used in winter to lower the zone temperature set points during unoccupied times and reduce the heating requirements. Setup and setbacks can also be used during occupied periods to temporarily curtail energy consumption.

Thermal energy storage (TES): thermal energy storage systems are of three general types. **Discrete TES** uses a tank of water (usually stratified), packed bed of rock or phase-change material, or a tank of ice and water with immersed coil. **Intrinsic (or passive) TES** uses the thermal capacitance of the building fabric, such as concrete columns, beams and decks, or wall board, possibly augmented by phase-change material.

Thermally activated building systems (TABS): floors or other elements are cooled directly with embedded pipes or ducts, giving storage capacity and efficiency substantially greater than can achieved by passive TES.

Total cooling load: integrated thermal load that must be met by the cooling plant over a given period of time.

Variable-air-volume (VAV) systems: systems that use a feedback controller that regulates the airflow to each zone to maintain zone temperature set point. The zone airflows are regulated using dampers located in VAV boxes in each zone. VAV systems also incorporate feedback control of the primary airflow through various means of fan capacity control. Typically, inputs to a fan outlet damper, inlet vanes, blade pitch, or variable speed motor are adjusted to maintain a **duct static pressure** set point in the supply duct, as described in Chapter 48.

2. METHODS

2.1 CONTROL VARIABLES

Systems and Controls

Figures 1 and 2 show schematics of typical centralized cooling and heating systems for which control strategies are presented in this chapter. For cooling systems, the strategies in this chapter generally assume that the equipment is electrically driven and that heat is rejected to the environment by cooling towers. For heating systems, boilers may be fired by a variety of fuels or powered by electricity, but are typically fired from either natural gas or #2 or #6 fuel oil. However, some strategies apply to any type of system (e.g., return from night setup or setback). For describing different systems and controls, it is useful to divide the system into the subsystems depicted in Figures 1 and 2: air distribution system, chilled-/hot-water loop, chiller/boiler plant, condenser water loop. A variant of the chilled-water system shown in Figure 1 uses chilled water directly for sensible cooling by radiant panels, chilled beams, or radiant floors. Similar strategies can be applied to variable-speed controls for air-cooled chiller condenser fans.

VAV cooling system controls (Figure 1) respond to changes in building cooling requirements. As the cooling load increases, the zone temperature rises as energy gains to the zone air increase. The zone controller responds to higher temperatures by increasing local flow of cool air by opening the damper in the VAV unit. Opening the damper reduces static pressure in the primary supply duct, which

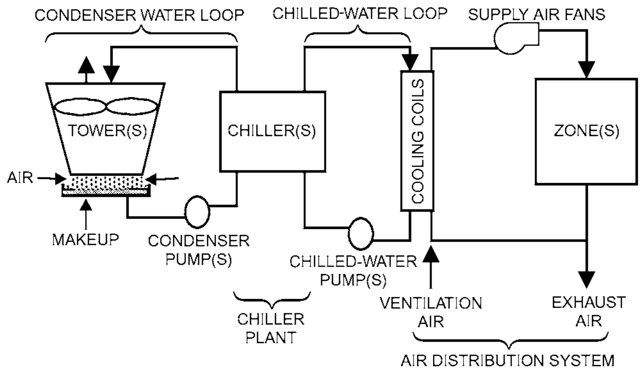

Fig. 1 Schematic of Chilled-Water Cooling System

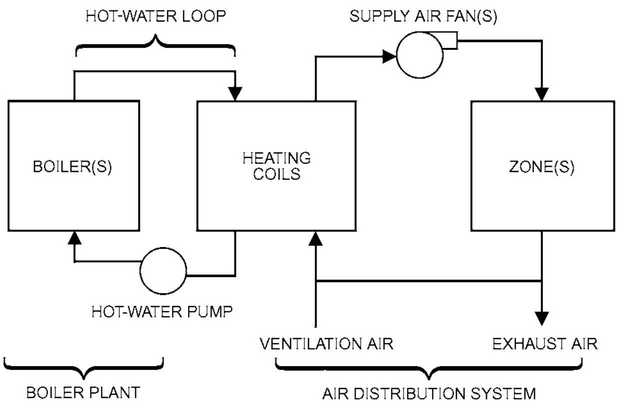

Fig. 2 Schematic of Hot-Water Heating System

causes the fan controller to create additional airflow. With greater airflow, the supply air temperature of the cooling coils increases, which causes the air handler feedback controller to increase the water flow by further opening the cooling coil valves. This increases the chilled-water flow and/or the chilled water return temperature (i.e., increases the cooling load).

Control of a radiant cooling system (a variant of Figure 1) responds directly to zone load by increasing the chilled-water flow rate. The chilled-water temperature may be controlled by the zone with greatest demand or by an open-loop control.

Control of a hot-water heating system (Figure 2) is similar. As the heating load increases, the zone temperature falls as energy gains to the zone air decrease. The zone controller responds to lower temperatures by opening a control valve and increasing the flow of hot water through the local reheat coil. The supply airflow rate is usually maintained at its minimum value when a VAV system is in heating mode. Increasing water flow through the reheat coils reduces the temperature of the water returned to the boiler. With lower return water temperature, the supply water temperature drops, which causes the feedback controller to increase the boiler firing rate to maintain the desired supply water temperature.

For both heating and cooling modes, an increase in the building load results in an increase in water flow rate, which is ultimately propagated through the central heating/cooling system. For fixed-speed chilled- or hot-water pumps, the differential pressure controller closes the chilled- or hot-water bypass valve and keeps the overall flow relatively constant. For variable-speed pumping, the differential pressure controller increases pump speed. In a chilled-water system, the return water temperature and/or flow rate to the chillers increases, leading to an increase in the chilled-water supply temperature. The chiller controller responds by increasing the chiller cooling capacity to maintain the chilled-water supply set point (and match the cooling coil loads). The increased energy removed by the chiller increases the heat rejected to the condenser water loop, which increases the temperature of water leaving the condenser. The increased water temperature entering the cooling tower increases the water temperature leaving the tower. The tower controller responds to the higher condenser water supply temperature and increases the tower airflow. At some load, the current set of operating chillers is not sufficient to meet the load (i.e., maintain the chilled-water supply set points) and an additional chiller is brought online. For a hot-water system, the return water temperature and/or flow rate to the boilers decreases, leading to a decrease in the hot-water supply temperature. The boiler controller responds by increasing the boiler heating capacity to maintain the hot-water supply set point (and match the heating coil loads).

For all-electric cooling without thermal storage, minimizing power at each point in time is equivalent to minimizing energy costs. Therefore, supervisory control variables should be chosen to maximize the **coefficient of performance (COP)** of the system at all times while meeting the building load requirements. The system COP is defined as the ratio of total cooling load to total system power consumption. In addition to the control variables, the COP depends primarily on the cooling load and the ambient wet- and dry-bulb temperatures. Often, the cooling load is expressed in a dimensionless form as a part-load ratio (PLR), which is the cooling load under a given condition divided by the design cooling capacity.

For cooling or heating systems with thermal storage, performance depends on the time history of charging and discharging. In this case, controls should minimize operating costs integrated over the billing period or storage cycle. In addition, safety features that minimize the risk of prematurely depleting storage capacity may be important.

2.2 SUPERVISORY CONTROL STRATEGIES

For any of the scenarios listed previously, several local-loop controllers respond to load change to maintain specified set points. A supervisory controller establishes modes of operation and chooses (or resets) values of set points. At any given time, cooling or heating needs can be met with various combinations of modes of operation and set points. This chapter discusses several methods for determining supervisory control variables that provide good overall performance, including resetting set points such as chilled- or hot-water supply temperature, supply air temperatures, differential pressure on water loops, and supply air static pressure. Another form of supervisory control includes sequencing equipment such as chillers, boilers, pumps, and fans to achieve energy-efficient operation. Optimization may be applied to cost, energy, or comfort constraints.

Sampling Intervals for Reset Controls

Proper sampling intervals are required when resetting the set point for proportional-integral (PI) feedback control loops to prevent oscillation of the process variable in those loops. In general, the sampling time interval between reset commands should be greater than the settling time for the loop. For example, resetting both the chilled-water supply temperature set point and cooling coil discharge air temperature set point is necessary for optimal control. In this case, resetting the set points for chilled-water supply temperature and cooling coil discharge air temperature should not occur simultaneously, but at staggered intervals; the interval of reset for either loop should be greater than the settling time for the coil (the time for the discharge air temperature of the coil to reach a new steady-state temperature).

For cascaded loops, the sampling interval between reset commands should be greater than the settling time for the faster inner loop. An example of a cascaded loop is a VAV box controller with its flow set point determined from the space temperature of its associated zone, and the box damper controlled to maintain the flow set point. For example, in resetting static pressure set point on a variable-speed air-handler fan based on VAV box damper position, the interval between resets should be greater than the settling time of the flow control loop in a pressure-independent VAV box. (Settling time in this example is the time for the flow rate to reach a new steady-state value.)

2.3 STATIC OPTIMIZATION

Optimal supervisory control of building systems involves determining the control that minimizes the total operating cost. Static optimization addresses the problem of optimizing the operation of a system at a given instant in time by operating each component of the system at the conditions which achieve an optimal result, such as minimal cost. Static optimization techniques applied to a general simulation can be used to determine optimal supervisory control variables. The simulation may be based on physical (Hiller and Glicksman 1977; Stoecker 1980) or empirical models. However, for control variable optimization, empirical and semiempirical models (where model parameters are estimated from measurements) are often used. This section presents methods for static optimization useful in determining optimal control for various applications.

General Static Optimization Problem

Figure 3 depicts the general nature of the static optimization problem for a system of interconnected components. Each component in a system is represented as a separate set of mathematical relationships organized into a computer model. Its output variables and operating cost are functions of parameters, input, output, and uncontrolled and controlled variables. The structure of the system of

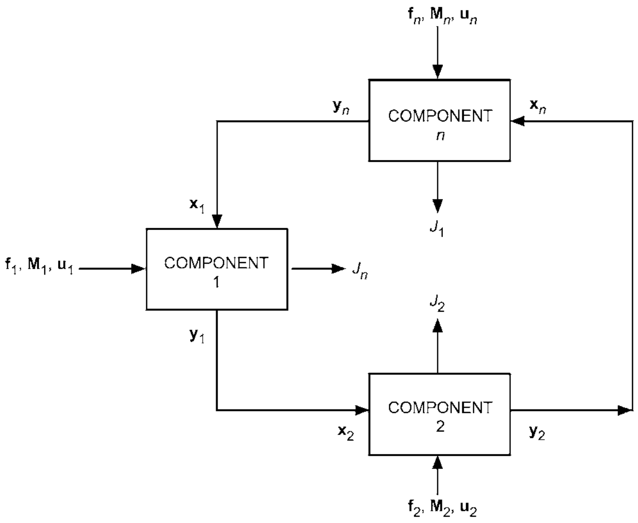

Fig. 3 Schematic of Modular Optimization Problem

equations to be solved is dictated by the manner in which the components are interconnected.

A typical optimization problem is formally stated as the minimization of the sum of the operating costs of each component J_i with respect to all discrete and continuous controls, or

Minimize

$$J(\mathbf{f}, \mathbf{M}, \mathbf{u}) = \sum_{i=1}^{n} J_i(\mathbf{x}_i, \mathbf{y}_i, \mathbf{f}_i, \mathbf{M}_i, \mathbf{u}_i) \tag{1}$$

with respect to **M** and **u**, subject to equality constraints of the form

$$\mathbf{g}(\mathbf{f}, \mathbf{M}, \mathbf{u}) = \begin{bmatrix} \mathbf{g}_1(\mathbf{f}_1, \mathbf{M}_1, \mathbf{u}_1, \mathbf{x}_1, \mathbf{y}_1) \\ \mathbf{g}_2(\mathbf{f}_2, \mathbf{M}_2, \mathbf{u}_2, \mathbf{x}_2, \mathbf{y}_2) \\ \cdot \\ \mathbf{g}_n(\mathbf{f}_n, \mathbf{M}_n, \mathbf{u}_n, \mathbf{x}_n, \mathbf{y}_n) \end{bmatrix} = 0 \tag{2}$$

and inequality constraints of the form

$$\boldsymbol{h}(\mathbf{f}, \mathbf{M}, \mathbf{u}) = \begin{bmatrix} \boldsymbol{h}_1(\mathbf{f}_1, \mathbf{M}_1, \mathbf{u}_1, \mathbf{x}_1, \mathbf{y}_1) \\ \boldsymbol{h}_2(\mathbf{f}_2, \mathbf{M}_2, \mathbf{u}_2, \mathbf{x}_2, \mathbf{y}_2) \\ \cdot \\ \boldsymbol{h}_n(\mathbf{f}_n, \mathbf{M}_n, \mathbf{u}_n, \mathbf{x}_n, \mathbf{y}_n) \end{bmatrix} \geq 0 \tag{3}$$

where, for any component i,

- $\mathbf{x}_i$ = vector of input stream variables
- $\mathbf{y}_i$ = vector of output stream variables
- $\mathbf{f}_i$ = vector of uncontrolled variables
- $\mathbf{M}_i$ = vector of discrete control variables
- $\mathbf{u}_i$ = vector of continuous control variables
- J_i = operating cost
- $\mathbf{g}_i$ = vector of equality constraints
- $\boldsymbol{h}_i$ = vector of inequality constraints

Typical input and output stream variables for thermal systems are temperature and mass flow rate. Uncontrolled variables are quantities that may not be controlled, but that affect component performance and/or costs, such as ambient dry- and wet-bulb temperature.

Both equality and inequality constraints arise in the optimization of HVAC systems. One example of an equality constraint that arises when two or more chillers are in operation is that the sum of their capacities must equal the total load. The simplest type of inequality constraint is a bound on a control variable. For example, lower and upper limits are necessary for the chilled-water set temperature, to avoid freezing in the evaporator and to provide adequate dehumidification for the zones. Any equality constraint may be rewritten in the form of Equation (2) such that when it is satisfied, the constraint equation is equal to zero. Similarly, inequality constraints may be expressed as Equation (3), so that the constraint is satisfied when the result is greater than or equal to zero.

Braun (1988) and Braun et al. (1989a) presented a component-based nonlinear optimization and simulation tool and used it to investigate optimal performance. Each component is represented as a separate subroutine with its own parameters, controls, inputs, and outputs. The optimization problem is solved efficiently by using second-order representations of costs. Applying component-based optimization led to many guidelines for control and a simplified system-based optimization methodology. In particular, the results showed that optimal set points could be correlated as linear functions of load and ambient wet-bulb temperature.

Zakula et al. (2011, 2012) show that, for chillers with high part-load efficiency over a wide range of compressor speed, optimal condenser fan speed and chilled-water specific flow rate are highly nonlinear functions of cooling load, and without optimal control, transport power can be much greater than compressor power at part-load and low-lift conditions. Gayeski et al. (2012) demonstrated an empirical method for deriving near-optimal control laws from measured performance.

Cumali (1988, 1994) presented a method for real-time global optimization of HVAC systems, including the central plant and associated piping and duct networks. The method uses a building load model for the zones, based on a coupled weighting-factor method similar to that used in DOE-2 (Winkelman et al. 1993). Variable time steps are used to predict loads over a 5 to 15 min period. The models are based on thermodynamic, heat transfer, and fluid mechanics fundamentals and are calibrated to match actual performance, using data obtained from the building and plant. Pipe and duct networks are represented as incidence and circuit matrices, and both dynamic and static losses are included. Fluid energy transfers are coupled with zone loads using custom weighting factors calibrated for each zone. The resulting equations are grouped to represent feasible equipment allocations for each range of building loads, and solved using a nonlinear solver. The objective function is the cost of delivering or removing energy to meet the loads, and is constrained by the comfort criteria for each zone. The objective function is minimized using the reduced gradient method, subject to constraints on comfort and equipment operation. Optimization starts with the feasible points as determined by a nonlinear equation solver for each combination of equipment allocation. The values of set points that minimize the objective function are determined; the allocation with the least cost is the desired operation mode. Results obtained from this approach have been applied to high-rise office buildings in San Francisco with central plants, VAV, dual-duct, and induction systems. Electrical demand reductions of 8 to 12% and energy savings of 18 to 23% were achieved.

2.4 DYNAMIC OPTIMIZATION

Whereas static optimization addresses operation of a building system at a given point in time, accounting for the operating characteristics of each component, dynamic optimization addresses control of buildings systems over time. As such, dynamic optimization must account for the possibility that future conditions (e.g., weather, utility prices) may affect present optimal control decisions, and that present control decisions will affect operating conditions and optimal control decisions in the future. Established methods of optimal control (e.g., model-predictive control, dynamic programming) may be used to implement dynamic optimization of a building system. Daily, monthly, and annual cooling costs are particularly sensitive to time of use. Specific methods of dynamic optimization presented here are relevant to the applications in this chapter, with a focus on cooling systems largely because of the highly weather- and load-dependent nature of optimal cooling system controls.

Cooling Systems with Discrete Storage

Optimal supervisory control for cooling systems with discrete storage, such as water- or ice-storage, is a function of several factors including utility rate structure, load profile, chiller characteristics, storage characteristics, and weather. For a utility rate structure that includes both time-of-use energy and demand charges, the optimal strategy can depend on variables that extend over a monthly time scale. The overall problem of minimizing the utility cost over a billing period (e.g., a month) can be mathematically described as follows:

Minimize

$$J = \sum_{k=1}^{N} (E_k P_k \Delta\tau) + \text{Max}_{1 \le k \le N}(D_k P_k) \tag{4}$$

with respect to the control variables ($u_1, u_2, \ldots, u_N$) and subject to the following constraints for each stage k:

$$u_{min,k} \le u_k \le u_{max,k} \tag{5}$$

$$x_k = f(x_{k-1}, u_k, k) \tag{6}$$

$$x_{min} \le x_k \le x_{max} \tag{7}$$

$$x_N = x_0 \tag{8}$$

where J is the utility cost associated with the billing period (e.g., a month); $\Delta\tau$ is the stage time interval (typically equal to the time window over which demand charges are levied, e.g., 0.25 h); N is the number of time stages in a billing period, and for each stage k, P is the average building electrical power (kW); E is the energy cost rate or cost per unit of electrical energy ($/kWh); D is the demand charge rate or cost per peak power rate over the billing period ($/kW); u is the control variable that regulates the rate of energy removal from or addition to storage over the stage; u_{max} is the maximum value for u; u_{min} is the minimum value for u; x is the state of storage at the end of the stage; x_{max} is the maximum admissible state of storage; x_{min} is the minimum admissible state of storage; and f is a state equation that relates the state of storage at stage k to the previous state and current control.

The first and second terms in Equation (4) are the total cost of energy use and building demand for the billing period. Both energy and demand cost rates can vary with time, but typically have two values associated with on- and off-peak periods. An even more complex cost optimization results if the utility includes ratchet clauses in which the demand charge is the maximum of the monthly peak demand cost and some fraction of the previous monthly peak demand cost during the cooling season. With real-time pricing, the demand charge (the second term in Equation [4]) might not exist and the hourly energy rates would vary over time according to generation and transmission costs.

For ice or chilled-water storage systems, the control variable could be the rate at which energy is added or removed from storage. In this case, the constraint given by Equation (5) arises from capacity limits of the chiller and storage heat exchanger and can also depend on the state of storage. For use of building thermal mass, the control variable could be the zone temperature(s) and the constraint of Equation (5) would be associated with comfort considerations or capacity constraints. Different comfort limits would probably apply for occupied and unoccupied periods.

In this general formulation the state equation, Equation (6), is treated as an equality constraint. The state of storage at any stage k is a function of the previous state x_{k-1}, the control u_k, and other time-dependent factors (e.g., ambient temperature). For lumped storage systems (e.g., ice), the state of storage can be characterized with a single-state variable. However, for a distributed storage (e.g., a building structure), multiple-state equations may be necessary to properly characterize the dynamics. The state of storage may be constrained to always lie between states corresponding to full discharge and full charge [Equation (7)]. The constraint of Equation (8) forces a steady-periodic solution to the problem. This constraint becomes less important as the length of analysis (**control horizon**) increases.

To determine a control strategy for charging and discharging storage that minimizes utility cost, Equation (4) must be minimized over the entire billing period because of the influence of the demand charge. Alternatively, the optimization problem can be posed as a series of shorter-term (e.g., daily or weekly) optimizations with a constraint on the peak demand charge according to the following:

Minimize

$$J = \sum_{k=1}^{N} (E_k P_k \Delta\tau) + \text{TDC} \tag{9}$$

with respect to the control variables ($u_1, u_2, \ldots, u_N$) and a billing period **target demand cost (TDC)** and subject to the constraints of Equations (5) to (8) and the following additional constraint:

$$D_k P_k \le \text{TDC} \tag{10}$$

which arises from the form of the cost function chosen for Equation (9). At each stage, the demand cost must be less than or equal to the peak demand cost for the billing period. The peak or target demand cost TDC is an optimization variable that affects both energy and demand costs. Using Equation (9) rather than Equation (4) simplifies the numerical solution.

Two types of solutions to the optimization problem are of interest: (1) minimum billing-period operating cost and (2) minimum energy cost for a specified TDC and short-term horizon (e.g., a day). The first problem is useful for benchmarking the best control and minimum cost through simulation, but is not useful for online control because forecasts beyond a day are unreliable. Mathematical models of the building, equipment, and storage can be used to estimate load requirements, power, and state of storage. The second solution can be used for online control in conjunction with a system model and a forecaster.

For minimum operating costs (first optimization problem), $N + 1$ variables must be determined to minimize the cost function of Equation (9) over the length of the billing period. For a given value of TDC, minimization of Equation (9) with respect to the N charging (and discharging) control variables may be accomplished using dynamic programming (Bellman 1957) or some other direct search method. The primary advantages of dynamic programming are that it handles constraints on both state and control variables in a straightforward manner and also guarantees a global minimum. However, the computation becomes excessive if more than one state variable is needed to characterize storage. The N-variable optimization problem is resolved at each iteration of an outer loop optimization for TDC. Brent's (1973) algorithm is a robust method for solving the one-dimensional optimization for the demand target because it does not require derivative information. This is important because TDC appears as an inequality constraint in the dynamic programming solution and may not always be triggered.

For shorter-term optimizations (second optimization problem), dynamic programming can still be used to minimize Equation (9) with respect to the N charging (and discharging) control variables for a specified TDC. However, an optimal value for TDC cannot be determined when demand charges are imposed. For ice storage, Drees and Braun (1996) found that a simple and near-optimal approach is to set TDC to zero at the beginning of each billing period. Therefore, the optimizer minimizes the demand cost for the first optimization period (e.g., a day) and then uses this demand as the target for the billing period unless it is exceeded. For online optimization, the optimization problem can be resolved at regular intervals (e.g., 1 h) during each day's operation.

Ice Storage Control Optimization. Several researchers have studied optimal supervisory control of ice storage systems. Braun (1992) solved daily optimization problems for two limiting cases: minimum energy (i.e., no demand charge) and minimum demand (no energy charge). Results of the optimizations for different days and utility rates were compared with simple chiller-priority and load-limiting control strategies (see the section on Supervisory Control Strategies). For the ice-on-pipe system considered, load-limiting control was found to be near optimal for both energy and demand costs with on-peak to off-peak energy cost ratios greater than about 1.4.

Drees and Braun (1996) solved both daily and monthly optimization problems for a range of systems with internal-melt area-constrained ice storage tanks. The optimization results were used to develop rules that became part of a rule-based, near-optimal controller presented in the section on Supervisory Control Strategies. For a range of partial-storage systems, load profiles, and utility rate structures, the monthly electrical costs for the rule-based control strategy were, on average, within about 3% of the optimal costs.

Henze et al. (1997a) developed a simulation environment that determines the optimal control strategy to minimize operating cost, including energy and demand charges, over the billing period. A modular cooling plant model was used that includes three compressor types (screw, reciprocating, and centrifugal), three ice storage media (internal melt, external melt, and ice harvester), a water-cooled condenser, central air handler, and all required fans and pumps. The simulation tool was used to compare the performance of chiller-priority, constant-proportion, storage-priority, and optimal control.

Henze et al. (1997b) presented a predictive optimal controller for use with **real-time pricing (RTP)** structures. For the RTP structure considered, the demand term of Equation (9) disappears and the optimization problem only involves a 24 h period. The controller calculates the optimal control trajectory at each time step (e.g., 30 min), executes the first step of that trajectory, and then repeats that process at the next time step. The controller requires a model of the plant and storage, along with a forecast of the future cooling loads.

To apply the optimization approach described in the previous section, models for storage, system power consumption, and building loads are needed. For online optimization, simple empirical models that can be trained using system measurements are appropriate. However, physically based models would be best for simulation studies.

The optimization studies that have been performed for ice storage assumed that the state of storage could be represented with a single-state variable. Assuming negligible heat gains from the environment, the relative state of charge (i.e., fraction of the maximum available storage capacity) for any stage k is

$$x_k = x_{k-1} + \frac{u_k \Delta t}{C_s} \tag{11}$$

where C_s is the maximum change in internal energy of the storage tank that can occur during a discharge cycle and u_k is the storage charging rate. The state of charge defined in this manner must be between zero and one.

The charging rate for storage depends on the storage heat exchanger area, secondary fluid flow rate and inlet temperature, and the thickness of ice. At any stage, the maximum charging rate can be expressed as

$$u_{k,max} = \varepsilon_{c,k,max} \dot{m}_{f,max} c_f (t_s - t_{f,i}) \tag{12}$$

where $\varepsilon_{c,k,max}$ is the heat transfer effectiveness for charging at the current state of storage if the secondary fluid flow rate were at its maximum value of $\dot{m}_{f,max}$, c_f is the secondary fluid specific heat, $t_{f,i}$ is the temperature of secondary fluid inlet to the tank, and t_s is the temperature at which the storage medium melts or freezes (e.g., 0°C).

The minimum charging rate is actually the negative of the maximum discharging rate and can be given by

$$u_{k,min} = \varepsilon_{d,k,max} \dot{m}_{f,max} c_f (t_s - t_{f,i}) \tag{13}$$

where $\varepsilon_{d,k,max}$ is the heat transfer effectiveness for discharging at the current state of storage if the secondary fluid flow rate were at its maximum value of $\dot{m}_{f,max}$.

In general, the heat transfer effectiveness for charging and discharging at the design flow can be correlated as a function of state of charge using manufacturers' data (e.g., Drees and Braun 1995).

A model for the total building power is also needed. At any time

$$P = P_{noncooling} + P_{plant} + P_{dist} \tag{14}$$

where $P_{noncooling}$ is the building electrical use that is not associated with the cooling system (e.g., lights), P_{plant} is the power needed to operate the cooling plant, and P_{dist} is the power associated with the distribution of secondary fluid and air through the cooling coils. The models used by Henze et al. (1997a) predict cooling plant and distribution system power with a component-based simulation that is appropriate for simulation studies. Alternatively, for online optimization, plant and distribution system power can be represented with empirical correlations. Drees (1994) used curve-fits of plant power consumption in terms of cooling load and ambient wet-bulb temperature. At any time, the cooling requirement for the chiller is the difference between the building load requirement and the storage discharge rate. The chiller supply temperature is then determined from an energy balance on the chiller and used to evaluate the limits on the storage charging and discharging rates in Equations (12) and (13). The chiller cooling rate must be greater than a minimum value for safe operation and less than the chiller capacity. Drees (1994) correlated the maximum cooling capacity as a function of the ambient wet-bulb temperature and the chiller supply temperature. For simulation studies, a building model may be used to estimate building cooling loads. For online optimization, a forecaster would provide estimates of future building cooling loads.

Cooling Systems with Thermally Activated Building Systems

Optimal supervisory control for precooling building mass usually requires transient thermal response models of the conditioned zones, because the state of charge cannot be measured and the fully charged and discharged states are not well defined. For passive TES, Equation (4) is retained as the objective function and Equation (14) also applies, with P_{plant} a function of capacity u_k and conditions that affect system COP. One of these conditions is chilled-water return temperature, which is in turn a function of current and past capacities and zone temperatures and past return temperatures: essentially, a conduction transfer function. The constraint on plant capacity (Equation [5]) is retained as well.

Equation (6) is replaced by a transient thermal response model that expresses room temperature x_k in terms of current and past weather, direct heating and cooling (including direct solar and internal gains), and control actions $u_k \ldots u_{k-n}$, and in terms of past room temperatures $x_{k-1} \ldots x_{k-n}$. Seem et al.'s (1989a) **comprehensive room transfer function (CRTF)** is such a model. Methods and results of training a CRTF have been reported by Armstrong et al. (2000, 2006a, 2006b) and Gayeski et al. (2012). Equation (7) serves to constrain room temperature during occupied hours, and Equation (8) is not normally needed if time step 0 is assigned to an occupied hour. Note that, for TABS, the supervisory control cannot generally be expressed in terms of zone temperature set points.

Equation (4) may involve only the chiller power used to meet sensible load, $P = u/\text{COP}(u,t)$. It is possible (e.g., with liquid desiccant storage or ice storage) to shift latent load. However, with enthalpy recovery (see Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*), latent loads are a small fraction of total load and not usually considered to be attractive for peak shifting; in this case, DOAS system power may be treated as part of the non-cooling power term in Equation (14). Setting $E = 1$ and $D = 0$ in Equation (4) will produce the highest energy savings.

3. CONTROL STRATEGIES AND OPTIMIZATION

3.1 CONTROL STRATEGIES FOR COOLING TOWER FANS

Figure 4 shows a schematic of the condenser loop for a typical chilled-water unit consisting of centrifugal chillers, cooling towers, and condenser water pumps. Typically, the condenser water pump control is directed by the chiller control to provide relatively constant flow for individual chillers. However, the cooling tower cells may be independently controlled to maximize system efficiency.

Typically, cooling tower fans are controlled using a feedback controller that attempts to maintain a temperature set point for the water supplied to the chiller condensers. Often, the condenser water supply temperature set point is held constant. However, a better strategy is to maintain a constant temperature difference between the condenser water supply and the ambient wet bulb (constant approach). Additional savings are possible through optimal control.

With a single feedback controller, the controller output signal must be converted to a specific fan sequence that depends on the number of operating cells and the individual fan speeds. Typically, with the discrete control associated with one- or two-speed tower fans, the set point cannot be realized, resulting in the potential for oscillating tower fan control. Fan cycling can be reduced by using dead bands, "sluggish" control parameters, and/or lower limits for on and off periods.

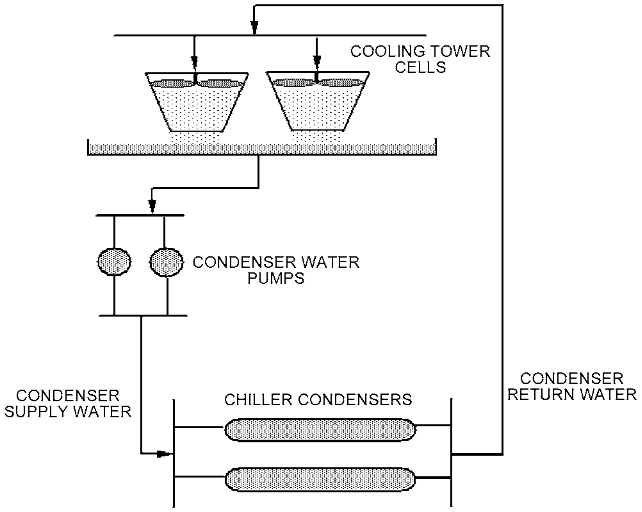

Fig. 4 Condenser Water Loop Schematic

Braun and Diderrich (1990) demonstrated that feedback control for cooling tower fans could be eliminated by using an open-loop supervisory control strategy. This strategy requires only measuring chiller loading to specify the control and is inherently stable. The tower fan control is separated into two parts: tower sequencing and optimal airflow. For a given total tower airflow, general rules for optimal tower sequencing are used to specify the number of operating cells and fan speeds that give the minimum power consumption for both the chillers and tower fans. The optimal tower airflow is estimated with an open-loop control equation that uses design information for the cooling tower and chiller. The computational procedure is presented in this section, and the control strategy is summarized in a set of steps and sample calculations. The procedures can be adapted to applications where fan and cell performance characteristics vary among cells.

Near-Optimal Tower Fan Sequencing

For variable-speed fans, minimum power consumption results when all cooling tower cells are operated under all conditions. Tower airflow varies almost linearly with fan speed, whereas the fan power consumption varies approximately with the cube of the speed. Thus, for the same total airflow, operating more cells in parallel allows for lower individual fan speeds and lower overall fan power consumption. An additional benefit associated with full-cell operation is lower water pressure drops across the spray nozzles, which results in lower pumping power requirements. However, at very low pressure drops, inadequate spray distribution may adversely affect the thermal performance of the cooling tower.

Most cooling towers use multiple-speed rather than continuously adjustable variable-speed fans. In this case, it is not optimal to operate all tower cells under all conditions. The optimal number of cells operating and individual fan speeds depend on the system characteristics and ambient conditions. However, simple relationships exist for the best sequencing of cooling tower fans as capacity is added or removed. When additional tower capacity is required, Braun et al. (1989b) showed that, in almost all practical cases, the speed of the tower fan operating at the lowest speed (including fans that are off) should be increased first. The rules for bringing cell fans online are as follows:

- **All variable-speed fans:** Operate all cells with fans at equal speeds.
- **Multiple-speed fans:** Activate lowest-speed fans first when adding tower capacity. Reverse for removing capacity.
- **Variable/multiple-speed fans:** Operate all cells with variable-speed fans at equal speeds. Activate lowest-speed fans first when adding tower capacity with multiple-speed fans. Add multiple-speed fan capacity when variable-speed fan speeds match the fan speed associated with the next multiple-speed fan increment to be added.

Similarly, for removing tower capacity, the highest fan speeds are the first to be reduced and sequences defined here are reversed.

These guidelines were derived by evaluating incremental power changes for fan sequencing. For two-speed fans, incremental power increase associated with adding a low-speed fan is less than that for increasing one to high speed if the low speed is less than 79% of the high fan speed. In addition, if the low speed is greater than 50% of the high speed, then the incremental increase in airflow is greater (and therefore thermal performance is better) for adding the low-speed fan. Most commonly, the low speed of a two-speed cooling

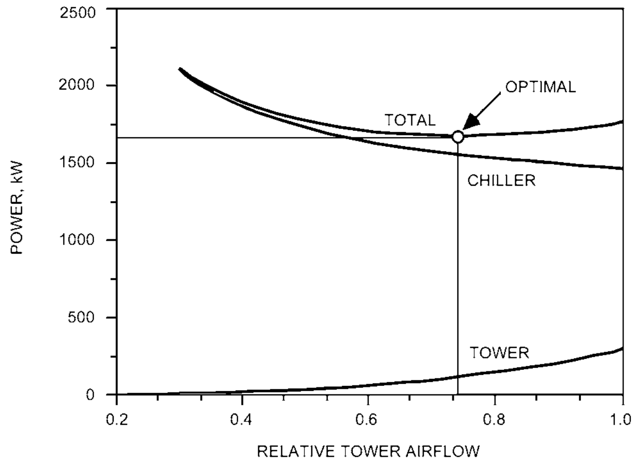

Fig. 5 Trade-Offs Between Chiller Power and Fan Power with Tower Airflow

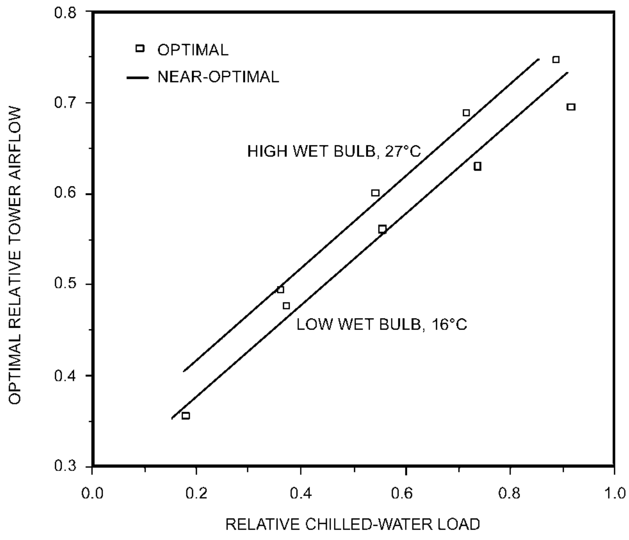

Fig. 6 Example of Optimal Tower Fan Control

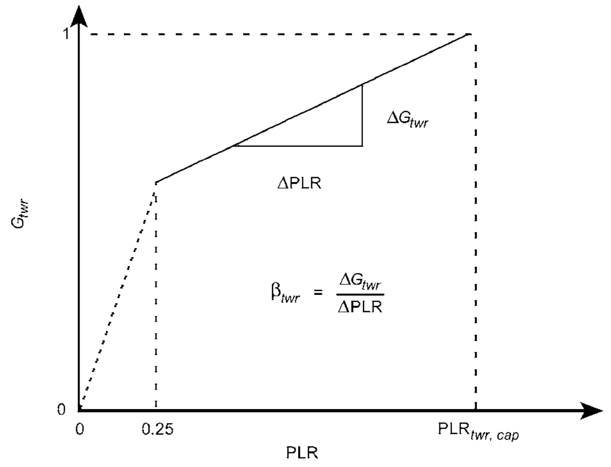

Fig. 7 Fractional Tower Airflow Versus Part-Load Ratio

tower fan is between one-half and three-quarters of full speed. In this case, tower cells should be brought online at low speed before any operating cells are set to high speed. Similarly, the fan speeds should be reduced to low speed before any cells are brought offline.

For three-speed fans, low speed is typically greater than or equal to one-third of full speed, and the difference between the high and intermediate speeds is equal to the difference between the intermediate and low speeds. In this situation, the best sequencing strategy is to activate the lowest fan speeds first when adding tower capacity and deactivate the highest fan speeds first when removing capacity. Typical three-speed combinations that satisfy these criteria are (1) one-third, two-thirds, and full speed or (2) one-half, three-quarters, and full speed.

Another issue related to control of multiple cooling tower cells with multiple-speed fans concerns the distribution of water flow to individual cells. Typically, water flow is divided equally among operating cells. Even though the overall thermal performance of the cooling tower is best when the flow is divided such that the ratio of water-to-airflow rates is identical for all cooling tower cells, equal water flow distribution results in near-optimal performance.

Near-Optimal Tower Airflow

Figure 5 shows the trade-off between the chiller and cooling tower fan power associated with increasing tower airflow for variable-speed fans given a chilled-water load. As airflow increases, fan power increases with a cubic relationship. At the same time, there is a reduction in the temperature of the water supplied to the condenser of the chiller, resulting in lower chiller power consumption. The minimum total power occurs at a point where the rate of increase in fan power with airflow is equal to the rate of decrease in chiller power. Near the optimum, the total power consumption is not very sensitive to the control. This "flat" optimum indicates extreme accuracy is not needed to determine the optimum control. In general, it is better to have too high rather than too low a fan speed.

Braun et al. (1989b) showed that the tower control that minimizes a cooling plant's instantaneous power consumption varies as a near-linear function of the load over a wide range of conditions. Although optimal control depends on the ambient wet-bulb temperature, this dependence is small compared to the load effect. Figure 6 shows an example of how the optimal tower control varies for a specific plant. The tower airflow as a fraction of the design capacity is plotted as a function of load relative to design load for two different wet-bulb temperatures. For a 10 K change in wet-bulb temperature, the optimal control varies by only about 5% of the tower capacity. This difference in control results in less than a 1% difference in the plant power consumption. Figure 6 also shows that linear functions work well in correlating the optimal control over a wide range of loads for the two wet-bulb temperatures. Given the insensitivity to wet-bulb temperature and the fact that the load is highly correlated with wet bulb, a single linear relationship is adequate in correlating the optimal tower control in terms of load.

Figure 7 depicts the general form to determine tower airflow as a function of load. The (unconstrained) relative tower airflow is computed as a linear function of the part-load ratio as

$$G_{twr} = 1 - \beta_{twr}\,(PLR_{twr,cap} - PLR) \text{ for } 0.25 < PLR < 1.00 \quad (15)$$

where

G_{twr} = optimal tower airflow divided by maximum airflow with all cells operating at high speed
PLR = chilled-water load divided by design total chiller plant cooling capacity (part-load ratio)
$PLR_{twr,cap}$ = part-load ratio (value of PLR) at which tower operates at its capacity (G_{twr} = 1)
β_{twr} = slope of relative tower airflow (G_{twr}) versus part-load ratio (PLR) function

Table 1 Parameter Estimates for Near-Optimal Tower Control Equation

Parameter	One-Speed Fans	Two-Speed Fans	Variable-Speed Fans
$PLR_{twr,cap}$	PLR_0	$\sqrt{2}PLR_0$	$\sqrt{3}PLR_0$
β_{twr}	$\dfrac{1}{PLR_{twr,cap}}$	$\dfrac{2}{3PLR_{twr,cap}}$	$\dfrac{1}{2PLR_{twr,cap}}$

Note: $$PLR_0 = \frac{1}{\sqrt{\dfrac{P_{ch,des}}{P_{twr,des}}S_{cwr,des}(a_{twr,des}+r_{twr,des})}}$$

The linear relationship between the optimal airflow and load is only valid for loads greater than about 25% of the design load. For many installations, chillers do not operate at these small loads. However, for those situations in which chiller operation is necessary below 25% of full load, the tower airflow should be reduced to zero as the load goes to zero according to

$$G_{twr} = 4PLR\,[1 - \beta_{twr}\,(PLR_{twr,cap} - 0.25)] \text{ for } PLR < 0.25 \quad (16)$$

The results of either Equation (15) or (16) must be constrained between 0 and 1. This fraction of tower capacity is then converted to a tower control using the sequencing rules of the section on Near-Optimal Tower Fan Sequencing.

The variables of the open-loop linear control Equation (15) that yield near-optimal control depend on the system's characteristics. Detailed measurements may be taken over a range of conditions and used to accurately estimate these variables. However, this requires measuring component power consumption along with considerable time and expertise, and may not be cost effective unless performed by on-site plant personnel. Alternatively, simple estimates of these parameters may be obtained using design data.

Open-Loop Parameter Estimates Using Design Data. Good estimates for the parameters of Equation (15) may be determined analytically using design information as summarized in Table 4. These estimates were derived by Braun and Diderrich (1990) by applying optimization theory to a simplified mathematical model of the chiller and cooling tower, assuming that the tower fans are sequenced in a near-optimal manner. In general, these estimates are conservative in that they should provide greater rather than less than the optimal tower airflow. The results given in Table 1 for variable-speed fans should also provide adequate estimates for three-speed fans.

Design factors that affect the parameter estimates given in Table 1 are the (1) ratio of chiller power to cooling tower fan power at design conditions $P_{ch,des}/P_{twr,des}$, (2) sensitivity of chiller power to changes in condenser water return temperature at design conditions $S_{cwr,des}$, and (3) sum of the tower approach and range at design conditions $(a_{twr,des} + r_{twr,des})$. Chiller power consumption at design conditions is the total power consumption of all plant chillers operating at their design cooling capacity. Likewise, the design tower fan power is the total power associated with all tower cells operating at high speed. As the ratio of chiller power to tower fan power increases, it becomes more beneficial to operate the tower at higher airflows. This is reflected in a decrease in the part-load ratio $PLR_{twr,cap}$ at which the tower reaches its capacity. If the tower airflow were free (i.e., zero fan power), then $PLR_{twr,cap}$ would go to zero, and the best strategy would be to operate the towers at full capacity independent of the load. A typical value for the ratio of the chiller power to the cooling tower fan power at design conditions is 10.

The chiller sensitivity factor $S_{cwr,des}$ is the incremental increase in chiller power for each degree increase in condenser water temperature as a fraction of the power, or

$$S_{cwr,des} = \frac{\text{Change in chiller power}}{\text{Change in cond. water return temp.} \times \text{Chiller power}} \quad (17)$$

If the chiller power increases by 2% for a 0.5 K increase in condenser water temperature, $S_{cwr,des}$ is equal to 0.04/K. A large sensitivity factor means that the chiller power is very sensitive to the cooling tower control favoring operation at higher airflow rates (low $PLR_{twr,cap}$). The sensitivity factor should be evaluated at design conditions using chiller performance data. Typically, the sensitivity factor is between 0.02 and 0.06/K. For multiple chillers with different performance characteristics, the sensitivity factor at design conditions may be estimated by

$$S_{cwr,des} = \frac{\sum_{i=1}^{N_{ch}} S_{cwr,des,i}P_{ch,des,i}}{\sum_{i=1}^{N_{ch}} P_{ch,des,i}} \quad (18)$$

where $S_{cwr,des,i}$ is the sensitivity factor and $P_{ch,des,i}$ is the power consumption for the ith chiller at the design conditions, and N_{ch} is the total number of chillers.

The design approach to wet bulb $a_{twr,des}$ is the temperature difference between the condenser water supply and the ambient wet bulb for the tower, operating at its air and water flow capacity at plant design conditions. The design range $r_{twr,des}$ is the water temperature difference across the tower at these same conditions (condenser water return minus supply temperature). The sum of $a_{twr,des}$ and $r_{twr,des}$ is the temperature difference between the tower inlet and the ambient wet bulb and represents a measure of the tower's capability to reject heat to ambient relative to the system requirements. A small temperature difference (tower approach plus range) results from a high tower heat transfer effectiveness or high water flow rate and yields lower condenser water temperatures with lower chiller power consumption. Typical values for the design approach and range are 4 and 6 K.

The part-load ratio $PLR_{twr,cap}$ associated with the tower operating at full capacity may be greater than or less than one. Values less than unity imply that, from an energy point of view, the tower is not sized for optimal operation at design load conditions and that it should operate at its capacity for a range of loads less than the design load. Values greater than one imply that the tower is oversized for the design load and that it should never operate at its capacity.

For multiple chillers with very different performance characteristics, different open-loop parameters may be used for any combination of operating chillers. The sensitivity factors and chiller design power used to determine the open-loop control parameters in Table 1 should be estimated for each combination of operating chillers, and the part-load ratio used in Equation (15) should be determined using the design capacity for the operating chillers (not all chillers). In this case, N_{ch} in Equation (18) represents the number of operating chillers.

Open-Loop Parameter Estimates Using Plant Measurements. Energy consumption may be somewhat further reduced by determining the open-loop control parameters from plant measurements. However, this results in additional complexity associated with implementation. One method for estimating the open-loop control parameters of Equation (16) from plant measurements involves performing a set of one-time trial-and-error experiments. At a given set of conditions (i.e., cooling load and ambient conditions), the optimal tower control is estimated by varying the fan settings and monitoring the total chiller and fan power consumption. Each tower control setting and load condition must be maintained for a sufficient time for the power consumption to approach steady state and to hold the chilled-water supply temperature constant. The control setting that produces the minimum total power consumption is deemed optimal. This set of experiments is performed for a number of chilled-water cooling loads and the best-fit straight line through the resulting data points is used to estimate the parameters of Equation (15). As initial control settings for each load, Equation (15) may be used with estimates from design data as summarized in the previous section.

Another method for estimating the variables of Equation (15) uses an empirical model for total power consumption that is fit to plant measurements. The control that minimizes the power consumption associated with the model is then determined analytically. The section on Simplified Static Optimization of Cooling Plants describes a general method for determining linear control relations in this manner using a quadratic model. For cooling tower fan control, chiller and fan power consumption are correlated with load and tower airflow for a constant chilled-water supply temperature using a quadratic function as follows:

$$P = a_0 + a_1\text{PLR} + a_2\text{PLR}^2 + a_3G_{twr} + a_4G^2_{twr} + a_5\text{PLR} \times G_{twr} \quad (19)$$

where a_0 to a_5 are empirical constants determined through linear regression applied to measurements. For the quadratic function of Equation (19), the tower airflow that results in minimum power is a linear function of the PLR. The parameters of the open-loop control Equation (15) are then

$$\text{PLR}_{twr,cap} = -\frac{a_3 + 2a_4}{a_5} \quad (20)$$

$$\beta_{twr} = -\frac{a_5}{2a_4} \quad (21)$$

For multiple chillers with very different performance characteristics, different open-loop parameters can be determined for any combination of operating chillers. In this case, separate correlations for near-optimal airflow or power consumption must be determined for each chiller combination.

Overrides for Equipment Constraints

The fractional tower airflow as determined by Equations (15) or (16) must be bounded between 0 and 1 according to the physical constraints of the equipment. Additional constraints on the temperature of the supply water to the chiller condensers are necessary to avoid potential chiller maintenance problems. Many (older) chillers have a low limit on the condenser water supply temperature that is necessary to avoid lubrication migration from the compressor. A high-temperature limit is also necessary to avoid excessively high pressures in the condenser, which can lead to compressor surge in centrifugal chillers. If condenser water temperature falls below the low limit, then it is necessary to override the open-loop tower control and reduce tower airflow to go above this limit. Similarly, if the high limit is exceeded, then tower airflow should be increased as required.

Implementation

Before commissioning, the parameters of the open-loop control Equation (15) must be specified. These parameters are estimated using Table 1. After the system is in operation, these parameters may be fine-tuned with measurements as outlined previously. If multiple chillers have significantly different performance characteristics, it may be advantageous to determine different parameters for Equation (15), depending on the combination of operating chillers.

The relative tower airflow must be converted to a specific set of tower fan settings using the sequencing rules defined previously. This involves defining a relationship (i.e., table) for fan settings as a function of tower airflow. The table is constructed by defining the best fan settings for each possible increment of airflow. The conversion process between the continuous output of Equations (15) or (16) and the fan control involves choosing the set of discrete fan settings from the table that produces a tower airflow closest to the desired flow. However, in general, it is better to have greater rather than less than the optimal airflow. A good general rule is to choose the set of discrete fan controls that results in a relative airflow that is closest to, but not more than 10% less than, the output of Equations (15) or (16).

With the parameters of Equation (15) specified, the following procedure is applied at each decision interval (e.g., 15 min) to determine the tower control:

1. If the temperature of supply water to the chiller condenser is less than the low limit, then reduce tower airflow by one increment according to the near-optimal sequencing rules and exit the algorithm. Otherwise go to step 2.
2. If the temperature of supply water to the chiller condenser is greater than the high limit, then increase tower airflow by one increment according to the near-optimal sequencing rules and exit the algorithm. Otherwise go to step 3.
3. Determine the chilled-water load relative to the design load.
4. If the chilled-water load has changed by a significant amount (e.g., 10%) since the last control change, then go to step 5. Otherwise, exit the algorithm.
5. If the part-load ratio is greater than 0.25, then compute the near-optimal tower airflow as a fraction of tower capacity G_{twr} with Equation (15). Otherwise, determine G_{twr} with Equation (16).
6. Limit G_{twr} to keep the change from the previous decision interval less than a minimum value (e.g., less than 0.1 change).
7. Restrict the value of G_{twr} between 0 and 1.
8. Convert the value of G_{twr} to a specific set of control functions for each of the tower cell fans according to the near-optimal sequencing rules.

This procedure requires some estimate of the chilled-water load, along with a measurement of the condenser water supply temperature. However, accuracy of the load estimates is not extremely critical. In general, near-optimal control determined with load estimates that are accurate to within 5 to 10% results in total power consumption that is within 1% of the minimum. The best method for determining the chilled-water load is from the product of the measured chilled-water flow rate and the temperature difference between the chilled-water return and supply. For systems that use constant-flow pumping to the chillers, flow rates may be estimated from design data for the pumps and system pressure-drop characteristics.

Example 1. Consider an example plant consisting of four 2000 kW chillers with four cooling tower cells, each having two-speed fans. Each chiller consumes approximately 340 kW at design capacity, and each tower fan uses 42 kW at high speed. At design conditions, the chiller power increases approximately 12.2 kW for a 1 K increase in condenser water temperature, giving a sensitivity factor of 12.2/340 or 0.036/K. The tower design approach and range from manufacturer's data are 4 and 6 K.

Solution:

The first step in applying the open-loop control algorithm to this problem is determining the parameters of Equation (15) from the design data. From Table 1, the part-load ratio at which operation of the tower is at its capacity is estimated for the two-speed fans as

$$\text{PLR}_{twr,cap} = \frac{1}{\sqrt{\frac{1}{2}(0.036/\text{K})\frac{4 \times 340\ \text{kW}}{4 \times 42\ \text{kW}}(4+6)}} = 0.83$$

and the slope of the fractional airflow versus part-load ratio is estimated to be

$$\beta_{twr} = \frac{2}{3 \times 0.83} = 0.80$$

Given these parameters and the part-load ratio, the fractional tower airflow is estimated as

IF (PLR > 0.25) THEN
$$G_{twr} = 1 - \beta_{twr}(\text{PLR}_{twr,cap} - \text{PLR})$$
ELSE
$$G_{twr} = 4\text{PLR}[1 - \beta_{twr}(\text{PLR}_{twr,cap} - 0.25)]$$
$$G_{twr} = \text{MIN}[1, \text{MAX}(0, G_{twr})]$$

To convert G_{twr} into a specific tower control, the tower sequencing must be defined. The following table gives this information in a form that specifies the relationship between G_{twr} and tower control for this example.

Cooling Tower Fan Sequencing for Example 1

Sequence No.	G_{twr}	Tower Fan Speeds Cell #1	Cell #2	Cell #3	Cell #4
1	0.125	Low	Off	Off	Off
2	0.250	Low	Low	Off	Off
3	0.375	Low	Low	Low	Off
4	0.500	Low	Low	Low	Low
5	0.625	High	Low	Low	Low
6	0.750	High	High	Low	Low
7	0.875	High	High	High	Low
8	1.000	High	High	High	High

For a specific chilled-water load, the fan control should be the sequence of tower fan settings from the table that results in a value of G_{twr} that is closest to, but not more than 10% less than, the output of Equations (15) or (16). Note that this example assumes that proper water flow can be maintained over all cooling tower cells.

3.2 CHILLED-WATER RESET WITH FIXED-SPEED PUMPING

Figure 8 shows a common configuration using fixed-speed chilled-water pumps with two-way valves at the cooling coils. A two-way bypass valve controlled to maintain a fixed pressure difference between the main supply and return lines is used to ensure relatively constant flow through chiller evaporators and reduce pressure drop and pumping costs at low loads. However, additional pump and chiller power savings can be realized by adjusting the chilled-water supply temperature to keep some cooling coil valves open and thereby minimize the bypass flow.

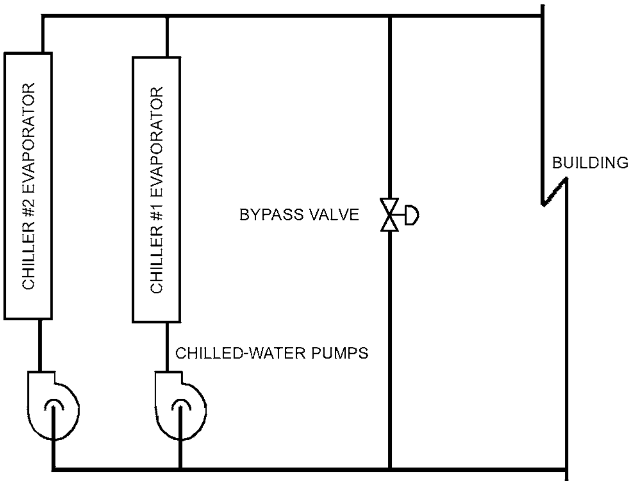

Fig. 8 Typical Chilled-Water Distribution for Fixed-Speed Pumping

Ideally, the chilled-water temperature should be adjusted to maintain all discharge air temperatures with a minimal number of cooling-coil control valves in a saturated (fully open) condition. The procedure described in this section is designed to accomplish this goal in a reliable and stable manner that reacts quickly to changing conditions.

Pump Sequencing

In plants where one chilled-water pump is dedicated to each chiller, the sequencing of chilled-water pumps is defined by the sequencing of chillers. In some installations, the chiller pumps are not dedicated to chillers, but instead are arranged in parallel, sharing common headers. In this case, the order for bringing pumps online and off-line and the conditions for adding or removing chilled-water pump capacity must be specified. For pumps of different capacities, the logical order for bringing pumps online is from small to large. For pumps of similar capacity, the most efficient pumps should be brought online first and taken off-line last.

Optimal Chilled-Water Temperature

One method for determining the optimal chilled-water temperature is to monitor the water control valve positions of “representative” air handlers and to adjust the set temperature incrementally at fixed decision intervals until a single control valve is fully open. The representative air handlers should be chosen to include load diversity at all times and ensure reliable data. One difficulty of this control approach is that valve position data are often unreliable. The valve could be stuck open or the saturation indicator could be faulty. This problem can be overcome by also monitoring discharge air temperatures, using them as a consistency check on valve position data. If a valve is unsaturated, this implies that the coil has sufficient capacity to maintain the discharge air temperature near the set point. Conversely, if a valve remains saturated at 100% open, the discharge air temperature should ultimately increase above the set point. These considerations lead to the following simple rules for increasing or decreasing the chilled-water set point in response to valve position and discharge air temperature data.

- If all water valves are unsaturated or the discharge air temperatures associated with all saturated valves are lower than the set point, increase the chilled-water set temperature.
- If more than one valve is saturated at 100% open and their corresponding discharge air temperatures are greater than their set points, decrease the chilled-water temperature.

In implementing these rules, a fixed increment for increasing or decreasing the chilled-water temperature must be chosen. A small increment results in more stable control, but also results in a slow response to sudden changes in load or supply air temperature set points. Using a first-order approximation, the chilled-water temperature can be reset in response to sudden changes in load and supply air temperature set point according to

$$t_{chws} = t_{as} - \frac{\text{PLR}}{\text{PLR}_o}(t_{as,o} - t_{chws,o}) \quad (22)$$

where

t_{chws} = new chilled-water set-point temperature
t_{as} = current supply air set-point temperature
PLR = current part-load ratio (chiller load divided by total design load for all chillers)
$t_{chws,o}$ = chilled-water set point associated with last control decision
$t_{as,o}$ = supply air set point associated with last control decision
PLR_o = part-load ratio associated with last control decision

Equation (22) assumes that the chilled-water temperature associated with the last control decision was optimal. As a result, it only applies to anticipating the effects of significant changes in the load and supply air set-point temperature on the optimal chilled-water set point. The “bump-and-wait” strategy fine-tunes the chilled-water supply temperature when the load and supply air set point are stable. For a variable-air-volume system, the supply air set points are most often constant and identical for all air-handling units. However, for a constant-air-volume system, these set points may vary with different air handlers. In this case, the supply air set point to use in Equation (22) should be a capacity weighted average value for the representative air handlers.

Equation (22) indicates that the optimal chilled-water supply temperature increases with increasing supply air temperature and decreasing load. This is because these changes cause the cooling-coil valves to close; optimal control involves keeping at least one valve open. Increasing supply air temperature causes the cooling-coil valves to close somewhat because of a larger average temperature difference for heat transfer between the water and air. A lower load requires smaller air-to-water temperature differences, which also leads to control valves closing.

Overrides for Equipment and Comfort Constraints

For a given chiller load, the chilled-water temperature has both upper and lower limits. The lower limit is necessary to avoid ice formation on the evaporator tubes of the chiller. This limit depends primarily on the load in relation to the size of the evaporator or, in other words, the temperature difference between the chilled water and refrigerant. At small temperature differences (large area or small load), the evaporator can tolerate a lower chilled-water temperature to avoid freezing than at large temperature differences. The lower limit on the chilled-water set point should be evaluated at the design load, because the overall system performance is improved by increasing chilled-water temperature above this limit for loads less than design. This lower limit can range from 3 to 7°C when chilled water is used for dehumidification, to 13°C for TABS, and as high as 15.6°C for chilled water serving radiant or chilled-beam cooling systems.

An upper limit on the chilled-water temperature arises from comfort constraints associated with the zones and the possibility of microbial growth associated with high humidities. For the available flows, the chilled-water temperature should be low enough to provide discharge air at a temperature and humidity sufficient to maintain all zones in the comfort region and avoid microbial growth. This upper limit varies with both load and entering air conditions and is accounted for by monitoring the zone conditions to ensure that they are in the comfort zone. If zone temperatures or humidities are not within reasonable bounds, then the discharge air temperature set point should be lowered. For radiant panel, chilled-beam, or TAB systems, there is no specific upper chilled-water limit as long as the load is satisfied.

Implementation

At each decision interval (e.g., 5 min), the following algorithm would be applied for determining the optimal chilled-water set-point temperature:

1. Determine the time-averaged total chilled-water load for the previous decision interval.
2. If the chilled-water load or supply air set-point temperature has changed by a significant amount (e.g., 10%) since the last control change, then estimate a new optimal chilled-water set point with Equation (22) and go to step 6. Otherwise, go to step 3.
3. Determine the time-averaged position of (or controller output for) the cooling-coil water valves and corresponding discharge air temperatures for representative air handlers.
4. If more than one valve is saturated at 100% open and their corresponding supply air temperatures are greater than set point (e.g., 0.5 K), then decrease the chilled-water temperature by a fixed amount (e.g., 0.25 K) and go to step 6. Otherwise, go to step 5.
5. If all water valves are unsaturated or the supply air temperatures associated with all valves that are saturated are lower than the set point, then raise the chilled-water set temperature by a fixed amount (e.g., 0.25 K). Otherwise, exit the algorithm with the chilled-water set point unchanged.
6. Limit the chilled-water set-point temperature between the upper and lower limits dictated by comfort, humidity, and equipment safety.

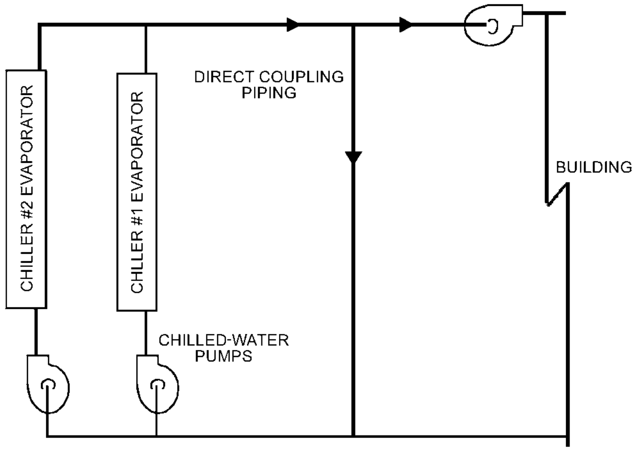

Fig. 9 Typical Chilled-Water Distribution for Primary/Secondary Pumping

Implementing this algorithm requires some estimate of the chilled-water load, along with a measurement of the discharge air temperatures and control valve positions. However, a highly accurate estimate of the load is not necessary.

3.3 CHILLED-WATER RESET WITH VARIABLE-SPEED PUMPING

Figure 9 shows a common configuration for systems using variable-speed chilled-water pumps with primary/secondary water loops. The primary pumps are fixed speed and are generally sequenced with chillers to provide a relatively constant flow of water through the chiller evaporators. The secondary chilled-water pumps are variable speed and are typically controlled to maintain a specified set point for pressure difference between supply and return flows for the cooling coils.

Although variable-speed pumps are usually used with primary/secondary chilled-water loops, they may also be applied to systems with a single chilled-water loop. In either case, variable-speed pumps offer the potential for a significant operating cost saving when both chilled-water and pressure differential set points are optimized in response to changing loads. This section presents an algorithm for determining near-optimal values of these control variables.

Optimal Differential Pressure Set Points

In practically all variable-speed chilled-water pumping applications, pump speed is controlled to maintain a constant pressure differential between the main chilled-water supply and return lines. However, this approach is not optimal. To maintain a constant pressure differential with changing flow, the control valves for the air-handling units must close as the load (i.e., flow) is reduced, resulting in an increase in the flow resistance. The best strategy for a given chilled-water set point is to reset the differential pressure set point to maintain all discharge air temperatures with at least one control valve in a saturated (fully open) condition. This results in a relatively constant flow resistance and greater pump savings at low loads. With variable differential pressure set points, optimizing the chilled-water loop is described in terms of finding the chilled-water temperature that minimizes the sum of chiller and pumping power, with pump control dependent on set point and load.

Near-Optimal Chilled-Water Set Point

The optimal chilled-water supply temperature at a given load results from a trade-off between chiller and pumping power, as shown in Figure 10. As the chilled-water temperature increases, chiller power is reduced because of a reduction in the lift requirements of the chiller. For a higher set temperature, more chilled-water flow is necessary to meet the load requirements, and the pumping power requirements increase. The minimum total power occurs at a point where the rate of increase in pumping power with chilled-water temperature is equal to the rate of decrease in chiller power. This optimal set point moves to lower values as the load increases.

Braun et al. (1989b) demonstrated that the optimal chilled-water set point varies as a near-linear function of both load and wet-bulb temperature entering cooling coils over a wide range of conditions.

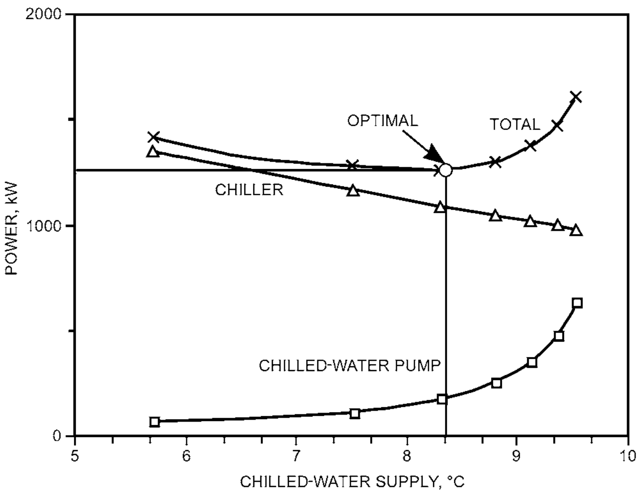

Fig. 10 Trade-off of Chiller and Pump Power with Chilled-Water Set Point

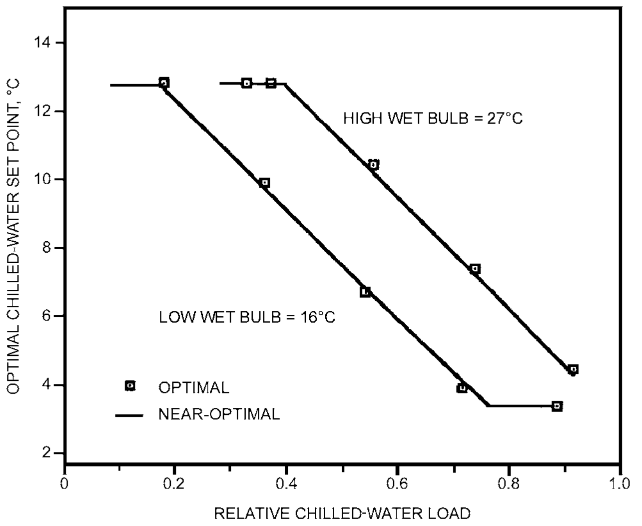

Fig. 11 Comparisons of Optimal Chilled-Water Temperature

Figure 11 shows an example of how the optimal set point varies for a specific plant. The set point is plotted as a function of load relative to design load for two different wet-bulb temperatures. In general, the optimal chilled-water temperature decreases with load because pump power becomes a larger fraction of total power. A lower set-point limit is set to avoid conditions that could form ice on evaporator tubes or too high a chiller “lift,” and an upper limit is established to ensure adequate cooling-coil dehumidification. For a given load, the chilled-water set point increases with wet-bulb temperature because energy transfer across each cooling coil is proportional to the difference between its entering air wet-bulb temperature and the entering water temperature (the chilled-water set point). For a constant load, this temperature difference is constant and the chilled-water supply temperature increases linearly with entering air wet-bulb temperature.

The results in Figure 11 were obtained for a system where both the chilled-water supply and supply air set points to the zones were optimized. For this case, the supply air temperatures varied between 13°C at high loads and 16°C at low loads. More typically, supply air temperatures are constant at 13°C, and the variation in chilled-water supply temperature is smaller than that shown in Figure 10.

Figure 12 depicts the general form for an algorithm to determine chilled-water supply set points as a function of load and the average wet-bulb temperature entering the cooling coils. A normalized difference between the entering air wet-bulb temperature and the chilled-water supply temperature is shown as a linear function of the part-load ratio. The (unconstrained) chilled-water set point is determined as

$$t_{chws} = t_{mx,wb} - \Gamma(t_{mx,wb,des} - t_{chws,des}) \tag{23}$$

where

$$\Gamma = 1 - \beta_{chws}(\text{PLR}_{chws,cap} - \text{PLR}) \tag{24}$$

t_{chws} = chilled-water supply temperature set point
$t_{mx,wb}$ = average or “representative” wet-bulb temperature of air entering cooling coils
$t_{chws,des}$ = chilled-water supply temperature at design conditions
$t_{mx,wb,des}$ = wet-bulb temperature of air entering cooling coils at design conditions
PLR = chilled-water load divided by the total chiller cooling capacity (part-load ratio)
$\text{PLR}_{chws,cap}$ = part-load ratio (value of PLR) at which $\Gamma = 1$
β_{chws} = slope of the Γ versus part-load ratio (PLR) function

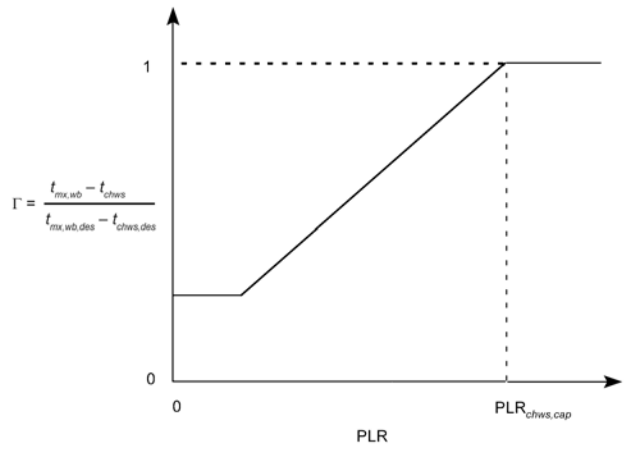

Fig. 12 Dimensionless Chilled-Water Set Point Versus Part-Load Ratio

Table 2 Parameter Estimates for Near-Optimal Chilled-Water Set Point Equation

Parameter	Estimate
$PLR_{chws,cap}$	$\sqrt{\frac{1}{3} \times \frac{P_{ch,des}}{P_{chwp,des}} S_{chws,des}(t_{mx,wb,des} - t_{chws,des})}$
β_{chws}	$\frac{0.5}{PLR_{chws,cap}}$

For radiant ceiling panel (RCP) and chilled-beam systems that provide sensible cooling only, replace $t_{mx,wb}$ and $t_{mx,wb,des}$ by the corresponding zone operative temperatures. The result of Equation (23) must be constrained between upper and lower limits dictated by equipment safety (evaporator freezing), machine operating envelope, and comfort and humidity concerns.

The variables of Equation (24) that yield near-optimal control depend on the system characteristics. Detailed measurements over a range of conditions may be used to estimate these parameters. However, this requires measuring component power consumption along with considerable time and expertise, and may not be cost effective unless performed by on-site plant personnel. Alternatively, simple estimates of these parameters may be obtained using design data.

Open-Loop Parameter Estimates Using Design Data. Reasonable estimates of the parameters of Equation (24) may be determined analytically using design information as summarized in Table 2. These estimates were derived by applying optimization theory to a simplified mathematical model of the chiller and secondary-loop water pumps, assuming that a differential pressure reset strategy is used, pump efficiencies are constant, and the supply air temperature is not varied in response to changes in chilled-water supply temperature. In general, these parameter estimates are conservative in that they should provide a relatively low estimate of the optimal chilled-water set point.

The design factors that affect the parameter estimates given in Table 2 are the (1) ratio of the chiller power to chilled-water pump power at design conditions $P_{ch,des}/P_{chwp,des}$, (2) chiller power's sensitivity to changes in chilled-water temperature at design conditions $S_{chws,des}$, and (3) difference between design entering air wet-bulb temperature to the cooling coil and the chilled-water supply temperature $(t_{mx,wb,des} - t_{chws,des})$.

Chiller power consumption at design conditions is the total power consumption of all plant chillers operating at their design cooling capacity. Likewise, the design pump power is the total power associated with all secondary chilled-water supply pumps operating at high speed. As the ratio of chiller power to pump power increases, it becomes more beneficial to operate the chillers at higher chilled-water temperatures and the pumps at higher flows. This is reflected in an increase in $PLR_{chws,cap}$. If chiller power were free, then $PLR_{chws,cap}$ would go to zero, and the best strategy would be to operate the chillers at the minimum possible set point, resulting in low chilled-water flow rates. Typical values for the ratio of chiller power to pump power at design conditions are between 10 and 20, depending mainly on whether primary/secondary pumping is used.

Chiller sensitivity factor $S_{chws,des}$ is the incremental increase in chiller power for each degree decrease in chilled-water temperature as a fraction of the power:

$$S_{cwr,des} = \frac{\text{Increase in chiller power}}{\text{Decrease in chilled-water return temp.} \times \text{Chiller power}} \quad (25)$$

If chiller power increases by 2% for a 0.5 K decrease in chilled-water temperature, then $S_{chws,des}$ is equal to 0.04/K. A large sensitivity factor means that chiller power is very sensitive to the set point control favoring operation at higher set point temperatures and flows (higher $PLR_{chws,cap}$). The sensitivity factor should be evaluated at design conditions using chiller performance data. Typically, the sensitivity factor is between 0.02 and 0.06/K. For multiple chillers with different performance characteristics, the sensitivity factor at design conditions is estimated as

$$S_{chws,des} = \frac{\sum_{i=1}^{N_{ch}} S_{chws,des,i} P_{ch,des,i}}{\sum_{i=1}^{N_{ch}} P_{ch,des,i}} \quad (26)$$

where $S_{chws,des,i}$ is the sensitivity factor and $P_{ch,des,i}$ is the power consumption for the *i*th chiller at design conditions, and N_{ch} is the total number of chillers.

The design difference between coil inlet air wet-bulb temperature and entering water temperature should be evaluated for a typical air handler operating at design load and flows. A small temperature difference results from a high coil heat transfer effectiveness or high water flow rate, allowing higher chilled-water temperatures with lower chiller power consumption. This is evident from Equation (23), where chilled-water set point decreases linearly with $(t_{mx,wb,des} - t_{chws,des})$ for a given Γ, and Γ is inversely related to the square root of $(t_{mx,wb,des} - t_{chws,des})$. Typically, this temperature difference is about 10 K.

Example 2. Consider an example plant with primary/secondary chilled-water pumping. There are four 2000 kW chillers, each with a dedicated primary pump. Each chiller consumes approximately 340 kW at design capacity. At design conditions, chiller power increases approximately 2.2 kW for a 0.5 K decrease in chilled-water temperature, giving a sensitivity factor of 2.2/340 or 0.04/K. The design chilled-water set point is 5°C, and the coil entering wet-bulb temperature is 16°C at design conditions. The secondary loop uses three identical 45 kW chilled-water pumps: one with a variable-speed and two with fixed-speed motors.

Solution:

The first step in applying the open-loop control algorithm to this problem is determining the parameters of Equation (24) from the design data. From Table 2, the part-load ratio at which the chilled-water temperature reaches a minimum (with the design entering wet-bulb temperature to the coils) is

$$PLR_{chws,cap} = \sqrt{\frac{1}{3} \times \frac{4 \times 340}{3 \times 45}(0.036/\text{K})(11)} = 1.15$$

and the slope of the set point versus part-load ratio is estimated to be

$$\beta_{chws} = \frac{0.5}{1.15} = 0.43$$

Given these parameters and the part-load ratio, the unconstrained chilled-water set-point temperature is then

$$t_{chws} = t_{mx,wb} - [1 - 0.43(1.15 - PLR)](11°C)$$

Pump Sequencing

Variable-speed pumps are sometimes used in combination with fixed-speed or other variable-speed pumps. Pump sequencing involves determining both the order and point that pumps should be brought online and off-line.

Pumps should be brought online in an order that allows a continuous variation in flow rate and maximized operating efficiency of the pumps at each switch point for the specific pressure loss characteristic. For a combination of fixed- and variable-speed pumps, at least one variable-speed pump should be brought online before any fixed-speed pumps. For single-loop systems (i.e., no secondary loop) with variable-speed pumps, the pressure drop characteristics change when chillers are added or removed and the optimal sequencing of pumps depends on the sequencing of chillers.

An additional pump should be brought online whenever the current set of pumps is operating at full capacity and can no longer satisfy the differential pressure set point. This situation can be detected by monitoring the differential pressure or the controller output signal. Insufficient pump capacity leads to extended periods with differential pressures that are less than the set point and a controller output that is saturated at 100%. A pump may be taken off-line whenever the remaining pumps have sufficient capacity to maintain the differential pressure set point. This condition can be determined by comparing the current (time-averaged) controller output with the controller output (time-averaged) at the point just after the last pump was brought online. The pump can be brought off-line when the current output is less than the switch point value by a specified dead band (e.g., 5%).

Overrides for Equipment and Comfort Constraints

The chilled-water temperature is bounded by upper and lower limits dictated by comfort, humidity, and equipment safety concerns. However, within these bounds, the chilled-water temperature may not always be low enough to maintain supply air set-point temperatures for the cooling coils. This situation might occur at high loads when the chilled-water flow is at a maximum and is detectable by monitoring the coil discharge air temperatures. Limits on the minimum pressure differential set point might also be imposed to ensure adequate controllability of the cooling-coil control valves.

Implementation

Before commissioning, the parameters of the open-loop control for chilled-water set point (Equation [24]) must be estimated using the results of Table 2. After the system is in operation, these parameters may be fine-tuned with measurements as outlined in the section on Simplified Static Optimization of Cooling Plants. With the parameters specified, the control algorithm is separated into two reset strategies: chilled-water temperature and pressure differential.

Chilled-Water Temperature Reset. The chilled-water supply temperature set point is reset at fixed decision intervals (e.g., 15 min) using the following procedure:

1. Determine the time-averaged position of (or controller output for) the cooling-coil water valves and corresponding discharge air temperatures for "representative" air handlers over the previous decision interval.
2. If more than one valve is saturated at 100% open and their corresponding discharge air temperatures are greater than set point (e.g., 0.5 K), then decrease the chilled-water temperature by a fixed amount (e.g., 0.25 K) and go to step 5. Otherwise, go to step 3.
3. Determine the total chilled-water flow and load.
4. Estimate an optimal chilled-water set point using static optimization. Increase or decrease the actual set point in the direction of the near-optimal value by a fixed amount (e.g., 0.5 K).
5. Limit the new set point between upper and lower constraints dictated by comfort and equipment safety.

Pump Sequencing. Secondary pumps should be brought online or off-line at fixed decision intervals (e.g., 15 min) with the following logic:

1. Evaluate the time-averaged pump controller output over the previous decision interval.
2. If the pump controller is saturated at 100%, then bring the next pump online. Otherwise, go to step 3.
3. If the pump control output is significantly less (e.g., 5%) than the value associated with the first time interval after the last pump was brought online, then bring that pump off-line.

Differential Pressure Reset. The set point for differential pressure between supply and return lines should be reset at smaller time intervals than the supply water temperature reset and pump sequencing strategies (e.g., 5 min) using the following procedure:

1. Check the water valve positions (or controller output) for "representative" air handlers and determine the time-averaged values over the last decision interval.
2. If more than one valve has been saturated at 100% open, then increase the differential pressure set point by a fixed value (e.g., 5% of the design value) and go to step 4. Otherwise, go to step 3.
3. If none of the valves have been saturated, then decrease the differential pressure set point by a fixed value (e.g., 5% of the design value).
4. Limit the differential pressure set point between upper and lower constraints.

3.4 SEQUENCING AND LOADING MULTIPLE CHILLERS

Multiple chillers are normally configured in parallel and typically controlled to give identical chilled-water supply temperatures. In most cases, controlling for identical set temperatures is the best and simplest strategy. With this approach, the relative loading on operating chillers is controlled by the relative chilled-water flow rates. Typically, the distribution of flow rates to heat exchangers for both chilled and condenser water are dictated by chiller pressure drop characteristics and may be adjusted through flow balancing, but are not controlled using a feedback controller. In addition to the distribution of chilled and condenser water flow rates, the chiller sequencing affects energy consumption. Chiller sequencing defines the conditions under which chillers are brought online and off-line. Simple guidelines may be established for each of these controls to provide near-optimal operation.

Near-Optimal Condenser Water Flow Distribution

In general, the condenser water flow to each chiller should be set to give identical leaving condenser water temperatures. This condition approximately corresponds to relative condenser flow rates equal to the relative loads on the chillers, even if the chillers are loaded unevenly. Figure 13 shows results for four sets of two chillers operated in parallel. The curves represent data from chillers at three different installations: (1) a 19 300 kW variable-speed chiller at the Dallas-Ft. Worth airport, Texas (Braun et al. 1989b); (2) a 1930 kW fixed-speed chiller at an office building in Atlanta (Hackner et al. 1984, 1985); and (3) a 4400 kW fixed-speed chiller at a large office building in Charlotte, North Carolina (Lau et al. 1985). The capacities of the chillers in the two office buildings were scaled up for comparison with the Dallas-Ft. Worth airport chiller.

The overall chiller coefficient of performance (COP) is plotted versus the difference between the condenser water return temperatures for equal chiller loading. For multiple chillers having similar performance characteristics (either variable- or fixed-speed), it is best to distribute the condenser water flow rates so that each chiller has the same leaving condenser water temperature. For situations where chillers do not have identical performance, equal leaving condenser water temperatures result in chiller performance that is close to the optimum. Even for variable- and fixed-speed chiller combinations that have very different performance characteristics, the penalty associated with using identical condenser leaving-water temperatures is small. To achieve equal condenser leaving-water temperatures, it is necessary to properly balance the condenser water flow rates at design operating conditions.

Optimal Chiller Load Distribution

Assuming identical chilled-water return and chiller supply temperatures, the relative chilled-water load for each parallel chiller (load divided by total load) that is operating could be controlled by its relative chilled-water flow rate (flow divided by total flow). To change the relative loadings in response to operating conditions, the individual flow rates must be controlled. However, this is typically not done and it is probably sufficient to establish the load distributions based on design information and then balance the flow rates to achieve these load distributions. Alternatively, the individual chiller loads can be precisely controlled through variation of individual chiller supply water set points.

Chillers with Similar Performance Characteristics. Braun et al. (1989b) showed that, for chillers with identical design COPs and part-load characteristics, a minimum or maximum power consumption occurs when each chiller is loaded according to the ratio of its capacity to the total capacity of all operating chillers. This is equivalent to each chiller operating at equal part-load ratios (load divided by cooling capacity at design conditions). For the *i*th chiller, the optimal chiller loading is then

$$\dot{Q}^*_{ch,i} = \frac{\dot{Q}_{load}}{\sum_{i=1}^{N} \dot{Q}_{ch,des,i}} \dot{Q}_{ch,des,i} \quad (27)$$

where $\dot{Q}_{load}$ is total chiller load, $\dot{Q}_{ch,des,i}$ is cooling capacity of the *i*th chiller at design conditions, and *N* is the number of chillers operating.

The loading determined with Equation (27) could result in either minimum or maximum power consumption. However, this solution gives a minimum when the chillers are operating at loads greater than the point at which the maximum COP occurs (i.e., chiller COP decreases with increased loading). Typically, the maximum COP occurs at loads that are less than chiller design capacity.

Figure 14 shows the effect of relative loading on chiller COP for different sets of identical chillers loaded at approximately 70% of their total capacities. Three of the chiller sets have maximum COPs when evenly loaded (matching the criterion of Equation [27]), whereas the fourth (Dallas-Ft. Worth fixed-speed) obtains a minimum at that point. The part-load characteristic of the Dallas-Ft. Worth fixed-speed chiller is unusual in that the maximum overall COP occurs at its maximum capacity. This chiller was retrofitted with a different refrigerant and drive motor, which derated its capacity from 30 6000 to 19 300 kW. As a result, the evaporators and condensers are oversized for its current capacity. Overall, the penalty associated with equally loading the Dallas-Ft. Worth fixed-speed chillers is small compared with optimal loading, and this strategy is probably appropriate. However, a slight reduction in energy consumption is possible if one of the two chillers operates at full capacity. The loading criterion of Equation (27) also works well for many combinations of chillers with different performance characteristics.

To achieve specified relative chiller loadings with equal chilled-water set points, chilled-water flow rates must be properly balanced. The relative loadings of Equation (27) only depend on design information, and flow balancing can be achieved through proper design and commissioning.

Chillers with Different Performance Characteristics. For the general case of chillers with significantly different part-load characteristics, a point of minimum or maximum overall power occurs where the partial derivatives of the individual chiller's power consumption with respect to their loads are equal:

$$\frac{\partial P_{ch,i}}{\partial \dot{Q}_{ch,i}} = \frac{\partial P_{ch,j}}{\partial \dot{Q}_{ch,j}} \quad \text{for all } i \text{ and } j \quad (28)$$

and subject to the constraint that

$$\sum_{i=1}^{N} \dot{Q}_{ch,i} = \dot{Q}_{load} \quad (29)$$

where $\dot{Q}_{ch,i}$ is the cooling load for the *i*th chiller and $\dot{Q}_{load}$ is the total cooling load.

In general, the power consumption of a chiller can be correlated as a quadratic function of cooling load and difference between the leaving condenser water and chilled-water supply temperatures according to

$$P_{ch,i} = a_{0,i} + a_{1,i}(t_{cwr,i} - t_{chws,i}) + a_{2,i}(t_{cwr,i} - t_{chws,i})^2 + a_{3,i}\dot{Q}_{ch,i} + a_{4,i}\dot{Q}^2_{ch,i} + a_{5,i}(t_{cwr,i} - t_{chws,i})\dot{Q}_{ch,i} \quad (30)$$

where, for the *i*th chiller, t_{cwr} is the leaving condenser water temperature and t_{chws} is the chilled-water supply temperature. The coefficients of Equation (30) ($a_{0,i}$ to $a_{5,i}$) can be determined for each

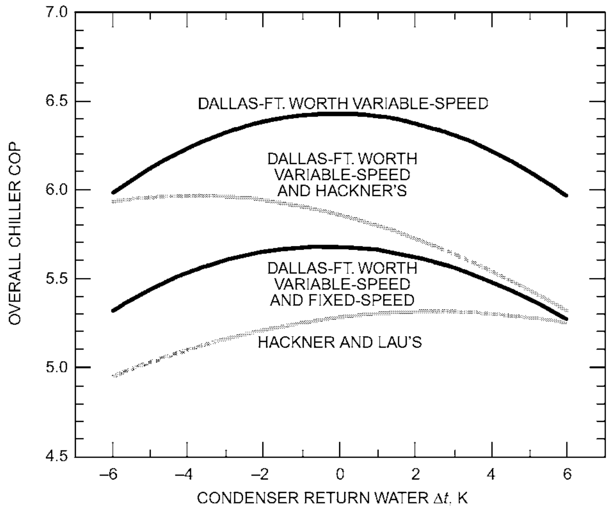

Fig. 13 Effect of Condenser Water Flow Distribution for Two Chillers In Parallel

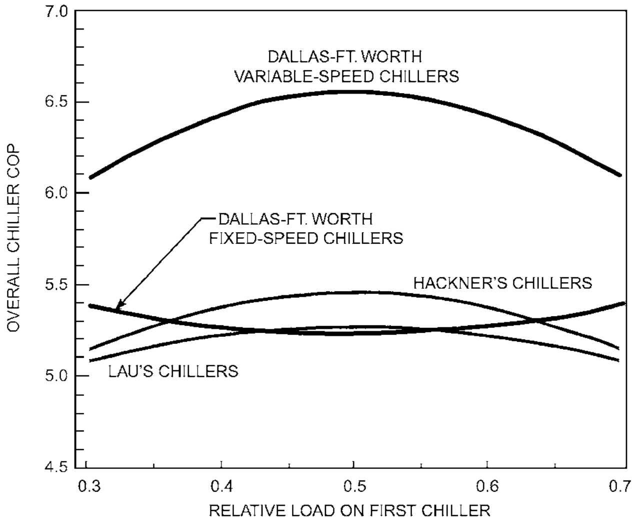

Fig. 14 Effect of Relative Loading for Two Identical Parallel Chillers

chiller through regression applied to measured or manufacturers' data.

If each chiller has identical leaving condenser and chilled-water supply temperatures, the criterion of Equation (28) applied to the correlation of Equation (30) leads to

$$a_{3,i} + 2a_{4,i}\dot{Q}^*_{ch,i} + a_{5,i}(t_{cwr} - t_{chws}) = a_{3,j} + 2a_{4,j}\dot{Q}^*_{ch,j} + a_{5,j}(t_{cwr} - t_{chws}) \quad \text{for } i \neq j \tag{31}$$

where $\dot{Q}^*_{ch,i}$ is the optimal load for the ith chiller.

Equations (29) and (31) represent a system of N linear equations in terms of N chiller loads that can be solved to give minimum (or possibly maximum) power consumption. For a given combination of chillers, the solution depends on the operating temperatures and total load. However, the individual chiller loads must be constrained to be less than the maximum chiller capacity at these conditions. If an individual chiller load determined from these equations is greater than its cooling capacity, then this chiller should be fully loaded and Equations (29) and (31) should be resolved for the remaining chillers (Equation [31] should only include unconstrained chillers).

To control individual chiller loads with identical chilled-water supply temperatures, individual chilled-water flow rates need to be controlled with two-way valves, which is not typical. However, the distribution of chiller loads could be changed for a fixed-flow distribution by using different chilled-water set-point temperatures. For a given flow and load distribution, the individual chiller set point for parallel chillers is determined according to

$$t_{chws,i} = t_{chwr} - \frac{\dot{Q}_{ch,i}}{f_{F,i}\dot{Q}_{load}}(t_{chwr} - t^*_{chws}) \tag{32}$$

where $f_{F,i}$ is the flow for the ith chiller divided by total flow, t^*_{chws} is the chilled-water supply temperature set point for the combination of chillers determined using the previously defined reset strategies, and t_{chwr} is the temperature of water returned to chillers from the building.

Substituting Equation (32) into Equation (30) and then applying the criterion of Equation (28) leads to the following:

$$A_i + B_i\dot{Q}^*_{ch,i} = A_j + B_j\dot{Q}^*_{ch,j} \quad \text{for } i \neq j \tag{33}$$

where

$$A_i = a_{3,i} + [a_{1,i} + 2a_{2,i}(t_{cwr} - t_{chwr})]\frac{t_{chwr} - t^*_{chws}}{f_{F,i}\dot{Q}_{load}} + a_{5,i}(t_{cwr} - t^*_{chws})$$

$$B_i = 2\left[a_{4,i} + a_{5,i}\frac{t_{chwr} - t^*_{chws}}{f_{F,i}\dot{Q}_{load}} + a_{2,i}\left(\frac{t_{chwr} - t^*_{chws}}{f_{F,i}\dot{Q}_{load}}\right)^2\right]$$

Optimal chiller loads are determined by solving the linear system of equations represented by Equations (33) and (29). The individual chiller set points are then evaluated with Equation (32). If any set points are less than the minimum or greater than the maximum set point, then the set point should be constrained and Equations (33) and (29) should be resolved for the remaining chillers (Equation [33] should only include unconstrained chillers).

Example 3. Determine the optimal loading for two chillers using the three methods outlined in this section. Table 3 gives the design cooling capacities and coefficients of the curve-fit of Equation (30) for the two chillers. The chillers are operating with a total cooling load of 5064 kW, condenser water return temperature of 29°C, an overall chilled-water supply temperature set point of 7°C, and a chilled-water return temperature of 13°C. Figure 15 shows the COPs for the two chillers as a function load relative to their design loads for the given operating temperatures. Chiller 1 is more efficient at higher part-load ratios and less efficient at lower part-load ratios as compared with chiller 2.

Table 3 Chiller Characteristics for Optimal Loading Example 3

Variable	Units	Chiller 1	Chiller 2
$\dot{Q}_{ch,des,i}$	kW	4396	1934
$a_{0,i}$	kW	106.4	119.7
$a_{1,i}$	kW/K	11.06	0.3376
$a_{2,i}$	kW/K^2	0.5806	0.1552
$a_{3,i}$	kW/kW	–0.0208	–0.1045
$a_{4,i}$	kW/kW^2	0.000 010 7	0.000 043 04
$a_{5,i}$	kW/(kW·K)	–0.000 516 3	0.004 364

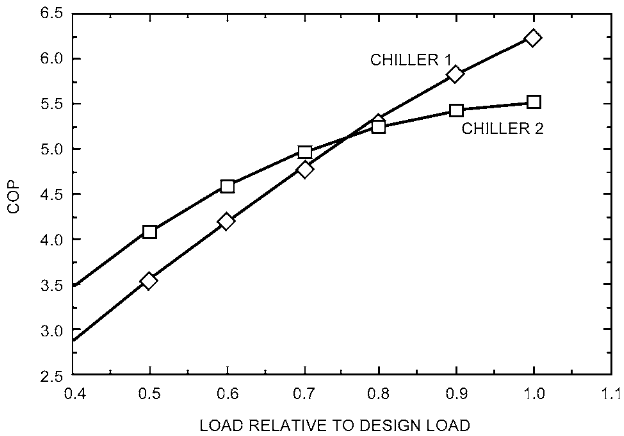

Fig. 15 Chiller COP for Two Chillers

Solution:

First, consider operating the chillers at equal part-load ratios. The ratio of the cooling load to the cooling capacity of the operating chillers is 5064/(4396 + 1934) = 0.8. From Equation (27), the individual chiller loads are

$$\dot{Q}^*_{ch,1} = 0.8(4396 \text{ kW}) = 3517 \text{ kW}$$

$$\dot{Q}^*_{ch,2} = 0.8(1934 \text{ kW}) = 1547 \text{ kW}$$

The power for each chiller is computed for the specified operating conditions with Equation (30) and the coefficients of Table 3. For the case of equal part-load ratios, the total chiller power consumption is

$$P_{ch} = P_{ch,1} + P_{ch,2} = 649.7 \text{ kW} + 292.2 \text{ kW} = 941.9 \text{ kW}$$

A second solution is determined for optimal chiller loads for the case of equal chilled-water temperature set points and controllable flow for each chiller. In this case, algebraic manipulation of Equations (29) and (31) produces the following results for the individual chiller loads:

$$\dot{Q}^*_{ch,1} = \frac{(a_{3,2} - a_{3,1}) + 2a_{4,2}\dot{Q}_{load} + (a_{5,2} - a_{5,1})(t_{cwr} - t_{chws})}{2(a_{4,1} + a_{4,2})} = 4277 \text{ kW}$$

$$\dot{Q}_{ch,2} = \dot{Q}_{load} - \dot{Q}_{ch,1} = 787 \text{ kW}$$

The resulting power consumption is then

$$P_{ch} = P_{ch,1} + P_{ch,2} = 688.9 \text{ kW} + 222.2 \text{ kW} = 910.8 \text{ kW}$$

Optimal loading of the chillers reduces overall chiller power consumption by about 4% through heavier loading of chiller 1 and lighter loading of chiller 2 (see Figure 15).

Finally, optimal chiller loading is determined for the case where the individual loadings are controlled by using different chilled-water temperature set points (individual flow is not controllable). To apply Equations (32) and (33), the relative chilled-water flow rate for each chiller must be known. For this example, the relative flow for the ith chiller is assumed to be equal to the ratio of its design capacity to the design capacity for the operating chillers, so that

$$f_{F,1} = \frac{\dot{Q}_{ch,des,1}}{\dot{Q}_{ch,des,1} + \dot{Q}_{ch,des,2}} = \frac{4396}{4396 + 1934} = 0.694$$

$$f_{F,2} = \frac{\dot{Q}_{ch,des,2}}{\dot{Q}_{ch,des,1} + \dot{Q}_{ch,des,2}} = \frac{4396}{4396 + 1934} = 0.306$$

Then, solving Equations (29) and (32) leads to the following results for the individual chiller loads:

$$\dot{Q}^*_{ch,1} = \frac{(A_2 - A_1) + B_2\dot{Q}_{load}}{B_1 + B_2} = 4034 \text{ kW}$$

$$\dot{Q}_{ch,2} = \dot{Q}_{load} - \dot{Q}_{ch,1} = 1030 \text{ kW}$$

These loads lead to a total chiller power consumption of

$$P_{ch} = P_{ch,1} + P_{ch,2} = 705.8 \text{ kW} + 216.4 \text{ kW} = 922.2 \text{ kW}$$

Individual chilled-water set points are determined from Equation (32) and are 6.1 and 9°C for chillers 1 and 2, respectively. Power consumption has increased slightly from the case of identical chiller set points and variable flow.

Note that changing either flows or chilled-water set points complicates overall system control as compared with loading the chillers with fixed part-load ratios, and leads to relatively small savings.

Order for Bringing Chillers Online and Off-Line

For chillers with similar efficiencies, the order in which chillers are brought online and off-line may be dictated by their cooling capacities and the desire to provide even runtimes. However, whenever beneficial and possible, chillers should be brought online in an order that minimizes the incremental increase in energy consumption. At a given condition, the power consumption of any chiller can be evaluated using the correlation given by Equation (30), where the coefficients are determined using manufacturers' data or in situ measurements. Then, the overall power consumption for all operating chillers is

$$P_{ch} = \sum_{i=1}^{N} P_{ch,i} \qquad (34)$$

When additional chiller capacity is required (see the section on Load Conditions for Bringing Chillers Online or Off-Line), the projected power of all valid chiller combinations should be evaluated using Equation (30), with the projected load determined by Equation (27) for chillers with similar performance characteristics, or the solution of Equations (28) subject to the constraint in Equation (29) for chillers with significantly different performance characteristics. Valid chiller combinations involve chillers that are not in alarm or locked out, and with load ratios between a low limit (e.g., 30%) and 100%. The best chiller combination to bring on line should result in the smallest increase (or largest decrease) in overall chiller power consumption as estimated with Equations (34) and (30) with chiller loading determined as outlined in the previous section. For systems with dedicated chilled-water and condenser water pumps and/or cooling towers, the associated power of this equipment should be added to Equation (30) to estimate the load of the chiller plus its auxiliary equipment. It is recommended that these estimates be performed online using in-situ measurements of each chiller's discharge chilled-water temperature and entering condenser water temperature, and the projected load of the chiller. A chiller should be shut down when its load drops below the spare capacity load of the current number of online chillers; for a primary/secondary chilled-water system, the primary chilled-water flow will remain above the secondary chilled-water flow once the chiller is shut down. (The spare capacity load is equal to the rated capacity of the online chillers minus the actual measured load of the online chillers.)

For chillers with similar design cooling capacities, a simpler (although suboptimal) approach can be used for determining the order for bringing chillers online and off-line. In this case, the chiller with the highest peak COP can be brought online first, followed by the second most efficient chiller, etc., and then brought off-line in reverse order. The maximum COP for each chiller can be evaluated using manufacturers' design and part-load data or from curve-fits to in-situ performance.

The chiller load associated with maximum COP for each chiller can be determined by applying a first-order condition for a maximum, using Equation (30) and the definition of COP. For this functional form, the maximum (or possibly minimum) COP occurs for

$$\dot{Q}^*_{ch,i} = \sqrt{\frac{a_{0,i} + a_{1,i}(t_{cwr} - t_{chws}) + a_{2,i}(t_{cwr} - t_{chws})^2}{a_{4,i}}} \qquad (35)$$

The load determined from Equation (35) yields a maximum COP whenever it is real and bounded between upper and lower limits. Otherwise, it can be assumed that the maximum COP occurs at full load conditions. Typically, the maximum COP for centrifugal chillers occurs between about 40 and 80% and, for small multi-compressor or inverter drive chillers, between 15 and 40% of design load. COP increases as the temperature difference between the condenser leaving water and chilled-water supply decreases. Equation (35) could be applied online to determine the rank ordering of chillers to bring online as a function of operating temperatures. However, it is often sufficient to use Equation (35) at the design temperature difference and establish a chiller sequencing order at the design or commissioning stage.

Example 4. Determine the loads for maximum COP for two different chillers at a chilled-water set point of 7°C and a condenser water return temperature of 27°C. Table 4 gives the design cooling capacities and coefficients of the curve-fit of Equation (30) for the two chillers. Figure 16 shows the COPs of the two chillers determined from the correlations as a function of relative load (PLR) and temperature difference ($t_{cwr} - t_{chws}$). These chillers have identical performance at design conditions, but very different part-load characteristics because of different methods used for capacity control.

Solution:

Loading associated with the maximum COP for each chiller is determined using Equation (35) and the coefficients of Table 4. Power for each chiller is then determined using Equation (30) and the COP follows directly. Results of the calculations are given in Table 5. The maximum COP for chiller A is about 20% greater than that for chiller B at the specified operating temperatures and should be brought online first.

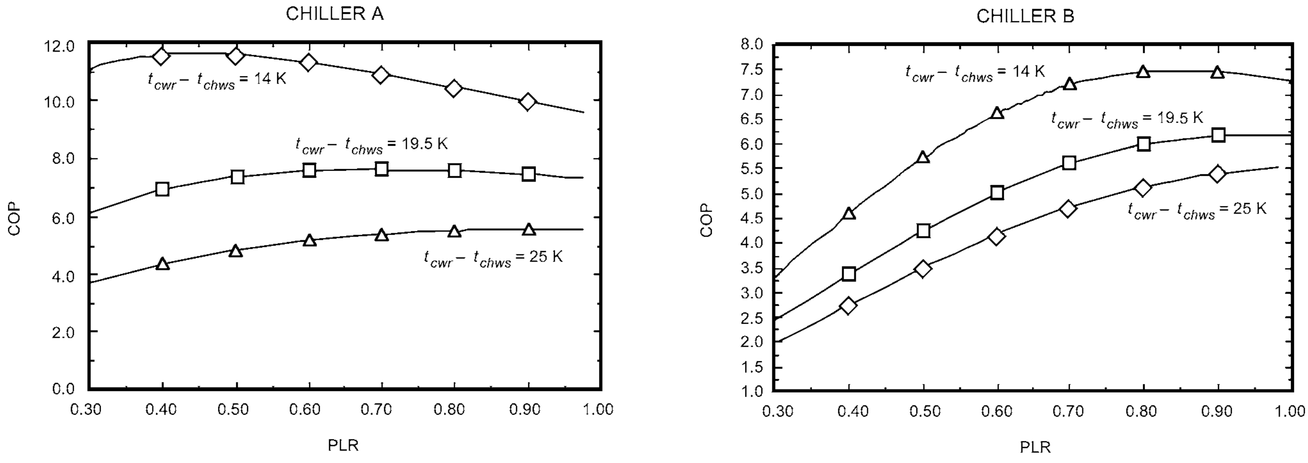

Fig. 16 Chiller A and B Performance Characteristics for Maximum COP, Example 4

Table 4 Chiller Characteristics for Maximum COP, Example 4

Variable	Unit	Chiller A	Chiller B
$\dot{Q}_{ch,des,i}$	MW	19.07	19.07
$a_{0,i}$	kW	262.6	187.2
$a_{1,i}$	kW/K	–45.65	173.1
$a_{2,i}$	kW/K^2	3.149	–1.398

Table 5 Results for Maximum COP, Example 4

Variable	Chiller A	Chiller B
$\dot{Q}^*_{ch,i}$	13.65 MW	18.59 MW
PLR_i	0.716	0.975
$P_{ch,i}$	1857 kW	3038 kW
COP_i	7.35	6.12

Load Conditions for Bringing Chillers Online or Off-Line

In general, chillers should be brought online at conditions where the total power (including pumps and tower or condenser fans) of operating with the additional chiller would be less than without it. Conversely, a chiller should be taken off-line when the total power of operating with that chiller would be less than with it. In practice, the switch point for bringing a chiller online should be greater than that for bringing that same chiller off-line (e.g., 10%), to ensure stable control. The optimal sequencing of chillers depends primarily on their part-load characteristics and the manner in which the chiller pumps are controlled.

Dedicated Pumps. Where individual condenser and chilled-water pumps are dedicated to the chiller, Braun et al. (1989b) and Hackner et al. (1985) showed that a chiller should be brought online when the operating chillers reach their capacity. This conclusion is the result of considering both the chiller and pumping power in determining optimal control. If pumping power is ignored, the optimal chiller sequencing occurs when chiller efficiency is maximized at each load. Because maximum efficiency often occurs at part-load conditions, the optimal point for adding or removing chillers may occur when chillers are operating at less than their capacity. However, the additional pumping power required for bringing additional pumps online with the chiller usually offsets any reductions in overall chiller power consumption associated with part-load operation.

When pumps are dedicated to chillers, situations may arise where chillers are operating at less than their capacity but chilled-water flow to the cooling coils is insufficient to meet the building load. This generally results from inadequate design or improper maintenance. Under these circumstances, either some zone conditions need to float to reduce the chilled-water set point (if possible), or an additional chiller needs to be brought online. Monitoring the zone air-handler conditions is one way to detect this situation. If (1) the chilled-water set point is at its lower limit, (2) any air-handler water control valves are saturated at 100% open, and (3) their corresponding discharge air temperatures are significantly greater (e.g., 1 K) than set point, then the chilled-water flow is probably insufficient and an additional chiller/pump combination could be brought online. One advantage of this approach is that it is consistent with the reset strategies for both fixed- and variable-speed chilled-water systems.

Chillers can be brought online or off-line with the following logic:

1. Evaluate the time-averaged values of the chilled-water supply temperature and overall cooling load over a fixed time interval (e.g., 5 min).
2. If the chilled-water supply temperature is significantly greater than the set point (e.g., 0.5 K), then bring the next chiller online. Otherwise, go to step 3.
3. Determine the time-averaged position of the cooling-coil water valves and corresponding discharge air temperatures for “representative” air handlers.
4. If (a) the chilled-water supply set point is at its lower limit, (b) more than one valve is saturated at 100% open, and (c) their corresponding discharge air temperatures are significantly greater than set point (e.g., 0.5 K), then bring another chiller/pump combination online. Otherwise, go to step 5.
5. If the cooling load is significantly less (e.g., 10%) than the value associated with the first time interval after the last chiller was brought online, then take that chiller off-line.

Nondedicated Pumps. For systems without dedicated chiller pumps (e.g., variable-speed primary systems), the optimal load conditions for bringing chillers online or off-line do not generally occur at full chiller capacity. In determining optimal chiller switch points, ideally both chiller and pumping power should be considered because pressure drop characteristics and pumping change when a chiller is brought online or off-line. However, approximate values of optimal switch points may be estimated by considering only chiller power.

A chiller should be brought online whenever it would reduce the overall chiller power or if the current chillers can no longer meet the load (see previous section). A chiller should be added if the power consumption associated with (N + 1) chillers is significantly less (e.g., 5%) than the current N chillers, with both conditions evaluated using Equation (34) with correlations of the form given in Equation (30), and sequencing and loading determined as outlined in previous sections. Conversely, a chiller should be removed if the power consumption associated with the (N – 1) chillers is significantly less (e.g., 5%) than the current N chillers. The decision to add or remove chillers is readily determined using the current load and operating temperatures.

3.5 SIMPLIFIED STATIC OPTIMIZATION OF COOLING PLANTS

Optimal supervisory control of cooling equipment may involve determining the control that minimizes the total operating cost. For an all-electric system without significant storage, cost optimization leads to minimization of power at each instant in time. Optimal control depends on time, albeit indirectly through changing cooling requirements and ambient conditions. In this section, the static optimization methods described in the Methods section are simplified and applied to cooling.

Simplified System-Based Optimization Approach

The component-based optimization method presented by Braun et al. (1989a) described in the Methods section was used to develop a simpler method for determining optimal control. The method involves correlating overall cooling plant power consumption using a quadratic functional form. Minimizing this function leads to linear control laws for control variables in terms of uncontrolled variables. The technique may be used to tune parameters of the cooling tower and chilled-water reset strategies presented in the section on Supervisory Control Strategies. It may also be used to define strategies for supply air temperature reset for VAV systems and flow control for variable-speed condenser water pumps.

In the vicinity of any optimal control point, plant power consumption may be approximated as a quadratic function of the continuous control variables for each of the operating modes (i.e., discrete control mode). A quadratic function also correlates power consumption in terms of uncontrolled variables (i.e., load, ambient temperature) over a wide range of conditions. This leads to the following general functional relationship between overall cooling plant power and the controlled and uncontrolled variables:

$$J(\mathbf{f}, \mathbf{M}, \mathbf{u}) = \mathbf{u}^T \mathbf{A}\mathbf{u} + \mathbf{b}^T\mathbf{u} + \mathbf{f}^T\mathbf{C}\mathbf{f} + \mathbf{d}^T \mathbf{f} + \mathbf{f}^T \mathbf{E}\mathbf{u} + g \tag{36}$$

where J is the total plant power, **u** is a vector of continuous and free control variables, **f** is a vector of uncontrolled variables, **M** is a vector of discrete control variables, and the superscript T designates the transpose operator. **A**, **C**, and **E** are coefficient matrices, **b** and **d** are coefficient vectors, and g is a scalar. The empirical coefficients of this function depend on the operating modes so that these constants must be determined for each feasible combination of discrete control modes, **M**.

A solution for the optimal control vector that minimizes power may be determined analytically by applying the first-order condition for a minimum. Equating the Jacobian of Equation (36) with respect to the control vector to zero and solving for the optimal control set points gives

$$\mathbf{u}^* = \mathbf{k} + \mathbf{K}\mathbf{f} \tag{37}$$

where

$$\mathbf{k} = -\mathbf{A}^{-1}\mathbf{b}/2 \tag{38}$$

$$\mathbf{K} = -\mathbf{A}^{-1}\mathbf{E}/2 \tag{39}$$

The cost associated with unconstrained control of Equation (37) is

$$J^* = \mathbf{f}^T \theta \mathbf{f} + \sigma^T \mathbf{f} + \tau \tag{40}$$

where

$$\theta = \mathbf{K}^T \mathbf{A}\mathbf{k} + \mathbf{E}\mathbf{K} + \mathbf{C} \tag{41}$$

$$\sigma = 2\mathbf{K}\mathbf{A}\mathbf{k} + \mathbf{K}\mathbf{b} + \mathbf{E}\mathbf{k} + \mathbf{d} \tag{42}$$

$$\tau = \mathbf{K}^T \mathbf{A}\mathbf{k} + \mathbf{b}^T \mathbf{k} + g \tag{43}$$

The control defined by Equation (37) results in a minimum power consumption if **A** is positive definite. If this condition holds and if the system power consumption is adequately correlated with Equation (36), then Equation (37) dictates that the optimal continuous, free control variables vary as a nearly linear function of the uncontrolled variables. However, a different linear relationship (i.e., different **A**, **C**, **E**, **b**, **d**, and g) applies to each feasible combination of discrete control modes defined by **M**. The minimum cost associated with each mode combination must be computed from Equation (40) and compared to identify the global minimum.

Uncontrolled Variables. As mentioned, optimal control variables primarily depend on ambient wet-bulb temperature (or dry-bulb temperature in the case of air-cooled chillers) and total chilled-water load. The load affects the heat transfer requirements for all heat exchangers, whereas the wet-bulb temperature affects chilled- and condenser water temperatures necessary to achieve a given heat transfer rate. As discussed in the section on Supervisory Control Strategies, cooling coil heat transfer depends on the coil entering wet-bulb temperature. However, this reduces to an ambient wet-bulb temperature dependence for a given ventilation mode (e.g., minimum outdoor air or economizer) and fixed zone conditions. Thus, separate cost functions are necessary for each ventilation mode, with load and ambient wet bulb as uncontrolled variables. Alternatively, for a specified ventilation strategy (e.g., the economizer strategy from the section on Supervisory Control Strategies), three uncontrolled variables could be used for all ventilation modes: load, ambient wet-bulb temperature, and average cooling-coil inlet wet-bulb temperature.

For radiant cooling systems, if latent cooling is handled by package dehumidifying equipment (e.g., a dedicated outdoor air system), the chilled-water set point can be raised well above what is needed for dehumidification and the main chiller will operate more efficiently. Gayeski et al. (2011a) and Katipamula et al. (2010a) show that part-load efficiency may benefit greatly from using optimal chilled-water flow rate and temperature in response to part-load ratio.

Additional uncontrolled variables that could be important if varied over a wide range are the individual-zone latent-to-sensible load ratios and the ratios of individual sensible zone loads to the total sensible loads for all zones. However, these variables are difficult to determine from measurements and are of secondary importance.

Free Control Variables. The number of independent or "free" control variables in the optimization can be reduced significantly by using the simplified strategies presented in the section on Supervisory Control Strategies. For instance, the optimal static pressure set point for a VAV system should keep at least one VAV box fully open and should not be considered as a free optimization variable. Similarly, supply air temperature for a constant-air-volume (CAV) system should be set to minimize reheat. Additional near-optimal guidelines were presented for sequencing of cooling tower fans, sequencing of chillers, loading of chillers, reset of pressure differential set point for variable-speed pumping, and chilled-water reset with fixed-speed pumping. Furthermore, Braun et al. (1989b) showed that using identical supply air set points for multiple air handlers gives near-optimal results for VAV systems.

For all variable-speed auxiliary equipment (i.e., pumps and fans), the free set-point variables to use in Equation (1) could be reduced to the following: (1) supply air set temperature, (2) chilled-water set temperature, (3) tower airflow relative to design capacity, and (4) condenser water flow relative to design capacity. All other continuous supervisory control variables are dependent on these variables with the simplified strategies presented in the section on Supervisory Control Strategies.

Some of the dependent control variables may be discrete control variables. For instance, variable-flow pumping may be implemented with multiple fixed- and variable-speed pumps, where the number of operating pumps is a discrete variable that changes when a variable-speed pump reaches its capacity. These discrete changes could lead to discrete changes in cost because of changes in overall pump efficiency. However, this has a relatively small effect on overall power consumption and may be neglected in fitting the overall cost function to changes in the control variables.

Some discrete control variables may also be independent variables. In general, different cost functions arise for all operating modes consisting of each possible combination of discrete control variables. With all variable-speed pumps and fans, the only significant discrete control variable is the number of operating chillers. Then, optimization involves determining optimal values of only four continuous control variables for each of the feasible chiller modes. A chiller mode defines which of the available chillers are to be online. The chiller mode giving the minimum overall power consumption represents the optimum. For a chiller mode to be feasible, the specified chillers must operate safely within their capacity and surge limits. In practice, avoid abrupt changes in the chiller modes; large chillers should not be cycled on or off except when the savings associated with the change are significant.

Using fixed-speed equipment reduces the number of free continuous control variables. For instance, supply air temperature is removed as a control variable for CAV systems, and chilled-water temperature is not included for fixed-speed chilled-water pumping. However, for multiple chilled-water pumps not dedicated to chillers, the number of operating pumps can become a free discrete control variable. Similarly, for multiple fixed-speed cooling tower fans and condenser water pumps, each of the discrete combinations can be considered as a separate mode. However, for multiple cooling tower cells with multiple fan speeds, the number of possible combinations may be large. A simpler approach that works satisfactorily is to treat relative flows as continuous control variables during the optimization and to select the discrete relative flow that is closest to the optimal value. At least three relative flows (discrete flow modes) are necessary for each chiller mode to fit the quadratic cost function. The number of possible sequencing modes for fixed-speed pumps is generally much more limited than that for cooling tower fans, with two or three possibilities (at most) for each chiller mode. In fact, with many current designs, individual pumps are physically coupled with chillers, and it is impossible to operate more or fewer pumps than the number of operating chillers. Thus, it is generally best to treat the control of fixed-speed condenser water pumps with a set of discrete control possibilities rather than use a continuous control approximation.

Training. The coefficients of Equation (36) must be determined empirically, and a variety of approaches have been proposed. One approach is to apply regression techniques directly to measurements of total power consumption. Because the cost function is linear with respect to the empirical coefficients, linear regression techniques may be used. A set of experiments can be performed over the expected range of operating conditions. Large amounts of data that include the entire range must be taken to account for measurement uncertainty. The regression could possibly be performed online using least-squares recursive parameter updating (Ljung and Söderström 1983). However, precautions should be taken to ensure that the matrix **A** is positive definite, which guarantees a minimum. If system power is relatively "flat," automated methods could generate coefficients that produce a maximum in power consumption rather than a minimum (Brandemuehl and Bradford 1998).

Rather than fitting empirical coefficients of the system-cost function of Equation (36), the coefficients of the optimal control Equation (37) and the minimum-cost function of Equation (40) may be estimated directly. At a limited set of conditions, optimal values of the continuous control and free variables may be estimated through trial-and-error variations. Only three independent conditions are necessary to determine coefficients of the linear control law given by Equation (37) if the load and wet bulb are the only uncontrolled variables. The coefficients of the minimum cost function can then be determined from system measurements with the linear control law in effect. The disadvantage of this approach is that there is no direct way to handle physical constraints on the controls.

Summary and Constraint Implementation. The methodology for determining the near-optimal control of a chilled-water system may be summarized as follows:

1. Change the chiller operating mode if system operation is at the limits of chiller operation (near surge or maximum capacity).
2. For the current set of conditions (load and wet bulb), estimate the feasible modes of operation **M** that avoid operating the chiller and condenser pump at their limits.
3. For the current operating mode, determine optimal values of the continuous controls using Equation (37).
4. Determine a constrained optimum if controls exceed their bounds.
5. Repeat steps 3 and 4 for each feasible operating mode.
6. Change the operating mode if the optimal cost associated with the new mode is significantly less than that associated with the current mode.
7. Change the values of the continuous control variables. When treating multiple-speed fan control with a continuous variable, use the discrete control closest to the optimal continuous value.

If the linear optimal control Equation (37) is directly determined from optimal control results, then the constraints on controls may be handled directly. Otherwise, a simple solution is to constrain the individual control variables as necessary and neglect the effects of the constraints on the optimal values of the other controls and the minimum cost function. The variables of primary concern for constraints are the chilled-water and supply air set temperatures. These controls must be bounded for proper comfort and safe operation of the equipment. On the other hand, cooling tower fans and condenser water pumps should be sized so the system performs efficiently at design loads, and constraints on control of this equipment should only occur under extreme conditions.

The optimal value of the chilled-water supply temperature is coupled to the optimal value of the supply air temperature, so decoupling these variables in evaluating constraints is generally not justified. However, optimization studies indicate that when either control is operated at a bound, the optimal value of the other free control is approximately bounded at a value that depends only on the ambient wet-bulb temperature. The optimal value of this free control (either chilled-water or supply air set point) may be estimated at the load at which the other control reaches its limit. Coupling between optimal values of the chilled-water and condenser water loop controls is not as strong; interactions between constraints on these variables may be neglected.

Case Studies. Braun et al. (1987) correlated the power consumption of the Dallas-Ft. Worth airport chiller, condenser pumps, and cooling tower fans with the quadratic cost function given by Equation (40) and showed good agreement with data. Because the chilled-water loop control was not considered, the chilled-water set point was treated as a known uncontrolled variable. The discrete control variables associated with the four tower cells with two-speed fans and the three condenser pumps were treated as continuous control variables. The optimal control determined by the near-optimal

Equation (37) also agreed well with that determined using a nonlinear optimization applied to a detailed simulation of the system.

In subsequent work, Braun et al. (1989a) considered complete system simulations (cooling plant and air handlers) to evaluate the performance of the quadratic, system-based approach. Several different system characteristics were considered. Figures 6, 11, 17, and 18 show comparative results between the controls as determined with the component- and system-based methods for a range of loads, for a relatively low and high ambient wet-bulb temperature (16 and 27°C).

In Figures 11 and 17, optimal values of the chilled-water and supply air temperatures are compared for a system with variable air and water flow. The near-optimal control equation provides a good fit to the optimization results for all conditions considered. The chilled-water temperature was constrained between 3 and 13°C, while the supply air set point was allowed to float freely. Figures 11 and 17 show that, for the conditions where the chilled-water temperature is constrained, the optimal supply air temperature is also nearly bounded at a value that depends on the ambient wet bulb.

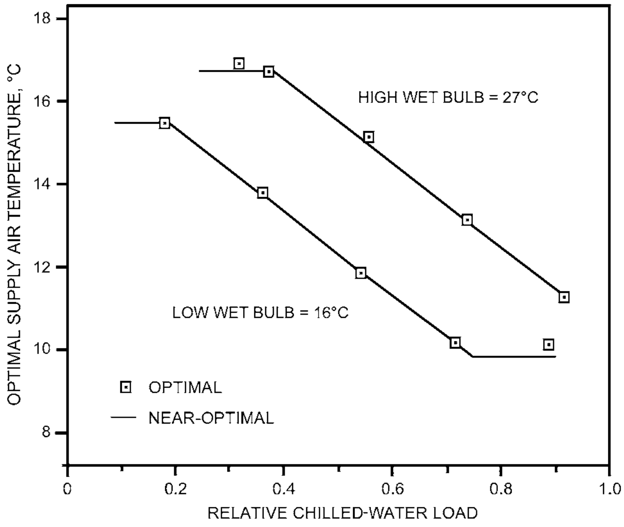

Fig. 17 Comparisons of Optimal Supply Air Temperature

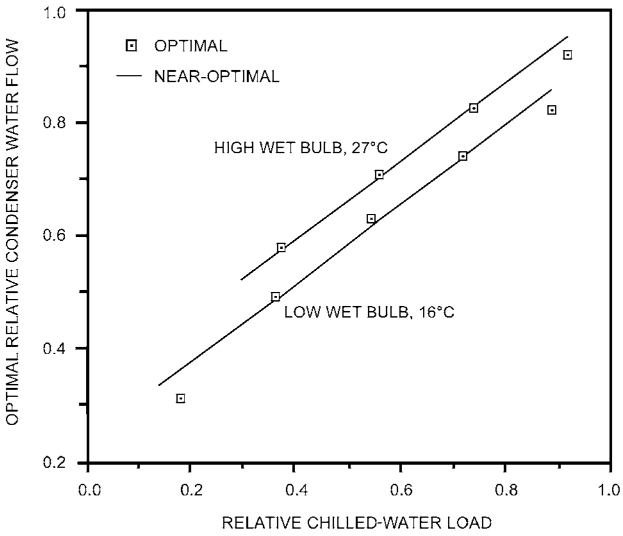

Fig. 18 Comparisons of Optimal Condenser Pump Control

Optimal relative cooling tower air and condenser water flow rates are compared in Figures 6 and 18 for a system with variable-speed cooling tower fans and condenser water pumps. Although the optimal controls are not exactly linear functions of the load, the linear control equation provides an adequate fit. The differences in these controls result in insignificant differences in overall power consumption, because, as discussed in the background section, the optimum is extremely flat with respect to these variables. The nonlinearity of the condenser loop controls is partly caused by the constraints imposed on the chilled-water set temperature. However, this effect is not very significant. Figures 6 and 18 also suggest that the optimal condenser loop control is not very sensitive to ambient wet-bulb temperature.

Static Optimization for Cooling Plants

The cooling system shown in Figure 1 depicts multiple chillers, cooling towers, and pumps providing chilled water to air-handling units to cool air that is supplied to building zones. Although cooling needs at any given time may be met with different modes of operation and set points only one set of controls and mode results in minimum power consumption. This optimal control point results from trade-offs between the energy consumption of different components. For instance, increasing the number of cooling tower cells (or increasing fan speeds) increases fan power but reduces chiller power because the temperature of the water supplied to the chiller's condenser is decreased. Similarly, increasing condenser water flow by adding pumps (or increasing pump speed) decreases chiller power but increases pump power.

Similar trade-offs exist for the chilled-water loop variables of systems with variable-speed chilled-water pumps and air handler fans. For instance, increasing the chilled-water set point reduces chiller power but increases pump power because greater flow is needed to meet the load. Increasing the supply air set point increases fan power, but decreases pump power.

Figure 19 shows the sensitivity of the total power consumption to condenser water-loop controls (from Braun et al. [1989b]) for a single chiller load, ambient wet-bulb temperature, and chilled-water supply temperature. Contours of constant power consumption are plotted versus cooling tower fan and condenser water pump speed for a system with variable-speed fans and pumps. Near the optimum, power consumption is not sensitive to either of these control variables, but increases significantly away from the optimum. The rate of increase in power consumption is particularly large at low condenser pump speeds. A minimum pump speed is necessary

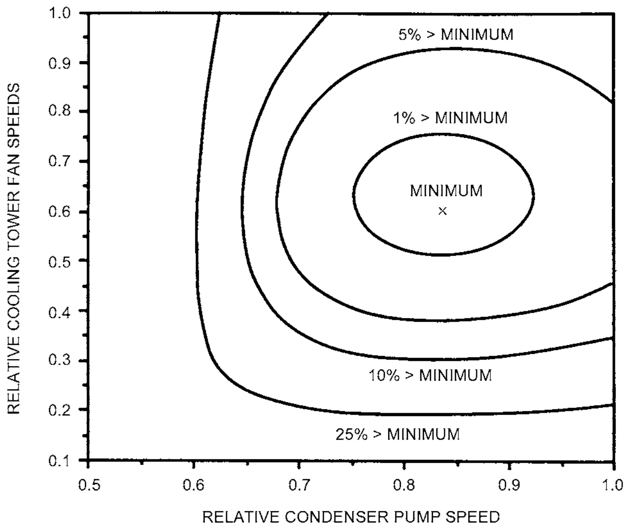

Fig. 19 Example Chiller Plant Power Contours for Condenser-Loop Control Variables

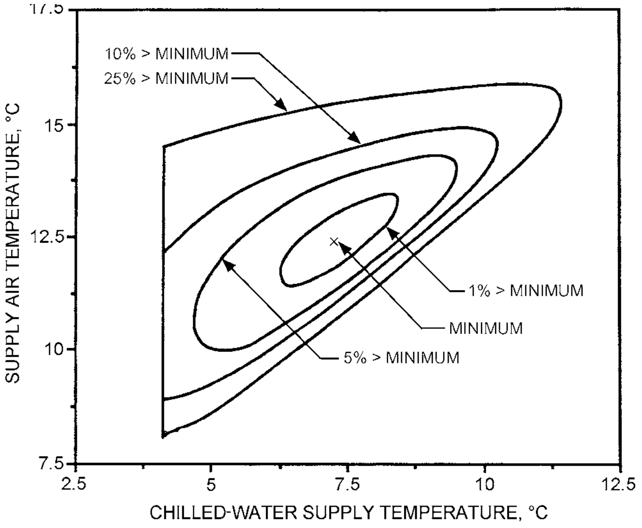

Fig. 20 Example Chiller Plant Power Contours for Chilled-Water and Supply Air Temperatures

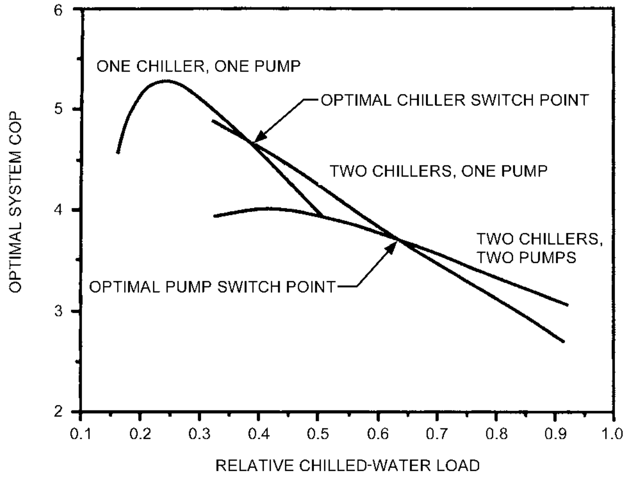

Fig. 21 Example of Effect of Chiller and Pump Sequencing on Optimal Performance

to overcome the static pressure associated with the height of the water discharge in the cooling tower above the sump. As the pump speed approaches this value, condenser flow approaches zero and chiller power increases dramatically. A pump speed that is too high is generally better than one that is too low. The broad area near the optimum indicates that, for a given load, the optimal setting does not need to be accurately determined. However, optimal settings change significantly when there are widely varying chiller loads and ambient wet-bulb temperature.

Figure 20 shows the sensitivity of power consumption to chilled-water and supply air set-point temperatures for a system with variable-speed chilled-water pumps and air handler fans (Braun et al. 1989b). Within about 2 K of the optimum values, power consumption is within 1% of the minimum. Outside this range, sensitivity to the set points increases significantly. The penalty associated with operation away from the optimum is greater in the direction of smaller differences between the supply air and chilled-water set points. As this temperature difference is reduced, the required flow of chilled water to this coil increases and the chilled-water pumping power is greater. For a given chilled-water or supply air temperature, the temperature difference is limited by the heat transfer characteristics of the coil. As this limit is approached, the required water flow and pumping power would become infinite if the pump speed were not constrained. It is generally better to have too large rather than too small a temperature difference between the supply air and chilled-water set points.

For constant chilled-water flow, trade-offs in energy use with chilled-water set point are very different than for variable-flow systems. Increasing the chilled-water set point reduces chiller power consumption, but has little effect on chilled-water pumping energy. Therefore, the benefits of chilled-water temperature reset are more significant than for variable-flow systems (although variable-flow systems use less energy). For constant chilled-water flow, the minimum-cost strategy is to raise the chilled-water set point to the highest value that will keep all discharge air temperatures at their set points and keep zone humidities within acceptable bounds.

For constant-volume (CAV) air-handling systems, trade-offs in energy use with supply air set point are also very different than for variable-air-volume systems. Increasing the supply air set point for cooling reduces both the cooling load and reheat required, but does not change fan energy. Again, the benefits of supply air temperature reset for CAV systems are more significant than for VAV systems (although VAV systems use less energy). In general, the set point for a CAV system should be at the highest value that will keep all zone temperatures at their set points and all humidities within acceptable limits.

In addition to the set points used by local-loop controllers, some operational modes can affect performance. For instance, significant energy savings are possible when a system is properly switched over to an economizer cycle. At the onset of economizer operation, return dampers are closed, outdoor air dampers are opened, and the maximum possible outdoor air is supplied to cooling coils. Two different types of switchover are typically used: (1) dry-bulb and (2) enthalpy. With a dry-bulb economizer, the switchover occurs when the ambient dry-bulb temperature is less than a specified value, typically between 13 and 18°C. With an enthalpy economizer, the switchover typically happens when the outdoor enthalpy (or wet-bulb temperature) is less than the enthalpy (or wet-bulb temperature) of the return air. Although the enthalpy economizer yields lower overall energy consumption, it requires wet-bulb temperature or dry-bulb and relative humidity measurements.

Another important operation mode is the sequencing of chillers and pumps. Sequencing defines the order and conditions associated with bringing equipment online or off-line. Optimal sequencing depends on the individual design and part-load performance characteristics of the equipment. For instance, more-efficient chillers should generally be brought online before less-efficient ones. Furthermore, the conditions where chillers and pumps should be brought online depend on their performance characteristics at part-load conditions.

Figure 21 shows an example of optimal system performance (i.e., optimal set-point choices) for different combinations of chillers and fixed-speed pumps in parallel as a function of load relative to the design load for a given ambient wet-bulb temperature. For this system (from Braun et al. [1989b]), each component (chillers, chilled-water pumps, and condenser water pumps) in each parallel set is identical and sized to meet half of the design requirements. The best performance occurs at about 25% of the design load with one chiller and pump operating. As load increases, system COP decreases because of decreasing chiller COP and a nonlinear increase in the power consumption of cooling tower and air handler fans. A second chiller should be brought online at the point where the overall COP of the system is the same with or without the chiller. For this system, this optimal switch point occurs at about 38% of the total design load or about 75% of the individual chiller's capacity. The optimal switch point for bringing a second condenser and chilled-water pump online occurs at a much higher relative chilled load (0.62) than the switch point for adding or removing a chiller (0.38). However, pumps are typically sequenced with chillers (i.e., they are brought online together). In this case, Figure 21 shows that the optimal switch point for bringing a second chiller online (with pumps) is about 50% of the overall design load or at the design capacity of the individual chiller. This is generally the case for sequencing chillers with dedicated pumps.

In most cases, zone humidities are allowed to float between upper and lower limits dictated by comfort (see Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*). However, VAV systems can control zone humidity and temperature simultaneously. For a zone being cooled, equipment operating costs are minimized when the zone temperature is at the upper bound of the comfort region. However, operating simultaneously at the upper limit of humidity does not minimize operating costs. Figure 22 shows an example comparison of system COP and zone humidity associated with fixed and free-floating zone humidity as a function of the relative load (from Braun et al. [1989b]). Over the range of loads, allowing the humidity to float within the comfort zone produces a lower cost and zone humidity than setting the humidity at the highest acceptable value. The largest differences occur at the highest loads. Operation with the zone at the upper humidity bound results in lower latent loads than with a free-floating humidity, but this humidity control constraint requires a higher supply air temperature, which in turn results in greater air-handler power consumption. For minimum energy costs, the humidity should be allowed to float freely within the bounds of human comfort.

Effects of Load and Ambient Conditions on Optimal Supervisory Control. When the ratio of individual zone loads to total load does not change significantly with time, the optimal control variables are functions of the total sensible and latent gains to the zones and of the ambient dry- and wet-bulb temperatures. For systems with wet cooling towers and climates where moisture is removed from conditioned air, the effect of the ambient dry-bulb temperature alone is small because air enthalpy depends primarily on wet-bulb temperature, and the performance of wet-surface heat exchangers is driven primarily by the enthalpy difference. Typically, zone latent gains are on the order of 15 to 25% of the total zone gains, and changes in latent gains have a relatively small effect on performance for a given total load. Consequently, in many cases optimal supervisory control variables depend primarily on ambient wet-bulb temperature and total chilled-water load. However, load distributions between zones may also be important if they change significantly over time.

Generally, optimal chilled-water and supply air temperatures decrease with increasing load for a fixed ambient wet-bulb temperature and increase with increasing ambient wet-bulb temperature for a fixed load. Furthermore, optimal cooling tower airflow and condenser water flow rates increase with increasing load and ambient wet-bulb temperature.

Performance Comparisons for Supervisory Control Strategies. Optimization of plant operation is most important when loads vary and when operation is far from design conditions for a significant period. Various strategies are used for chilled-water systems at off-design conditions. Commonly, the chilled-water and supply air set-point temperatures are changed only according to the ambient dry-bulb temperature. In some systems, cooling tower airflow and condenser water flow are not varied in response to changes in the load and ambient wet-bulb temperature. In other systems, these flow rates are controlled to maintain constant temperature differences between cooling tower outlet and ambient wet-bulb temperature (approach) and between cooling tower inlet and outlet (range), regardless of load and wet-bulb temperature. Although these strategies seem reasonable, they do not generally minimize operating costs.

Figure 23 shows a comparison of the COPs for optimal control and three alternative strategies as a function of load for a fixed ambient wet-bulb temperature. This system (from Braun et al. [1989b]) incorporated the use of variable-speed pumps and fans. The three strategies are

- Fixed chilled-water and supply air temperature set points (4.5 and 11°C, respectively), with optimal condenser-loop control
- Fixed tower approach and range (3 and 6.5 K, respectively), with optimal chilled-water loop control
- Fixed set points, approach, and range

Because the fixed values were chosen to be optimal at design conditions, differences in performance for all strategies are minimal at high loads. However, at part-load conditions, Figure 23 shows that the savings associated with the use of optimal control can become significant. Optimal control of the chilled-water loop results in greater savings than that for the condenser loop for part-load ratios less than about 50%. The overall savings over a cooling season depend on

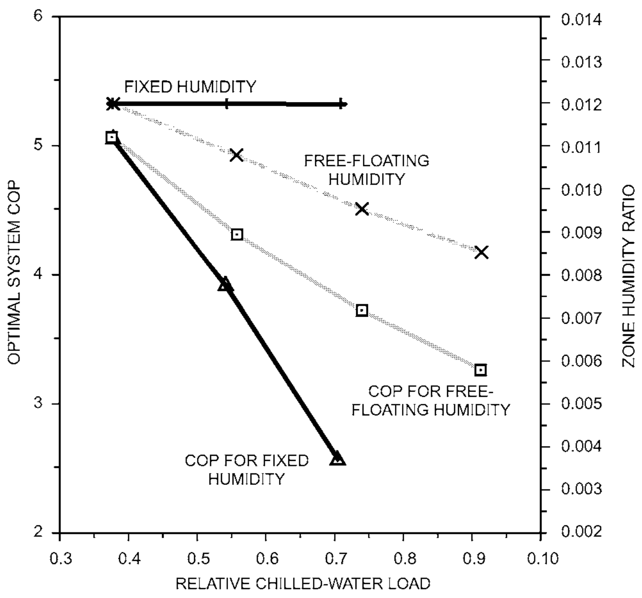

Fig. 22 Example Comparison of Free-Floating and Fixed Humidity

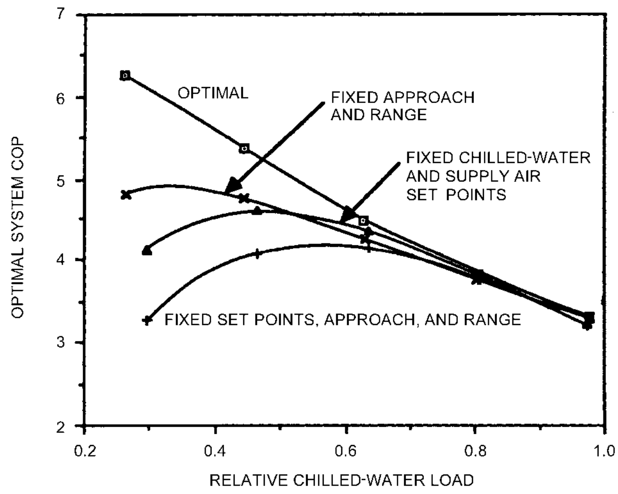

Fig. 23 Comparisons of Optimal Control with Conventional Control Strategies

the time variation of the load. If the cooling load is relatively constant and near the design load, fixed values of temperature set points, approach, and range could be chosen to give near-optimal performance. However, for typical building loads with significant daily and seasonal variations, the penalty for using a fixed set-point control strategy is typically in the range of 5 to 20% of the cooling system energy.

Even greater energy savings are possible with economizer control and discharge air temperature reset with constant-volume systems. Kao (1985) investigated the effect of different economizer and supply air reset strategies on both heating and cooling energy use for CAV, VAV, and dual-duct air-handling systems for four different buildings. The results indicated that substantial improvements in a building's energy use may be obtained.

Variable- Versus Fixed-Speed Equipment. Using variable-speed motors for chillers, fans, and pumps can significantly reduce energy costs but can also complicate the problem of determining optimal control. The overall savings from using variable-speed equipment over a cooling season depend on the time variation of the load. Typically, using variable-speed drives reduces equipment operating costs 20 to 50% compared to equipment with fixed-speed drives.

Figure 24 gives the overall optimal system performance for a cooling plant with either variable- or fixed-speed, variable-vane control of a centrifugal chiller. At part-load conditions, the system COP associated with using a variable-speed chiller is improved as much as 25%. However, the power requirements are similar at conditions associated with peak loads, because at full load the vanes are wide open and the speed under variable-speed control and fixed-speed operation is the same. The results in Figure 24 are from a single case study of a large chilled-water facility at the Dallas/Ft. Worth Airport (Braun et al. 1989b), constructed in the mid-1970s, where the existing chiller was retrofitted with a variable-speed drive. Differences in performance between variable- and fixed-speed chillers may be smaller for current equipment.

The most common design for cooling towers places multiple tower cells in parallel with a common sump. Each tower cell has a fan with one, two, or possibly three operating speeds. Although multiple cells with multiple fan settings offer wide flexibility in control, using variable-speed tower fans can provide additional improvements in overall system performance. Figure 25 shows an example comparison of optimal performance for single-speed, two-speed, and variable-speed tower fans as a function of load for a given wet-bulb temperature for a system with four cells (Braun et al. 1989b). The variable-speed option results in higher COP under all conditions. In contrast, for discrete fan control, the tower cells are isolated when their fans are off and the performance is poorer. Below about 70% of full-load conditions, there is a 15% difference in total energy consumption between single-speed and variable-speed fans. Between two-speed and variable-speed fans, the differences are much smaller, about 3 to 5% over the entire range.

Fixed-speed pumps that are sized to give proper flow to a chiller at design conditions are oversized for part-load conditions. Thus, the system will have higher operating costs than with a variable-speed pump of the same design capacity. Multiple pumps with different capacities have increased flexibility in control, and using a smaller fixed-speed pump for low loads can reduce overall power consumption. The optimal performance for variable-speed and fixed-speed pumps applied to both the condenser and chilled-water flow loops is shown in Figure 26 (Braun et al. 1989b). Large fixed-speed pumps were sized for design conditions; the small pumps were sized to have one-half the flow capacity of the large pumps. Below about 60% of full-load conditions, a variable-speed pump showed a significant improvement over the use of a single, large fixed-speed pump. With the addition of a small fixed-speed pump, improvements with the variable-speed pump were significant at about 40% of the maximum load.

Fan energy consumed by VAV systems is strongly influenced by the device used to vary the airflow. Centrifugal fans with variable-speed drives typically provide the most energy-efficient performance. Brothers and Warren (1986) compared the fan energy consumption for a typical office building in various U.S. locations. The analysis focused on centrifugal and vaneaxial fans with three typical flow modulation devices: (1) dampers on the outlet side of the fan, (2) inlet vanes on the fan, and (3) variable-speed control of the fan motor. In all locations, the centrifugal fan used less energy than the vaneaxial fan. Vaneaxial fans have higher efficiencies at the full-load design point, but centrifugal fans have better off-design characteristics that lead to lower annual energy consumption. For a centrifugal fan, inlet vane control saved about 20% of the energy compared to damper control. Variable-speed control produced average savings of 57% compared to inlet vane control.

Hybrid Cooling Plants. Hybrid cooling plants use a combination of chillers that are powered by electricity and natural gas. Braun (2007a) developed a set of near-optimal operating strategies for hybrid cooling plants to reduce operating costs. Operating cost min-

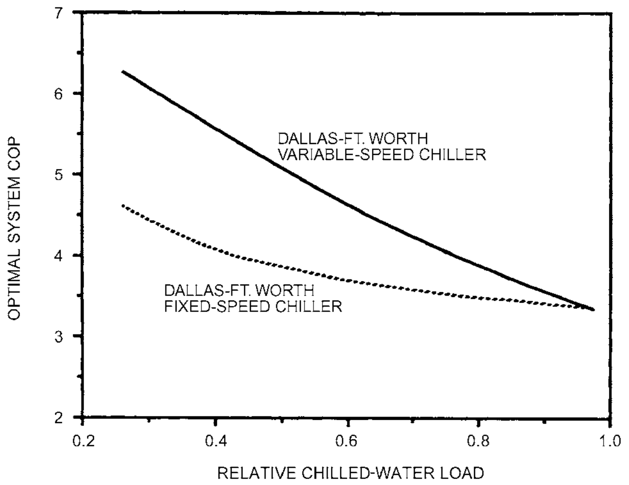

Fig. 24 Example of Optimal Performance for Variable- and Fixed-Speed Chillers

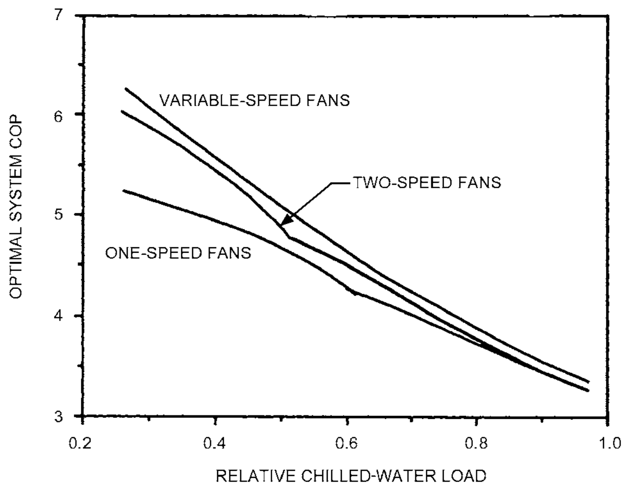

Fig. 25 Example Comparison of One-, Two-, and Variable-Speed Fans for Four-Cell Cooling Tower

imization for hybrid plants must account for effects of electrical and gas energy costs, electrical demand costs, and differences in maintenance costs associated with different chillers. Control strategies for hybrid cooling plants were developed by separating hourly energy cost minimization from the problem of determining tradeoffs between monthly energy and demand costs. A demand constraint was set for each month, based on a heuristic strategy, and energy cost optimal strategies that attempted to satisfy the demand constraint were applied for cooling tower and chiller control at each decision interval. Simulated costs associated with the individual control strategies compared well with costs for optimal control.

Moreover, Braun (2007b) presented an algorithm for determining cooling tower fan settings in hybrid plants in response to loadings on individual chillers. Parameters of the algorithm were evaluated using design information for the chillers and cooling tower fans. In addition to reducing operating costs, use of the open-loop control strategy simplifies the control and improves the stability of tower control compared with using a constant condenser water supply or approach to wet-bulb. Simulated plant cooling costs associated with the algorithm were compared with costs for optimized settings, and were within 1% of the minimum costs. The developed control method is general, in the sense that it also applies to cooling plants that have all-electric or all-natural-gas chillers.

3.6 DYNAMIC OPTIMIZATION FOR COOLING USING DISCRETE STORAGE

Thermal storage systems allow part or all of the cooling load to be shifted from on-peak to off-peak hours. Discrete cool storage systems typically use water or ice in unpressurized tanks as the thermal storage medium. Charging and discharging rates can be controlled from zero to a maximum design rate, which in some cases may equal the design load. In building structure (passive) storage, the building thermal mass is the storage medium; charging and discharging are accomplished by adjusting space temperatures over a relatively narrow range. Thermally active building systems (TABS), on the other hand, use structural elements with embedded pipes (e.g., radiant floor slabs) to promote controllable charging from within the mass. Conventional TABS relies on passive (uncontrolled) discharge. An active discharge mode has recently been demonstrated in a 250 m^2 occupied building. Phase-change materials may be used to increase the capacity of passive or TAB systems.

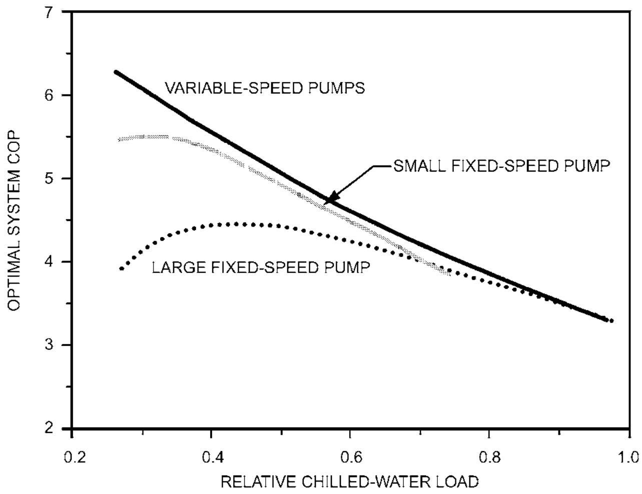

Fig. 26 Example of Optimal Performance for Variable- and Fixed-Speed Chillers

Utility incentives encouraging use of thermal storage are generally in the form of time-varying energy and peak demand charges. The commercial consumer is charged more for energy during the daytime, and is also levied an additional charge each month based on the peak power consumption during the on-peak period. These incentives can be significant, depending on location, and are often the most important factor affecting an optimal control strategy for systems with thermal storage.

Cooling Systems with Discrete Thermal Storage

Chapter 51 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* describes several possible storage media and system configurations for discrete thermal storage. Figure 27 depicts a generic storage system coupled to a cooling system and a building load. The storage medium could be chilled water, ice or some other phase change material. Cooling equipment **charges** (operates at low temperatures to make ice) during unoccupied periods when the cost of electricity is low. During times of occupancy and higher electric rates, ice is melted (**storage discharging**) as the storage meets all or part of the building load in combination with the primary cooling equipment. Stratified water storage is charged and discharged from the bottom (cold end) of the tank, with water returning from the load to the top of the tank during discharge and returning from the top of the tank to the chiller during charging.

The primary control variables for the thermal storage systems depicted in Figure 27 are the rate of (1) energy removal from storage by the cooling system (charging rate) and (2) energy addition because of the load (discharging rate). Determining the optimal charging and discharging rates differs considerably from determining optimal set points for cooling plants that do not have storage. With thermal storage, control decisions (i.e., charging and discharging rates) determined for the current hour affect costs and control decisions for several hours in the future. Optimal control of thermal storage systems involves finding a sequence of charging and discharging rates that minimizes the total cost of providing cooling over an extended period of time, such as a day, and requires forecasting and application of dynamic optimization techniques. Constraints include limits on charging and discharging rates. The optimal control sequence results from trade-offs between the costs of cooling the storage during off-peak hours and the cost of meeting the load during on-peak hours. Without utility incentives to use electricity at night, optimal control generally minimizes use of ice storage because the cooling equipment operates less efficiently while charging at low temperatures. For building thermal mass systems, precooling increases heat gains from

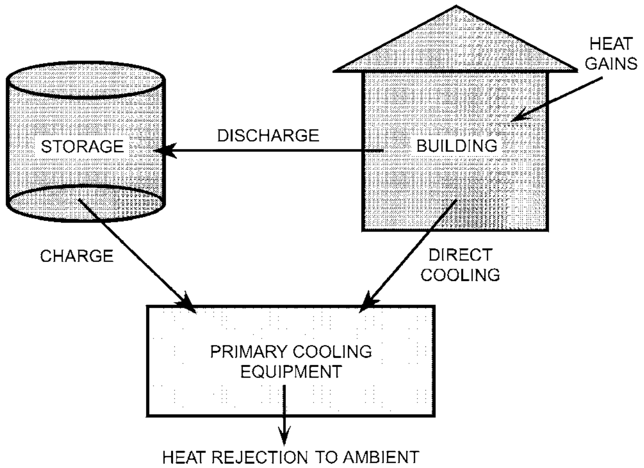

Fig. 27 Generic Storage System for Cooling (Arrows Show Direction of Heat Flow)

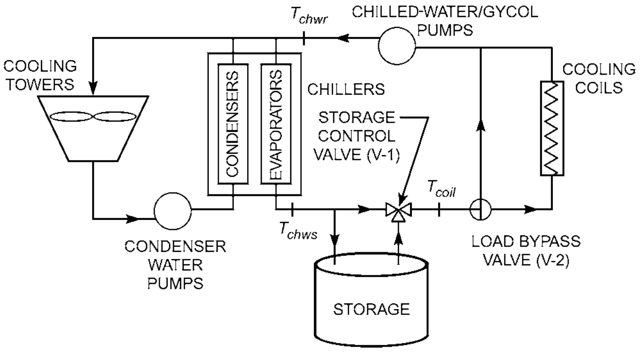

Fig. 28 Schematic of an Ice Storage System

the ambient to the building. Close attention to system design and supervisory control is essential if this penalty is to be offset by potentially more efficient operation of the chiller at higher chilled-water and lower average heat rejection (night operation) temperatures.

Online optimal control of thermal storage, like other HVAC optimal control schemes, is rarely implemented because of the high initial costs associated with sensors (e.g., power) and software implementation. However, heuristic control strategies have been developed that provide near-optimal performance under most circumstances. The following sections provide background on developing control strategies for ice storage and building thermal mass. Detailed descriptions of some specific control strategies are given in the Supervisory Control Strategies section of this chapter.

Ice Storage. This section emphasizes ice storage applications, although much of the information applies to chilled-water storage as well. Figure 28 shows a schematic of a typical ice storage system. The system consists of one or more chillers, cooling tower cells, condenser water pumps, chilled-water/glycol distribution pumps, ice storage tanks, and valves for controlling charging and discharging modes of operation. Ice is made at night and used during the day to provide part of a building's cooling requirements; the storage is not sized to handle the full on-peak load requirement on the design day. Typically, in a load-leveling scheme, the storage and chiller capacity are sized such that chiller operates at full capacity during the on-peak period on the design day.

Typical modes of operation for the system in Figure 28 are as follows:

- **Storage charging mode:** Typically, charging (i.e., ice making) only occurs when the building is unoccupied and off-peak electric rates are in effect. In this mode, the load bypass valve V-2 is fully closed to the building cooling coils, the storage control valve V-1 is fully open to the ice storage tank (the total chilled-water/glycol flow is through the tank), and the chiller produces low temperatures (e.g., –7°C) sufficient to make ice within the tank.
- **Storage discharging mode:** Discharging of storage (i.e., ice melting) only occurs when the building is occupied. In this mode, valve V-2 is open to the building cooling coils and valve V-1 modulates the mixture of flows from the storage tank and chiller to maintain a constant supply temperature to the building cooling coils (e.g., 3°C). Individual valves at the cooling coils modulate their chilled-water/glycol flow to maintain supply air temperatures to the zones.
- **Direct chiller mode:** The chiller may operate to meet the load directly without using storage during the occupied mode (typically when off-peak electric rates are in effect). In this mode, valve V-1 is fully closed with respect to the storage tank.

For a typical partial-storage system, the storage meets only a portion of the on-peak cooling loads on the design day and the chiller operates at capacity during the on-peak period. Thus, the peak power is limited by the capacity of the chiller. For off-design days, there are many different control strategies that meet the building's cooling requirements. However, each method has a different overall operating cost.

The best control strategy for a given day is a function of several factors, including utility rates, load profile, chiller characteristics, storage characteristics, and weather. For a utility rate structure that includes both time-of-use energy and demand charges, the optimal strategy can depend on variables that extend over a monthly time scale. Consider the charges typically associated with electrical use within a building. The first charge is the total cost of energy use for the building over the billing period, which is usually a month. Typically, the energy cost rate varies according to time of use, with high rates during the daytime on weekdays and low costs at night and on weekends. The second charge, the building demand cost, is the product of the peak power consumption during the billing period and the demand cost rate for that stage. The demand cost rate can also vary with time of day, with higher rates for on-peak periods. To determine a control strategy for charging and discharging storage that minimizes utility costs for a given system, it is necessary to perform a minimization of the total cost over the entire billing period because of the demand charge. An even more complicated cost optimization results if the utility rate includes ratchet clauses, whereby the demand charge is the maximum of the monthly peak demand cost and some fraction of the previous monthly peak demand cost within the cooling season. In either case, it is not worthwhile to perform an optimization over time periods longer than those for which reliable forecasts of cooling requirements or ambient conditions could be performed (e.g., 1 day). It is therefore important to have simple control strategies for charging and discharging storage over a daily cycle.

The following control strategies for limiting cases provide further insight:

- If the demand cost rate is zero and the energy cost rate does not vary with time, minimizing cost is equivalent to minimizing total electrical energy use. In general, cooling plant efficiency is lower when it is being used to make ice than when it is providing cooling for the building. Thus, in this case, the optimal strategy for minimum energy use minimizes the use of storage. This approach is used by chiller-priority control, the most common control strategy for partial ice storage systems.
- If the demand cost rate is zero but energy costs are higher during on-peak than off-peak periods, minimizing cost then involves trade-offs between energy use and energy cost rates. For relatively small differences between on-peak and off-peak rates of less than about 30%, energy penalties for ice making typically outweigh the effect of reduced rates, and chiller-priority control is optimal for many cases. However, with higher differentials between on-peak and off-peak energy rates or with chillers having smaller charging-mode energy penalties, the optimal strategy might maximize the use of storage. A control strategy that attempts to maximize the load-shifting potential of storage is called storage-priority control; in this scheme, the chiller operates during the off-peak period to fully charge storage. During the on-peak period, storage is used to cool the building in a manner that minimizes use of the chiller(s). Partial-storage systems that use storage-priority control strategies require forecasts for building cooling requirements to avoid prematurely depleting storage.
- If only on-peak demand costs are considered, then the optimal control strategy tends to maximize the use of storage and controls the discharge of storage in a manner to always minimize the peak building power. A storage-priority, demand-minimization control strategy for partial-storage systems requires both cooling load and non-cooling electrical use forecasts.

Several control strategies based on these three simple limiting cases have been proposed for ice storage systems (Braun 1992; Drees and Braun 1996; Grumman and Butkus 1988; Rawlings 1985; Spethmann 1989; Tamblyn 1985). Braun (1992) appears to have been the first to evaluate the performance of chiller-priority and storage-priority control strategies as compared with optimal control. The storage-priority strategy was termed load-limiting control because it attempts to minimize the peak cooling load during the on-peak period. For the system considered, the load-limiting strategy provided near-optimal control in terms of demand costs in all cases and worked well with respect to energy costs when time-of-day energy charges were available. However, the scope of the study was limited in terms of the systems considered.

Krarti et al. (1996) evaluated chiller-priority and storage-priority control strategies as compared with optimal control for a wide range of systems, utility rate structures, and operating conditions. Similar to Braun (1992), they concluded that load-limiting, storage-priority control provides near-optimal performance when there are significant differentials between on-peak and off-peak energy and demand charges. However, optimal control provides superior performance in the absence of time-of-day incentives. In general, the monthly utility costs associated with chiller-priority control were significantly higher than optimal and storage-priority control. However, without time-of-use energy charges, chiller-priority control did provide good performance for individual days when the daily peak power was less than the monthly peak. General guidance based on the work is presented by Henze et al. (2003). Drees and Braun (1996) developed a simple rule-based control strategy that combines elements of storage- and chiller-priority strategies in a way that results in near-optimal performance under all conditions. The strategy was derived from heuristics obtained through both daily and monthly optimization results for several simulated systems. A modified version of this strategy is presented in the Supervisory Control Strategies section of this chapter.

Braun (2007c, 2007d) also developed a near-optimal control method for charging and discharging of cool storage systems when real-time pricing (RTP) electric rates are available The algorithm requires relatively low-cost measurements (cooling load and storage state of charge) and very little plant specific information, is computationally simple, and ensures that building cooling requirements are always met (e.g., storage is not prematurely depleted). The control method was evaluated for ice storage systems using a simulation tool for different combinations of cooling plants, storage sizes, buildings, locations, and RTP rates.

Control Strategies for Cooling Systems with Discrete Thermal Storage

The choice of a control strategy for a cooling system with discrete thermal storage system results from a trade-off between performance (i.e., operating costs) and ease of implementation (i.e., initial costs). Chiller-priority control has the lowest implementation costs, but generally leads to the highest operating costs. Storage-priority strategies provide superior performance, but require the use of a forecaster and a measurement of state of charge for storage. This section presents details of chiller-priority, load-limiting, and rule-based control applied to ice storage systems. Each of these strategies shares the same procedures for charging storage, but differs in how storage is discharged. In general, the control strategies presented in this section are appropriate for systems with utility rate structures that include time-of-use energy and demand charges, but would not be appropriate in conjunction with real-time pricing. Additional information on control strategies for cool storage systems can be found in Chapter 51 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Charging Strategies

Ice making should be initiated when both the building is unoccupied and off-peak electrical rates are in effect. During the ice-making period, the chiller should operate at full capacity. Cooling plants for ice storage generally operate most efficiently at full load because of the auxiliaries and the characteristics of ice-making chillers. With feedback control of the chilled-water/glycol supply temperature, full capacity control is accomplished by establishing a low enough set point to ensure this condition (e.g., –7°C).

Internal Melt Storage Tanks. The chiller should operate until the tank reaches its maximum state of charge or the charging period (i.e., off-peak, unoccupied period) ends. This strategy ensures that sufficient ice will be available for the next day without the need for a forecaster. Typically, only a small heat transfer penalty is associated with restoring a partially discharged, internal melt storage tank to a full charge. For this type of storage device, the charging cycle always starts with a high transfer effectiveness because water surrounds the tubes regardless of the amount of ice melted. The heat transfer effectiveness drops gradually until the new ice formations intersect with old formations, at which point the tank is fully recharged.

External Melt Storage Tanks. These tanks have a more significant heat transfer penalty associated with recharging after a partial discharge, because ice forms on the outside of existing formations during charging. In this case, it is more efficient to fully discharge the tank each day and only recharge as necessary to meet the next day's cooling requirements. To ensure that adequate ice is available, the maximum possible storage capacity needed for the next day must be forecast. The storage requirements for the next day depend on the discharge strategy used and the building load. In general, the state of charge for storage necessary to meet the next day's load can be estimated according to

$$X_{chg} = \sum_{k=1}^{\substack{\text{occupied}\\\text{period}}} \frac{\hat{Q}_{load,k} - \hat{Q}_{ch,k}}{C_s} \tag{44}$$

where X_{chg} is the relative state of charge at the end of the charging period, C_s is the maximum change in internal energy of the storage tank that can occur during a normal discharge cycle, and $\hat{Q}_{load,k}$ and $\hat{Q}_{ch,k}$ are forecasts of the building load and chiller cooling requirement for the kth stage (e.g., hour) of the occupied period. The relative state of charge is defined in terms of two reference states: the fully discharged and fully charged conditions that correspond to values of zero and one. These conditions are defined for a given storage based on its particular operating strategy (ASHRAE *Standard* 150; Elleson 1996). The fully charged condition exists when the control stops the charge cycle as part of its normal sequence. Similarly, the fully discharged condition is the point where no more usable cooling is recovered from the tank. Typically, zero state of charge corresponds to a tank of water at a uniform temperature of 0°C and a complete charge is associated with a tank having maximum ice build at 0°C. (The fully discharged and fully charged conditions are arbitrarily selected reference states.) In abnormal circumstances, a storage tank can be discharged or charged beyond these conditions, resulting in relative states of charge below zero or above one.

Hourly forecasts of the next day's cooling requirement can be determined using the algorithm described in the section on Forecasting Diurnal Cooling and Whole Building Demand Profile. However, long-term forecasts are highly uncertain and a safety factor based on previous forecast errors is appropriate (e.g., uncertainty of two or three times the standard deviation of the errors of previous forecasts). Estimates of hourly chiller requirements should be determined using the intended discharge strategy (described in the next section) and building load forecasts.

Discharging Strategies

Three discharge strategies are presented for use with utility structures having on-peak and off-peak energy and demand charges: (1) chiller-priority control, (2) storage-priority, load-limiting control, and (3) a rule-based strategy that uses both chiller-priority and load-limiting strategies.

Chiller-Priority Discharge. During the storage discharge mode, the chiller operates at full cooling capacity (or less if sufficient to meet the load) and storage matches the difference between the building requirement and chiller capacity. For the example system shown in Figure 28, the chiller supply temperature set point t_{chws} is set equal to the desired supply temperature for the coils t_{coil}. If the capacity of the chiller is sufficient to maintain this set point, then storage is not used and the system operates in the direct chiller mode. Otherwise, the storage control valve modulates the flow through storage to maintain the supply set point, providing a cooling rate that matches the difference between the building load and the maximum cooling capacity of the chillers.

This strategy is easy to implement and does not require a load forecast. It works well for design conditions, but can result in relatively high demand and energy costs for off-design conditions because the chiller operates at full capacity during the on-peak period.

Storage-Priority, Load-Limiting Control. Several storage-priority control approaches ensure that storage is not depleted prematurely. Braun (1992) presented a storage-priority (load-limiting) control strategy, which tends to minimize the peak cooling plant power demand. The operation of equipment for load-limiting control during different parts of the occupied period can be described as follows:

- **Off-Peak, Occupied Period.** During this period, the goal is to minimize use of storage, and the chiller-priority described in the previous section should be applied.
- **On-Peak, Occupied Period.** During this period, the goal is to operate the chillers at a constant load while discharging the ice storage such that the ice is completely melted when the off-peak period begins. This requires using a building cooling-load forecaster. At each decision interval (e.g., 15 min), the following steps are applied:

  (1) Forecast the total integrated building cooling requirement until the end of the discharging period.

  (2) Estimate the state of charge of the ice storage tank from measurements.

  (3) At any time, the chiller loading for load-limiting control is determined as

$$\dot{Q}_{LLC} = \mathrm{Max}\left[\frac{\hat{Q}_{load,occ} - (X - X_{min})C_s}{\Delta t_{on}}, \hat{Q}_{ch,min}\right] \qquad (45)$$

  where $\hat{Q}_{load,occ}$ is a forecast of the integrated building load for the rest of the on-peak period, Δt_{on} is the time remaining in the on-peak period, X is the current state of charge defined as the fraction of the maximum storage capacity, X_{min} is a minimum allowable state of charge, C_s is the maximum possible energy that could be added to storage during discharge, and $\hat{Q}_{ch,min}$ is the minimum allowable chiller cooling capacity. If the chiller does not need to be operated during the remainder of the occupied, on-peak period, the minimum allowable cooling capacity could be set to zero. Otherwise, the cooling capacity should be set to the minimum at which the chiller can safely operate.

  (4) Determine the chiller set-point temperature necessary to achieve the desired loading as

$$t_{chws} = t_{chwr} - \frac{\dot{Q}_{LLC}}{C_{chw}} \qquad (46)$$

  where t_{chwr} is the temperature of water/glycol returned to the chiller and C_{chw} is the capacitance rate (mass flow times specific heat) of the flow stream.

Hourly forecasts of cooling loads can be determined using the algorithm described in the section on Forecasting Diurnal Cooling and Whole-Building Demand Profiles. The hourly forecasts are then integrated to give a forecast of the total cooling requirement. To ensure sufficient cooling capacity, a worst-case forecast of cooling requirements could be estimated as the sum of the best forecast and two or three times the standard deviation of the errors of previous forecasts.

Rule-Based Controller. Drees and Braun (1996) presented a rule-based controller that combines elements of chiller-priority and storage-priority strategies, along with a demand-limiting algorithm to achieve near-optimal control. The demand-limiting algorithm requires a measurement of the total building electrical use. A simpler strategy is described here that does not require this measurement and yields equivalent performance whenever the peak demand for the billing period is coincident with the peak cooling load.

Figure 29 shows a flowchart for the discharge strategy that is applied during each decision interval (e.g., 15 min) during the occupied period. Block 1 determines whether storage use should be maximized or minimized. Block 2 is used if storage use lowers daily energy costs and storage is sufficient to meet the remainder of the load for the occupied period without operating the chillers. Otherwise, the goal of the strategy in block 3 is to minimize storage use while keeping peak load below a limit. This strategy tends to keep the chiller(s) heavily loaded (and therefore, if part-load efficiency is poor, operating efficiently) until they are no longer needed. The logic in each block is as follows:

- **Block 1: Discharge Strategy Selection.** The discharge of storage will not reduce the energy cost whenever the cost of replenishing the ice is greater than the cost of providing direct cooling by the chiller(s). This situation is always the case during the off-peak, occupied period because the electricity rates are the same as those associated with the charging period and chillers are less efficient in ice-making mode than when providing direct cooling. Furthermore, during the on-peak, occupied period, using storage generally reduces energy costs whenever the following criterion holds:

$$\mathrm{ECR} > \mathrm{COP}_d/\mathrm{COP}_c \qquad (47)$$

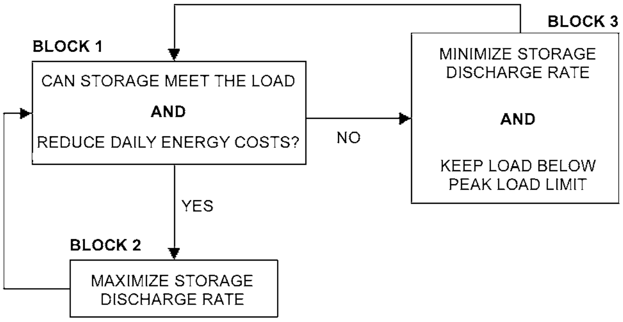

Fig. 29 Flowchart for Rule-Based Controller Discharge Strategy

where ECR is the ratio of on-peak to off-peak energy charges and COP_d and COP_c are coefficients of performance for the cooling plant (including chiller, pumps, and cooling tower fans) during discharging and charging of the tank. The COPs should be evaluated at the worst-case charging and discharging conditions associated with the design day. Typically, this ratio is between about 1.2 and 1.8 for systems with cooling towers. However, the ratio can be lower because of the effect of cool nighttime temperatures, especially for systems with air-cooled condensers in dry climates.

If the criterion of Equation (47) is satisfied, control switches from chiller-priority to storage-priority strategy whenever storage capacity is greater than the remaining integrated load. Therefore, storage-priority control is enabled whenever

$$(X - X_{min})C_s \geq \hat{Q}_{load,occ} \quad (48)$$

Hourly forecasts of cooling loads can be determined using the algorithm described in the section on Forecasting Diurnal Cooling and Whole-Building Demand Profiles and then integrated to give a forecast of the total cooling requirement. To ensure that adequate ice is available, worst-case hourly forecasts can be determined by adding the expected value of the hourly forecasts and the forecast errors associated with a specified confidence interval (e.g., two standard deviations for a 95% confidence interval). The worst-case hourly forecasts can then be integrated to give a worst-case integrated forecast.

- **Block 2: Maximum Use of Storage.** In this mode, the chillers are turned off and storage is used to meet the entire load throughout the remainder of the occupied period. However, a chiller may need to be turned on if the storage discharge rate is not sufficient to meet the building load (i.e., the coil supply temperature set point cannot be maintained).
- **Block 3: Minimize Use of Storage with Peak Load Limiting.** At any time, a target chiller load is determined as

$$\dot{Q}_{ch} = \mathrm{Min}\left[\mathrm{Max}\left(\dot{Q}_{ch,peak}, \dot{Q}_{LCC}\right), \dot{Q}_{load}\right] \quad (49)$$

where $\dot{Q}_{ch,peak}$ is the peak chiller cooling requirement that has occurred during the on-peak period for the current billing period, $\dot{Q}_{LCC}$ is the chiller load associated with load-limiting control and determined with Equation (45), and $\dot{Q}_{load}$ is the current building load. The chiller set-point temperature necessary to achieve the desired loading is determined as

$$t_{chws} = \mathrm{Max}\left(t_{chwr} - \frac{\dot{Q}_{ch}}{C_{chw}}, t_{coil}\right) \quad (50)$$

On the first day of each billing period, $\dot{Q}_{ch,peak}$ is set to zero. For this first day, applying Equation (49) leads to the load-limiting control strategy described in the previous section. On subsequent days, load-limiting control is used only if the current peak limit would lead to premature depletion of storage. Whenever the current load is less than $\dot{Q}_{ch,peak}$ and $\dot{Q}_{LCC}$, Equations (49) and (50) lead to chiller-priority control.

3.7 DYNAMIC OPTIMIZATION FOR COOLING USING THERMAL MASS OR TABS

Precooling of Building Thermal Mass

For conventional night setup strategies, building mass works to increase operating costs (Bloomfield and Fisk 1977). A massless building would require no time for precooling or preheating and would have lower overall cooling or heating loads than an actual building. However, under proper circumstances, using a building's thermal storage for load shifting can significantly reduce operational costs and energy use, even though the total zone loads may increase. This is especially true for cooling of high-performance buildings, in which internal loads may dominate.

At any given time, the cooling requirement for a space is caused by convection from internal gains (lights, equipment, and people) and interior surfaces. Because a significant fraction of the internal gain is radiated to interior surfaces, the state of a building's thermal storage and the convective coupling dictates the cooling requirement. Precooling the building during unoccupied times reduces the overall convection from exposed surfaces during the occupied period as compared with night setup control and can reduce daytime cooling requirements. The potential for storing thermal energy in the structure and furnishings of conventional commercial buildings is significant compared to the load requirements. Typically, internal gains are about 20 to 40 W per square metre of floor space. The thermal capacity for typical concrete building structures is approximately 40 to 80 (W·h)/K per square metre of floor area. Thus, for an internal space, the energy storage can handle the load for about 1 h for every 0.6 K of precooling of the thermal mass.

Opportunities for reducing operating costs by using building thermal mass for cooling derive from four effects: (1) reduction in demand costs, (2) use of low-cost off-peak electrical energy, (3) reduced mechanical cooling from the use of cool nighttime air for ventilation precooling, and (4) improved mechanical cooling efficiency from increased operation at more favorable part-load and ambient conditions. However, these benefits must be balanced with the increase in total cooling requirement that occurs with precooling the thermal mass. Therefore, the savings associated with load shifting and demand reductions depend on both the method of control and the specific application.

Several simulation studies have been performed that demonstrate a substantial benefit to precooling buildings in terms of cost savings and peak cooling load reduction (Andresen and Brandemuehl 1992; Braun 1990; Rabl and Norford 1991; Snyder and Newell 1990). Possible energy savings ranged from 0 to 25%; possible reductions in total building peak electrical demand ranged from 15 to 50% compared with conventional control. The results can be sensitive to the convective coupling between the air and the thermal mass, and the mass of the furnishings may be important (Andresen and Brandemuehl 1992).

Determining the optimal set of building temperatures over time that minimizes operating costs is complex. Keeney and Braun (1996) developed a simplified approach for determining optimal control of building thermal mass using two optimization variables for the precool period and a set of rules for the occupied period of each day. This approach significantly reduces the computation required for determining the optimal control as compared with considering hourly zone set points as optimization variables. Results of the simplified approach compared well with those of detailed optimizations for a range of systems (over 1000 different combinations of building types, weather conditions, cooling plants, and utility rates).

Morris et al. (1994) performed a set of experiments using a test facility at the National Institute of Standards and Technology (NIST) to demonstrate the potential for load shifting and load leveling when control was optimized. Two different control strategies were considered: (1) minimum cooling system energy use and (2) minimum peak cooling system electrical demand. The two strategies were implemented in the test facility and compared with night setup control. Figure 30 shows the 24 h time variation in the cooling requirement for the test facility allowed to reach a steady-periodic condition, for both the minimum energy use strategy and conventional night setup control. The results indicate a significant load-shifting potential for the optimal control. Overall, cooling requirements during the occupied period were approximately 40% less for optimal than for night setup control.

Comfort conditions were also monitored for the tests. Figure 31 gives the time variation of predicted mean vote (PMV) for the two control strategies as determined from measurements at the facility. A PMV of zero is a thermally neutral sensation, positive is too warm, and negative too cool. In the region of ±0.5, comfort is not compromised to any significant extent. Figure 31 shows that comfort conditions were essentially identical for the two control methods during the occupied period. The space temperature, which has the dominant effect on comfort, was maintained at 24°C during the occupied period for both control methods. During the unoccupied period, the cooling system was off for night setup control and the temperature floated to warm comfort conditions. On the other hand, the optimal controller precooled the space, resulting in cool comfort conditions before occupancy. During these tests, the minimum space temperature during precooling was 20°C, and the space temperature set point was raised to 24°C just before occupancy.

Figure 32 shows the 24 h time variation in the cooling requirement for the test facility for both the minimum peak demand strategy and conventional night setup. Optimal control involved precooling the structure and adjusting space temperatures within the comfort zone (–0.5 < PMV < 0.5) during the occupied period to achieve minimum demand. Although the true minimum was not achieved during the tests, the peak cooling rate during the occupied period was approximately 40% less for minimum peak demand control than for night setup control.

Morris et al. (1994) demonstrated significant savings potential for control of building thermal mass; however, they also showed that the cost savings are very sensitive to the application, operating conditions, and method of control. For example, an investigation into the effect of precooling on the on-peak cooling requirements for an existing building (which may not have been a good candidate for use of building thermal storage) showed only a 10% reduction in the cooling energy required during the occupied period, with a substantial increase in the total cooling required and no reduction in the peak cooling requirement (Ruud et al. 1990). System simulations can be used to identify (1) whether the system is a good candidate for using building thermal mass and (2) an effective method for control, before implementing a strategy in a particular building.

Keeney and Braun (1997) used system simulation to develop a control strategy that was then tested in a large commercial building located northwest of Chicago. The goal of the control strategy was to use building thermal mass to limit the peak cooling load for continued building operation in the event of the loss of one of the four central chiller units. The algorithm was tested using two nearly identical buildings separated by a large, separately cooled entrance area. The east building used the existing building control strategy; the west building used the precooling strategy developed for this project. The precooling control strategy successfully limited the peak load to 75% of the cooling capacity for the west building, whereas the east building operated at 100% of capacity. Details of the strategy and case study results are presented in the Supervisory Control Strategies section of this chapter.

Braun et al. (2001) used on-site measurements from the same building used by Keeney and Braun (1997) to train site-specific models that were then used to develop site-specific control strategies for using building thermal mass and to evaluate the possible

(Morris et al. 1994)

cost savings of these strategies. The building was an excellent candidate for using building thermal mass because it had (1) a large differential between on-peak and off-peak energy rates (about a 2-to-1 ratio), (2) a large demand charge (about $16/kW), (3) a heavy structure with significant exposed mass, and (4) cooling loads that are dominated by internal gains, leading to a high storage efficiency. The model underpredicted the total HVAC bill by about 5%, but worked well enough to be used in comparing the performance of alternative control strategies.

Table 6 gives estimates of cooling-related costs and savings over the course of three summer months for different control strategies. The light and moderate precool strategies are simple strategies that precool the building at a fixed set point of 19.5°C before occupancy and then maintain a fixed discharge set point in the middle of the comfort range (23°C) during occupancy. The light precool begins at 3 AM, whereas moderate precool starts at 1 AM. The extended precool strategy attempts to maintain the cooled thermal mass until the onset of the on-peak period. In this case, the set point at occupancy is maintained at the lower limit of comfort (20.5°C) until the on-peak period begins at 10 AM. At this point, the set point is raised to the middle of the comfort range (23°C). The other strategies use the extended precooling, but the entire comfort range is used throughout the on-peak, occupied period. The maximum discharge strategy attempts to discharge the mass as quickly as possible after the on-peak period begins. In this case, the set point is raised to the upper limit of comfort within an hour after the on-peak period begins. The slow linear rise strategy raises the set point linearly over the entire on-peak, occupied period (9 h in this case), whereas the fast linear rise strategy raises the set point over 4 h.

The strategies that do not use the entire comfort range during the occupied period (light precool, moderate precool and extended precool) all provided about 20% savings compared to night setup. Each of these strategies reduced both energy and demand costs, but the demand costs and reductions were significantly greater than the energy costs and savings. The decreases in energy costs were caused by favorable on-to-off peak energy rate ratios of about 2 to 1. The high on-peak demand charges provided even greater incentives for precooling. The savings increased with the length of the precooling period, particularly when precooling was performed close to the onset of on-peak rates. The maximum discharge strategy, which maximizes discharge of the thermal storage within the structure, provided the largest savings (41%). Much of the additional savings came from reduced demand costs. The linear rise strategies also provided considerable savings with greater savings associated with faster increases in the set point temperature.

Morgan and Krarti (2006) performed both simulation analyses and field testing to evaluate various precooling strategies. They found that energy cost savings associated with precooling thermal mass depends on several factors, including thermal mass level, climate, and utility rate. For time-of-use (TOU) utility rates, they found that energy cost savings are primarily affected by the ratio of on-peak to off-peak demand charges as well as the ratio of on-peak to off-peak energy charges (see Chapter 51 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*).

ASHRAE research project RP-1313 conducted an extensive study of building thermal mass control (Henze et al. 2007), in which optimal building thermal mass control strategies were investigated for time-of-use electric utility rates structures, including demand charges, with the help of a newly developed integrated optimization and building simulation tool (Henze et al. 2008). Cheng et al. (2008) identified the primary factors that influence optimal control of passive thermal storage, where optimal control strategies are determined with the objective of minimizing total energy and demand costs. A fractional factorial analysis was used to investigate how cost savings are affected by several building and system characteristics, utility rate structures, and climates. Utility rates, internal

Table 6 Cooling Season Energy, Demand, and Total Costs and Savings Potential of Different Building Mass Control Strategies

Strategy	Costs in U.S. Dollars: Energy	Demand	Total	Savings, %
Night setup	$90 802	$189 034	$279 836	0.0
Light precool	$84 346	$147 581	$231 928	17.1
Moderate precool	$83 541	$143 859	$227 400	18.7
Extended precool	$81 715	$134 551	$216 266	22.7
Maximum discharge	$72 638	$91 282	$163 920	41.4
Two-hour linear rise	$72 671	$91 372	$164 043	41.4
Four-hour linear rise	$73 779	$115 137	$188 916	32.5
Nine-hour linear rise	$77 095	$141 124	$218 219	22.0

loads, building mass level, and equipment efficiency were found to have the largest impacts on cost savings, whereas building envelope characteristics did not have a significant impact. Although the magnitude of savings is affected by climate, the relative influences of each of these factors are largely independent of weather.

Using the same simulation and optimization environment, Henze et al. (2009) presented advances toward near-optimal building thermal mass control derived from full factorial analyses of the important parameters influencing passive thermal storage for a range of buildings and climate/utility rate structure combinations. In response to the actual utility rates imposed in the investigated cities, insights and control simplifications were derived from those buildings deemed suitable candidates. The near-optimal strategies were derived from the optimal control trajectory, consisting of four variables, and then tested for effectiveness and validated with respect to uncertainty regarding building parameters and climate variations. Although no universally applicable control guideline could be found, a significant number of cases (i.e., combinations of buildings, weather, and utility rate structure) were investigated and offer both insight into and recommendations for simplified control strategies. These recommendations are a good starting point for experimentation with building thermal mass control for a substantial range of building types, equipment, climates, and utility rates.

The cost savings potential of optimal passive thermal storage controls were examined by Greensfelder et al. (2011) for the case of day-ahead, real-time electricity rate structures. The operational strategies of three office building models were optimized in four U.S. cities (Chicago, New York, Houston, and Los Angeles) using price and weather data for the summer of 2008. Building thermal mass was optimized using a predictive optimal controller to define supervisory control strategies in terms of building global cooling temperature set points. A global minimization algorithm determined optimal set-point trajectories for each day divided into four distinct time periods (called building modes). Cost savings were found to range from 0 to 14%, depending on the building, climate, and characteristics of the rate signal. The best cost savings occurred in the presence of price spikes or cool nighttime temperatures. Moreover, it was found that low internal gains favored a more flexible precooling strategy, whereas high internal gains coupled with low thermal mass resulted in poor precooling performance.

Thermally Activated Building Systems (TABS)

One way to reduce cooling energy further along the path to net-zero-energy buildings is **thermally activated building systems (TABS)**: direct cooling of building mass by chilled water in conjunction with chillers designed for very high part-load efficiency in low-lift operation and enthalpy-recovery dedicated outdoor air systems (DOAS).

TABS differs from passive storage by cooling the mass directly from the inside, thus eliminating charging-mode convective or radiative coupling resistances. By directly precooling the mass, instead of the occupied space, substantially better storage efficiency and larger effective diurnal storage capacity are achieved. Precooling energy percentage savings may be 5 to 35% higher because the condenser-evaporator temperature difference is lower to begin with and because, with the elimination of supply fans and mechanical cooling, energy use is dominated by compressor operation at very low pressure ratios (Armstrong et al. 2009; Katipamula et al. 2010b). Economizer mode, which involves mainly pumping rather than fan transport energy, is extremely energy efficient as well.

Katipamula et al. (2010a, 2010b) simulated idealized thermal energy storage (TES) to approximate TABS, and a variable-speed air-cooled chiller with variable-speed distribution pump. The TES and distribution options are shown schematically in Figure 33.

The chiller/distribution system was modeled with compressor, condenser fan, and chilled-water pump capable of wide 10:1 speed ranges and statically optimized control, resulting in evaporator temperatures of up to 18°C at 10% of design load. Chiller performance was measured by an independent testing laboratory over a wide range of part-load fraction, outdoor temperatures, and chilled-water temperatures (Katipamula et al. 2010a). Performance curves fit to the data are shown in Figure 34. The performance map on the left is for a standard chilled-water reset schedule recommended for VAV systems (ASHRAE *Standard* 90.1), and the right-hand map represents performance of the chiller with radiant ceiling panels (RCPs) or chilled-beam distribution system serving a conditioned space at T_{op} = 24°C. Compressor, condenser fan, and chilled-water pump are operated at optimal speed under any given condition and part-load fraction.

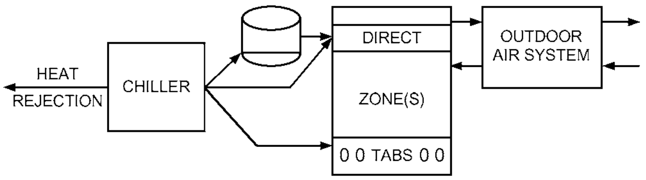

Fig. 33 Schematic of Thermally Activated Building System with Three Cooling Options

A flat electricity rate was assumed, to achieve minimum annual energy use, and the performance of standard and high-performance versions of 12 building types was simulated in 16 climates. The load shifting achieved by TES is shown in Figure 35. The joint distribution of chiller output is expressed in full-load operating hours for each bin cell of 2.8 K in outdoor temperature by 10% in rated capacity. Compared to the base-case load distribution, operation hours for the TES system are significantly shifted in two respects. The bin in which the full-load equivalent operating hours (FLEOH) peak occurs is typically 8.3 K lower than in the baseline chiller load distribution. Although the chiller continues to operate at high outdoor temperatures, it does so at much lower part-load ratios. Conversely, the FLEOH of operation at low outdoor temperature and low part-load ratio significantly increased.

The base case for savings used a two-speed chiller built from the same components as the statically optimized chiller and VAV or CAV air-handling unit, depending on building type, with air-side economizer for distribution and no storage. The controller objective function for the TABS storage case, Equation (4), involves only the chiller power used to meet sensible load, $P = u/\text{COP}(u,t)$ with $E = 1$ and $D = 0$ to produce the highest energy savings. The need for the upper-bound constraint of Equation (7) was eliminated by providing sufficient mass to satisfy the peak day sensible cooling load and assuming zero charge carryover from day to day. In the simulations, perfect 24 h forecasts of load and outdoor temperature were used; in practice, a model-based predictive control using the forecast methods from this chapter and publicly or commercially available forecasts of weather would result in some loss of performance (Krarti et al. 2007). The results in Table 7 indicate substantial energy savings potential for most of the building types in all 16 climates. For high-performance buildings, the savings were substantial in most building types and climates where economizer cooling potential is modest and the annual sensible load is dominant. Capital costs of the base and low-lift TABS systems were estimated and compared. For large office buildings, the TABS cooling system capital cost was estimated to be less than that of the VAV system.

These results are based on simulations in which the control for charging of the TABS is assumed to be modeled exactly. One problem with TABS is that precooling can no longer be reliably controlled by room temperature set-point adjustments. A further

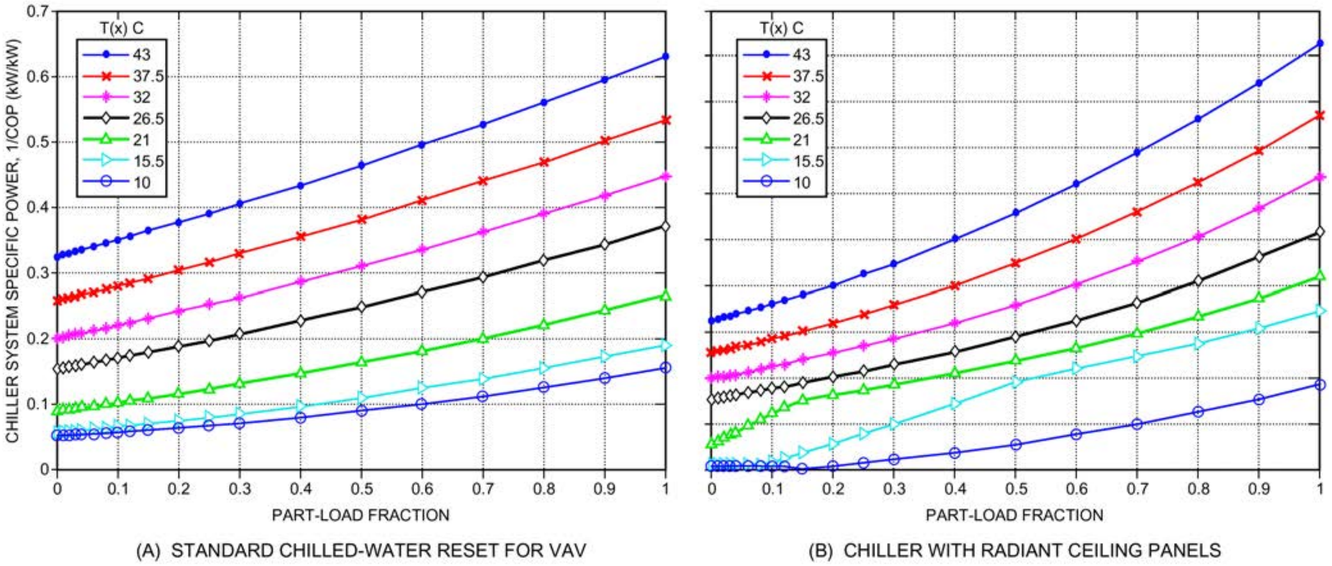

Fig. 34 Performance of Optimally Controlled Chiller for Two Different Load-Side Boundary Conditions

problem is that the state of charge cannot be readily measured. For these reasons, supervisory control of a real TABS implementation is considered to require some form of model-based predictive control.

A full-scale laboratory test of TABS cooling with model-based predictive control was conducted by Gayeski et al. (2012). The test results showed energy savings of 25 to 30% compared to an SEER-16 all-air system for typical Atlanta and Phoenix summer conditions. In each two-week-long test, the same variable-speed compressor/condenser unit was connected to a conventional indoor unit for the baseline case and to a hydronic evaporator supplying chilled water to a 150 mm concrete slab for the optimal precooling case. The results were comparable to the simulation results of Katipamula et al. (2010b) for a medium office building in Atlanta and Phoenix.

Combined Thermal Energy Storage Systems

Combination of TABS and Direct Sensible Cooling. Using two weeks of data from Gayeski et al. (2011b) and Seem et al.'s (1989a) CRTF model, Zakula et al. (2014) compared seasonal performance of a TABS model using TRNSYS software (University of Wisconsin–Madison 2013). They simulated (1) cooling with TABS only, (2) optimal scheduling of VAV precooling, and (3) both TABS and VAV, for dates between May 1 and September 30. Percentages of energy savings for options 1 and 3 are shown in Figure 36. The exposed floor mass in the model achieved about 70% of the savings with TABS alone, through passive precooling; thus, greater savings can be seen by sharing the cooling load between TABS and sensible-only variable-refrigerant flow (VRF) precooling.

Niswander (2013) modeled the combination of TABS and sensible-only VRF, with model-predictive control deciding the sequence of capacity delivered to the TABS and directly to the room over each 24 h planning horizon. A third mode was also modeled, in which heat was rejected from the VRF terminal units to the TABS at very high COP to reduce the impact of high RTP rates in mid-late afternoon. The controller objective function (Equation [4]) thus

includes three modes of heat pump operation: $P = u_p/\mathrm{COP}(u_p,t) + u_q/\mathrm{COP}(u_q,t) + u_r/\mathrm{COP}(u_r,t)$ where subscript p denotes precooling of TABS, q denotes direct cooling (possibly to effect passive precooling) and r denotes rejection of heat to TABS. Simulations were carried out with $E = 1$ and $D = 0$ to produce the highest energy savings, and with RTP rates to produce the largest shifting of load. The upper-bound constraint of Equation (7) was eliminated, but the states of both passive storage and TABS were carried from day to day. Some typical peak-shifting results are shown in Figure 37 for flat rate (left) and a mode of the utility company's RTP rate (right).

Combined Passive and Discrete Thermal Storage. Most investigations into the optimal control of combined discrete and passive building thermal storage inventory rely on a detailed white-box or gray-box model of building thermal response and equipment performance (see, e.g., Henze et al. [2005]). However, Liu and Henze (2006a, 2006b) describe a novel approach to optimally control commercial building passive and discrete thermal storage inventory simultaneously: a hybrid control scheme that combines features of model-based optimal control and model-free reinforcement learning control.

Theoretically, the reinforcement learning algorithm, based on Watkins and Dayan (1992), approximates dynamic-programming-based optimal control by sampling the cost space and can reach the true optimum, given properly selected learning parameters and enough learning time. The amount of required training is not yet realistic if the controller is directly implemented in a commercial building application. This constitutes the major drawback of the reinforcement learning control approach; contextual information in some form needs to be introduced to expedite learning the problem's fundamental features, whereas reinforcement learning fine-tunes the controller. This realization inspired the development of the hybrid learning control scheme (Liu and Henze 2006a).

Liu and Henze (2006b) analyzed the performance of this hybrid controller installed in a full-scale laboratory facility. Using the hybrid control approach saved costs when using either discrete or passive TES, compared with conventional building control; however, the savings were lower than for model-based predictive optimal control. In model-based predictive control, the hybrid controller's performance is largely affected by the quality of the training model, and extensive real-time learning is required for the learning controller to eliminate any false cues it receives during the initial training period. Nevertheless, compared with standard reinforcement learning, Liu and Henze's proposed hybrid controller is much more readily implemented in a commercial building.

3.8 FORECASTING DIURNAL COOLING AND WHOLE-BUILDING DEMAND PROFILES

As discussed previously, forecasts of cooling requirements and electrical use in buildings are often necessary for the control of thermal storage to shift electrical use from on-peak to off-peak periods. In addition, forecasts can help plant operators anticipate major changes in operating modes, such as bringing additional chillers online.

In most methods, predictions are estimated as a function of time-varying input variables that affect cooling requirements and electrical use. Examples of inputs that affect building energy use include (1) ambient dry-bulb temperature, (2) ambient wet-bulb temperature, (3) solar radiation, (4) building occupancy, and (5) wind speed. Methods that include time-varying measured input variables are often termed **deterministic methods**.

Not all inputs affecting cooling requirements and electric use are easily measured. For instance, building occupancy is difficult to determine and solar radiation measurements are expensive. In addition, the accuracy of forecast models that use deterministic inputs depends on the accuracy of future predictions of the inputs. As a result, most inputs that affect building energy use are typically not used.

Much of the time-dependent variation in cooling loads and electrical use for a building can be captured with time as a deterministic input. For instance, building occupancy follows a regular schedule that depends on time of day and time of year. In addition, variations in ambient conditions follow a regular daily and seasonal pattern. Many forecasting methods use time in place of unmeasured deterministic inputs in a functional form that captures the average time dependence of the variation in energy use.

A deterministic model has limited accuracy for forecasts because of both unmeasured and unpredictable (random) input variables. Short-term forecasts can be improved significantly by adding previous values of deterministic inputs and previous output measurements (cooling requirements or electrical use) as inputs to the forecasting model. The time history of these inputs provides valuable information about recent trends in the time variation of the forecasted variable and the unmeasured input variables that affect it. Most forecasting methods use historical variables to predict the future.

Any forecasting method requires that a functional form is defined and the parameters of the model are learned based on measured data. Either off-line or online methods can be used to estimate parameters. Off-line methods involve estimating parameters from a batch of collected data. Typically, parameters are determined by minimizing the sum of squares of the forecast errors. The parameters of the process are assumed to be constant over time in the off-line methods. Online methods allow the parameters of the forecasting model to vary slowly with time. Again, the sum of squares of the forecast errors is minimized, but sequentially or recursively. Often, a forgetting factor is used to give additional weight to the recent data. The ability to track time-varying systems can be important when forecasting cooling requirements or electricity use in buildings, because of the influence of seasonal variations in weather.

Forrester and Wepfer (1984) presented a forecasting algorithm that uses current and previous ambient temperatures and previous loads to predict future requirements. Trends on an hourly time scale are accounted for with measured inputs for a few hours preceding the current time. Day-to-day trends are considered by using the value of the load that occurred 24 h earlier as an input. One of the major limitations of this model is its inability to accurately predict loads when an occupied day (e.g., Monday) follows an unoccupied (e.g., Sunday) or when an unoccupied day follows an occupied day (e.g., Saturday). The cooling load for a particular hour of the day on a Monday depends very little on the requirement 24 h earlier on Sunday. Forrester and Wepfer (1984) described a number of methods for eliminating this 24 h indicator. MacArthur et al. (1989) also presented a load profile prediction algorithm that uses a 24 h regressor.

Armstrong et al. (1989) presented a very simple method for forecasting either cooling or electrical requirements that does not use the 24 h regressor; Seem and Braun (1991) further developed and validated this method. The "average" time-of-day and time-of-week trends are modeled using a lookup table with time and type of day (e.g., occupied versus unoccupied) as the deterministic input variables. Entries in the table are updated using an exponentially weighted, moving-average model. Short-term trends are modeled using previous hourly measurements of cooling requirements in an autoregressive (AR) model. Model parameters adapt to slow changes in system characteristics. The combination of updating the table and modifying model parameters works well in adapting the forecasting algorithm to changes in season and occupancy schedule.

Kreider and Wang (1991) used artificial neural networks (ANNs) to predict energy consumption of various HVAC equipment in a commercial building. Data inputs to the ANN included (1) previous hour's electrical power consumption, (2) building occupancy, (3) wind speed, (4) ambient relative humidity, (5) ambient dry-bulb temperature, (6) previous hour's ambient dry-bulb temperature, (7) two hours' previous ambient temperature, and (8) sine and cosine of the hour number to roughly represent the diurnal change of temperature and solar insolation. The primary purpose in developing these models was to detect changes in equipment and system performance for monitoring purposes. However, the authors suggested that an ANN-based predictor might be valuable when used to predict energy consumption with a network based on recent historical data. Forecasts of all deterministic input variables are necessary to apply this method.

Gibson and Kraft (1993) used an ANN to predict building electrical consumption as part of the operation and control of a thermal energy storage (TES) cooling system. The ANN used the following inputs: (1) electric demand of occupants (lighting and other loads), (2) electric demand of TES cooling tower fans, (3) outdoor ambient temperature, (4) outdoor ambient temperature/inside target temperature, (5) outdoor ambient relative humidity, (6) on/off status for building cooling, (7) cooling system on/off status, (8) chiller #1 direct-cooling mode on/off status, (9) chiller #2 direct-cooling mode on/off status, (10) ice storage discharging mode on/off status, (11) ice storage charging mode on/off status, (12) chiller #1 charging mode on/off status, and (13) chiller #2 charging mode on/off status. To use this forecaster, values of each of these inputs must be predicted. Although the authors suggest that average occupancy demand profile be used as an input, they do not state how the other input variables should be forecast.

Data-Driven Algorithms

The development of machine learning and information science has allowed sophisticated data-driven algorithms to be applied in the field of building energy forecasting.

A **decision (regression) tree** is a flow-chart-like structure, where each internal node denotes a test on an attribute, and each branch represents the outcome of a test. The topmost node in a tree is the root node, and the lowermost node is the leaf node. Yu et al. (2010) proposed a decision tree method (C4.5) for building energy demand modeling, and found that the C4.5 algorithm can classify and predict building energy demand levels accurately (93% for training data and 92% for test data), identify and rank significant factors of building EUI levels automatically, and provide the combination of significant factors as well as the threshold values that lead to high building energy performance.

Chou and Bui (2014) apply a regression tree algorithm (chi-squared automatic interaction detector [CHAID]) to forecast short-term cooling and heating load. However, they find that an ensemble approach (support vector regression [SVR]+ANN) has better prediction accuracy than CHAID.

Capozzoli et al. (2015), Idowu et al. (2016), and Williams and Gomez (2016) also examine decision tree algorithms in the modeling process.

Ensemble learning is a powerful machine learning method which integrates several base models to generate the final output. It has gained great popularity because of its excellent generalization performance. Fan et al. (2014) developed ensemble models that more accurately predict next-day energy consumption and peak power demand, compared to eight base models (multiple linear regression, autoregressive integrated moving average, support vector regression, random forests, multilayer perceptron, boosting tree, multivariate adaptive regression splines, and *k*-nearest neighbors). Jovanović et al. (2015) use an ensemble consisting of a feed-forward, back-propagation neural network, a radial basis function network, and an adaptive neuro-fuzzy interference system to predict short-term building heating energy consumption. The ensemble model achieves better prediction results than a single network.

Deep learning is a class of machine learning algorithms that use a cascade of multiple layers of nonlinear processing units for feature extraction and transformation (Deng and Yu 2014). As an evolution of artificial neural network (ANN)-based prediction methods, it is expected to increase prediction accuracy through higher levels of abstraction, better scalability, and automatic hierarchical feature learning. Mocanu et al. (2016a) investigated two newly developed stochastic models for time-series short-term prediction of energy consumption: conditional restricted Boltzmann machine (CRBM) and factored conditional restricted Boltzmann machine (FCRBM). FCRBM outperform ANN, SVM, recurrent neural networks (RNN), and CRBM models. Mocanu et al. (2016b) also incorporate a deep belief network as an automated feature extraction into short-term building energy modeling process.

Other sophisticated predictive algorithms include multivariate adaptive regression splines (MARS) (Cheng and Cau 2014; Williams and Gomez 2016), Bayesian networks (BNs) (O'Neill and O'Neill 2016), extreme learning machine (ELM) (Sajjadi et al. 2016), case-based reasoning (CBR) (Monfet et al. 2014), self-recurrent wavelet neural network (SRWNN) (Chitsaz et al. 2015), meta learning (Cui et al. 2016; Tian et al. 2015), and random forest (RF) (Fan et al. 2014).

A Forecasting Algorithm

This section presents an algorithm for forecasting hourly cooling requirements or electrical use in buildings that is based on the method developed by Seem and Braun (1991). At a given hour *n*, the forecast value is

$$\hat{E}(n) = \hat{X}(n) + \hat{D}(h,d) \tag{51}$$

where

$\hat{E}(n)$ = forecast cooling load or electrical use for hour *n*

$\hat{X}(n)$ = stochastic or probabilistic part of forecast for hour *n*

$\hat{D}(h,d)$ = deterministic part of forecast at hour *n* associated with *h*th hour of day and current day type *d*

The deterministic part of the forecast is simply a lookup table for the forecasted variable in terms of hour of day *h* and type of day *d*. Seem and Braun recommend using three distinct day types: unoccupied days, occupied days following unoccupied days, and occupied days following occupied days. The three day types account for differences between the building responses associated with return from night setup and return from weekend setup. The building operator or control engineer must specify the number of day types and a calendar of day types.

Given the hour of day and day type, the deterministic part of the forecast is simply the value stored in that location in the table. Table entries are updated when a new measurement becomes available for that hour and day type. Updates are accomplished through the use of an exponentially weighted, moving-average (EWMA) model as

$$\hat{D}(h,d) = \hat{D}(h,d)_{old} + \lambda[E(n) - \hat{D}(h,d)_{old}] \tag{52}$$

where

$E(n)$ = measured value of cooling load or electrical use for current hour *n*

λ = exponential smoothing constant, $0 < \lambda < 1$

$\hat{D}(h,d)_{old}$ = previous table entry for $\hat{D}(h,d)$

As λ increases, the more recent observations have more influence on the average. As λ approaches zero, the table entry approaches the average of all data for that hour and day type. When λ equals one, the table entry is updated with the most recent measured value. Seem and Braun recommend using a value of 0.30 for λ in conjunction with three day types and 0.18 with two day types.

The stochastic portion of the forecast is estimated with a third-order autoregressive model, AR(3), of forecasting errors associated with the deterministic model. With this model, the following equation estimates the next hour's error in the deterministic model forecast:

$$\hat{X}(n+1) = \phi_1 X(n) + \phi_2 X(n-1) + \phi_3 X(n-2) \tag{53}$$

where

$X(n)$ = difference between measurement and deterministic forecast of cooling load or electrical use at any hour *n*

ϕ_1, ϕ_2, ϕ_3 = parameters of AR(3) model that must be learned

The error in the deterministic forecast at any hour is simply

$$X(n) = E(n) - \hat{D}(h,d) \tag{54}$$

For forecasting more than one hour ahead, conditional expectation is used to estimate the deterministic model forecast errors using the AR(3) model as follows:

$$\begin{aligned}
\hat{X}(n+2) &= \phi_1 \hat{X}(n+1) + \phi_2 X(n) + \phi_3 X(n-1) \\
\hat{X}(n+3) &= \phi_1 \hat{X}(n+2) + \phi_2 \hat{X}(n+1) + \phi_3 X(n) \\
&\vdots \\
\hat{X}(n+k) &= \phi_1 \hat{X}(n+k+1) + \phi_2 \hat{X}(n+k-2) \\
&\quad + \phi_3 \hat{X}(n+k-3) \qquad \text{for } k > 3
\end{aligned} \tag{55}$$

Online estimation of the AR(3) model parameters is accomplished by minimizing the following time-dependent cost function:

$$J(\phi) = \sum_{k=1}^{n} \alpha^{n-k}[X(k) - \hat{X}(k)]^2 \tag{56}$$

where the constant α is called the forgetting factor and has a value between 0 and 1. With this formulation, the residual for the current time step has a weight of one and the residual for *k* time steps back has a weight of α_k. By choosing a value of α that is positive and less than one, recent data have greater influence on the parameter estimates. In this manner, the model can track changes caused by seasonal or other effects. Seem and Braun recommend using a forgetting factor of 0.99. Parameters of the AR(3) model should be updated at each hour when a new measurement becomes available.

Ljung and Söderström (1983) describe online estimation methods for determining coefficients of an AR model. The parameter estimates should be evaluated for stability. If an AR model is not stable, then the forecasts will grow without bound as the time of forecasts increases. Ljung and Söderström discuss methods for checking stability.

Seem and Braun (1991) compared forecasts of electrical usage with both simulated and measured data. Figure 38 shows the standard deviation of the 1 h to 24 h errors in electrical use forecasts for annual simulation results. Results are given for the deterministic model alone, deterministic plus AR(2), and deterministic plus AR(3). For the combined models, the standard deviation of the residuals increases as the forecast length increases. For short time steps (i.e., less than 6 h), the combined deterministic and stochastic models provide much better forecasts than the purely deterministic model (i.e., lookup table).

Seem and Braun also investigated a method for adjusting the deterministic forecast based on using weather service forecasts of maximum daily ambient temperature as an input. For short periods (i.e., less than 4 h), forecasts for the temperature-dependent model were nearly identical to forecasts for the temperature-independent model. For longer periods, the temperature-dependent model provided better forecasts than the temperature-independent model.

3.9 PREDICTIVE HVAC CONTROL STRATEGIES

Model predictive control (MPC) is a multivariable control algorithm that uses an internal dynamic model of the system, a history of past control moves, forecasts of future disturbances (i.e., weather forecasts), and an algorithm to solve an optimization problem over the receding prediction horizon (i.e., the period for which future information is available, ranging from a few hours to a few days). The potential of MPC to improve energy management in buildings has been amply demonstrated over the last decade (Cigler et al. 2013; Kummert 2001; Oldewurtel et al. 2012; Touretzky and Baldea 2014).The basic principle of MPC in buildings is that knowledge of forecast weather, anticipated occupancy schedules, and building envelope and system dynamics enable better control of the building energy systems (e.g., by better managing thermal storage capabilities). One of the most attractive features of MPC is its ability to specify multi-objective cost functions (e.g., energy consumption and thermal comfort) while handling constraints for states and control (actuator or control set point) variables in a systematic manner. Because of the number of variables and constraints that must be considered, optimization can be complex. Once the optimization algorithm determines the optimal sequence of control moves, these moves are applied to a **control horizon**, which is often shorter than the prediction horizon.

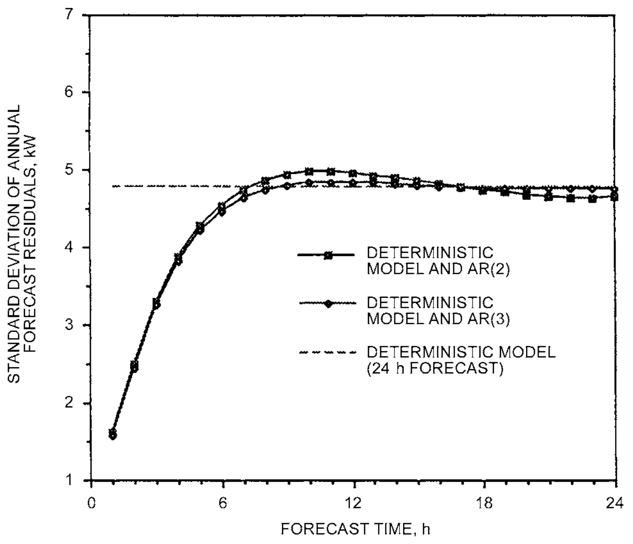

Fig. 38 Standard Deviation of Annual Errors for 1 to 24 h Forecasts

Setting up a suitable control-oriented model for the building is crucial for MPC. The degree of modeling effort is difficult to assess in advance, because each model is typically tailored for one specific building. MPC design requires a degree of knowledge of building modeling, such as good understanding on what details are appropriate to include or exclude in the control model. Li and Wen (2014) provide a detailed literature review on reported modeling approaches for MPC purposes.

Considerable research has been performed on methods for obtaining reliable models for building systems. The primary focus of research has been to select a proper model structure and identification algorithm. Various model structures, including black-box types (e.g., autoregressive with exogenous inputs [ARX], autoregressive moving-average with exogenous inputs [ARMAX], state-space forms) and gray-box types, have been investigated. Many identification algorithms developed from other fields, such as signal processing and statistics, have been applied to the field of building science. Popular methods are least squares (Armstrong et al. 2006a), prediction error (Kim et al. 2016), maximum likelihood (Bloem 1994), and subspace identification (Ferkl and Široký 2011). Other identification methods, such the identification for long-range predictive control (Prívara et al. 2013), extended or unscented Kalman filters, and machine learning methods, also have been applied to building systems. Case study comparisons between several model structures and algorithms can be found in Bacher and Madsen (2011), Jimenez and Madsen (2008), and Prívara et al. (2013).

One of the most popular modeling approaches is to develop a low-order resistance-capacitance (RC) thermal network to represent the building. The parameters of this gray-box model should be calibrated by using real measurement data from the existing building. Purely data-driven models are reliable and robust, but they cannot be easily applied in other buildings. Simulation studies often use two building models: a simulation model, meant to represent the building as accurately as possible, and a control-oriented model, a simpler representation that facilitates solution of the optimization problem (Hu and Karava 2014; Moroşan et al. 2010; Oldewurtel et al. 2012). In field studies or experiments, only the control-oriented model is necessary (De Coninck and Helsen 2016). Li et al. (2015) demonstrate the effectiveness of a linear-zone dynamic state-space model in a field demonstration of MPC in a medium-sized commercial building.

Nonlinear forecasting models, such as those based on neural networks (NNs), have also been investigated as alternatives to traditional time-series analysis. Florita and Henze (2009) sought to identify the complexity required for short-term weather forecasting in the context of a MPC environment. Moving average (MA) models with various enhancements and neural network models were used to predict weather variables seasonally in numerous geographic locations. Their performance was statistically assessed using the coefficient of variation (CV) and mean bias error (MBE) values. When a cyclical two-stage MPC process of policy planning followed by execution was used, Florita and Henze (2009) found that even the most complicated nonlinear autoregressive neural network with exogenous input does not appear to warrant the additional efforts in forecasting model development and training, in comparison to the simpler MA models.

Predictive control strategies for both passive and discrete thermal storage systems have been studied (Braun 2003; Henze 2003) and field tested (Krarti et al. 2007; Morgan and Krarti 2010). Morgan and Krarti (2010) investigated performance of various control strategies for combined passive and discrete TES systems in a Colorado elementary school equipped with an ice storage system. The predictive optimal control strategies were developed using an EnergyPlus-based simulation environment (Krarti et al. 2007; Zhou et al. 2005). The simulation environment was found to be effective in defining and implementing predictive optimal controls for both

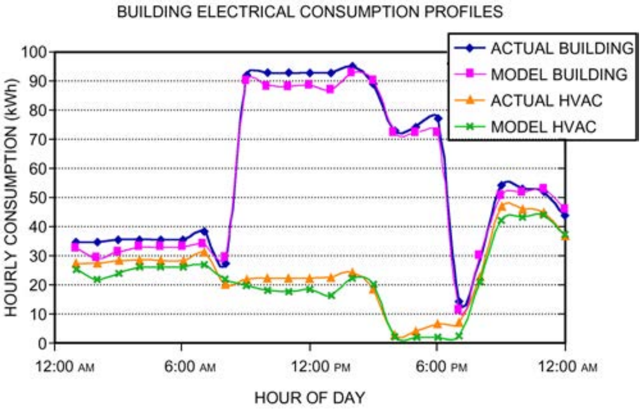

Fig. 39 Building Electricity Use Profiles for 6 h Predictive Optimal Control

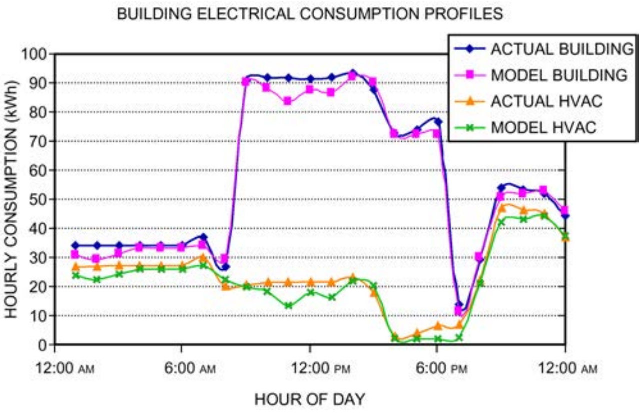

Fig. 40 Building Electricity Use Profiles for 24 h Predictive Optimal Control

passive and discrete TES systems for the buildings. Figures 39 and 40 show examples of the field testing results for the building energy use performed by Morgan and Krarti (2010).

An alternative to a formal MPC approach for identifying optimal temperature set points consists of implementing simple linear ramping profiles in place of abrupt setup or setback profiles. Gradual ramps over a given period of time can significantly reduce the peak power demand required to change from one set point value to another, as demonstrated in Date et al. (2016a, 2016b) and Morris et al. (1994). Ramp set-point profiles with different start times can be used in different zones of a building to stagger when heating the zones begins. By staggering the start times, building heating demand is smoothed over a certain period. Preheating by a few degrees can also be used when transitioning from night setback to a comfort temperature. By preheating during an off-peak time and to a temperature that is still satisfactory to occupants, the peak demand during critical times can be further reduced. Predetermined rules of operation based on building dynamics and short-term dynamics allow optimization of building operation. For example, Candanedo et al. (2015) proposed near-optimal profiles for transitioning between night setback and a daytime temperature profile. This optimal transition curve, which significantly reduces peak load in this period, depends only on the time constant of the space and the "transition time" established by the building operator.

3.10 CONTROL STRATEGIES FOR HEATING SYSTEMS

Boiler efficiency depends on many factors, such as combustion airflow rate, load factor, and water temperature in hot-water boilers (or pressure for steam boilers). Opportunities for energy and cost reduction in boiler plants by supervisory control include sequencing and loading of multiple boilers and resetting the hot-water supply temperature set point (for hot-water boilers) or the steam pressure set point (for steam boilers) (Dyer and Maples 1981).

Excess Air in Combustion Process

Combustion would occur with greatest efficiency (**stoichiometric combustion**) if air and fuel could be mixed in the exact proportions indicated in the chemical reaction equation. The ratio of the volume of air needed to burn completely one unit volume of the fuel is known as the **stoichiometric air/fuel ratio**. The heat released when the fuel burns completely is called the **heat of combustion**.

In practice, it is impossible to achieve stoichiometric combustion because burners cannot mix air and fuel perfectly. In combustion processes, excess air is generally defined as air introduced above the stoichiometric or theoretical amount required for complete combustion of the fuel. Only the minimum amount of excess air to ensure complete combustion should be supplied to the burner; more air increases the heat rejected to the stack and reduces efficiency. Combustion efficiency depends on the amount of excess air (or oxygen [O_2]) in the flue gas, stack temperature rise above

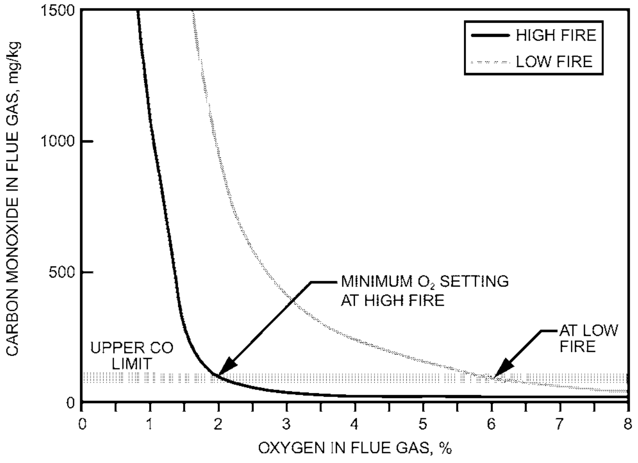

Fig. 42 Hypothetical CO-O_2 Characteristic Combustion Curves for a Gas-Fired Industrial Boiler

burner inlet air temperature, and amount of unburned hydrocarbons. As shown in Figure 41, combustion efficiency drops sharply when deficient air is supplied to the burner: the amount of unburned hydrocarbons rises sharply, thereby wasting fuel. Operating a boiler with high excess air also heats the air unnecessarily, resulting in lower combustion efficiency. Combustion efficiency is optimized when excess air is reduced to the minimum.

To determine the minimum excess air for a particular boiler, flue gas combustible content as a function of excess O_2 should be charted as shown in Figure 42. For a gas-fueled boiler, carbon monoxide should be monitored; for liquid or solid fuel, monitor the smoke spot number (SSN). Different firing rates should be considered because the excess air minimum varies with the firing rate (percent load). Figure 42 shows curves for high and low firing rates. As shown, low firing rates generally produce a more gradual curve; high-rate curves are steeper. For burners and firing rates with a steep combustible content curve, small changes in the amount of excess O_2 may cause unstable operation. The optimal control set point for excess air should generally be 0.5 to 1% above minimum, to allow for slight variations in fuel composition, intake air temperature and humidity, barometric pressure, and control system characteristics. Table 8 lists typical, normally attainable optimum excess air levels, classified by fuel type and firing method.

Carbon monoxide upper control limits vary with the boiler fuel used. The CO limit for gas-fired boilers may be set typically at 400, 200, or 100 mg/kg. For No. 2 fuel oil, the maximum SSN is typically 1; for No. 6 fuel oil, SSN = 4. However, for any fuel used, local environmental regulations may require lower limits.

To maintain safe unit output conditions, excess air requirements may be greater than the levels indicated in this table. This condition may arise when operating loads are substantially less than the design rating. Where possible, the vendor's predicted performance curves should be checked. If they are unavailable, excess air should be reduced to minimum levels consistent with satisfactory output.

Oxygen Trim Control. An oxygen trim control system adjusts the airflow rate using an electromechanical actuator mounted on the boiler's forced-draft fan damper linkage, and measures excess oxygen using a zirconium oxide sensor mounted in the boiler stack. The oxygen sensor signal is compared with a set point value obtained from the boiler's excess air set point curve for the given firing rate. The oxygen trim controller adjusts ("trims") the damper setting to regulate the oxygen level in the boiler stack at this set point. In the event of an electronic failure, the boiler defaults to the air setting determined by the mechanical linkages.

Table 8 Typical Optimum Excess Air for Various Boiler Types

Fuel Type	Firing Method	Optimum Excess Air, %	Equivalent O_2 (by Volume)
Natural gas	Natural draft	20-30	4-5
	Forced draft	5-10	1-2
	Low excess air	0.4-2.0	0.1-0.5
Propane	—	5-10	1-2
Coke oven gas	—	5-10	1-2
No. 2 oil	Rotary cup	15-20	3-4
	Air-atomized	10-15	2-3
	Steam-atomized	10-15	2-3
No. 6 oil	Steam-atomized	10-15	2-3
Coal	Pulverized	15-20	3-3.5
	Stoker	20-30	3.5-5
	Cyclone	7-15	1.5-3

Carbon Monoxide Trim Control. Carbon monoxide trim control systems are also used to control excess air, and offer several advantages over oxygen trim systems. In carbon monoxide trim systems, the amount of unburned fuel (in the form of carbon monoxide) in the flue gas is measured directly by a carbon monoxide sensor and the air/fuel ratio control is set to actual combustion conditions rather than preset oxygen levels. Thus, the system continuously controls for minimum excess air. Carbon monoxide trim systems are also independent of fuel type and are virtually unaffected by combustion air temperature, humidity, and barometric pressure conditions. However, they cost more than oxygen trim systems because of the expense of the carbon monoxide sensor. Also, the carbon monoxide level in the boiler stack is not always a measure of excess air. A dirty burner, poor atomization, flame chilling, flame impingement on the boiler tubes, or poor fuel mixing can also raise the carbon monoxide level in the boiler stack (Taplin 1998).

Sequencing and Loading of Multiple Boilers

Generally, boilers operate most efficiently at a 65 to 85% full-load rating. Boiler efficiencies fall off at higher and lower load points, with the decrease most pronounced at low loads. Boiler efficiency can be calculated by means of stack temperature and percent O_2 (or percent excess air) in the boiler stack for a given fuel type. Part-load curves of boiler efficiency versus hot-water or steam load should be developed for each boiler. These curves could be dynamically updated at discrete load levels based on the hot-water or steam plant characteristics to allow the control strategy to continuously predict the input fuel requirement for any given heat load. When the hot-water temperature or steam pressure drops below set point for the predetermined time interval (e.g., 5 min), the most efficient combination of boilers must be selected and turned on to meet the load. The least efficient boiler should be shut down and banked in hot standby if its capacity drops below the spare capacity of the current number of boilers operating (or, for primary/secondary hot-water systems, if the flow rate of the associated primary hot-water pump is less than the difference between primary and secondary hot-water flow rates) for a predetermined time interval (e.g., 5 min). The spare capacity of the current online boilers is equal to their full-load capacity minus the current hot water load.

Load Conditions for Bringing Boilers Online or Off-Line

The specifics of the strategy for bringing boilers online depend on the type of boiler. Hot-water boilers have dedicated or nondedicated hot-water pumps; steam boilers do not have hot-water pumps, but rely on differences in steam pressure between the boiler steam header discharge and the point of use to distribute steam throughout the system.

Hot-Water Boilers with Dedicated Pumps. The strategy for hot-water boilers with dedicated hot-water pumps is similar to that for chillers with dedicated chilled-water and condenser water pumps: another boiler should be brought online when operating boilers reach capacity, because the efficiency of the boiler should include the power to drive its associated hot-water pump. This can be determined when hot-water temperature drops below its set point for a predetermined time interval (e.g., 5 min).

Hot-water boilers with dedicated pumps can be brought online and off-line with the following logic:

1. Continuously calculate the load ratio of each boiler or boiler combination. For the ith boiler,

$$\mathrm{LR}_i = \frac{\dot{Q}_{load}}{\dot{Q}_{blr,des,i}} \quad (57)$$

   where LR_i is load ratio of the ith boiler combination, $\dot{Q}_{load}$ is the total boiler plant load, and $\dot{Q}_{blr,des,i}$ is the design (rated) output of the ith boiler combination.
2. Every sampling interval (e.g., 60 s), calculate the predicted input fuel requirement for each boiler combination as

$$\mathrm{IF}_i = \frac{(\mathrm{LR}_i)\dot{Q}_{blr,des,i}}{\eta_i} \quad (58)$$

   where IF_i is the input fuel requirement and η_i is the efficiency of the ith boiler combination.
3. Continuously evaluate time-averaged values of the hot-water supply temperature over a fixed time interval (e.g., 5 min).
4. If the hot-water supply temperature drops below its set point for a predetermined time interval (e.g., 5 min), then, from boiler part-load performance curves, select the boiler combination with a load ratio between 0.5 and 1.0 and with the least input fuel requirement to meet the load, and turn this combination of boilers on. Note that this strategy greatly reduces the possibility of short-cycling boilers because the new combination of boilers to be started likely includes boilers already operating (i.e., only one additional boiler is likely to be added).
5. If the capacity of the least-efficient online boiler drops below the spare capacity of the current number of boilers operating (or for a primary/secondary hot-water system, if the flow rate of the associated primary hot-water pump is less than the difference between primary and secondary hot-water flow rates) for a predetermined time interval (e.g., 5 min), then shut down and bank this boiler in hot standby.

Hot-Water Boilers with Nondedicated Pumps or Steam Boilers. For hot-water systems without dedicated hot-water pumps or for steam systems, the optimal load conditions for bringing boilers online or off-line do not generally occur at the full capacity of the online boilers. For these systems, a new boiler combination should be brought online whenever the hot-water supply temperature or steam pressure falls below set point for a predetermined time interval (e.g., 5 min) *and* the part-load efficiency curves of the boiler combination predicts that the new combination of boilers can meet the required load using significantly less (e.g., 5%) input fuel.

Optimal Boiler Load Distribution

Optimal load distribution strategies for boilers are similar to those for chillers. For boilers with similar performance characteristics, the optimal boiler loading is similar to Equation (27) for chillers:

$$\dot{Q}^*_{blr,i} = \frac{\dot{Q}_{load}}{\sum_{i=1}^{N} Q_{blr,des,i}} \dot{Q}_{blr,des,i} \quad (59)$$

where $\dot{Q}^*_{blr,i}$ is the optimal load for the ith boiler.

For boilers with significantly different performance characteristics, the criterion for optimal boiler loading is similar to Equations (28) and (29) for chillers, except that boiler cost of operation is used:

$$\frac{\partial C_{blr,i}}{\partial \dot{Q}_{blr,i}} = \frac{\partial C_{blr,j}}{\partial \dot{Q}_{blr,j}} \qquad \text{for all } i \text{ and } j \quad (60)$$

and subject to the constraint that

$$\sum_{i=1}^{N} \dot{Q}_{blr,i} = \dot{Q}_{load} \quad (61)$$

where $C_{blr,i}$ and $C_{blr,j}$ are the operating costs of boiler i and j, respectively, $\dot{Q}_{blr,i}$ is heating load for the ith boiler, and $\dot{Q}_{load}$ is total heating load.

In general, the boiler operating-cost curve can be calculated as a quadratic function of heating load only. For the ith boiler,

$$C_{blr,i} = b_{0,i}\dot{Q}^2_{blr,i} + b_{1,i}\dot{Q}_{blr,i} + b_{2,i} \quad (62)$$

Applying the criterion of Equation (60) to Equation (62),

$$2b_{0,i}\dot{Q}^*_{blr,i} + b_{1,i} = 2b_{0,j}\dot{Q}^*_{blr,j} + b_{1,j} \quad (63)$$

where $\dot{Q}^*_{blr,i}$ is the optimal load for the ith boiler.

Maintaining Boilers in Standby Mode

It is generally more economical to run fewer boilers at a high rating. However, the integrity of the steam or hot-water supply must be maintained in the event of a forced outage of one of the operating boilers or if the facility experiences highly diverse load swings throughout the heating season. Both conditions can often be satisfied by maintaining a boiler in standby or “live bank” mode. For example, in this mode, a steam boiler is isolated from the steam system at no load but is kept at system operating pressure by periodic firing of either the igniters or a main burner to counteract ambient heat losses.

Supply Water and Supply Pressure Reset for Boilers

Standby losses are reduced and overall efficiencies enhanced by operating hot-water boilers at the lowest acceptable temperature. Condensing boilers achieve significantly higher combustion efficiencies at water temperatures below the flue gas dew point when they are operating in condensing mode (see Chapter 32 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*). Hot-water boilers of this type are very efficient at part-load operation when a high water temperature is not required. Energy savings are therefore possible if the supply water temperature is maintained at the minimum level required to satisfy the largest heating load. However, to minimize condensation of flue gases and consequent boiler damage from acid, water temperature should not be reset below that recommended by the boiler manufacturer (typically 60°C). Similarly, energy can be saved in steam heating systems by maintaining supply pressure at the minimum level required to satisfy the largest heating load.

Simple control strategies can be used to generate a suboptimal hot-water temperature (for hot-water boilers) or steam pressure (for steam boilers). An energy management and control system must be interfaced to the boiler controls and be capable of monitoring the position of the valve controlling the flow of hot water to the heating coils or steam pressure at the most critical zone. For a hot-water system,

1. Continuously monitor the hot-water valve position of the various heating zones.
2. If none of the hot-water valves are greater than 95% open, lower boiler hot-water supply temperature by a small increment (e.g., 0.5 K) each reset time interval (a predetermined interval established by system thermal lag characteristics, e.g., 15 to 20 min).
3. Once one hot-water valve opens beyond 95%, stop downward resets of boiler hot-water temperature set point.
4. If two or more hot-water valves open beyond 95%, raise boiler hot-water temperature set point by a small increment (e.g., 0.5 K) each reset interval.

For a steam system, the steam header pressure should be lowered to a value that just satisfies the highest pressure demand. *Caution*: for nongravity condensate return systems, steam pressure reset could impede condensate return (see Chapter 10 of the 2008 *ASHRAE Handbook—HVAC Systems and Equipment*).

Operating Constraints

Note that there are practical limitations on the extent of automatic operation if damage to the boiler is to be prevented. Control strategies to reduce boiler energy consumption can also conflict with recommended boiler operating practice. For example, in addition to the flue gas condensation concerns mentioned previously, rapid changes in boiler jacket temperature (thermal shock) brought about by abrupt changes in boiler water temperature or flow, firing rate, or air temperature entering the boiler should be avoided. The repeated occurrence of such transient conditions may weaken the metal and lead to cracking and/or loose tubes. It is therefore important to follow all of the recommendations of the American Boiler Manufacturers Association (ABMA 1998).

3.11 CONTROL STRATEGIES FOR AIR-HANDLING UNITS

Air Handler Sequencing and Economizer Cooling

Traditional air-handler sequencing strategies use a single proportional-integral (PI) controller to control heating, cooling with outdoor air, mechanical cooling with 100% outdoor air, and mechanical cooling with minimum outdoor air. Sequencing between these different modes is accomplished by splitting the controller output into different regions of operation, as shown in Figure 43.

Figure 43 depicts the relationship between the control signal to the valves and dampers and the feedback controller output. The controller adjusts its output to maintain the supply air temperature set point. If output is between 100 and 200%, mechanical cooling is used. When outdoor conditions are suitable, the outdoor air dampers switch from minimum position (minimum ventilation air) to fully open. For a dry-bulb economizer, this switch point occurs when ambient air is less than a specified value. This switch point should be less than the switch point to return to minimum outdoor air, to ensure stable control. The economizer switchover temperature may be significantly lower than the return air temperature (e.g., 5 K lower) in humid climates where latent ventilation loads are significant. However, in dry climates, the switchover temperature may be close to the return temperature (e.g., 24°C). An enthalpy (or wet-bulb) economizer compares outdoor and return air enthalpies (or wet-bulb temperatures) to initiate or terminate economizer operation. In general, enthalpy economizers yield lower energy costs than dry-bulb economizers, but require measurements of outdoor and return air humidity. Humidity sensors require regular maintenance to ensure accurate readings. When controller output is between 0 and 100% (see Figure 43), the cooling coil valve is fully closed and cooling is provided by ambient air only. In this case, the controller output modulates the position of the outdoor air dampers to maintain the set point. If the controller output signal is between –100 and 0%, the heating coil is used to maintain set point and the outdoor air dampers are set at their minimum position.

A single feedback controller is difficult to tune to perform well for all four modes of operation associated with an AHU. An alternative to the traditional sequencing strategy is to use three separate feedback controllers, as described by Seem et al. (1999). This approach can improve temperature control, reduce actuator usage, and reduce energy costs. Figure 44 shows a state transition diagram for implementing a sequencing strategy that incorporates separate feedback controllers.

In state 1, a feedback controller adjusts the heating valve to maintain the supply air set-point temperature with minimum outdoor air. The transition to state 2 occurs after the control signal has been saturated at the no-heating position for a period equal to a specified state transition delay (e.g., 3 min). In state 2, a second feedback controller adjusts the outdoor and return air dampers to achieve set point with heating and cooling valves closed. Transition back to state 1 only occurs after the damper control signal is saturated at its minimum value for the state transition delay, whereas transition to state 3 is associated with saturation at the maximum damper position for the

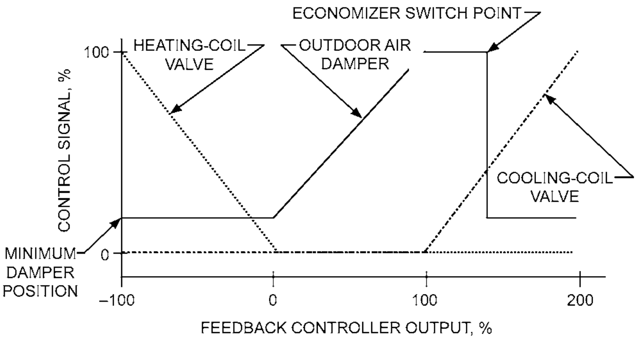

Fig. 43 AHU Sequencing Strategy with Single Feedback Controller

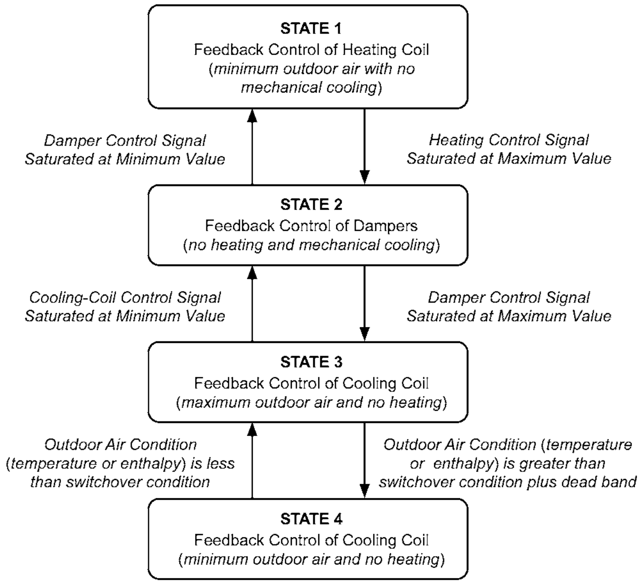

Fig. 44 AHU Sequencing Strategy with Multiple Feedback Controllers

state transition delay. In state 3, the outdoor air damper remains fully open and a third feedback controller is used to adjust the flow of cooling water to maintain the supply air temperature at set point. Transition back to state 2 occurs if the controller output is saturated at its minimum value for the state transition delay. For a dry-bulb economizer, transition to state 4 occurs when the ambient dry-bulb temperature is greater than the switchover temperature by a dead band (e.g., 1 K). The feedback controller continues to modulate the cooling-coil valve to achieve set point. Transition back to state 3 occurs when the ambient dry-bulb is less than the switchover temperature (e.g., 18°C). For an enthalpy economizer, the ambient enthalpy is compared with return air enthalpy to initiate transitions between states 3 and 4.

Supply Air Temperature Reset for Constant Air Volume (CAV)

The benefits of resetting supply air temperature set points for CAV systems are significant. Increasing the supply air set point for cooling reduces both the cooling and reheat required, but does not change fan energy. In general, the set point for a CAV system could be set at the highest value that will keep all zone temperatures at their set points and all humidities within acceptable limits. A simple reset strategy based on this concept follows.

At each the decision interval (e.g., 5 min), the following logic can be applied:

1. Check controller outputs for representative zone reheat units and determine time-averaged values over the last decision interval.
2. If any controller output is less than a threshold value (e.g., 5%), then decrease the supply air set point by a fixed value (e.g., 0.25 K) and go to step 4. Otherwise, go to step 3.
3. If all zone humidities are acceptable and all controller outputs are greater than a threshold value (e.g., 10%), then increase the discharge air set point by a fixed value (e.g., 0.25 K) and go to step 4. Otherwise, do not change the set point.
4. Limit the set point between upper and lower limits based on comfort considerations.

Static Pressure Reset for Variable Air Volume (VAV)

Flow may be modulated in a VAV system by using dampers on the outlet side of the fan, inlet vanes on the fan, vane-axial fans with controllable pitch fan blades, or variable-speed control of the fan motor. Typically, inputs to any of these controlled devices are modulated to maintain a duct static pressure set point as described in Chapter 48. In a single-duct VAV system, the duct static pressure set point is typically selected by the designer to be a fixed value. The sensor is located at a point in the ductwork such that the established set point will ensure proper operation of the zone VAV boxes under varying load (supply airflow) conditions. A shortcoming of this approach is that static pressure is controlled based on a single sensor intended to represent the pressure available to all VAV boxes. Poor location or malfunction of this sensor will cause operating problems.

For a fixed static pressure set point, all of the VAV boxes tend to close as zone loads and flow requirements decrease. Therefore, flow resistance increases with decreasing load. Significant fan energy savings are possible if the static pressure set point is reset so that at least one of the VAV boxes remains open. With this approach, flow resistance remains relatively constant. Englander and Norford (1992), Hartman (1993), Warren and Norford (1993), and Wei et al. (2004) proposed several different strategies based on this concept. Englander and Norford used simulations to show that either static pressure or fan speed can be controlled directly using a flow error signal from one or more zones and simple rules. Their technique forms the basis of the following reset strategy.

At each decision interval (e.g., 5 min), the following logic can be applied:

1. Check the controller outputs for representative VAV boxes and determine time-averaged values over the last decision interval.
2. If any of the controller outputs are greater than a threshold value (e.g., 98%), then increase the static pressure set point by a fixed value (e.g., 5% of the design range) and go to step 4. Otherwise, go to step 3.
3. If all controller outputs are less than a threshold value (e.g., 90%), then decrease the static pressure set point by a fixed value (e.g., 5% of the design range) and go to step 4. Otherwise, do not change the set point.
4. Limit the set point between upper and lower limits based on upper and lower flow limits and duct design.

3.12 CONTROL STRATEGIES FOR BUILDING ZONES

Recovery from Night Setback or Setup

For buildings that are not continuously occupied, significant savings in operating costs may be realized by raising the building set-point temperature for cooling (setup) and by lowering the set point for heating (setback) during unoccupied times. Bloomfield and Fisk (1977) showed energy savings of 12% for a heavyweight building and 34% for a lightweight building.

An optimal controller for return from night setback or setup returns zone temperatures to the comfort range precisely when the building becomes occupied. Seem et al. (1989b) compared seven different algorithms for minimum return time. Each method requires estimating parameters from measurements of the actual return times from night setback or setup.

Seem et al. (1989b) showed that the optimal return time for cooling was not strongly influenced by the outdoor temperature. The following quadratic function of the initial zone temperature was found to be adequate for estimating the return time:

$$\tau = a_0 + a_1 t_{z,i} + a_2 t_{z,i}^2 \tag{64}$$

where τ is an estimate of optimal return time, $t_{z,i}$ is initial zone temperature at the beginning of the return period, and a_0, a_1, and a_2 are empirical parameters. The parameters of Equation (51) may be estimated by applying linear least-squares techniques to the difference between the actual return time and the estimates. These parameters may be continuously corrected using recursive updating schemes as outlined by Ljung and Söderström (1983).

For heating, Seem et al. (1989b) found that ambient temperature has a significant effect on the return time and that the following relationship works well in correlating return times:

$$\tau = a_0 + (1 - w)(a_1 t_{z,i} + a_2 t_{z,i}^2) + w a_3 t_a \tag{65}$$

where t_a is the ambient temperature, and w is a weighting function given by

$$w = 1000^{-(t_{z,i} - t_{unocc})/(t_{occ} - t_{unocc})} \tag{66}$$

where t_{unocc} and t_{occ} are the zone set points for unoccupied and occupied periods. In the context of Equation (52), this function weights the outdoor temperature more heavily when the initial zone temperature is close to the set-point temperature during the unoccupied time. Again, the parameters of Equation (52) may be estimated by applying linear least-squares techniques to the difference between the actual return time and the estimates.

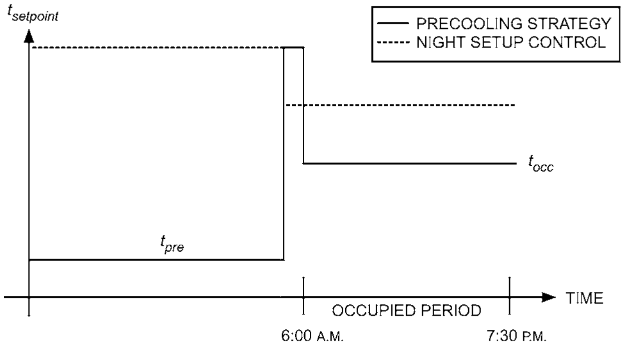

Fig. 45 Zone Air Temperature Set Points

Ideally, separate equations should be used for zones that have significantly different return times. Equipment operation is initiated for the zone with the earliest return time. In a building with a central cooling system, the equipment should be operated above some minimum load limit. With this constraint, some zones need to be returned to their set points earlier than the optimum time.

Optimal start algorithms often use a measure of the building mass temperature rather than the space temperature to determine return time. Although use of space temperature results in lower energy costs (i.e., shorter return time), the mass temperature may result in better comfort conditions at the time of occupancy.

Emergency Strategy to Limit Peak Cooling Requirements

Keeney and Braun (1997) developed a simple control strategy that uses building thermal mass to reduce peak cooling requirements a chiller is lost. This emergency strategy is used only on days where cooling capacity is not sufficient to keep the building in the comfort range using night setup control. It involves precooling the building during unoccupied times and allowing the temperature to float through the comfort zone during occupancy.

The precooling control strategy is depicted in Figure 45 along with conventional night setup control. Precooling is controlled at a constant temperature set point t_{pre}. The warm-up period is used to reset the zone air temperature set point so that the cooling system turns off without calling for heating. During this time, the zone air is warmed by lighting and equipment loads. The occupied set point t_{occ} is set at the low end of the comfort region so that the building mass charge is held as long as cooling capacity is available. This set point is maintained until the limit on cooling capacity is reached. After this point, temperatures in the zones float up and the building thermal mass provides additional cooling. If the precooling and occupied set points have been chosen properly and the cooling capacity is sufficient, zone conditions will remain comfortable throughout the occupied period. The peak cooling requirement can be reduced by as much as 25% using this strategy as compared with night setup control. Thus, the loss of one of four identical chillers could be tolerated. This strategy could also be used for spaces such as auditoriums that have a high occupancy density for a short period.

The length of time and temperature for precooling and the occupied temperature set point chosen for this strategy strongly influence the capacity reduction and could affect occupant comfort. A reasonable strategy is to precool at 20°C beginning at midnight, allow a 30 min warm-up period before occupancy, and then adjust the occupied set point to 21°C. The zone temperature will then rise above this set point when the chillers are operating at capacity.

Case Study. The control strategy was tested in a 130 000 m^2 office building located near Chicago, Illinois (Keeney and Braun 1997). The facility has two identical buildings with very similar in-

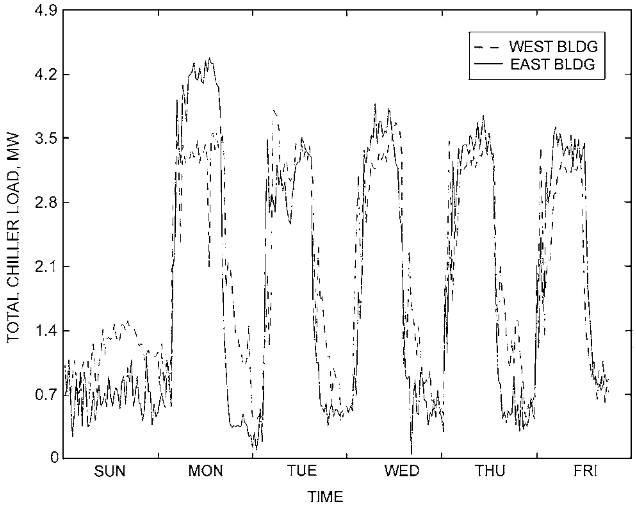

Fig. 46 Total Coil Load for East and West Chiller Units

ternal gains and solar radiation loads, connected by a large, separately cooled entrance area. During tests, the east building used the existing building control strategy and the west building used the precooling strategy.

Four 3200 kW vapor compression chillers normally provide chilled water to the air-handling units. Loss of one chiller results in a 25% reduction of the total capacity. This condition was simulated by limiting the vane position of the two chiller units that cool the west building to 75%. The capacity limitation was imposed directly at the chiller control panels. Set points were provided to local zone controllers from a modern energy management and control system. Chiller cooling loads and zone thermal comfort conditions were monitored throughout the tests.

Consistent with simulation predictions, the precooling control strategy successfully limited the peak load to 75% of the cooling capacity for the west building, whereas the east building operated at 100% of capacity. Figure 46 shows the total chiller coil load for the east and west buildings for a week of testing in the middle of August 1995. The cooling-coil load profile on Monday is the most dramatic example of load shifting during this test period. The peak cooling load for this facility often occurs on Monday morning. The cooling limit was achieved on Monday during a period in which a heat emergency had been declared in the city. The severe ambient conditions were compounded by a power outage that caused a loss of the west-side chiller units for approximately 20 min. Under these demanding conditions, the precooling strategy maintained occupant comfort while successfully limiting cooling demand of the west side of the building to less than 75% of that for the east side.

The east-side cooling requirement was at or below the 75% chiller capacity target for Tuesday through Friday, so the emergency precooling strategy was not necessary. For these off-design days, the emergency strategy was not effective in reducing the on-peak cooling requirements because discharge of the mass was not initiated when capacity was below the target. The thermal mass remained charged so that peak reduction would occur if the target value on the off-design days were reset to a lower value.

Precooling the top floor of the facility had already been implemented into the conventional control strategy used for the east building. This was necessary to maintain comfort conditions with full cooling capacity on hot days. As a result, even greater peak reduction would have been recorded if the precool strategy had been compared with conventional night setup control. The total electrical use was greater for the precooled west building; however, the strategy was designed for an emergency and does not attempt to minimize costs.

This emergency strategy should only be applied on days when the available cooling capacity is not sufficient to maintain comfort conditions when using night setup control. Otherwise, the costs of providing cooling could increase significantly. ASHRAE research project RP-1313 (Cheng et al. 2008; Henze et al. 2007, 2008) developed simplified strategies for optimal control of building zone set points to minimize operating costs.

CHAPTER 44

HVAC COMMISSIONING

CONSIDERATIONS 44.1
Commissioning Objective 44.2
Management and Responsibilities 44.2
COMMISSIONING PROCESS 44.4
Predesign-Phase Commissioning 44.5
Design-Phase Commissioning 44.5
Construction-Phase Commissioning 44.8
Occupancy- and Operations-Phase Commissioning 44.11
Life and Property Safety Check 44.11
COMMISSIONING COSTS 44.12
Design-Phase Costs (Including Predesign and Design) 44.12
Construction- and Occupancy/Operations-Phase Costs 44.12
Existing Buildings 44.13
Certification 44.13

COMMISSIONING implements a quality-oriented process for achieving, verifying, and documenting that the performance of facilities, systems, and assemblies meets defined objectives and criteria. The defined objectives and criteria are often referred to as the **owner's project requirements (OPR)**. The commissioning process uses the owner's project requirements as the reference to determine acceptance of the design and construction. Commissioning includes verifying and documenting that the project operational and maintenance documentation and training of operation and maintenance personnel occur. The result should be fully functional systems that can be properly operated and maintained throughout the life of the building.

This chapter gives an overview of the general commissioning process as covered in ASHRAE *Guideline* 0-2013, developed for the National Institute of Building Sciences' total building commissioning program, as well as the best practices for applying the process from ASHRAE *Guideline* 1.1-2007. The minimum acceptable process for commissioning is detailed in ASHRAE *Standard* 202-2013. This chapter provides more narrative discussion on some issues than these two guidelines and the standard.

Recommissioning applies commissioning to a project that has been previously delivered using the commissioning process. This may be a scheduled recommissioning developed as part of ongoing commissioning, or it may be triggered by use change, operational problems, or other needs. **Existing building commissioning** (often called **retrocommissioning**) applies commissioning to an existing facility that may or may not have been previously commissioned. It consists of systematically investigating, analyzing, and adjusting operations of existing building equipment, systems, and assemblies, as well as training and documentation for operators to ensure that required performance (including energy, comfort, and IAQ) is achieved. Buildings require maintenance and tuning to prevent performance degradation. Existing building commissioning should be performed as part of ongoing efforts to maintain a comfortable and efficient environment within the building. It has broad application to virtually every building type with excellent cost/benefit results and payback ratios. Existing building commissioning starts with development of the owner's current facility requirements, reviewing the existing design, and testing of the existing systems. Any major retrofits required follow the process for new building commissioning as defined in this chapter.

1. CONSIDERATIONS

Applicability

The commissioning process described here applies to new construction, major renovations, and all systems and assemblies. Although this chapter focuses on HVAC systems, commissioning can be applied to the building as a total system, which includes structural elements, building envelope, life safety features, electrical systems, communication systems, plumbing, irrigation, controls, and HVAC systems (ASHRAE *Guideline* 0). Based on owners' preference and project contract scope, total commissioning can include industrial process and process equipment, systems, piping, instrumentation, electrical, and related control, or these topics may be treated as an independent phase of project commissioning.

Systems to be commissioned vary with the systems and assemblies used, building size, project type, and objectives. Owners and commissioning providers often focus on systems and assemblies under the commissioning umbrella that have (1) historically not performed well at turnover (e.g., outside air economizers and variable-speed drives), (2) are mission critical (e.g., air cleanliness in a cleanroom, emergency power in a hospital), (3) will be costly to fix during occupancy if they fail (e.g., chilled-water piping, window flashing assemblies), or (4) present a life-safety risk if they fail (e.g., fire alarm, smoke control, moisture penetration). Recommendations in this chapter should be appropriately modified for each project. Although commissioning may begin at any time during the project life cycle, owners obtain the highest benefits when commissioning begins at the conceptual or predesign phase.

Background

Equipment, components, systems, and assemblies have become more complex. More specialization has occurred in the disciplines and trades, with increased interactions between all elements. This increased specialization and interaction requires increased integration between disciplines and specialized systems by the delivery team. Owners often use low-bid policies, and scopes of design professionals are often narrowed. The result has been buildings that do not meet owner expectations and often do not work as intended because of programming, design, and construction deficiencies. Commissioning is a value-added service that helps overcome these infrastructure inadequacies and fundamentally improve the performance of building systems and living conditions for occupants.

Benefits

The primary benefits of commissioning include improvements in all of the following areas:

- **Predesign and design**
  - Owners develop better understanding of what they want and need through clear, documented OPR
  - Designers understand better what owner is requesting
  - Designers reduce their risk with better communication and input from owner
  - Owners understand better what designers are proposing through a clear, documented **basis of design (BOD)**

The preparation of this chapter is assigned to TC 7.9, Building Commissioning.

Experts review and improve commissioning documents
Resolves many potential issues more cost effectively before construction phase
Verifies planned systems can be commissioned and tested, and are within owner's ability to maintain
Improves specifications and drawings, resulting in improved coordination between all groups
Includes thorough training requirements in the construction documents

- **Construction (including system and assembly performance)**
  Increases accountability in submittal process, leading to higher-quality installation
  Provides tools to help contractors perform installations that meet the project requirements (e.g., construction checklists)
  Provides performance accountability through construction observation, issue management, and testing
  Documents verification of system and assembly performance
  Verifies training completion
  Includes formal functional testing at completion
- **Occupancy and operations (including maintenance)**
  Improves performance (IAQ, comfort, energy) from start of occupancy
  Reduces amount of troubleshooting
  Has fewer contractor call backs
  Ensures thorough documentation in **operation and maintenance (O&M)** manuals
  Provides a systems manual
  Verifies documentation submittals

Commissioning also reduces potential change orders, requests for information, contractor callbacks, and time required to fine-tune and debug systems during occupancy, and smooths turnover. Building performance improvements give better building and system control, improve energy efficiency, enhance indoor environmental quality, and contribute to increased occupant productivity.

Key Contributors

- Owner/end user
- Architect
- Mechanical engineer
- Electrical engineer
- Commissioning authority (CxA)
- Mechanical contractor
- Electrical contractor
- Controls contractor
- Sheet metal contractor
- Testing, adjusting, and balancing (TAB) agency
- Owner's O&M staff
- General contractor/construction manager

Definitions

Basis of Design (BOD). A document that records the concepts, calculations, decisions, and product selections used to meet the OPR and to satisfy applicable regulatory requirements, standards, and guidelines. The document includes both narrative descriptions and lists of individual items that support the design process.

Commissioning Authority (CxA). An entity identified by the owner who leads, plans, schedules, and coordinates the commissioning team to implement the commissioning process.

Commissioning Plan (Cx Plan). A document that outlines the organization, schedule, allocation of resources, and documentation requirements of the commissioning process.

Construction Checklist. A form used by the contractor to verify that appropriate components are on site, ready for installation, correctly installed, and functional.

Current Facility Requirements (CFR). A written document in which the owner details a facility's current functional requirements and the expectations of how it should be used and operated. This may include goals, measurable performance criteria, cost considerations, benchmarks, success criteria, and supporting information to meet the requirements of occupants, users, and owners of the facility.

Existing Building Commissioning (EBCx) Process. A quality-focused process for attaining the CFR of an existing facility and its systems and assemblies being commissioned. The process focuses on planning, investigating, implementing, verifying, and documenting that the facility and/or its systems and assemblies are operated and maintained to meet the CFR with a program to maintain the enhancements for the remaining life of the facility.

Facility Guide (FG). A basic building systems description and operating plan with general procedures and confirmed facility operating conditions, set points, schedules, and operating procedures to properly operate the facility.

Owner's Project Requirements (OPR). A document that details the functional requirements of a project and the expectations of how it will be used and operated. These include project goals, measurable performance criteria, cost considerations, benchmarks, success criteria, and supporting information. (The term **project intent** is used by some owners.)

Systems Manual. A system-focused, composite document that includes the operation manual, maintenance manual, and additional information of use to the owner during occupancy and operations.

Test Procedures. A written protocol that defines methods, personnel, and expectations for tests conducted on components, equipment, assemblies, systems, and interfaces among systems.

1.1 COMMISSIONING OBJECTIVE

The commissioning objective focuses on documented confirmation that a facility fulfills the specified performance requirements for the building owner, occupants, and operators. To reach this objective, it is necessary to (1) clearly document the owner's project requirements, including performance and maintainability; and (2) verify and document compliance with these criteria throughout design, construction, acceptance, and initial operation phases.

Specific goals for commissioning include

- Providing documentation and tools to improve quality of deliverables (e.g., forms, tracking software, performance calculation tools)
- Verifying and documenting that systems and assemblies perform according to OPR by end of construction with building occupancy
- Providing a uniform and effective process for delivery of construction projects
- Using quality-based sampling techniques to detect systemic problems
- Verifying proper coordination among all contractors, subcontractors, vendors, and manufacturers of all furnished equipment and assemblies in the completed systems
- Verifying that adequate and accurate system and assembly documentation is provided to owner
- Verifying that operation and maintenance personnel and occupants are properly trained

1.2 MANAGEMENT AND RESPONSIBILITIES

Management Strategies

In each project, a qualified party should be designated as the commissioning authority (CxA).

Predesign and Design. Commissioning during predesign and design is most often managed by an independent CxA who is not part of the formal designer-of-record team. An independent, objective view is critical. The CxA normally provides input to the owner and designers but does not have ultimate authority over design decisions. The CxA should also coordinate, conduct, or approve activities such as assisting in development of the OPR, conducting statistical sampling reviews, and developing commissioning specifications and test procedures. The CxA may also review plan designs.

Construction. During construction, because of the variety of players, construction management scenarios, and the owner's objectives, numerous methods are used to manage the commissioning process. To maintain objectivity, the CxA should be independent. If the contractor or designer hires the CxA, the potential conflict of interest must be carefully managed. The two primary methods to manage commissioning during construction are commissioning-authority-managed and contractor-managed.

In the **commissioning-authority-managed approach**, the CxA performs many of the planning and technical tasks, such as developing the commissioning plan and test procedures and directing, witnessing, and documenting execution of tests, performed by either the contractor or the CxA.

In the **contractor-managed approach**, the contractor may develop the commissioning plan, write test procedures, and direct and document testing, with the CxA reviewing and approving the plan, witnessing selected tests, and reviewing completed test reports. The CxA should report to the owner on the adequacy of a contractor-managed commissioning plan. The contractor may assign staff, a subcontractor, or a subconsultant to manage and coordinate commissioning responsibilities. This approach gives the contractor more responsibility. Some view this method as less objective, but others consider it more integrated into the building delivery process than the CxA-managed approach.

Some project plans use both management approaches, particularly when a substantial amount of electrical equipment is being tested. HVAC and controls follow the commissioning-authority-managed approach, and electrical system commissioning follows the contractor-managed approach, but the entire process is still overseen by the single CxA.

Team Members

Effective building commissioning requires a team effort. The size and makeup of the team depends on the size and complexity of the project and the owner's desire for quality assurance. Team members include the owner, occupants, design professionals, construction manager, general contractor, subcontractors, suppliers, equipment manufacturers, and the CxA.

The level of effort of team members changes during the different project phases. For example, during design, the designer is a key player in the commissioning process, whereas the contractor may not have been selected. During construction, the general contractor's and installing subcontractors' roles increase.

The scope of work of the CxA, design professionals, and contractors should be clearly and completely identified in their contracts. Without this, change orders, incomplete or missed tasks, and otherwise dysfunctional commissioning may result.

Roles and Responsibilities

The commissioning team's responsibilities are to conduct commissioning activities in a logical, sequential, and efficient manner using consistent protocols and forms, centralized documentation, clear and regular communications and consultations with all necessary parties, frequently updated timelines and schedules, and appropriate technical expertise. The following sections summarize the responsibilities of each party. Additional detail is found in the Commissioning Process section.

Commissioning Authority. Specific responsibilities vary with the management scenario and the CxA's specific scope of services. Ideally, the same party or firm acts as CxA through all project phases. The CxA organizes and leads the commissioning team throughout the project.

Predesign and Design Phase. During predesign, the CxA develops the predesign and design-phase commissioning plan and ensures the OPR is developed.

During design, the CxA develops detailed commissioning activities. The core CxA responsibilities are

- Reviewing designer's BOD, plans, and specifications, ensuring they meet the OPR
- Developing initial construction-phase commissioning plan
- Ensuring that the commissioning, training, and documentation requirements for all contractors and suppliers are reflected in construction contract documents

Construction. During construction, the CxA is in charge of the commissioning process and makes the final recommendations to the owner about functional performance of commissioned building systems and assemblies. The CxA directs commissioning activities, and is an independent and objective advocate for the owner. The core commissioning activities during construction involve

- Reviewing selected construction submittals to verify conformance with OPR, with updates in commissioning plan as needed
- Observing selected installations, start-up, and functional performance tests, including documenting any conditions that require correction
- Co-organizing with the discipline design engineer, and planning, developing, reviewing, and observing testing
- Codeveloping or assisting with systems manual
- Reviewing O&M manual submissions
- Verifying operator and maintenance personnel training and documentation
- Submitting documented results to owner on all commissioning performed

These tasks may vary (e.g., some commissioning scopes involve preparing the O&M or electronic facility's manuals, preparing detailed maintenance management plans, or conducting operator and maintenance personnel training).

Occupancy and Operations. During occupancy and operations, the CxA helps resolve commissioning issues and directs opposite-season testing. Often, the CxA participates in a near-warranty-end review of system and assembly performance.

Independence. If the CxA's firm has other project responsibilities, a potential conflict of interest exists. Wherever this occurs, the CxA should disclose in writing the nature of the conflict and the means by which it will be managed. If the CxA is not under direct contract to the owner, the owner's interests need to be protected through appropriate oversight of the CxA's work.

Qualifications. The CxA should fully understand commissioning, design, and construction processes and have technical design, operations, maintenance, and troubleshooting knowledge of the systems and assemblies being commissioned. Excellent written and verbal communication skills are critical. The CxA may represent an individual or a team of commissioning experts, depending on system complexity, the number of disciplines involved, and commissioning scope. Thus, the ability to manage diverse disciplines over long timelines is also important.

Construction Manager. The construction manager's role varies on each project. When they have significant oversight for the owner (e.g., schedule management, submittal review, change order authority), their commissioning role is more like the owner's: they ensure the contractors execute their commissioning responsibilities according to the commissioning plan, and help resolve issues.

General Contractors.

Design. The general contractor (if yet selected) reviews commissioning requirements and performance criteria for coordination, schedule, and cost implications.

Construction. The contractor's role and responsibilities are

- Ensuring subcontractors' commissioning work is completed and cooperating with CxA in executing the commissioning plan
- Providing input into commissioning plan for CxA's review and approval
- Integrating commissioning schedule into overall project schedule
- Participating in commissioning meetings
- Responding to questions and issues raised by CxA
- Resolving issues identified during commissioning and coordinating correction of identified deficiencies
- Providing equipment, system, and assembly data needed by CxA
- Performing specified training
- Submitting required portions of systems manuals

In the contractor-managed approach, the general contractor is often required to hire a third party with direct commissioning skills to manage and execute the contractor commissioning requirements.

Trade Contractors.

Design. Trade contractors of specialty or complex systems or designs should review commissioning requirements and performance criteria of their systems for coordination, schedule, and cost implications.

Construction. The responsibilities of the installing trade contractors (and vendors, as appropriate) include

- Participating with CxA (and the contractor's commissioning manager, when applicable) in executing commissioning plan
- Providing input into commissioning plan for CxA's review and approval
- Coordinating with other trades as necessary to facilitate a smooth and complete commissioning process
- Participating in commissioning meetings
- Responding to questions and issues concerning their work raised by CxA
- Executing and documenting tasks in construction checklist and start-up process
- Performing and documenting tests when in their scope
- Participating in resolving issues within their scope identified during commissioning
- Correcting identified deficiencies within their scope
- Providing required documentation for systems manuals and commissioning reports

Commissioning-related activities of trade contractors are to prepare O&M manuals and submissions to the systems manual and provide training on commissioned systems and assemblies. To avoid confusion, the OPR should specify which commissioning activities are the trade contractor's responsibility, and which are the CxA's.

Architect and Engineers (Designers).

Design. The design professionals should develop complete basis-of-design (BOD) documentation, including design narratives, rationale, and criteria, according to their scopes of services, and update this document with each new design submission. They provide input to the commissioning plan, respond to questions and concerns by the CxA and others, respond to design review comments, and incorporate commissioning requirements in construction contract documents.

Construction. During construction, designers

- Review the commissioning plan
- Attend selected commissioning meetings
- Answer questions about system design and intended operation
- Update design narratives in the BOD to reflect as-built conditions
- Respond to or incorporate CxA comments on construction submittals and O&M manuals
- Help resolve design-related issues raised during commissioning
- Perform specified training
- Submit required portions of systems manuals

Additional tasks sometimes required are to present system description overviews for primary systems during O&M staff training, review and approve testing plans and procedures, review completed test forms, or witness selected tests.

Owner's Project Management Staff. The owner's project management staff's ultimate responsibility is to see that the commissioning plan is executed. The owner, with guidance from the CxA, should include specific responsibilities in all commissioning team members' scopes of services, make sure there is sufficient time for commissioning in the project schedule, ensure the CxA is receiving cooperation from other team members, and ensure that other owner responsibilities (e.g., developing the OPR, having O&M staff participate during construction) are fulfilled. The owner ensures that all design review and construction-phase issues identified through commissioning are resolved in a timely manner.

Owner's Representatives. The owner's representatives are individuals or firms hired to represent the owner's interest during specified phases of the building process. The owner typically retains the project architect or project engineer responsible for HVAC design and the CxA as a team of owner's representatives.

Owner's Operations and Management (O&M) Staff.

Predesign. The owner's O&M staff should participate in the development of the OPR during predesign.

Design. During design, O&M staff may contribute to reviews of the designer's BOD, plans, and specifications.

Construction. During construction, the owner's O&M staff should

- Assist in reviewing selected submittals
- Assist in construction observation, verifying completion of construction checklists and observing start-up
- Participate in or witness testing, within pre-established lines of responsibility and authority
- Review O&M and systems manual
- Participate in training

Occupancy. During occupancy, the O&M staff should identify any warranty or operational issues and report back to the commissioning team. They should participate in the warranty review and may participate in any seasonal testing. O&M staff might also participate as needed in additional training, particularly any related to the control system or other complex or unfamiliar technology.

Occupants and Users.

Predesign. The occupants and users should participate in the development of the OPR during predesign.

Design. During design, occupants and users may contribute to reviews of the designer's BOD, plans, and specifications.

Construction. During construction, occupants and users may participate in select training and final inspection and walk-throughs.

Occupancy. The occupants and users report back to the owner and/or the commissioning team about warranty items and other issues they observe related to the performance of the building.

2. COMMISSIONING PROCESS

Commissioning should begin during predesign, and formally continue through the first year of occupancy and operations. Although circumstances may require owners to begin commissioning at the design or construction stage of a project, this later implementation should, when possible, capture the same information and verifications developed when commissioning begins at project inception.

2.1 PREDESIGN-PHASE COMMISSIONING

Objectives

The primary activities and objectives of commissioning during predesign are to

- Develop owner's project requirements (OPR)
- Identify scope and budget for commissioning process
- Develop initial commissioning plan
- Review and accept predesign-phase commissioning-process activities
- Review and use lessons learned from previous projects

Activities

Commissioning Team and Management. During the predesign phase, a team is formed to oversee and accomplish commissioning. Responsibility for leadership of the commissioning team should be defined and assigned to the CxA at the beginning of predesign.

Owner's Project Requirements (OPR). The OPR forms the basis from which all design, construction, acceptance, and operational decisions are made. It describes the functional requirements of the facility and expectations of how it will be used and operated. It includes project and design goals, budgets, limitations, schedules, owner directives, and supporting information, as well as necessary information for all disciplines to properly plan, design, construct, operate, and maintain systems and assemblies (ASHRAE *Guideline* 0).

The OPR is generally a set of concise objective qualitative statements, each with one or more quantitative performance metrics or criteria. The following information should be included:

- Functional requirements, needs and goals for building use, operation, maintenance, renovation, and expansion, including user's requirements and space temperature requirements
- Occupancy schedules and space plan requirements, including zone-based control areas
- Sustainability, reliability, durability, safety, and aesthetic goals
- Quality of materials and construction
- Warranty, project documentation, and training requirements
- Goals for the process and outcome of design and construction (e.g., budgets, schedules, change orders, safety, aesthetics, effects on adjacent or integral occupied spaces and tenants)
- General commissioning scope and objectives
- General statements about codes, standards, and regulations to be followed
- Limitations likely to affect design decisions
- Specific features, systems, assemblies, or brands the owner requires (these will be repeated in the design narrative)
- Instructions to designers on types of design tools and aids expected to be used

The CxA ensures that the OPR is developed and is clear and complete. The CxA may develop or help develop the OPR with the owner or provide direction and review of the OPR developed by others. Facilitated workshops, surveys, and questionnaires are useful for developing the OPR. Later during design, additional OPR statements with performance criteria may be added to the formal list, as desired by the owner and commissioning team. The OPR should still be developed, even if not originally generated in predesign, and included in the systems manual.

Scope and Budget for Commissioning. During predesign, the owner, with assistance from the CxA, develops a scope and a rough budget for commissioning. At minimum, design-phase activities should be initially scoped. Once a design-phase commissioning plan is developed, the scope and budget may need to be adjusted. The scope and budget should reflect the commissioning objectives in the OPR.

Selecting areas to commission is typically based on the budget, systems or assemblies with which the owner has experienced problems on previous projects, complexity of systems and assemblies, and criticality of the system or assembly in meeting the OPR. During predesign and design, the list of areas to be commissioned may be general (e.g., electrical lighting controls, emergency power, general electrical equipment, HVAC, domestic water system, and envelope fenestration, etc.). Later in design but before scoping construction-phase commissioning, additional detail should be added to each of these categories, and others added as needed to ensure that the scope of commissioning is clear. Adding this detail increases the cost of commissioning, and needs to be specified early in the design phase.

Historically, commissioning focused on HVAC. Owners are now asking for more systems to be commissioned, including lighting controls, fire and life safety systems, vertical and horizontal transport systems, envelope, plumbing, landscaping, sustainability features, structural elements, many electrical equipment components, security, data, and communications. Refer to the section on Commissioning Costs for budgeting guidelines.

Predesign-Phase Commissioning Plan

One predesign-phase commissioning task should be drafting the commissioning plan for the design phase. The CxA develops this plan with review and comment by the owner and designer, and the plan is updated as the project progresses. The design-phase commissioning plan should include the following:

- Objectives and scope of commissioning
- Overview of the process
- Detailed commissioning-process activities for design phase
- General commissioning-process activities for construction and operations/occupancy phases
- Roles and responsibilities
- Deliverables
- Communication protocols
- Schedule
- Checklist of requirements and formats
- Verification and acceptance procedures

Acceptance of Predesign Commissioning

The owner's project requirements and commissioning plan should be formally accepted during predesign, after review and comment by the CxA.

2.2 DESIGN-PHASE COMMISSIONING

Objectives

Design-phase commissioning objectives include the following:

- Update the owner's project requirements (OPR)
- Verify basis of design (BOD) document against OPR
- Update the design-phase commissioning plan developed during predesign
- Develop and incorporate commissioning requirements into project specifications
- Develop commissioning plan for construction and occupancy/operations phases, including draft construction checklist
- Verify plans and specifications against BOD and OPR
- Begin codeveloping with relevant discipline design engineer for systems manual
- Define training requirements for O&M personnel
- Perform commissioning-focused design reviews

- Accept design-phase commissioning

Activities

Update Design-Phase Commissioning Plan. The initial design-phase commissioning plan is developed during predesign. As more becomes known about systems and assemblies likely to be a part of the project and as project objectives are clarified, the commissioning plan may need to be updated with additional details. The CxA must participate in value engineering and constructability review sessions to ensure that commissioning can be performed. The owner and designer then review and comment on the updated plan, which then becomes the guide for the rest of the design phase.

Update the OPR. As design progresses, additional OPR and performance criteria are likely to be identified. Other criteria may need to be altered as more detailed budget and design data become available.

Verify the Basis of Design. All BOD elements can be grouped under one of two terms: design narrative or design criteria. These two terms provide a useful separation when writing the design basis.

The **design narrative** is the written description and discussion of the concepts and features the designers *intend* (during schematic design phase) to incorporate into the design or what they *have* incorporated (during the balance of design) to meet the OPR and associated performance criteria as well as codes, standards, and regulations. This narrative should be understandable by all parties of the building construction and operation process, though it may address fairly technical and specialized issues. It includes a brief section on what systems were considered and why they were accepted or rejected, along with the rationale for the system selected. The design narrative should be updated with each phase of design.

The **design criteria** are the project-specific information, including underlying assumptions for calculations, calculation methodology, codes and standards followed, equipment used as the basis of design, and design assumptions needed to make design calculations and other decisions, such as

- Diversity and safety factors used in sizing
- Classes of systems and components (duct class, cleanroom class, explosive or other hazardous classifications, etc.)
- Level of redundancy
- Occupant density
- Limitations and restrictions of systems and assemblies
- Inside and outside conditions (space temperature; relative humidity; lighting power density; glazing fraction; U-value and shading coefficient; roof, wall, and ceiling R-values; ventilation and infiltration rates; etc.)
- Fire and life safety issues
- Summary of primary HVAC load calculations and the methods used

Development and Use. The BOD is written by the designer and increases in details as design progresses. The CxA may need to obtain this explanatory information from the designer. An updated BOD with increased detail should be submitted with each new design submission. Each submission is reviewed by the owner and CxA as part of design reviews.

Develop Commissioning Plan for Construction and Occupancy/Operations Phases. The commissioning plan (Cx plan) is a document that outlines the organization, schedule, allocation of resources, and documentation requirements of the commissioning process. This is an overall plan, developed during the predesign, design, and construction phases, that provides the structure, schedule, and coordination planning for commissioning. The Cx plan includes specifications detailing the scope, objectives, and process of commissioning during the construction and occupancy/operations phases of the project. It must specify the scope of work, roles, responsibilities, and requirements of the construction contractor. For the construction and occupancy/operations phases, it describes the following:

- Commissioning process
- Scope of commissioning effort, including systems, assemblies, and components being commissioned
- Rigor of commissioning
- Roles and responsibilities of each team member
- Team contact information
- Communication protocols between team members, including documentation requirements
- Commissioning overview and details of submittal activities
- Construction observation, following checklists, and performing start-up activities
- Preliminary schedule for commissioning activities
- Process for dealing with deficiencies
- Test procedure development and execution
- Prefunctional/functional test procedures
- Operation and maintenance (O&M) manual review
- Warranty-period activities
- Operation training procedures
- Systems manual development
- Description of summary report, progress and reporting logs, and initial schedule (including phasing, if applicable)
- Procedures for documenting commissioning activities and resolving issues

The commissioning plan developed during predesign is updated to include construction-phase activities. At the beginning of the design phase, the plan is general and is used primarily to guide development of commissioning specifications. The owner and designer review and comment on the plan. As design progresses, the CxA updates and finalizes the plan when the construction documents are completed. The commissioning plan can be issued with the bid documents for reference.

Develop and Incorporate Commissioning Requirements into Project Specifications. The specifications in the Cx plan are needed by contractors so they can include commissioning responsibilities in pricing and understand how to execute the work. Because commissioning is still relatively new to the building industry, descriptive process language should be included, rather than just delineating requirements. Frequently, for reference, the responsibilities of other team members not bound by the specifications (e.g., owner, CxA, construction manager, architect) are given in the commissioning specifications to ensure clarity and put the contractor's responsibilities in context.

The specification should include definitions, a list of equipment and systems to be commissioned, submittal, construction checklist, testing and documentation requirements, and sample checklists and test forms. If the project uses contractor-managed commissioning, the specification should identify skills and qualifications required of the contractor's commissioning lead.

The OPR, along with as much BOD information as possible, should be included in the construction documents and labeled as informational-purposes-only, to differentiate from the contractor's contractual obligations. Training and O&M manual requirements of the contractor also should be included.

It is critical that the project specifications in the Cx plan clearly define how the quality control and testing functions that have traditionally been a part of many construction projects (e.g., fire alarm, elevator, duct pressure, room pressurization, emergency power testing) will be integrated with HVAC commissioning. Responsibility for checkout and test procedures, including test procedure review, direction, execution, witnessing, documentation, and approval, must all be clearly described. The acceptance criteria for the test should be included in the specifications. Acceptance criteria should be based on the OPR and the systems selected. For example, a project may require tight temperature or humidity tolerances to meet certification criteria. Systems designed for these projects should be able to control to those tolerances. A system with staged cooling (direct expansion with compressor staging) may not be able to meet a ±0.5 K level of control. This should be taken into consideration when selecting the systems for the project.

The CxA ensures that contractor responsibilities for commissioning are appropriately incorporated into the project specifications. Placing the general commissioning requirements, process descriptions, and specifications in a single section is one method that makes it easy for all parties to know where to look for their responsibilities and find common terminology. The weakness of this method is that some contractors may not realize that this is part of their responsibilities, because it is not described in their sections; therefore, it might be beneficial to split at least part of the commissioning requirements into the applicable sections, with a reference back to the section that describes the common commissioning processes.

Often, the commissioning authority writes the commissioning specifications and then works with the designer to integrate them into the project specifications. Alternatively, the designer can develop the commissioning specifications, with the CxA reviewing and recommending revisions.

Begin Developing Systems Manual. During design, the systems manual contains the OPR, BOD, and drawings and specifications, updated at each design submission and during and after construction. The CxA is often responsible for assembling and maintaining the systems manual; however, the contract documents for the CxA or design professionals should delineate who is responsible for this task.

The systems manual differs significantly from traditional O&M manuals. This manual expands the scope to include other project information developed and gathered during commissioning, such as traditional equipment O&M data, design and construction documents (OPR, BOD, plans, specifications, and approved construction submittals), system schematics, final commissioning report, training records, commissioning test procedures (filled-in and blank), and optimization and diagnostic data (which can include operational procedures for specific emergency situations, seasonal changeover procedures, fire and emergency power response matrix, smoke management system operation during and after fire, energy efficiency recommendations, troubleshooting guide, recommissioning frequency, and diagnostic building automation system trend logs). Scopes of work should clearly identify whether the systems manual includes all project systems and assemblies or just commissioned ones. For more information, see ASHRAE *Guideline* 4-2008.

The owner, designer, contractor, and commissioning authority each have development responsibilities for parts of the systems manual. Construction documents should list the contents and requirements for the systems manual and the responsible party for generating, compiling, and finishing each part of the required documentation. Systems manuals should be available for and used in operator training. Much of the systems manual can be put into electronic media format. The ability to search and auto-update enhances the usability and accessibility of the data.

Define Training Requirements. During the design phase, the training requirements of O&M personnel and occupants are identified relative to the systems and assemblies to be installed in the facility. O&M personnel must have the knowledge and skills required to operate the facility to meet the OPR. Occupants also need to understand their effect on the use of the facility and the ability to meet project requirements. Both groups require training.

Training needs can be identified using a group-technique workshop, interviews, or surveys with the owner and occupant representatives after the systems and assemblies have been specified, and before issuing the construction documents. The contractor's training responsibilities need to be incorporated into the project specifications and should include requirements for the number of training hours for each item of equipment or assembly and submittals of training plans and qualifications of trainers. Training likely requires participation of the designer (for system overviews), the CxA (for system overviews, recommissioning, optimization, diagnostics, and using and maintaining the systems manual), and possibly the contractor, and should be included in their scopes of work. Because turnover in O&M and occupants will occur, training materials should be reusable (e.g., video, written manuals, computer presentations).

Perform Design Reviews. Design review by parties not part of the formal designer-of-record team should be conducted to provide an independent perspective on performance, operations, and maintenance. These document reviews, conducted by experts in the field, should start as early as possible, when options and issues can be more easily resolved. The reviews may be coordinated by the CxA and should include the owner's technical staff. The CxA may attend some design team meetings, and formally reviews and comments on the design at various stages of development [ideally, at least once during schematic design (predesign), design development, and construction document phases]. The CxA's design review is not intended to replace peer-to-peer design reviews that check for accuracy and completeness of the design and calculations.

A targeted design review may cover the following:

- General quality review of documents, including legibility, consistency, and level of completeness
- Coordination between disciplines
- Specification applicability to project and consistency with drawings
- Verification that BOD assumptions and rationale are reasonable
- Verification that system and assembly narrative descriptions are clear and consistent with OPR and the BOD is updated with resolved issues
- Verification that plans and specifications are consistent with BOD and OPR, and plans and specifications are updated with resolved issues

Potential system performance problems, issues likely to result in change orders, areas where correct installation is difficult, energy efficiency improvements, environmental sustainability, indoor environmental quality issues, fire and life safety issues, operation and maintenance issues, and other issues may be addressed in these design reviews, depending on the owner's desires and CxA's scope. Required reviews ensure that training and systems manual requirements are adequately reflected in construction documents.

Some reviews use sampling, giving 10 to 20% of the drawings and specifications for an in-depth review; if only minimal issues are identified, the owner accepts the submission. If significant issues are identified in the sample, either the submittal is sent back to the designer for revamping and a thorough review, or the CxA may perform a thorough review, depending upon the scope of work defined in the CxA's contract. After the design team has addressed the issues, the CxA performs a new review. In this type of review, the design team is still responsible for their traditional peer review of construction documents for accuracy. The CxA makes recommendations to facilitate commissioning and improve building performance, without approving or disapproving either design or documents. The design team is ultimately responsible for design. The CxA should be able to justify all of the recommendations made. It is the responsibility of the owner or project manager to evaluate all review findings with the design team and see that the responsible team member implements the approved ones. All issues are tracked to resolution and verified in later reviews to have been incorporated as agreed.

If the CxA is contracted through a designer, the designer's commissioning manager or subconsultant may manage the contractor's issues log. In that case, to minimize conflicts of interest, the CxA is often required to report all issues simultaneously to the designer and to the owner.

Accept Design-Phase Commissioning Activities. Commissioning should include the owner's formal acceptance of the BOD, updated OPR, Cx plan, and the design, after review and comment by the CxA.

Additional Commissioning Team Tasks. Additional design-phase responsibilities of the commissioning team (led by the CxA, who is frequently responsible for these requirements) include the following:

- Build and maintain cohesiveness and cooperation among the project team
- Assist owner in preparing requests for project services that outline commissioning roles and responsibilities developed in the commissioning plan
- Ensure that commissioning activities are clearly stated in all project scopes of work
- Develop scope and budget for project-specific commissioning-process activities
- Identify specialists responsible for commissioning specific systems and assemblies
- Conduct and document commissioning team meetings
- Inform all commissioning team members of decisions that result in modifications to the OPR
- Integrate commissioning into the project schedule
- Track and document issues and deviations relating to the OPR and document resolutions
- Write and review commissioning reports

2.3 CONSTRUCTION-PHASE COMMISSIONING

Objectives

Commissioning activities should take place throughout the construction phase and include verification and documentation that

- All acceptance testing requirements are documented
- All systems and assemblies are provided and installed as specified
- All systems and assemblies are started and function properly
- All acceptance testing requirements are documented
- All record documents are updated
- The systems manual is updated and provided to facility staff
- Facility staff and occupants receive specified training and orientation
- Acceptance testing occurs

Activities

The following primary commissioning activities (in approximately sequential order) address commissioning objectives. The CxA coordinates and ensures that all activities occur and perform successfully.

Bidding and Contract Negotiation. A member of the commissioning team (usually the CxA) may attend the prebid conference to present an overview of commissioning requirements and answer questions. Changes that occur during bidding and contract negotiations related to commissioned systems and assemblies are also reviewed to ensure they agree with the OPR.

Commissioning Planning and Kickoff Meetings. The CxA coordinates construction-phase planning and kickoff meetings. The planning meeting held with the contractor, owner, designer, and CxA focuses on reviewing requirements and establishing specific communication and reporting protocols. The commissioning plan is updated from this meeting. The kickoff meeting is held with additional construction team members, who generally include the mechanical, controls, electrical, and test and balancing contractors. At this meeting, the commissioning provider outlines the roles and responsibilities of each project team member, specifies procedures for documenting activities and resolving issues, and reviews the preliminary construction commissioning plan and schedule. Team members provide comments on the plan and schedule, and the CxA uses these suggestions to help finalize the commissioning plan and schedule.

Commissioning Plan Update. The planning and kickoff meetings usually result in an updated commissioning plan. Later, any project phasing or other schedule and scope-related issues (e.g., testing and training plans and schedules) are clarified in further updates.

Submittal Reviews.

Construction Submittals. The CxA reviews equipment and material submittals of commissioned systems and assemblies to obtain information needed to develop construction checklists, make meaningful observations of construction progress, and aid in developing comprehensive tests. This process also verifies that contractors are providing high-quality submittals that meet the construction document requirements, and that architects and engineers provide a quality review so construction-related performance issues are identified before construction progress makes them more difficult and expensive to address. Submittals could be reviewed concurrently by the design team to allow any discrepancies to be identified before formal approval, but the construction submittal review should also be compared to the architects' and engineers' reviews to verify that the architects and engineers are providing a thorough review of the submittals.

Controls Submittal and Integration Meeting. Before the contractor develops the controls submittal, the CxA coordinates a controls integration meeting to discuss and resolve methods for implementing performance specifications or strategies, interlocks between systems, priority of control between packaged controls and the central control system, the control system database, point names, graphic details and layout, access levels, etc.

Coordination Drawings. The CxA may help the owner monitor the development and coordination of shop drawings to ensure synchronization between trades.

Early O&M Data. Information beyond typical construction submittals requested by the CxA includes installation and start-up procedures, operation and maintenance information, equipment performance data, and control drawings before formal O&M manual submittals. This information allows the CxA to become familiar with systems and assemblies to develop construction checklists, start-up plans, and test procedures.

Contract Modifications Review. Construction documentation issued during this phase, including requests for information, construction field directives, and change orders, should be reviewed by the CxA to identify issues that may affect commissioning and compliance with construction documents, BOD, or OPR.

Schedule Commissioning Field Activities. The CxA works with the contractors and construction manager to coordinate the commissioning schedule and ensure that commissioning activities are integrated into the master construction schedule.

Construction and Commissioning Meetings. The CxA attends periodic planning and job-site meetings to stay informed on construction progress and to update parties involved in commissioning. During initial construction, the CxA may attend regular construction meetings and hold a line item on the agenda. Later, the CxA may convene entire meetings devoted to commissioning issues, with more frequent meetings as construction progresses. Attendees vary with the purpose of the meeting. Team members should be represented at meetings by parties with technical expertise who are authorized to make commitments and decisions for their respective organizations. The CxA should distribute minutes from these meetings.

Progress Reports. The CxA provides periodic progress reports to the owner and contractor with increasing frequency as construction progresses. These reports indicate current progress, next steps, and critical issues affecting progress and construction schedule.

Update Owner's Project Requirement and Basis of Design. When contract negotiations and/or changes and clarifications made during construction alter or add to the OPR or BOD, these documents should be updated. Normally, the CxA updates the OPR and the designer updates the BOD. Final construction updates to these documents are made at the end of testing, typically a few months into occupancy.

Coordinate Owner's Representatives Participation. The commissioning plan should describe participation of the owner's representatives in work such as submittal review, construction checklist verification, construction observation, test procedure review and execution, and O&M manual review. The CxA normally coordinates this participation with the contractors.

Construction Observation. The CxA should make planned, systematic visits to the site to observe installation of systems and assemblies. The owner's staff may assist in construction observation. The CxA should verify that the first few of any large-quantity items (e.g., variable-air-volume terminal units) are installed properly and used as a mock-up or standard to judge the rest of the installation. Any conditions not in compliance with the construction documents or BOD or that may affect system performance, commissioning, operation, or other project requirements should be documented. These observations normally focus on areas where observers have found problems before, or spot-check items on construction checklists. Less often, practitioners are tasked with validations or detailed inspections verifying that equipment or assemblies have been installed properly in every detail. Some practitioners make formal construction observation reports, whereas others merge findings into the regular issue logs and progress reports. Site visits should be used to verify completion of construction checklists.

The CxA normally witnesses many of the contractor's start-up activities for major equipment to ensure checklists and start-up are documented properly and to gain additional feature and function information from installing technicians.

Record Documents. Contractors should be required to immediately update the record drawings when any deviations from the construction document occur. During the construction phase, the CxA should verify that the record documents are kept up to date by comparing the installation with the construction documents, and verify that any changes have been recorded on the record documents.

Construction Checklists and Start-up. At the beginning of construction, construction checklists are developed (usually by the CxA in cooperation with the discipline engineer, but sometimes by the contractor or equipment manufacturer) for most commissioned systems and equipment. They are attached to or integrated with manufacturer's installation and start-up procedures. In most projects, contractors fill out the checklists during installation, during normal checkout of equipment and systems, and before and during system start-up, though some commissioning practitioners fill out the checklists themselves. The contractor fully documents start-up and initial checkout, including the construction checklists to ensure systems are ready for testing, and submits them to the CxA, who reviews the forms and spot-checks selected items in the field later in the project.

Some CxAs statistically sample items on checklists to verify proper completion (typically random or targeted sampling of 2 to 20%). If an inordinate fraction of the sampled items are deficient (typically more than 10%), the contractor is required to check and document all remaining items. The contractual documents need to contain details of the sampling and actions based on the results.

Commissioning Issues Management. The CxA keeps a record of all commissioning issues that require action by the design team, contractor, or owner. The issues should remain uniquely identified, be tied to equipment and systems, and prioritized relative to performance, cost, and schedule. Issues are tracked to resolution and completely documented. The CxA distributes the updated log to the owner, contractor, construction manager, and HVAC design engineer at construction and commissioning meetings. This log can also be placed on project web sites. If the CxA is hired through a contractor, the contractor's commissioning manager or subconsultant may manage the contractor's issues log. In that case, to minimize conflicts of interest, the CxA is often required to report all issues simultaneously to the contractor and to the owner.

Developing Test Procedures. Step-by-step test procedures and project-specific documentation formats are used for all commissioned equipment and assemblies. **Manual tests** evaluate systems with immediate results. **Monitoring testing** uses the building automation system or data loggers to record system parameters over time and analyze the data days or weeks later. **Automated testing** gathers or analyzes system performance data completely electronically, or with significant help from software.

Test procedure writing begins immediately after the submittal, because test procedures need to be reviewed and approved before testing occurs, which is generally scheduled about three to six weeks after the submittal review. Test procedures may be based on specifications, applicable standards and codes, submittal data, O&M data, data shipped with the equipment, approved control drawings, and existing test procedures of similar equipment or components. Tests should cover all functions and modes.

Procedural documents clearly describe the test prerequisites, required test conditions, individual systematic test procedures, expected system response and acceptance criteria for each procedure, actual response or findings, and any pertinent discussion. Test procedures differ from **testing requirements** found in the specifications, which describe *what* modes and features are to be tested and verified and under what conditions. Test procedures describe the step-by-step method of *how* to test. Simple checklists may be appropriate for testing simple components, but dynamic testing of interacting components requires more detailed procedures and forms.

The responsible HVAC design engineer should organize the preparation of HVAC system testing, adjusting, and balancing (TAB) procedure together with the test and balancing professional and the commissioning authority, depending on their scopes of work. The CxA is responsible for verifying that the test procedures are written and appropriate for determining that equipment, assemblies, and systems function correctly. All parties should have input into the final test procedures to ensure that equipment, assemblies, systems, or people will not be endangered or warranties voided. Industry standard test procedures [e.g., ASHRAE, Air-Conditioning and Refrigeration Institute (ARI), American Composites Manufacturers Association (ACMA)] should be referenced whenever possible.

Testing and Verification.

Responsibilities and Management. Traditional air and water testing, adjusting, and balancing is often performed by the contractor or by an independent contractor employed by the owner. Building envelope, elevators, and electrical system testing are generally excluded from HVAC commissioning, but may be included in whole-building commissioning. The CxA reviews the testing and verification plan and results, and may spot-check the results to verify the testing was completed. There is some movement in the industry to centralize coordination for quality assurance/quality control (QA/QC) functions under the commissioning team. Each project is unique, and different approaches can be warranted.

Critical issues include ensuring that

- Appropriate testing rigor is applied

- Technically qualified parties execute and document the testing
- Objectivity is maintained
- Testing is well documented

For systems not usually thoroughly tested by the contractor [e.g., HVAC systems and controls, lighting controls, specialty plumbing, and envelope and interfaces between systems (security, communications, controls, HVAC, fire protection, emergency power)], the CxA may write test procedures that go beyond HVAC tests. The CxA then directs, witnesses, and documents each test executed by the contractor after the contractors have ensured that the systems will pass these tests. The controls subcontractor usually executes the tests, although the CxA may test some equipment with or without the contractor present.

Testing that has traditionally been conducted by the contractor (e.g., fire alarm, fire protection, elevator, duct and pipe tests, emergency power, some electrical equipment) ideally should be centrally coordinated. This can be the responsibility of the contractor or of the CxA. The specifications should clearly establish testing and documentation requirements and define the responsible party. The level of confidence and objectivity can be increased by requiring experts in specific disciplines to witness tests, particularly in some electrical system and envelope assembly field testing. Increasing the required amount of field witnessing by the CxA also improves the confidence that commissioning was correctly performed.

Within a given discipline, there may be differing levels of autonomy. For example, in tests of electrical equipment (e.g., circuit breakers), the contractor may conduct and document the bolt-torque tests, and also be required to hire an independent certified testing agency to conduct other necessary tests that require more specialized expertise and test equipment.

The owner's technical staff can assist in and benefit from participation in any of the above scenarios. The designer and owner's project management staff may witness selected tests.

Verification Testing Scheduling. Verification testing should be performed after equipment and assemblies are complete and started up, construction checklists checked out and submitted, air and water balancing completed, and the contractors' systems testing finished. The contractor is then ready to turn the system over to the owner. Most projects require a certificate of readiness from the contractor certifying that the system has been thoroughly checked out and verified to be completely functional. Ideally, manual testing occurs before substantial completion, but schedule slippage may require testing to occur after this milestone. Some short-term monitoring may be completed with manual testing, but sometimes is postponed until early occupancy. Opposite-season and other deferred testing should be conducted during seasonal changes or peak seasonal conditions.

Testing Scope. At a minimum, testing includes observing and documenting system operation and function during normal operation, through each of their sequences of operation, and all other modes of operation and conditions, including manual, bypass, emergency, standby, high and low load, and seasonal extremes, and comparing actual performance to that specified in the construction documents. Testing may also be conducted to verify performance criteria found in the BOD and OPR, including system optimization, though deficiencies in these areas are not normally the contractor's responsibility.

Manual Testing Methods. Testing includes observing normal operation; changing set points, schedules, and timers; and exercising power disconnects, speed controls, overwriting sensor values, etc., to cause perturbations in the system. System response and results are recorded on test procedure forms, and any issues are documented. Small corrections are often made during testing. Less pressing corrections or issues with unknown solutions are investigated later, corrected, and retested.

Building automation systems (BAS), when present, can be the backbone for conducting much of the testing, collecting, and archiving data. Before using the BAS, critical sensors, actuators, and features should be verified as calibrated so the system readouts are reliable (although all sensors and actuators should have been calibrated by the contractor and documented on construction checklists). The results are viewed on the building automation system screen or at the equipment. Other tests may require hand-held instruments or visual verification (e.g., evaluating caulking and flashings on window installations).

Monitoring. Some testing requires monitoring (trending) system operation over time through the BAS or data loggers (when the BAS does not monitor desired points). Monitoring can be used to document that systems are performing properly during test conditions over the monitoring period. However, this is not a substitute for manual testing, which can cover a wide range of conditions. Monitoring provides a view of system interactions over the course of normal, start-up, shutdown, and weekend operation. Normally, the CxA analyzes monitored data and submits a report, with any concerns added to the issues log.

Automated Testing. Various semiautomated testing is conducted in permanent onboard equipment controllers. Currently, most truly automated testing focuses on identifying electrical faults in controller components and is used during vendor start-up and troubleshooting activities. Some use logic to identify parameters outside limits, which indicate component malfunctions such as hunting and calibration issues. Different types of automated testing intended to help commissioning are under development. Some are primarily tools to gather and display monitored data; others help the analyzer make diagnoses. Equipment manufacturers often integrate automated commissioning testing capabilities into onboard controllers on their equipment.

Training. Training should include, as appropriate, (1) the general purpose of the system; (2) use and management of the systems manual; (3) review of control drawings and schematics; (4) start-up, shutdown, seasonal changeover, and normal, unoccupied, and manual operation; (5) controls set-up and programming; (6) diagnostics, troubleshooting, and alarms; (7) interactions with other systems; (8) adjustments and optimizing methods for energy conservation; (9) relevant health and safety issues; (10) special maintenance and replacement sources; (11) tenant interaction issues; and (12) discussion of why specific features are environmentally sustainable. Occupants may also need orientation on certain systems, assemblies, and features in the building, particularly sustainable design features that can be easily circumvented.

The CxA helps the owner ensure that adequate training plans are used by the contractor and that training is completed according to the construction documents. (See the discussion of defining training requirements in the section on Commissioning During Design.) Some CxAs conduct testing with a sample of trainees to verify the efficacy of the training.

Most training should be accomplished during construction, before substantial completion. However, for complex systems (e.g., control systems), multiple training sessions should occur before and after substantial completion. Training for systems that will not come into operation until the next season may be delayed. A meaningful training program typically includes using the operation and maintenance components of the systems manual, which must be submitted before training begins. Selected training materials can be video-recorded as desired by the owner.

Commissioning Record. The CxA compiles all commissioning documentation and project data, which are submitted and become part of the systems manual. The commissioning record contains the salient documentation of commissioning, including the commissioning final report, issues log, commissioning plan, progress reports, submittal and O&M manual reviews, training record, test schedules, construction checklists, start-up reports, tests, and trend log analysis, grouped by equipment.

Final Commissioning Report. The CxA should write (or review) and submit a final commissioning report detailing, for each piece of commissioned equipment or assembly, the adequacy of equipment or assemblies meeting contract documents. The following areas should be covered: (1) installation, including procedures used for testing equipment with respect to specifications; (2) functional performance and efficiency, including test results; (3) O&M manual documentation; and (4) operator training. Noncompliance items should be specifically listed. A brief description of the verification method used (manual testing, trend logs, data loggers, etc.) and observations and conclusions from the testing should be included. The CxA updates the final commissioning report after occupancy/operations-phase commissioning. The commissioning documents also should include, among other things,

- Certificates and warranties of system completion with a complete set of as-built drawings submitted from mechanical, electrical, piping, plumbing, control, and fire protection contractors
- Complete records of all problems and solutions occurred during start-up, testing, and adjustments submitted by every individual contractor or subcontractor
- Certified system testing and balancing report from the licensed TAB company, with verified major equipment models, capacities, and all tested performance records conforming to system design criteria
- If room pressurization is required, a complete room-to-room pressurization map in the TAB report
- If room cleanliness is required, a certified as-built room cleanliness report of testing during completion of construction and installation

Systems Manual Submittal. The CxA usually compiles the systems manual and provides it to the owner. At the end of construction, the designer, contractor, owner, and CxA provide elements of the systems manual generated during the construction phase. The systems manual should include commissioning test procedures, results of commissioning tests, issue logs and resolution, system schematics, O&M information, record drawings, construction checklists, start-up reports, and trend log analysis, grouped by equipment. The CxA normally reviews and approves systems manual submissions by the contractor and designer, similar to traditional O&M manual reviews. Electronic systems manuals, now developed occasionally, will likely become standard in the future.

2.4 OCCUPANCY- AND OPERATIONS-PHASE COMMISSIONING

Occupancy- and operations-phase commissioning typically begins with resolving the findings from performance monitoring over the first month or two into occupancy, and ends with the completion of the first year of occupancy.

Objectives

Commissioning during this phase should ensure the following:

- Initial maintenance and operator training is complete.
- Systems and assemblies received functional opposite-season verification.
- Outstanding performance issues are identified and resolved before warranty expiration.
- Commissioning process evaluation is conducted and satisfactorily resolved.

Activities

Verifying Initial Training Completion. The CxA ensures that any remaining training is conducted according to the contract documents, either by reviewing documentation of the training or through witnessing portions of the training. This normally applies to control systems and training on major systems for which peak season is not near the end of the construction phase.

Seasonal Testing. Seasonal testing verifies proper operation of those systems for which peak-load conditions are not available before substantial completion. Additionally, intermediate-season testing may be required for part load, and changeover testing may be required. For example, when completion occurs in winter, final full-load cooling system testing must wait until the following summer. Intermediate-season testing verifies system changeover controls and ability to maintain space conditions per OPR. Testing should be performed by the appropriate contractor and witnessed by the CxA and building operators. However, the owner's operations staff and the CxA, if sufficiently proficient with the controls system, can execute the tests and recall contractors only if there are problems.

Near-Warranty-End Review. The CxA may also be asked to return a few months before the contractor's one-year warranty expires, to interview facility staff and review system operation. By acting as the owner's technical representative, the CxA assists facility staff to address any problems or warranty issues.

Documentation Update. Any identified operations-phase concerns are added to the issues log and the final commissioning report is amended to include occupancy/operations-phase commissioning activities. Changes to the BOD, OPR, or record documents are documented by updating the systems manual near the end of the warranty. Changes to sequences of operation require particular care in ensuring that these updates occur.

Commissioning Process Evaluation. The CxA should meet briefly with the owner; general, controls, mechanical, and electrical contractors; and mechanical and electrical designers to discuss the commissioning process for this project. Topics to be addressed include what went well, what could be improved, what would best be done differently next time, etc. This will benefit all parties in commissioning future projects. The CxA will submit a report on this meeting to the owner.

The occupancy/operations phase typically begins with resolving the findings from monitoring a month or two into occupancy, and ends when the one-year equipment warranties expire.

Additional Activities. The CxA may also be given other responsibilities during the warranty period, such as helping develop a maintenance management program, optimizing system performance, and developing electronic facility manuals.

Ongoing or Recommissioning. Ongoing monitoring and periodic retesting and calibration of selected systems and assemblies are recommended to ensure they comply with the OPR, operating and functioning optimally throughout their life. This is sometimes called recommissioning. Some recommissioning methods rely more on semicontinuous monitoring of primary system performance parameters with periodic analysis. Other approaches consist of recalibrating and retesting targeted systems and components on a regular schedule, including both manual testing and monitoring. Calibration and test frequency vary with equipment and its application.

2.5 LIFE AND PROPERTY SAFETY CHECK

Human life and property safety should be considered in all types of new or renovation projects, during all phases. The National Fire Protection Association (NFPA), American Conference of Governmental Industrial Hygienists (ACGIH), and U.S. Occupational Safety and Health Administration (OSHA) have detailed regulations for dealing with hazardous conditions that may be present, especially in industrial settings. The following are some of the essential categories to be checked during the entire project commissioning process.

Hazards Generated on Site

Hazards present on the project property require proper attention to safety issues; otherwise, the consequences could affect not only the occupancy's personnel and the property, but also the surrounding communities. Therefore, the CxA must understand the hazards generated in the property and how to minimize them. Typical sites with hazards include laboratories, manufacturing facilities, chemical plants, or other industrial facilities.

Different project properties include many different areas, each with distinct equipment or operating processes that have unique hazards; examples include fuel handling (gas, fuel oil, or coal), chemical emissions, heated lubrication and seal oil, oil-filled transformers, cable vaults, coal handling, and control rooms in industrial properties; and cross contamination in hospitals.

Implementing comprehensive human health and life protection requirements, as well as fire protection systems that include hazard detection, alarm, and suppression systems, can be a complex challenge that requires the CxA's thorough understanding and experience of the intricacies of different type of individual projects.

Effective Fire and Hazardous Gas Detection and Alarm Systems

The fire and hazardous gas detection system provides early and reliable detection of fire or hazardous gas, where such events are likely to occur, alerts personnel and initiates protective actions automatically or manually upon operator intervention. Call points include but are not limited to the following:

- Gas detectors for oil and gas skids
- Hydrogen (H_2) detectors for battery rooms
- Spark and flame detectors for coal conveyors and fuel oil tanks
- Heat detection for oil-filled transformers
- Lubrication oil and seal oil skids
- Linear heat detectors for cable galleries and fuel oil tanks
- Smoke and heat detection for plant and nonplant buildings
- Carbon dioxide (CO_2) detectors for school classrooms

Active Fire Protection Systems

These are automatic or manually activated systems involved in actual firefighting: for example, pumping systems, network with fire and gas detection and alarm systems, deluge spray systems, foam systems, CO_2 systems, clean agent systems, portable and mobile extinguishers, and fire station and fire tenders.

Careful design, high-quality installation, and continuous maintenance of explosion prevention and fire protection systems ensures proper safety to the industrial plants.

National Security and Emergency Response Plan

National security and emergency response have become increasingly prominent, and protecting first responders during extraordinary events is highly important. Emergency response plans need to include scheduled routines for training, drills, and fire protection system testing for the fire protection crew and others on staff, as well as instructions for cooperation with national security and civil defense programs. Major concerns include firefighter safety, and making sure that first responders have adequate training and clothing and equipment to deal with any emergency (e.g., hazardous materials, radiological attack, ordinary fires or explosions).

NFPA *Standard* 1600, one of NFPA's most widely implemented standards, establishes a common set of criteria for disaster management, emergency management, and business continuity programs. Also, Chapter 59 of this volume discusses security concerns and measures for HVAC systems.

3. COMMISSIONING COSTS

Commissioning costs vary considerably with project size and building type, equipment type, scope, and traveling requirements (Mills et al. 2004; Wilkenson 2000). Historically, commissioning focused on HVAC and controls, and started during construction. However, quality assurance/quality control (QA/QC) for increasing numbers of systems is included in commissioning, and the process now frequently begins in the design phase. Currently, the commissioning industry is not mature; budget estimates, even for relatively detailed scopes of work, vary widely.

Clear definition of tasks, deliverables, systems and components to be commissioned, rigor, and testing methods must be provided for comparative pricing. The costing guidelines that follow must be used with great caution and are provided only for rough planning purposes. Understanding what is and is not included in each cost number is critical. *Owners should consult commissioning providers with their planned projects to obtain budget estimates, and practitioners should use detailed cost breakdowns for their pricing.*

3.1 DESIGN-PHASE COSTS (INCLUDING PREDESIGN AND DESIGN)

Predesign-phase costs include the CxA's efforts in attending predesign meetings and design reviews with the architect's consulting team and owner's representatives. This portion of work may range from 8 to 12% of the CxA's contract. Design-phase costs include the CxA's reviewing design submittals, coordinated with the designer, and developing sections of the systems manual (design intent and basic operations from the control submittal). This portion of the work may range from 15 to 20% of the CxA contract.

For a project that includes the discussed tasks for all HVAC and controls components, a moderate level of electrical systems commissioning, and minor plumbing and envelope commissioning, the total commissioning costs (CxA cost plus the additional work of the designers) may range from 0.2 to 0.6% of the total construction cost for a typical office building. This estimate assumes two moderate design reviews. Different types of buildings or more complex buildings with larger scopes of design review may cost considerably more.

3.2 CONSTRUCTION- AND OCCUPANCY/ OPERATIONS-PHASE COSTS

Table 1 estimates the CxA's costs for the construction and occupancy/operation phases under the CxA-managed approach. It includes construction- and occupancy/operations-phase commissioning for the HVAC system (including fire and life safety controls, changeover season, and opposite season) and electrical system (including lighting controls, emergency power, and limited connection and grounding checks). It does not include specialty testing such as full infrared scanning, power quality, switchgear, transformer, or low-voltage-system testing. Complex systems and critical applications have higher costs. *For a given building type and complexity*, larger buildings tend to come in at the lower end of the range and smaller buildings at the higher.

The listed costs cover only the CxA fees; there are also costs to the contractor, designers, and owner's staff. Costs for the mechanical contractor attending meetings, documenting construction checklists, and assisting with testing approximate 10 to 20% of the CxA's mechanical commissioning costs. The electrical contractor's costs may equal the CxA's electrical commissioning costs for electrical commissioning (because contractors are usually responsible for hiring their own electrical testing company to perform electrical tests). International Electrical Testing Association (NETA) tests are often already part of the normal construction program, and the only

Table 1 Estimated Commissioning Authority Costs to Owner for Construction and Occupancy/Operations Phases

Commissioned System	Total Commissioning Cost
HVAC and controls[a]	2.0 to 3.0% of mechanical
Electrical system[a]	1.0 to 2.0% of electrical
HVAC, controls, and light electrical[b]	0.5 to 1.5% of construction

Sources: [a]Wilkinson (2000).
[b]PECI (2000).

additional commissioning costs are for the CxA to coordinate testing, spot-witness, and review reports.

3.3 EXISTING BUILDINGS

Existing building commissioning (EBCx) is a quality-focused process for attaining the current facility requirements (CFR) of an existing facility and/or its systems and assemblies. The process focuses on planning, investigating, implementing, verifying, and documenting that the facility and/or its systems and assemblies are operated and maintained to meet the CFR, with a program to maintain the enhancements for the remaining life of the facility. System performance normally degrades with use and time, at a rate depending on the quality of maintenance and operations and the number of hours of operation. Quality of maintenance also affects equipment life expectancy. An EBCx effort should include updating or developing an owner's current facility requirements, documenting existing systems, surveying the facility to identify operational inefficiencies, quantifying and prioritizing the inefficiencies found, determining how best to optimize equipment or operation, implementing changes, training operating personnel, documenting operations, and then reverifying with ongoing measurements that the EBCx process activities produced and continue to produce the desired effect.

EBCx is used by owners and facility decision makers to optimize the operations of their existing facilities to meet their current facility requirements. The process has five basic steps, with an additional step for multifacility projects:

- Multifacility planning (if multiple buildings are involved)
- Assessment
- Investigation
- Implementation
- Hand-off
- Ongoing commissioning

After assembling the team for commissioning, the goals and objectives of the process are defined and documented. Existing information on the facilities is gathered and analyzed to determine the order in which the facilities should be commissioned. The order is based on the goals and objectives of the process. Facility ranking can be based on a number of factors, including energy usage, occupant satisfaction, maintenance issues, or other factors determined during development of the goals and objectives. A plan is developed and documents how the EBCx process will proceed among the buildings in the multifacility EBCx program.

The assessment phase includes development of the CFR, an initial assessment of the facility, and development of the EBCx plan. The CFR is developed with the help of users, occupants, and owners to define their specific requirements for the facility based on its current use. The CFR may be different from the original OPR if the facility's use has changed. The initial assessment of the facility is based on existing documentation, benchmarks, interviews with building personnel, and a tour of the facility. From the assessment report, an EBCx plan is developed that defines the project's scope, schedule, team members, and approach of subsequent project phases.

The investigation phase includes more detailed interviews with maintenance personnel, testing and documentation of existing building performance, and identification and analysis of recommended changes. When existing systems may not have the capacity to meet the CFR, system deficiencies need to be documented with a decision on when (or whether) upgrading will be done. For example, indoor air quality objectives may not be met because a system was designed under an older standard or code; temperature objectives may not be met because additional computer equipment loads have been added, and the original system was designed to handle a lower load. In each case, a documented recommendation on the options available should be provided to the owner. After the EBCx team identifies recommended changes, the CxA develops an investigation report that documents the recommended changes and their associated costs and benefits. This report can be used by the owner to select recommendations for implementation.

The implementation phase begins with the owner selecting recommendations for implementation. The selected capital, repair, and upgrade projects are implemented and verified. Informal training on the systems and equipment is provided to the owner's personnel as the projects are implemented.

The hand-off phase transitions the improvements to the owner's O&M personnel. This phase includes developing and reviewing the systems manual, owner training, verification of training, and finalizing the existing building commissioning report.

The ongoing commissioning phase includes EBCx activities that will continue throughout the facility's life. This phase includes verifying achievement of the CFR, reviewing measurement and verification data, investigating unacceptable performance, implementing recommended changes to improve performance, updating facility personnel training, and updating building documentation.

EBCx has been shown to be a very cost-effective way to improve occupant comfort and productivity and optimize operational costs. Energy savings of 13 to 16% with a one- to four-year payback have been reported (Mills 2009).

Buildings with systems ranging from older pneumatic controls to newer **building automation systems (BASs)** have been successfully commissioned. Pneumatic controls limit the number of EBCx options that can be implemented, and may also require separate data logging for monitoring parameters used to calculate energy savings. Modern BASs allow lower-cost EBCx as well as trend logging of various parameters to sustain the savings achieved when the systems are verified to be functioning properly and calibrated.

3.4 CERTIFICATION

Several groups offer certification of commissioning authorities and providers, including the following:

- ASHRAE's Commissioning Process Management Professional (CPMP) program targets individuals who manage and oversee the commissioning process and commissioning team members. Recipients are usually design/consulting professionals and technologists.
- The AABC Commissioning Group (ACG) offers a certification program for TAB engineers.
- The American Society of Healthcare Engineering offers a Health Facility Commissioning® (HFCX) certification.
- The Association of Energy Engineers (AEE) offers a Certified Building Commissioning Professional (CBCP®) certification.
- The Building Commissioning Association (BCA) offers certification for a Certified Commissioning Professional™ (CCP™).
- The National Environmental Balancing Bureau (NEBB) offers certification for commissioning providers by system type (e.g., HVAC, plumbing, fire protection).
- The University of Wisconsin offers three levels of certification: professional, managerial, and technical support.

CHAPTER 45

BUILDING ENVELOPES

Terminology 45.1
Governing Principles 45.2
Design Principles 45.3
Quick Design Guide for High-Performance Building Envelopes 45.8
Roofs 45.8
Walls 45.8
Fenestration 45.10
Foundations 45.11
Existing and Historic Buildings 45.11

PROPER building envelope design requires knowledge of the physics governing building performance as well as of building materials and how they are assembled. This chapter provides practical information for designing new building envelopes and retrofits to existing envelopes, always with the notion that the envelope must work well in concert with the building's surroundings and the HVAC system. The information can also be useful for those involved with building envelope investigation and analysis.

This chapter was developed with the integrated design approach in mind and assumes that the architect, HVAC designer, building envelope designer, and others involved in envelope design and construction communicate and understand the interrelationships between the building enclosure and mechanical systems. Integrated design requires a clear statement of the owner's project requirements (OPR) and design intent, and is described in greater detail in Chapter 60. That chapter may be used as a basis for finding common agreement among designers and engineers using the integrated design approach. The growing use of integrated design in project delivery highlights the building envelope as the principal site where architectural design and mechanical engineering meet.

A successful building envelope design requires that the team be knowledgeable about and responsible for the performance requirements described in this chapter. This chapter does not distinguish the individual responsibilities of each team member, but rather is intended to serve the team as a whole.

Buildings are designed and constructed to provide shelter from the weather and house conditioned, habitable spaces for occupants. The **building envelope** is an assembly of components and materials that separate the conditioned indoor environment from the outdoor environment. The envelope typically includes the **foundation**, **walls**, **windows**, **doors**, and **roof**. Partitions between interior building zones that have substantially different environmental conditions (such as a swimming pool compared to an office area) are often required to function similarly to building envelopes.

Performance requirements for the building envelope include the following (Handegord and Hutcheon 1989; Hendriks and Hens 2000; Hutcheon 1963):

- Control heat flow
- Control airflow, including airborne contaminants
- Control liquid water penetration (with rain as the most important source)
- Control water vapor flow
- Control light, solar, and other radiation
- Control noise
- Control fire
- Provide strength and rigidity against outside influences (sometimes structural)
- Be durable
- Be constructable, maintainable, and repairable
- Be aesthetically pleasing
- Be economical
- Be sustainable

These performance requirements and their effects on one another must be understood by the project team. Building envelopes should be designed for good overall performance. The first eight listed items arise from the envelope's function of separating the conditioned and unconditioned environments. Parties responsible for HVAC and building envelope design must be knowledgeable about how each system affects the performance of the other. Review of the heat, air, and moisture characteristics of the proposed envelope is needed for appropriate design of HVAC systems. The building envelope must also be designed with an understanding of the interior and exterior environmental design conditions; consequently, the architect or principal designer needs to provide the specific performance requirements to the HVAC designer, including provisions to achieve minimum airtightness, interior occupancy criteria, and special-use considerations. With a building envelope design suited to the operating requirements, the space-conditioning (HVAC) system generally is smaller in capacity and may have simpler control and distribution systems, normally resulting in a system with greater efficiency.

This chapter applies information in Chapters 25 to 27 of the 2017 *ASHRAE Handbook—Fundamentals* to building envelope design. It also incorporates much of the material from previous versions (until 2005) of that volume's Chapter 24.

1. TERMINOLOGY

For definitions related to the physics of heat air and moisture transport, see the Terminology section in Chapter 25 of the 2017 *ASHRAE Handbook—Fundamentals*.

An **air barrier component** is a premanufactured element with air leakage characteristics that are determined during manufacturing.

An **air barrier material** is a material with a low air leakage.

An **air barrier accessory** is an element used to connect air barrier materials and components to form an air barrier assembly or an air barrier system, or used to fasten the air barrier material to a substrate or to framing members.

An **air barrier assembly** is a combination of air barrier materials and air barrier accessories that forms a continuous barrier that controls airflow in its immediate area.

An **air barrier system** is a combination of air barrier assemblies, components, and accessories in a building envelope, forming a continuous barrier that controls airflow across the envelope.

A **building assembly** is any part of the building envelope (e.g., wall, window, roof) that has boundary conditions at the conditioned space and the exterior.

A **building envelope** or **building enclosure** is the overall physical structure that provides separation between conditioned spaces and the outdoor environment or any indoor environment that is substantially different from the conditioned one.

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

A **(building) component** is any physical element or material within a building assembly.

Moisture **condensation** is the change in phase from vapor to liquid water. Condensation occurs typically on materials such as glass or metal that are not porous or hygroscopic and on capillary porous materials that are capillary saturated. Condensation should be distinguished from phase change between vapor and bound water in capillary or open porous materials (see **moisture content**).

Durability is the ability of a building or any of its components to perform its required functions in its service environment over a period of time without unforeseen cost for maintenance or repair (CSA 2007).

Fenestration includes all areas (including the frames) in the building envelope that let in light. Fenestration includes windows, curtain walls (vision areas), clerestories, skylights, and glazed doors. Fenestration excludes insulated spandrels and solid doors. **Fenestration area** is the total area of fenestration measured using the rough opening, including the rough opening for doors.

Hygrothermal design analysis is a set of calculation procedures that uses building design and component physical properties to predict heat, air, and moisture performance of envelopes and assemblies under design conditions. See Chapters 25 to 27 in the 2017 *ASHRAE Handbook—Fundamentals*.

Infiltration is uncontrolled inward air leakage through open, porous materials, cracks, and crevices in any building component and around windows and doors caused by pressure differences.

Exfiltration is uncontrolled outward air leakage through open, porous materials, cracks, and crevices in any building component and around windows and doors caused by pressure differences.

Wind washing is uncontrolled wind-induced flow of outdoor air in and behind insulation layers

Air intrusion is uncontrolled pressure-induced flow of indoor air in, through, and in front of air-permeable insulation layers, caused by wind pressures, stack effect, or HVAC systems.

Convective loop is uncontrolled stack-induced convective flow of cavity air in and around insulation layers

Thermal insulation is any material specifically designed to decrease heat flow by equivalent conduction through a building envelope or envelope assembly.

Moisture content is the ratio of mass of water to volume of dry material in porous and hygroscopic materials, in kg/m^3. **Bound water** describes the phase of water bound in hygroscopic materials. **Sorption** (and **desorption**) describes the change in phase between vapor and bound water.

A **plenum** is a compartment or chamber to which one or more ducts are connected, that forms part of an air distribution system, and is not used for occupancy or storage. A plenum is often under positive or negative air pressure relative to adjacent spaces.

The **R-value** of a material is the thermal resistance for a given thickness of that material, as provided by the manufacturer or listed in Table 4 of Chapter 26 in the 2017 *ASHRAE Handbook—Fundamentals*. The **system R-value** (R_S) is the sum of the individual R-values for each material, excluding air films. The **total R-value** (R_T) is the sum of the system R-value and the interior and exterior air-film resistances (see Chapter 25 in the 2017 *ASHRAE Handbook—Fundamentals*).

A **thermal break** is a thermally resistive element that decreases heat conduction through an assembly.

A **thermal bridge** is a thermally conductive element through an otherwise thermally resistive assembly.

U-factor or **thermal transmittance** is the rate of heat transfer per unit surface of an assembly per unit temperature difference between the environments at both sides of the assembly. The clear value only considers the surface film resistances and R-values of the material layers comprising the assembly. The U-factor is $1/R_T$. A **whole-wall** or **effective U-factor** also takes into account thermal bridging, convective loops, wind washing, and indoor air washing effects (see Chapter 25 in the 2017 *ASHRAE Handbook—Fundamentals*).

A **vapor retarder** or **vapor barrier** is any component in a building envelope with a low permeance to moisture flow by diffusion.

A **water-resistive barrier (WRB)** is a building envelope component designed to prevent inward movement of liquid water.

2. GOVERNING PRINCIPLES

The building envelope is the key element in managing the environmental loads on the building. These loads are a function of the climate and the indoor conditions, such as air temperature, relative humidity, and air pressure differential. There is a strong interdependence between a building HVAC system and the envelope that must be considered when designing or modifying a building. This interdependence centers on controlling heat flow, airflow (including control of airborne contaminants), and water and water vapor flow. Design parameters involved are as follows.

Design Parameters

Heat. The type and amount of insulation to be provided depends on the climate, governing codes, and building use. The insulation should be continuous, while considering the limitations of the materials and systems. Discontinuities (or thermal bridges) are the sites of unwanted heat transfer and reduce energy efficiency, which may result in premature soiling (e.g., ghosting), surface condensation, and/or mold growth. In heating- and cooling-dominated climates, reduced thermal performance can affect indoor conditions and increase HVAC loads. The thermal conductivities and R-values of insulating materials allow them to be compared for their effect on heat transfer, though their properties related to air and moisture transfer vary widely.

Air. Some buildings are designed for natural ventilation when building use and climate allow, and for mechanical space conditioning (with ventilation) at other times. During periods of space conditioning, the building envelope should show minimal air leakage. This allows better control of (1) HVAC, (2) inflow of airborne contaminants, and (3) noise transmission. The HVAC system can generate pressure differentials across the envelope that increase air leakage and may create moisture and thermal problems. It is important to review the interaction of the HVAC system and envelope at the design stage.

Moisture. Building envelopes should be designed to shed rainwater, prevent accumulation of moisture in moisture-sensitive materials, and allow draining and drying of water that accumulates. Airflow through openings in the envelopes a secondary means of moisture transport through building envelopes. Liquid water and frost can accumulate on cold materials in a wall assembly along air movement paths. Vapor diffusion can play a role in wetting and especially in drying of building materials.

Although vapor diffusion control in an envelope assembly is important, field experience shows that most moisture problems are associated with bulk water penetration and moisture accumulation caused by air leakage. Despite the historic and code emphasis on vapor barriers, their effect is often secondary.

A beneficial exercise during building envelope design is to trace the continuity of the elements providing thermal, air, and water protection to the envelope as assembly details are refined. Continuity of the WRB and the air barrier is essential to their performance. Absolute continuity of a vapor barrier is not essential to its performance.

Hygrothermal analysis can be used to predict envelope performance and compare these results with the requirements. ASHRAE *Standard* 160 provides guidance for performing a hygrothermal design analysis. Inputs for hygrothermal modeling include assembly configuration, material properties, initial conditions, and indoor and outdoor climate conditions. Analysis tools generate outputs that may include heat and moisture flux and material moisture content. Because of the number of assumptions and the limitations of calculations required to complete an analysis, results should be considered guidance to supplement the designer's understanding of envelope performance. They should not be considered an absolute prediction of actual hygrothermal performance.

Other Important Performance Criteria

Strength and Rigidity. The air barrier system must be able to withstand air pressures to which the building will be subjected. These pressures can often be large, and strength is critical in severe-weather areas such as hurricane zones.

Noise. For most occupancies, building envelopes should be designed and constructed to reduce noise transfer between conditioned and unconditioned spaces. Sound insulation can be particularly important near noisy areas such as airports, railways, and highways, especially for occupancies that require indoor quiet (e.g., hospitals, hotels, residences, theaters).

Constructability. During design, how a building envelope will be built must be considered. If there are practical limitations to how the envelope elements are physically put together, the design intent will be lost and problems are likely to develop during construction. Simplicity in design is an effective way to improve the chances of construction in accordance with the design intent. Construction of the various components must be sequenced so that all components can be correctly assembled, particularly when coordination between multiple trades is required. Investigation of many building failures demonstrates that poor sequencing between trades is a common contributing factor. Integrating constructability early in project design minimizes the number of failures and helps maximize the potential to achieve the results described in this chapter. During construction review, specific attention should be given to areas of the building where multiple systems are connected and multiple trades are involved. Use of mockups, design reviews, modeling, and other methods can enhance constructability.

Maintainability and Repairability. Building envelopes comprise many parts and components, with different anticipated service lives. Exterior cladding materials and fenestration may need replacement during the expected life of a building. Foundations and framing are the core elements of a building and should last for the entire building service life. Care should be taken not to cover shorter-lived building components with components having a longer anticipated lifespan.

Maintenance of the envelope and HVAC system is important to ensure a functional building. A poorly maintained HVAC system can result in substantial energy loss and have a detrimental effect on the building envelope by subjecting it to unexpected pressures and/or moisture loads. Verification of airflows and pressure differentials has been incorporated into many sustainable design tools as a check to ensure the building mechanical system is functioning as intended long after commissioning.

Sustainability. ASHRAE (2006) defines sustainability as "providing for the needs of the present without detracting from the ability to fulfill the needs of the future." In this chapter, *sustainability* refers primarily to durability and energy performance. Durability is essential for sustainable buildings, and moisture control is essential to durability. Additional information on sustainability can be found in Chapter 35 of the 2017 *ASHRAE Handbook—Fundamentals*.

With regard to durability, thermal insulation keeps interior and exterior materials near their respective ambient temperatures. In a well-insulated building in a cold climate, the exterior materials are subjected to harsher conditions (lower temperatures, wetter conditions, slower drying, and longer periods at subfreezing temperatures) than in one poorly insulated. Exterior materials for well-insulated buildings should therefore be sufficiently robust to withstand the conditions to which they will be exposed.

From an energy perspective, completeness of the air and thermal barrier is critical to achieve good performance. For details on sustainable energy use in buildings, see ASHRAE *Standard* 90.1.

Quality Control. Ensuring good envelope performance demands a well-established quality control program: the design must minimize damage risk while maximizing thermal efficiency (quality assurance). For that purpose, redundancies should be incorporated to allow for imperfections in construction (e.g., providing for drainage or drying to remove moisture from wall cavities). The building should be designed to enable effective maintenance and repair over its anticipated service life. Quality control methods such as construction review and the use of site mock-ups can be invaluable tools to increase the likelihood of good construction.

The building envelope differs greatly from mechanical and lighting systems in terms of inspections and commissioning. The building envelope is normally inspected during key phases of construction to check compliance with the construction documents and design intent, before many of the elements are enclosed within a wall system. Once enclosed, it is often very difficult to return to these areas to make repairs. At these key phases of completion, inspection measures are critical to ensure that any changes in design maintain the intent. Mechanical and lighting systems, on the other hand, are normally commissioned at the end of a project, meaning that their full-service testing for compliance does not occur until the building is operational and occupied.

3. DESIGN PRINCIPLES

Air conditioning and humidification can substantially change the moisture loads on the building envelope. New building materials may have significantly different thermal and moisture characteristics than traditional materials. The interdependency between the building envelope and the HVAC system has greater consequences to building durability and performance under problematic heat, air, and moisture conditions.

Heat Flow Control

A building envelope must adequately reduce heat flow to maintain energy efficiency and ensure indoor thermal comfort. Generally, heat flow control is achieved by installing thermal insulation as part of a wall, floor, or roof assembly.

The most common insulation materials used in building envelopes are glass fiber, mineral wool, cellulose, foam boards, and spray-applied foams. All these materials have exposure and performance limitations (e.g., fire, noise, moisture, ultraviolet) and should be selected carefully to promote long-term performance (see Table 1 in Chapter 26 of the 2017 *ASHRAE Handbook—Fundamentals* for common insulation materials and their properties).

Depending on the type of envelope assembly, the location of insulation in the wall can have a direct effect on thermal performance. For example, placing continuous insulation, such as rigid foam or mineral fiber board, outboard of the exterior sheathing on stud walls reduces conductive heat transfer through the studs and improves overall thermal performance.

As with all building envelope assemblies, correct installation of insulation is important in maintaining good thermal performance. For example, small voids left in insulation can result in an appreciable increase in heat flow, with the voids having a greater significance in more highly insulated assemblies. Verschoor (1977) found that convective air currents around thin wall insulation installed vertically with air spaces on both sides increased heat loss by 60%. Lecompte (1990) found losses up to 300% depending on the size and distribution of openings around insulation materials. Other factors, including vibration, temperature cycling, and other mechanical forces, can affect thermal performance by causing settling or other dimensional changes.

The thermal barrier should be continuous around the building envelope. This means aligning insulation planes in walls with thermal breaks in windows or providing continuity of the thermal plane around corners or at wall/roof connections.

Thermal Performance

Table 1 in Chapter 26 of the 2017 *ASHRAE Handbook—Fundamentals* gives thermal resistances of building materials. The thermal resistance of building assemblies is usually less than the sum of the material resistances (and may be significantly so). Data for clear-wall areas (summarized by James and Goss [1993]) do not include the effects of intersections with floors, roofs, and partitions, and do not account for thermal bridges at framing and partitions, air leakage, or convective air loops.

To test the validity of applying clear-wall data to the wall system, a series of three-dimensional heat conduction simulations was performed on a single-family, detached, one-story house, assuming no air leakage (Kosny and Desjarlais 1994). These simulations showed that, for a conventional wood-frame stud wall system with studs installed on 400 mm centers and no continuous outboard insulation, the average area-weighted whole-wall R-value was 91% of the clear-wall R-value. For a similar wall using 90 mm steel studs, the whole-wall R-value was only 83% of the clear-wall R-value. A similar two-dimensional analysis of an attached, two-story, steel-stud house by Tuluca et al. (1997) showed the R-value for the wall system to be 40 to 50% of the clear-wall R-value. Thermal bridging occurred through framing, metal ties, and exposed slab edges. Simply using the published insulation R-values alone as the R-value for the whole wall overestimates the real thermal performance. For constructions containing steel studs, for example, use either the R-value zone method or the modified zone method to determine real thermal performance that considers framing effects (see Chapter 27 of the 2017 *ASHRAE Handbook—Fundamentals*).

Thermal Mass

Thermal mass describes the ability of a material layer to store thermal energy and the ability of an opaque envelope component to dampen and delay transfer of heat. That damping, if combined with moderate glazing, effective solar shading, a correct ventilation strategy, and indoor partitioning with high thermal storage, can help moderate indoor temperature fluctuation under outdoor temperature swings (Brandemuehl et al. 1990). Increased thermal mass may also positively affect energy efficiency (Kosny et al. 1998; Newell and Snyder 1990; Wilcox et al. 1985). Finally, increased thermal mass can help to shift demand for heating and cooling to off-peak periods. Thermal mass is effective as a design tool where the outdoor diurnal temperature fluctuates around the indoor comfort range. In areas where this does not occur, thermal mass has little effect.

Damping and time delay are defined by the order in which opaque envelope components are arranged. Best results are achieved when the thermal insulation faces outside and layers with large heat capacity face the interior, as confirmed by an in-depth study of six wall configurations by Kosny et al. (1998). Damping capability of such walls also increases with thermal resistance (Van Geem 1986).

Hourly-based computer simulations using transient energy simulation tools may provide a good estimate of thermal mass effects.

Thermal Bridges

A thermal bridge is an envelope area with significantly higher rate of heat transfer than the contiguous enclosure. Primary causes for thermal bridging are (1) parts with low thermal resistance perforating layers with high thermal resistance, (2) geometries that create zones where large exterior surfaces connect to much smaller interior surfaces, and (3) chilled or warmed edges at the edge of insulation as a result of discontinuities.

Thermal bridges increase energy use. They may lead to moisture condensation in and on the envelope, result in possible mold growth, accelerate surface fouling (ghosting), increase crack risk, and create surfaces with non-uniform temperatures that can result in indoor comfort problems.

Slab edges, perimeter beams, balconies, and decks protruding from the building envelope are common areas for thermal bridging.

The effect of thermal bridges in envelopes can be assessed using the zone method, modified zone method, acceptable sources of test data, or computer simulation tools. Refer to Chapter 27 of the 2017 *ASHRAE Handbook—Fundamentals* for details.

Thermal bridges created by webs of concrete masonry units (CMUs) dictate the maximum thermal efficiency a CMU can attain. To reduce this effect, blocks containing two webs, instead of the usual three, have been used, and web cross section has been reduced by up to 40%. However, even such changes in block design have not significantly improved wall R-value. Instead, applying low-density concrete with significantly lower thermal conductivity effectively improved thermal performance of these masonry units (Kosny and Christian 1995a, 1995b). The same strategy can be used for CMUs containing core-insulating inserts or insulation fill.

A comparison between the uninsulated slab edge detail of Figure 1A and the insulated version in Figure 1B illustrates the importance of designing to reduce thermal bridging. (See Steven Winter Associates [1988] for numerical examples summarized in this section.)]

Air inside a masonry cavity often is at or near the outdoor air temperature. Figure 1A shows that, without cavity insulation, the concrete slab edge and steel beam are exposed to that outdoor air temperature. Both of these elements are made of relatively thermally conductive materials, steel being considerably more conductive than concrete. The result is significant heat loss and a low floor surface temperature near the slab edge, which can be a source of occupant discomfort and possible condensation if indoor humidity is sufficiently high. Adding insulation on the outside of these elements (Figure 1B) keeps them inside the thermal envelope. It keeps the structural steel warm, and prevents cold-weather condensation that could lead to corrosion, damage to the masonry below, and moisture damage to the surrounding finishes that could lead to interior mold growth.

Insulation is sometimes specified for the interior surface of the perimeter beam to increase the thermal resistance of this wall segment. Site conditions rarely allow thorough installation, so the top and bottom flange edges remain exposed, creating a strong thermal bypass and marginalizing the insulation's effectiveness. Moreover, use of a vapor-permeable insulation makes vapor condensation more likely because it decreases the temperature of the beam chord but does not stop water vapor migration.

Concrete balcony decks are often formed by slab extensions that pass through the building envelope. As the exposed exterior surface exchanges heat with the outdoors, the result is extra heat loss at the interior floor and low floor temperatures during cold weather. These low temperatures may extend to the top and bottom of close-by interior walls, with condensation each time their surface temperature drops below the dew point of the interior air. The same mechanism can increase energy use during hot weather because building mechanical systems compensate for additional heat gain. Thermal break elements between slab and balcony or a careful addition of insulation panels can moderate the thermal bridge effect. One- or two-dimensional heat transfer models can be used to analyze more complicated assemblies.

Air Leakage Control

Uncontrolled air leakage in the form of infiltration, exfiltration, intrusion, and wind washing increases space conditioning costs and

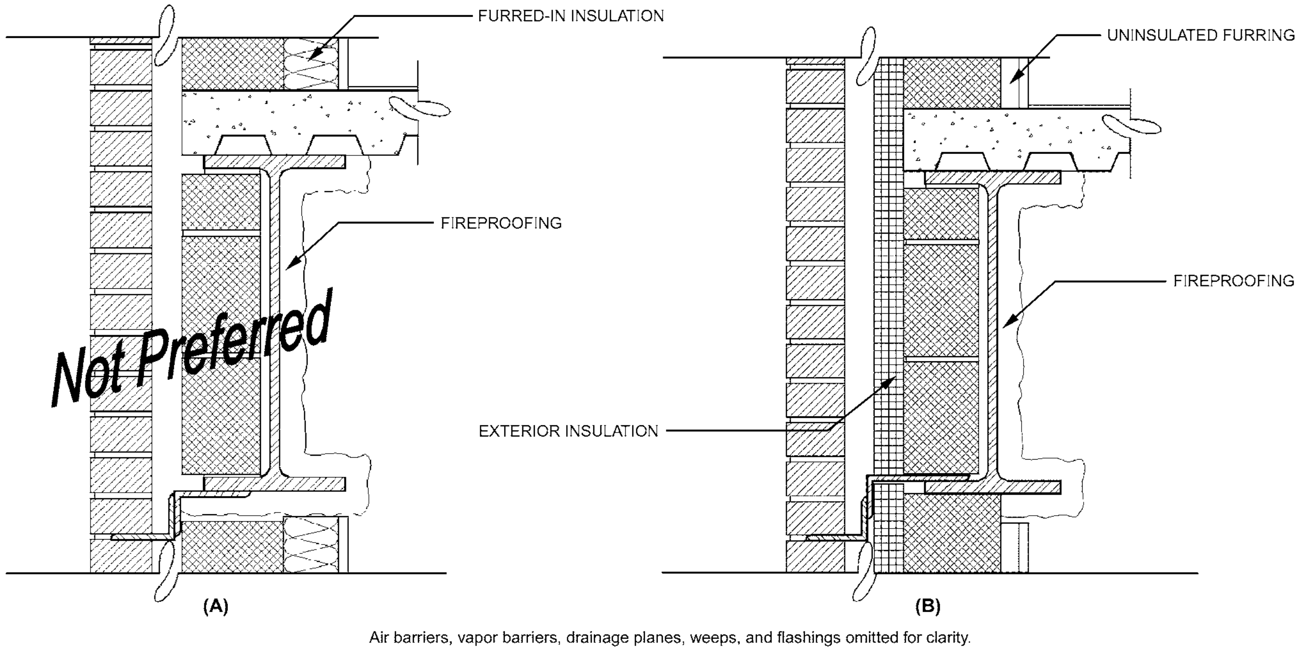

Fig. 1 Schematic Detail of (A) Uninsulated and (B) Insulated Slab Edge and Metal Shelf Angle.

may cause moisture problems (see Chapter 25 of the 2017 *ASHRAE Handbook—Fundamentals*). Air leakage is much more effective than diffusion for transporting water vapor in the building envelope and causing interstitial condensation. Forensic field observations support these research results. Uncontrolled air leakage also short-circuits the transient response of envelope assemblies. It degrades sound insulation of the envelope and may cause draft and related thermal discomfort. These drawbacks underline the need to plan for airflow control in building envelope design by installing an air barrier.

Most published literature on air barrier requirements stipulates that an air barrier's air leakage permeance should not exceed 0.02 L/(s·m^2) at 75 Pa when tested in accordance with ASTM *Standard* E2178 (NRCC 2005; U.S. ACE 2009).

The air barrier must be sufficiently supported on both sides and be strong enough to resist expected loads from stack effect, mechanical-system-induced pressures, and wind. For example, a sheet-membrane air barrier material installed using staples against a sheathing in a cavity wall is well supported by the sheathing in a positive-pressure direction, but may be subject to tearing at the fastener points under negative pressures, which tend to pull the membrane away from the wall.

The air barrier must be continuous across the entire building envelope. To ensure continuity at windows and other penetrations, components creating the barrier must be connected with an airtight, durable joint. It is particularly important to ensure continuity of air barrier systems at junctions that create complicated geometries where two or more elements in different planes intersect (e.g., roof/wall intersections, wall/floor intersections, corners). Maintaining continuity at these assemblies can be further complicated because they often involve different construction trades, requiring coordination between workers.

Penetrations (e.g., electrical outlets, light fixtures, plumbing stacks) should be minimized and, if unavoidable, sealed carefully. Airtight electrical boxes are available. Maintaining air barrier system integrity throughout the building's life should also be considered. Cutting holes in gypsum board assemblies during renovations, for example, can result in widespread air barrier failure if the board is intended to be the primary air barrier in the assembly.

The best location for the air barrier is generally where it is easiest to assemble into a continuous and durable system. The location of the air barrier in a wall assembly may affect overall hygrothermal performance. Permeance properties of the barrier material may be important; see the section on Water Vapor Control.

Although the intent should be to construct an airtight building envelope, not all cracks and openings can be sealed in existing buildings, nor can an absolutely tight construction be achieved in new buildings. The objective is to provide an enclosure that is as tight as possible. Calling out a vapor barrier (see the section on Water Vapor Control) as "continuous" is not a sufficient specification for an air barrier.

Moisture Control

Building envelopes are subject to several moisture loads (moisture entry mechanisms), including liquid water and water vapor from air leakage and/or diffusion. Historically, the primary moisture control strategy for walls was to restrict water entry by collecting and redistributing moisture that enters with air, before evaporation. Today, good envelope design still requires minimizing accumulation and maximizing removal of moisture. Although weather-resistive components may be designed with the goal of eliminating water infiltration, some redundancy is obtained when assemblies are also designed to accommodate drainage and drying of incidental moisture intrusion. Hygrothermal modeling tools, as described in Chapters 25 and 27 of the 2017 *ASHRAE Handbook—Fundamentals*, can assist designers in understanding the drying potential of assemblies based on the assumed loads; however, current models cannot effectively predict drainage.

Liquid Water Control

Field observations indicate that moisture problems in buildings are most frequently caused by exterior liquid water penetrating or passing through the building envelope.

Rain is the most significant moisture source for buildings. Strategies to reduce the rain load on exterior walls include using building overhangs to prevent wetting, flashings, drip edges, and other water-shedding elements. During rain, poor flashing details at the interface of dissimilar materials, incomplete terminations of cladding systems, and other discontinuities in the moisture barrier may result in water entry, which can cause severe damage and loss of durability. For roofs and walls, cladding and building envelope components must be integrated to prevent water infiltration. At grade, rainwater should be carried away from the foundation through gutters, downspouts, and positive grading (i.e., sloping the surrounding grade to direct water away from the building).

An important consideration when designing an envelope for liquid water control is sequencing during construction and coordination between trades. Proper sequencing is essential to ensure that systems are correctly connected. Building envelope failure investigations often reveal that water penetration problems result from poorly constructed connections between various elements, often caused by inadequate site coordination. Important connection details should be included in the construction documents with enough clarity to allow suitable construction. Lack of detail on drawings and in specifications can result in too many construction decisions being made on site.

One method of minimizing moisture entry through the building envelope is to use face sealing (i.e., sealing the outer face of the wall/window junction, interfaces with dissimilar materials, and at building expansion joints). The sealed exterior surface protects against rain and air infiltration and must remain continuous over time to maintain functionality. One example of this type of system is the use of water-resistive coatings over masonry and concrete walls. Great care must be taken when using these coatings to ensure that, when moisture gets into these materials through cracks in the coatings or by other pathways, there is opportunity for it to dry. By nature, face-sealed systems have little or no redundancy to prevent water ingress and accumulation, and they require rigorous maintenance schedules for long-term performance.

Rain screen design has greater redundancy than face-sealed systems. Rain screen design minimizes penetration by raindrop momentum, capillarity, gravity, and air pressure differences. A rain screen wall contains several components from inside to outside: an air barrier, a WRB (which may perform as air, moisture, and vapor barrier), the air space, and a rain screen. The air space may be an empty air cavity or a cavity filled with a material that drains freely. The air space must be vented to the outdoors through the rain screen and flashed to drain water that penetrates the rain screen. The rain screen's airflow resistance must be much lower than that of the air barrier, so that it acts as a deterrent for water penetration but is not a watertight seal. It is prudent to protect the WRB and air barrier from temperature extremes and direct exposure to ultraviolet light. With little pressure difference across the rain screen and with good cavity drainage detailing of the cavity, the potential for rain entry into the wall is significantly reduced. Interfaces of the exterior wall air barrier with fenestration air barriers, floors, and interior partition walls must be carefully considered, and may require site mock-ups to adequately determine the best solution.

For greater liquid water control, the air cavity may be designed as a pressure-moderation chamber, which involves making the WRB airtight. The cavity should also be compartmented to avoid lateral airflow, especially around corners of the building.

Water Vapor Control

Water vapor entry into the building envelope can be limited by airflow control and water vapor barriers. As described previously, air barriers are intended to restrict air leakage and control convective water vapor ingress, whereas vapor barriers are designed to restrict vapor flow caused by diffusion. It is important for building designers to understand the difference between the two mechanisms and how they are controlled.

Moisture deposition caused by air leakage is a point-load problem: a large volume of water can be deposited in a discrete location, often near the air leakage point, and can result in substantial damage. For that reason, an air barrier has to be continuous and sealed. This differs from moisture deposition cause by vapor diffusion, which is an area function that is directly related to the vapor drive and the vapor permeability of the materials that separate the two zones. A vapor barrier should therefore be continuous, but does not necessarily have to be sealed. The only time a vapor barrier is required to be sealed is when it also functions as the air barrier.

Water Vapor Transport Through Air Movement. Air leakage is more effective than diffusion for transporting water vapor in the building envelope, and therefore it is more important to control. To minimize water vapor ingress, the building envelope should be as airtight as possible using the principles described here. Moisture accumulation in the building envelope can also be minimized by controlling the dominant direction of airflow by operating the building at a small negative or positive pressure, depending on climate. In cooling climates, the pressure should be positive to keep out humid outdoor air. In heating climates, the building pressure should remain neutral, or slightly negative or positive relative to the outdoors. Strong negative pressure could risk drawing soil gas or combustion products indoors. Strong positive pressure could risk driving moisture into the envelope.

In wall systems where the air barrier system also functions as the vapor barrier, it is important to consider its location relative to the expected vapor drive and temperature gradient across the wall. To avoid condensation on the air and vapor barrier, either its surface temperature must be kept above the dew point of the surrounding air by locating it on the warm side of the insulation, or the permeance of the assembly must allow vapor transmission if located at the cold side of the insulation. In the latter case, the air barrier no longer functions as a vapor barrier.

Water Vapor Transport Through Diffusion. Moisture migration by diffusion through materials is a slow process and, as discussed previously, is less likely to contribute to moisture problems in buildings compared to liquid water intrusion or air leakage. However, diffusion can cause moisture problems in special occupancy types or in buildings that experience high moisture loads.

The overall diffusion performance of a building is a product of the diffusion characteristics of the envelope materials. A vapor barrier is not necessarily a sheet of plastic; many different materials or combination of materials can be used to control vapor diffusion, depending on design conditions. Many building envelope components, such as some peel-and-stick membranes, metal panels, and glass, have very low vapor permeance. Design and selection of building materials should be based on analysis to verify the desired performance of the assembly under the applicable loads.

Many common building and finish materials with low vapor permeance can have undesirable effects when placed in high-moisture-risk environments. One example is vinyl wallpaper placed at the interior wall surfaces. Under large inward vapor drives or excessive water penetration, this vapor-impermeable layer can lead to moisture accumulation through condensation, or can prevent drying by limiting vapor flows, both of which can lead to significant moisture damage. Careful attention must be paid to the type of materials selected for a wall construction, and where they are located in the wall assembly.

Use of vapor-impermeable layers at both the interior and exterior should generally be avoided so that the assembly can dry. Heat, air, and moisture calculations and modeling can be used to analyze an assembly, its climatic exposure, and desired indoor operating conditions to determine what methods of vapor control are appropriate. For details, see Chapters 25 to 27 of the 2017 *ASHRAE Handbook—Fundamentals*.

Common Envelope Problems

Wall/Window Interface. Air infiltration at the wall/window interface can reduce window performance and damage surrounding building materials and even remote materials, depending on the leakage path. In cold climates, warm, humid indoor air can increase moisture content in the wall cavity around the window. Excess moisture may damage the interior finish, seals of glazing units, insulation, exterior cladding, and possibly structural elements. Uncontrolled cold-air infiltration through the interface in turn can affect occupants' health and comfort by creating a dry indoor environment, cold drafts, and surface condensation on the window frame and glass edges. In warm, humid climates, leakage at the wall/window interface can result in interior fungal growth, distortion of interior window trim, and deterioration of the interior gypsum wallboard, particularly in air-conditioned buildings (because their interior surfaces are colder).

Control of air and water leakage at the wall/window interface is often difficult because that is where multiple systems intersect. Each system may incorporate a different approach for air and water control and must be integrated to provide continuity. Additionally, the different systems are commonly installed by different trades, which require deliberate sequencing to achieve the intended result. These intersections are often complex, making it difficult to inspect and test for performance compliance. Water penetration can result in moisture damage in any climate, although it is generally most severe in climates that impose a low drying potential on a building.

Control of Surface Condensation

To reduce the potential for condensation on the interior surface of glazing and the window frame, as well as on the surrounding interior wall finishes, the indoor surface temperature can be controlled in the following ways:

- Select windows with appropriate condensation resistance for new construction or retrofit.
- Seal the wall/window interface and between the sash and frame of operable windows to minimize air leakage.
- Make the area of window frame exposed to the interior larger than the area exposed to the outdoors. Window and curtain wall systems with metal frame extensions on the inside have a higher resistance to condensation but contribute to heat loss.
- Reduce excessive interior humidity levels.
- Keep thermal breaks in the window system in the same plane as the wall insulation.

Continuity of the plane of thermal insulation between wall and window maximizes a window's thermal potential and reduces the potential for condensation on interior surfaces of the window frame, glass, and surrounding finish. Insulation in the joint between wall and window frame also compensates for the expected differential movement between the frame and the wall rough opening.

Interzonal Environmental Loads

Indoor partition walls separating zones such as indoor swimming pools, ice rinks, and freezers from zones conditioned as normal environments should be treated as envelope assemblies. Apart from weather-related loads, these partition walls must perform as building envelopes and need to control airflow, heat flow, liquid water (e.g., swimming pools, industrial settings), and water vapor flow.

Interstitial Spaces

Building envelope design must consider that modern buildings comprise a collection of interconnected internal chambers and cavities that provide potential pathways for unplanned airflows throughout the building. Concrete masonry cavity walls, wood- and steel-stud gypsum board partitions, chases, soffits, shafts, utility service penetrations, and many other details contain cavities that connect adjacent elements to varying degrees wherever holes and openings have not been closed and sealed. The amount of air leakage depends on pressure differences, number and size of openings, and length and tortuosity of paths. Pressure differences generally derive from HVAC operation, differences in air density, and wind. These unplanned airflows often have no obvious adverse effects on occupants or the building, but in many cases they can significantly negatively affect energy demand, moisture deposition, and indoor air quality. Uncontrolled air leakage paths also add to the risk of undesirable sound transmission between rooms. A full discussion of all possible sources of unplanned airflows is beyond the scope of this chapter; see the References and Bibliography for additional information sources.

A common practice in commercial buildings is to use the space above a dropped ceiling as the HVAC system's return air plenum (Figure 2). The complex three-dimensional assemblies where the exterior wall adjoins a roof or floor at the building perimeter can be difficult to seal against air leakage and thermal bridging if the unique conditions of each design situation are not deliberately addressed. The interior gypsum board in the occupied space often terminates above the visual sight line of the suspended ceiling without extending to the roof or floor deck above. Unless carefully detailed and constructed, this can result in a leakage point at the building perimeter where negative pressure in the plenum can draw outdoor air into the return air system. If it is cold outdoors, an accidental sensible load penalty is imposed. For hot and humid climates, accidental latent and sensible loads are added that not only affect the energy required to condition the building, but also may lead to moisture and indoor air quality problems from condensation on interior surfaces that are cooler than the dew-point temperature of the incoming outdoor air. Sustained elevated relative humidity in the ceiling space can perpetuate mold growth. In general, but especially for demanding applications such as health-care and laboratory buildings, ducted returns should be used rather than depressurizing the entire ceiling plenum. Air pressure between the ceiling plenum and the occupied space can

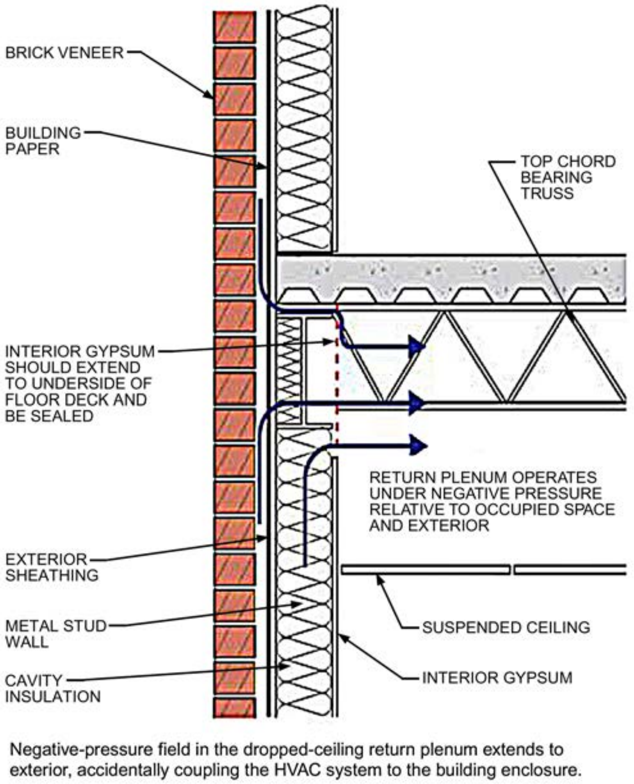

Fig. 2 Dropped-Ceiling Return Plenum
Lstiburek 2007

be equalized by installing ceiling grates in the suspended ceiling. Other configurations that may be more appropriate to the specific building design conditions can also be effective.

Similar considerations regarding energy loss and moisture deposition also apply to underfloor air supply systems that can force conditioned air out through the building envelope.

4. QUICK DESIGN GUIDE FOR HIGH-PERFORMANCE BUILDING ENVELOPES

1. Avoid excessive glazing. Follow energy standard and energy code requirements that set maximum glazed areas. Refer to the current version of ASHRAE *Standard* 90.1 for maximum roof and wall glazing areas.
2. Provide appropriate amounts of thermal insulation in foundation and above-grade walls and roofs. See current versions of ASHRAE *Standards* 90.1 and 90.2.
3. The completed building envelope should be airtight. Determine the level of airtightness to be achieved. Design airtight connections at all junctures in the air barrier system. Construction sequence should allow visual review and ensure performance with the selected criterion.
4. Resolve vapor barrier and vapor control issues using simplified or full hygrothermal analysis (ASHRAE *Standard* 160). The necessity and requirements for vapor control are specific to building usage, materials, and climate, and should be included in the design process.
5. Provide for effective shedding of rainwater away from the exterior wall. Rain screen principles to drain water away from the building should be used where possible.
6. Provide sound insulation appropriate for the building application. Some specialized facilities such as hospitals, libraries, and theaters require additional care to control sound transmission.
7. Refer to the ASHRAE *Advanced Energy Design Guide* series for additional information on building design.

5. ROOFS

Low-Slope Roof Assemblies

Low-slope roofs are typically compact insulated assemblies of a waterproofing membrane together with structural and insulating board material. Insulation is usually rigid board or foam products. The insulation may be below the roofing product(s), or above for an inverted roof membrane assembly (IRMA). If below, it is usually installed in two or more layers with staggered joints to prevent airflow at the panel joint. Tobiasson (2010) showed that venting low-slope roof systems between the insulation and the membrane is not effective for moisture control.

All roofing systems must be designed and constructed to resist wind uplift. Common methods of securing the roofing system to the decking are mechanically fastened, fully adhered, and ballasted. Light-colored roofing products, including ballasted roofs, reduce cooling loads (if kept clean), and help moderate the heat island effects in cities. Proper flashing details are important at drains, scuppers, equipment supports, control joints, and other penetrations. For low-slope roofing design and practice, see the National Roofing Contractors Association's (NRCA) *Roofing Manual* series.

Parapets and overhangs should be detailed for continuity of the thermal insulation and air barrier. Wall insulation should meet the roof insulation, so there is no thermal bridge. Roof and wall air barriers must be continuous. These two continuity requirements may require the parapet or overhang to be specified to be installed after the continuity of the insulation and air barrier is ensured. Some parapet details, such as upper termination of interior drywall, flutes in steel decks, three-dimensional conditions, and fireproofing sequence for steel, are often overlooked. The roof/wall junction requires coordination and proper sequencing between trades to ensure proper continuity of the air and thermal control layers.

Steep-Roof Assemblies

There are two main insulation locations in steep-roof assemblies: at the roof (cathedral) and in the ceiling. For both types, exterior sheathing and roof materials should be able to accommodate wide temperature swings caused by radiant exchange with the sun and sky.

Insulated Sloped-Roof (ISR) Assembly. An insulated sloped roof assembly (e.g., cathedral ceiling) is a compact system with insulation parallel to the roof and no air cavity. Principles used in the design and construction of low-slope roofs may be applied in steep-sloped roof construction. According to Hens and Janssens (1999), moisture control is ensured only if airtightness is effective and can be maintained. Air entry and wind washing in insulated cathedral ceilings lead to degraded thermal and moisture (durability) performance. TenWolde and Carll (1992) showed that ventilation of ISR assemblies may increase air leakage, and that the net moisture effect depends on whether the principal source of makeup air is from indoors or outdoors. Use of vapor-permeable versus low-permeance thermal insulation in ISR assemblies can be an important factor in assembly design and performance. Their selection depends on the expected direction of vapor flow within the roofing system, drying potential, and other design considerations.

Attics. Standard North American attic construction provides for insulation at the ceiling plane level, leaving the attic space as unconditioned. The ceiling should be made airtight (Jordan et al. 1948). Air exchange with the outdoors provided by vents typically reduces attic air temperature on sunny afternoons. Other effects of ventilation, such as wood moisture content and roof surface temperature attenuation, depend more on factors other than the presence or absence of ventilation. TenWolde and Rose (1999) critically review four commonly cited reasons for attic ventilation: (1) preventing moisture damage, (2) enhancing the service life of temperature-sensitive roofing materials, (3) preventing ice dams, and (4) reducing cooling load.

The following additional design and construction elements should be considered for attics and insulated sloped-roof construction:

- Valleys are areas of high water concentration and are common sites of leaks. They should be designed to channel high volumes of water and for ease of repair.
- Mechanical equipment and ductwork should be placed in conditioned spaces. Their placement in unconditioned spaces leads to excess heat loss, energy consumption, and potential condensation on cold ductwork surfaces.
- Ice dams are typically caused by snow melting on the roof. Heat sources in the attic that could cause ice dams (e.g., chimneys, air leakage through the ceiling, attic-mounted equipment) should be identified and addressed.

Vegetated Roofing

There has been significant interest in vegetated roofing in recent years in an attempt to save energy or to control building rainwater outflow. On vegetated roofs, both growth medium and vegetation are installed on top of the roof. These assemblies normally require additional precautions and materials to protect the roof membrane from the plants. Quality control is even more critical during installation of a vegetated roof, because repair and eventual replacement are normally considerably more expensive and resource-intensive because of the presence of growing medium.

Storing rainwater on the roof can reduce the load on a municipality's storm system. There are many methods and products to achieve this. Storage of water and placement of a growing medium can add a considerable amount of mass to a roofing system. Checks to ensure structural capacity are essential for existing buildings, and new buildings must include structural provisions to support the additional weight. Some structural designers include provisions for the weight of a possible future vegetated roofing system because the incremental costs to do so are very small.

Vegetated roofing is often referred to as **green roofing**. Green roofing also refers to roofing systems that have other sustainability attributes such as high albedo.

6. WALLS

Curtain Walls

There has been tremendous growth in the use of curtain-wall systems for new building construction in recent years. A modern curtain-wall system is a highly engineered product based on mass production, standardization, and precise manufacturing (CMHC 2004). The systems generally consist of lightweight metal framing components connected to form a matrix to contain transparent and opaque wall areas. The framing is typically anchored to the building structural columns or floor slabs. Window wall systems are types of curtain walls that are typically installed floor to floor. Many older systems left slab edges exposed. New window wall systems often include drop-down panels that cover and provide thermal protection to the slab edge.

There are two basic kinds of systems: **stick built**, which are assembled on site from horizontal (rails) and vertical members (mullions), and **unitized systems**, which are largely assembled in a shop and delivered in sections that are then connected to form the wall. Both types are generally field glazed. Custom systems are also available for specialized applications. Glazing and opaque elements of the curtain-wall frame are fastened using exterior battens (pressure plates), structural sealant, or both.

Detailed information on the various types of curtain wall systems and glazing methods can be found in Canada Mortgage and Housing Corporation's *Best Practice Guide—Glass and Metal Curtain Walls* (CMHC 2004), or the National Institute of Building Sciences' *Whole Building Design Guide* (NIBS 2010).

Curtain-wall assemblies form the entire exterior wall where installed. They need to perform all the functions of a building envelope, though they have some significant differences from other walls. Curtain-wall assemblies are made of materials that have no moisture storage capabilities, whereas most other wall types (masonry, concrete, etc.) can store and release moisture over time. They nevertheless can retain significant volumes of water that may lead to penetration if watertightness and drainage are not provided.

There are two common methods for a curtain-wall system to manage exterior moisture: face-sealed and rain-screen design. **Face-sealed systems** are more susceptible to water penetration because they have no redundancy. Once water penetrates the exterior moisture barrier, there is no way for it to drain back to the exterior. **Rain screen designs** provide redundancy by draining moisture that bypasses the primary outer seal to the outdoors. This provides more protection from rain penetration than face-sealed systems.

Because curtain-wall systems are highly engineered and assembled out of precisely manufactured components, it is essential that they are assembled in accordance with manufacturers' specifications, with all recommended accessories installed. Omission of any components, such as corner blocks or other drainage elements, can result in reduced drainage capacity, water storage, and eventual penetration to the interior.

Curtain-wall systems can be used to cover floor slab edges to reduce thermal bridging. They bring in lots of natural light and can provide great occupant views. However, heavy use of glass often results in poorer thermal performance than for traditional wall assemblies, or even spandrel sections in a curtain-wall system. The large glazing areas in curtain walls should be considered in terms of solar gain and sizing of mechanical equipment. In cold climates, the large areas of glass and framing can have a radiative cooling effect on a space, and adversely affect thermal comfort. Conversely, in hot climates, large areas of glass can result in heat gains that can overwhelm cooling equipment, or necessitate cooling equipment in areas where mechanical cooling is not typically required. Often, thermal performance of curtain-wall systems is overstated by reporting center-of-glass or center-of-spandrel-panel thermal performance values, rather than the overall thermal performance (U-value) of the assembly.

Whereas traditional wall assemblies are often built by a number of trades, curtain-wall systems are often constructed by one installer. Connecting the curtain-wall system to surrounding systems, such as roof assemblies or wall, requires coordination of trades. Common problems found in the field include

- Improper or poor connection of curtain wall to roofing system
- Missing corner blocks or drainage elements, resulting in reduced moisture performance
- Missing or blocked vertical drainage channels, resulting in stored water at the glazing head

Sloped glazing is similar to curtain-wall systems, although the importance of using a rain-screen design to prevent water penetration to a building interior is enhanced. Properly flashed head joints and detailed drainage at the base of the sloped glazing are essential for long-term performance.

Precast Concrete Panels

Insulated precast wall (sandwich) panels are often constructed with solid concrete at the perimeter that encloses the insulation (Figure 3A). This concrete has a much greater thermal conductivity than the insulation, resulting in appreciable heat loss through these areas, particularly when added up across an entire building envelope. By changing how panels are assembled (e.g., connecting inner and outer panel sections with plastic tie-rods), a much greater thermal performance is achieved and the excessive perimeter heat loss is

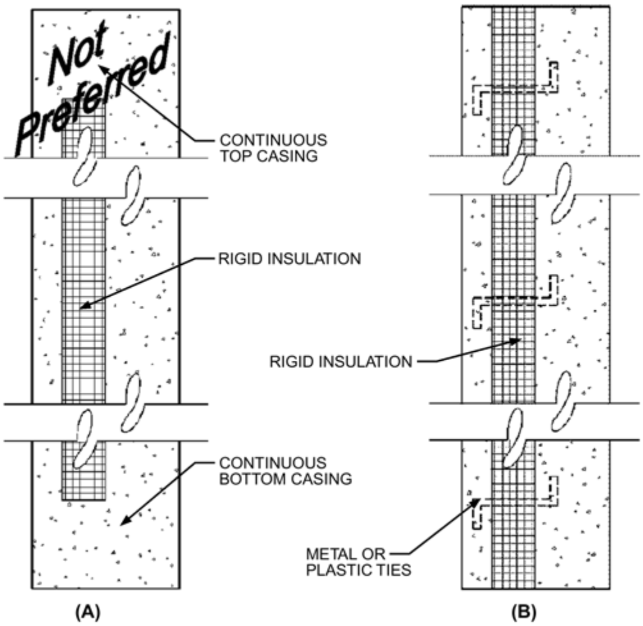

Fig. 3 Sandwich Panel with Insulation Encased in Concrete

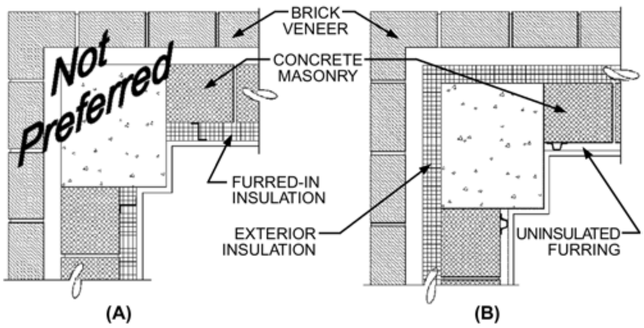

Fig. 4 Details of Insulation Around Column in Masonry Wall

eliminated (Figure 3B). These types of panels are more susceptible to water penetration, however, so proper panel joint design and execution are even more critical with these types of panels.

Precast concrete wall assemblies should be connected using two-stage jointing system. Two-stage joints consist of an inner and outer sealant joint. The exterior joint forms an outdoor weather barrier that keeps most exterior moisture from entering the joint. The inner joint is normally sloped at the bottom of each panel joint to drain water that bypasses the outer joint back to the outdoors, and forms part of the wall's air-barrier assembly. For more information on precast panel joinery, see CMHC (2002).

Steel-Stud Wall Assemblies

Steel-stud wall assemblies are commonly used in multifamily, commercial, and industrial construction. These wall assemblies represent a particular challenge because of the studs' high thermal conductivity. Adding thermal breaks can prevent excessive heat loss and problems associated with condensation in the wall assembly and on interior finishes.

Adding insulated sheathing or insulation outboard of the steel studs significantly reduces heat loss and helps avoid cold surfaces at the interior and in the wall cavity; however, system limitations and manufacturer's instructions should be considered.

Wall Geometry with High Thermal Conductivity

Concrete columns in masonry walls are often left uninsulated. Figure 4 illustrates a wall system with a column at the junction of two exterior brick walls with CMU back-up. The assembly in Figure 4A represents a significant thermal bridge. In Figure 4B, the walls are insulated with polystyrene on metal furring. The amount of heat flow is greatly reduced in this assembly, and no condensation or subsequent mold growth would be expected on interior surfaces of the column under normal operating conditions.

7. FENESTRATION

Conduction/Convection and Radiation Effects

Heat transfer through a window resulting from a temperature differential between the indoors and outdoors (i.e., conduction, convection, and radiation) is a complex and interactive phenomenon. Although glass itself is a poor insulator, technologies can be combined to improve a glazing system's overall thermal performance. Glass also decreases direct transmission of radiant energy from the room or ambient sources. Chapter 15 of the 2017 *ASHRAE Handbook—Fundamentals* discusses fenestration in much greater detail.

Examination of the modes of heat transfer in a double-glazed window indicates that approximately 70% of the heat flow is through radiation from one glazing layer to the other (Arasteh et al. 1985; Selkowitz 1979). Although glass is largely opaque to infrared radiation, energy is still absorbed and reemitted. Low-emittance coatings that are transparent to the eye significantly reduce the amount of radiant heat transfer through a glazing cavity. With that mode of heat transfer minimized, conductive and convective modes dominate. To reduce these effects, inert gases with low conductivity (e.g., argon, krypton) are used in low-emittance-coated, double-glazed windows. Inert-gas-filled triple or quadruple glazing layers with low-emittance coatings can additionally reduce heat transfer, although overall thermal performance normally remains significantly less than a common insulated wall assembly. See Chapter 15 of the 2017 *ASHRAE Handbook—Fundamentals* for design information.

Air Infiltration Effects

Air infiltration at fenestration is influenced by the pressure difference between the indoor and outdoor environments (a function of wind speed, indoor/outdoor temperature differences, and mechanical air balance) as well as window-sealing characteristics (Klems 1983; Weidt and Weidt 1980). The infiltration rate of a fenestration product is a function of its method of operating (if any), weatherstripping material used, and construction quality. See Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals* for design information.

Solar Gain

Solar gain through windows can play a significant role in a building's energy balance. Glazings transmit, reflect, or absorb a given wavelength of solar radiation, depending on glazing characteristics. Transmitted solar radiation contributes heat to a space. Absorbed solar radiation is reemitted and/or conducted either to the indoors or outdoors (depending on the glazing system configuration). Solar radiation that is reflected away from a building through the use of reflective glass does not contribute heat to a space (Arasteh et al. 1989), but the designer should be aware of the potential for secondary solar gains reflected from an adjacent structure. Clear glass, the most common glazing material, transmits fairly evenly across the solar spectrum. Tinted or heat-absorbing glass absorbs solar radiation and gives the glass a specific color. Some tints exhibit a significant degree of spectral sensitivity (i.e., they do not transmit, absorb, and reflect evenly across the solar spectrum). These types of glazing elements offer great flexibility and can be tailored for specific climates or uses (e.g., provide ample daylighting without overheating an interior space).

Interactions Between Thermal Loss and Solar Gain

In heating-dominated applications, solar gain provides a significant amount of heat. In some cases, heat supplied by the window can offset that lost through the window. The amount depends on characteristics of the site (e.g., how much solar gain is available, how cold the climate is) and the window (e.g., its U-factor and how much incident solar radiation is transmitted).

Typical passive solar applications try to maximize the amount of solar heat gain by installing significant areas of southeast- to southwest-facing glass, which receives the most solar radiation during the winter in the northern hemisphere. However, high-performance windows facing north in a heating-dominated but sunny climate can provide more solar gain to a space than heat loss (Arasteh et al. 1989; Dubrous and Wilson 1992; Sullivan et al. 1992).

Control of Rain Entry

Applying the rain screen principle at the wall/window interface requires the same features as applying it to the wall, including (1) an airflow retarder at the interior, (2) a rain deflector on the outside of the interface, and (3) a drainage path to the outdoors.

The line of airtightness is on the inside of the assembly, so it is protected from water, ultraviolet rays, and extremes of temperature. The rain deflector on the outside acts as a rain deterrent only, not as a watertight/airtight seal. A nonairtight rain deflector does not threaten system weathertightness, because pressure differences across the rain deflector are small. The key is to maintain airtightness on the inside of the joint. With little pressure difference across the rain deflector and with good detailing for outward drainage of the cavity, rain entry in the wall should be minimal. The interface between an exterior wall air barrier and an interior fenestration air barrier must be carefully considered during the design phase, and may require site mock-ups to adequately determine the best solution.

8. FOUNDATIONS

Three common types of below- and at-grade constructions are **basements**, **crawlspaces**, and **slabs**. Many buildings have combinations of these types. Key concerns for these assemblies are heat transfer and moisture management.

Heat Transfer

Heat transfer in below- and at-grade constructions is complex. Factors affecting it include thermal conductivity and wetness of the soil, height and temperature of the water table, amount and profile of insulation, and geometry. For a simplified means of estimating heat transfer in these constructions, see Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*.

Measured heat transfer through slabs on grade with 10 different insulation profiles can be found in Bareither et al. 1948. Kusuda and Bean (1987) and Mitalas (1983) provide slab shape factors for steady-state calculations of heat loss. Transient calculations are provided in Hagentoft (1988) and Shipp (1982). An overview is provided in Labs et al. (1988). The following general principles may be applied:

- Heat loss through slabs is concentrated at the slab edge. Insulation is more critical there than in the center of the slab.
- For sections of basements or crawlspaces that are above grade or shallow below grade, insulation on the outside is more effective than insulation at the interior. For deeper parts of a basement, interior insulation is more effective because of the thermal bridge effect of the footing, which is typically uninsulated.
- In crawlspaces and basements, insulation may be applied in the foundation walls or in the floor system above. If insulation is applied in the floor system, the space below may be cold and wet. Some form of moisture protection on the underside of an insulated floor system may be necessary.

Moisture

Below- and at-grade constructions are affected by rainwater surrounding the building and by the below-grade water table. For all construction types, ensure that the soil or other finish outside the building is sloped away from the building. Discharge from scuppers, gutters, and downspouts should be conducted far enough from the building that discharge water cannot saturate soil that is in contact with the below- or at-grade assembly (Rose 2010).

Foundation depth should correspond to the hydrologic conditions of the building site, so that the underground water table is not allowed to encroach on the below-grade space. If it does, then a sump pump must be used to locally lower the water table.

Basements and crawlspaces may encounter some flooding in the course of their service lives. Consequently, basement finishes should be selected so that they can withstand water loading and are readily cleaned afterwards.

Crawlspaces have been known to be sources of moisture to the building since their introduction in the mid-1900s. Britton (1947) found that the use of low-vapor-permeance ground covers with ventilation resulted in drier conditions. This recommendation for ventilation was picked up by many codes and guidelines. Venting crawlspaces, however, creates an unconditioned space beneath the building, which may lead to energy penalties and high relative humidity during warm weather. It is therefore recommended that crawlspaces should be treated like basements with insulated perimeter walls, insulated bottom floors, and protection from moisture ingress. The crawlspace should be accessible, well illuminated, and clean.

In cold climates, building foundations should resist frost heave. This is commonly done by ensuring footings are below frost depth. The frost-protected shallow foundation uses below-grade insulation outboard of the foundation to ensure nonfreezing conditions at the slab edge. Attachment frost heaving may occur (Labs et al. 1988); it is prevented by avoiding puddles of water in contact with the foundation during freezing weather by draining water away from the building, as described previously.

9. EXISTING AND HISTORIC BUILDINGS

In recent years, there has been a noticeable shift in emphasis from new construction to work on existing buildings. There can be tremendous advantages in materials use, embodied energy, carbon dioxide emissions, and other environmental issues to renovating existing buildings rather than replacing them with new structures, or adding new structures. In the United States, work on buildings of historic significance is addressed by the Secretary of the Interior's Standards for the Treatment of Historic Properties (1977). For more information, see Park (2009).

Determining what materials were used in the original construction and their actual properties can be a challenge. Many materials are hidden within the structure and require some disassembly to determine underlying structure and components. Necessary investigative work may range from review of accurate as-built drawings, to field testing, disassembly, and historical research. Depending on the age of the building, multiple renovations may have created many different assemblies in the building, so a review of available plans and permits issued for the building helps avoid unknown conditions during construction. Properties of older materials can be markedly different from their modern equivalents, so research may be necessary: in some cases, actual testing of the materials may be the only way to discover how the materials will react. Chemical compatibility between reused and newer materials may be a concern. For instance, new materials for roofing, waterproofing, and sealant or barrier systems may not be compatible with materials used in the past.

Existing buildings provide the benefit of having a performance history. This can be helpful in understanding the reality of energy consumption as well as moisture storage, air leakage, and water vapor movement through materials and assemblies. The building history can be used to identify defects or weak points in the assembly or interactions between the HVAC system and envelope. The building operates in an equilibrium that depends on indoor and outdoor conditions and building material properties. Changes to operating conditions or materials can affect everything and alter this equilibrium.

A review of changes such as HVAC upgrades or building envelope improvements should be incorporated into the design. Some sustainable practices are rapidly evolving, and applicable codes and guidelines are still developing. As a result, there can be challenges to following the letter of the code on renovation projects without fully understanding the physical phenomena behind envelope performance and interactions with HVAC system effects. This can result in problems ranging from water leakage to advanced degradation of wall components. Sometimes, novel approaches must be sought that allow compliance with the intent of the code while optimizing the durability and performance of existing materials/assemblies.

An additional concern for existing buildings involves a common practice of owners: some large-scale renovation projects are phased over a period of time. If an overall plan is not developed that includes understanding of the interdependence between the building envelope and HVAC systems, then problems and/or extra expense are very likely to occur over the multiple years that it takes to complete the entire renovation plan. The order in which changes are done (e.g., envelope first versus HVAC system first) could also greatly affect overall costs as well as the end result. For example, in hot, humid climates, if the HVAC system is replaced before an envelope-tightening project, extra capacity may have to be installed to meet the interim needs. This extra capacity could cause problems with overcooling and high relative humidity after the envelope tightening occurs.

Successful renovation projects begin with documenting existing conditions and careful analysis of the effects of potential changes. New materials and systems are selected based on compatibility with existing materials and systems as well as durability and long-term performance characteristics.

Building Materials

Specific issues to be considered for material changes and selections include addition of new materials, removal of old materials, and replacement of existing materials with a modern equivalent; a full understanding of the purpose of specific layers and materials in the original design is also required. An example involves the use of stone or brick masonry. In older buildings, solid stone or brick masonry walls were designed to perform as barrier systems by absorbing and gradually releasing moisture. These materials relied on heat flow to keep them dry and prevent freeze/thaw damage in cold climates.

Reuse of wall systems during energy retrofits poses particular challenges in cold climates. Adding exterior insulation has the benefit of providing continuous insulation and moisture control while insulating structural elements from thermal and moisture extremes, but it may conflict with preservation aesthetics as well as zoning requirements. Adding interior insulation increases thermal stresses while reducing the drying potential of the exterior facade, and may lead to increased freeze/thaw cycling in cold climates. It is also difficult to achieve continuous thermal insulation and air barrier around existing interior wall elements. Unavoidable discontinuities create thermal bridges that could become condensation sites. Floors supported by exterior masonry are one example. See Chapter 27 of the 2017 *ASHRAE Handbook—Fundamentals* for examples of calculating thermal resistance values for complex wall assemblies.

Hygrothermal analysis and understanding of the potential consequences of measures planned on the durability of facades and structural elements must be part of the renovation design process, because this may impose limits on the insulation strategy. Guidance for performing hygrothermal analysis can be found in ASHRAE *Standard* 160.

Changing HVAC Equipment and/or Control Strategy

When upgrading or replacing existing mechanical systems, the effect of the new HVAC system on the building envelope must be considered. This is particularly important with the addition of humidification. In cold, and even some mild, climates, humidifying a previously nonhumidified space may lead to damaging moisture accumulation in walls and roofs unless the building envelope can withstand the loads. For a typical nonhumidified building, the interior relative humidity is normally lowest when the exterior temperature is also at a minimum. This is beneficial to the building, because condensation risk on the interior is moderated during the coldest period of the year. Adding humidification (by mechanical means or occupant activities) reduces this benefit, and in cold climates may result in surface condensation and/or mold growth for several months out of the year. Durability often is negatively impacted when humidification is added to an existing building unless changes are also made to the envelope to resist condensation.

The building envelope requires more attention than just estimating its properties to calculate heating and cooling loads for new equipment. In older buildings with little to no insulation, successful HVAC system design needs to counteract the large envelope losses and solar gains; otherwise, occupant comfort can suffer. This can be particularly noticeable adjacent to windows with single-pane glazing or thermally inefficient walls where additional heating or cooling maybe required to compensate for excessive heat loss. Localized use of space heaters or fans in an existing building indicates deficiencies in the previous HVAC system. HVAC system design may have to include perimeter heaters, specialized VAV distribution, or localized heating to prevent low temperatures or moisture accumulation in concealed spaces. Additionally, information on existing drawings used to determine thermal performance properties for equipment sizing calculations may not reflect changes already made to the building envelope. Important changes that can affect performance can include window replacements or reflective coatings, adding insulation during reroofing or interior renovation projects, etc. Changing the pressure distribution in building zones or across the exterior envelope also significantly affects the building envelope’s moisture performance.

Envelope Modifications Without Mechanical System Upgrades

Building envelope systems are often upgraded without corresponding upgrades to mechanical systems. Failure to modify the existing mechanical system to account for changes in the dynamic performance of the building envelope can result in problems such as excess humidity or lack of interior environmental control. Retrofitting a building for improved thermal insulation or solar control at glazing systems can effectively reduce cooling loads. If the mechanical systems are not modified accordingly, they become oversized for the renovated conditions. This can result in numerous problems, such as poor interior temperature and relative humidity control, or more subtle issues such as inefficient operation. Retaining an older mechanical system may also prevent the full energy savings of an enclosure upgrade from being realized.

Improved airtightness should be a criterion of any building envelope retrofit project. For buildings in cold climates that previously relied on incidental air leakage to provide ventilation, reducing leakage rates may result in high interior air moisture levels. In the previously leaky building, incidental leakage was sufficient to dilute interior moisture with dry outdoor air and maintain reasonable humidity levels. These buildings should use a ventilation system using appropriate energy recovery techniques to maintain adequate fresh air.

Designers should assess the relationship between the building envelope and mechanical system, and design appropriate modifications. Design considerations for converting existing buildings to high-performance buildings include the following:

- Investigate existing building envelope conditions, taking care to note sites of damage and repair that may affect performance. In many cases, it may be beneficial to gather information on the building’s historical performance, including utility bills and past occupancy types.
- Provide documentation of existing conditions in the building, building envelope, and mechanical systems. For historic buildings, complete a historic structures report.
- Identify major air and/or water leakage sites, and provide remedial measures to correct flow through these sites. If appropriate, adopt a strategy to reach an airtightness performance target.
- Consider improving thermal performance. Exterior insulation is often preferred over interior or cavity insulation, because cavity

or interior insulation typically allows structural and other members to act as thermal bridges. Local preservation requirements may govern the location of insulation.

- Review possible changes to envelope operating characteristics that result from adding thermal insulation or changing HVAC operation. A change in the moisture and/or heat flow function of the envelope can have a significant effect on durability.
- With improved envelope performance, consider downsized mechanical equipment.

CHAPTER 46

BUILDING AIR INTAKE AND EXHAUST DESIGN

Exhaust Stack and Air Intake Design Strategies 46.1
Geometric Method for Estimating Stack Height 46.5
Exhaust-To-Intake Dilution or Concentration Calculations 46.7
Other Considerations 46.10

OUTDOOR air enters a building through its air intake to provide ventilation air to building occupants. Likewise, building exhaust systems remove air from a building and expel the contaminants to the atmosphere. If the intake or exhaust system is not well designed, contaminants from nearby outdoor sources (e.g., vehicle exhaust, emergency generators, exhaust stacks on nearby buildings) or from the building itself (e.g., laboratory fume hood exhaust, plumbing vents) can enter the building before dilution. Poorly diluted contaminants may cause odors, health impacts, and reduced indoor air quality. This chapter discusses proper design of exhaust stacks and placement of air intakes to avoid adverse air quality impacts. Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals* describes wind and airflow patterns around buildings in greater detail. Related information can also be found in Chapters 9, 18, 33, 34, and 35 of this volume, Chapters 11 and 12 of the 2017 *ASHRAE Handbook—Fundamentals*, and Chapters 29, 30, and 35 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. EXHAUST STACK AND AIR INTAKE DESIGN STRATEGIES

Stack Design Strategies

The dilution a stack exhaust can provide is limited by the dispersion capability of the atmosphere. Before discharging out the stack, exhaust contamination can be reduced by filters, collectors, and scrubbers to maintain acceptable air quality. The goal of stack design is to specify the minimum flow of the exhaust system, exhaust velocity, and stack height that ensures acceptable air quality at all locations of concern. This also reduces the exhaust system's energy consumption.

Central exhaust systems that combine airflows from many exhaust sources should always be used where safe and practical. By combining several exhaust streams, central systems can dilute contaminants in the exhaust airstream more efficiently. The combined flow can generate an exhaust plume that rises a greater distance above the emitting building. If necessary for air quality reasons, additional air volume can be added to the exhaust near the exit with a makeup air unit to increase initial dilution and exhaust plume rise. This added air volume does not need heating or cooling, and the additional energy cost is lower than increasing stack exit velocity. A small increase in stack height may also achieve the same benefit without an added energy cost.

In some cases, separate exhaust systems are mandatory. The nature of the contaminants to be combined, recommended industrial hygiene practice, and applicable safety codes need to be considered. Separate exhaust stacks could be grouped in close proximity to one another to take advantage of the larger plume rise of the resulting combined jet. Also, a single stack location for a central exhaust system or a tight cluster of stacks provides more options for locating building air intakes on the building facade or roof. Petersen and Reifschneider (2008) provide guidelines for optimal arrangements

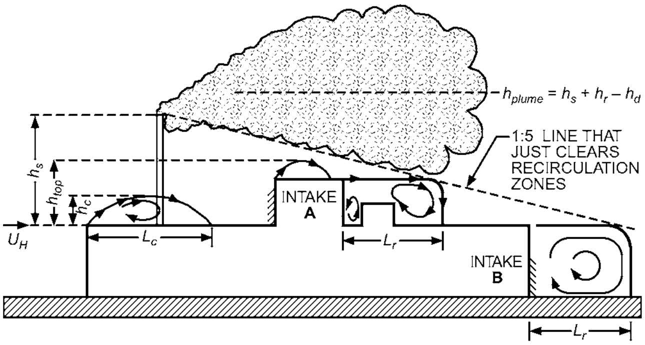

Fig. 1 Flow Recirculation Regions and Exhaust Parameters
(Wilson 1982)

of ganged stacks. In general, for a tight cluster to be considered as a single stack (i.e., to add stack momentums together) in dilution calculations, the stacks must be uncapped and nearly be touching the middle stack of the group.

As shown in Figure 1, stack height h_s is measured from the roof level on which the exhaust stack is located to the top of the stack. Wilson and Winkel (1982) demonstrated that stacks terminating below the level of adjacent walls and architectural enclosures frequently do not effectively reduce roof-level exhaust contamination. To take full advantage of their height, stacks should be located on the highest roof of a building.

Architectural screens used to mask rooftop equipment adversely affect exhaust dilution, depending on porosity, relative height, and distance from the stack. Petersen et al. (1999) found that exhaust dispersion improves with increased screen porosity.

Large buildings, structures, and terrain close to the emitting building can adversely affect stack exhaust dilution, because the emitting building can be within the recirculation flow zones downwind of these nearby flow obstacles (Wilson et al. 1998a). In addition, ventilation air entering air intakes located on nearby taller buildings can be contaminated by stack exhaust from shorter buildings. Wherever possible, facilities emitting toxic or highly odorous contaminants should not be located near taller buildings or at the base of steep terrain.

As shown in Figure 2, stacks should be vertically directed and uncapped. Stack caps that deflect the exhaust jet have a detrimental effect on exhaust plume rise. Small conical stack caps often do not completely exclude rain, because rain does not always fall straight down; periods of heavy rainfall may be accompanied by high winds that deflect raindrops under the cap and into the stack (Changnon 1966). A stack exhaust velocity V_e of about 13 m/s prevents condensed moisture from draining down the stack and keeps rain from entering the stack. For intermittently operated systems, protection from rain and snow should be provided by stack drains, as shown in Figure 2F to 2J, rather than stack caps.

Recommended Stack Exhaust Velocity

High stack exhaust velocity and temperatures increase plume rise, which tends to reduce intake contamination. Exhaust velocity

The preparation of this chapter is assigned to TC 4.3, Ventilation Requirements and Infiltration.

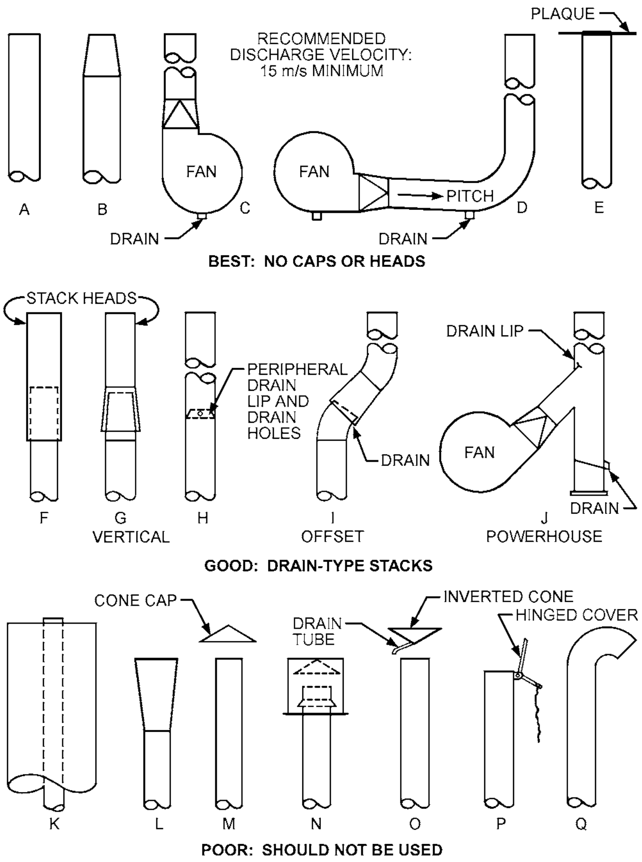

Fig. 2 Stack Designs Providing Vertical Discharge and Rain Protection

V_e should be maintained above 10 m/s (even with drains in the stack) to provide adequate plume rise and jet dilution. Velocities above 10 m/s provide greater plume rise and dilution, but above 15 to 20 m/s, noise, vibration, and energy costs can become an important concern. An exit nozzle (Figure 2B) can be used to increase exhaust velocity and plume rise. Many laboratory fume hood systems use variable-volume fans that reduce flow from hoods when they are closed. Stack exhaust velocity calculations must be based on the minimum total flow rate from the system, not the maximum.

An exception to these exhaust velocity recommendations include when corrosive condensate droplets are discharged. In this case, a velocity of 5 m/s in the stack and a condensate drain are recommended to reduce droplet emission. At this low exhaust velocity, a taller stack may be needed to counteract downwash caused by low exit velocity. Another exception is when a detailed dispersion modeling analysis is conducted. Such an analysis can determine the minimum exit velocity needed to maintain acceptable dilution versus stack height. Generally, the taller the stack, the lower the required exit velocity and fan energy consumption.

Stack wake downwash occurs where low-velocity exhausts are pulled downward by negative pressures immediately downwind of the stack, as shown in Figure 3. V_e should be at least 1.5 times the design speed U_H at roof height in the approach wind to avoid stack wake downwash. A meteorological station design wind speed U_{met} that is exceeded less than 1% of the time can be used as U_H. This value can be obtained from Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*, or estimated by applying Table 2 of Chapter 24 of that volume to annual average wind speed. Because wind speed increases with height, a correction for roof height should be applied

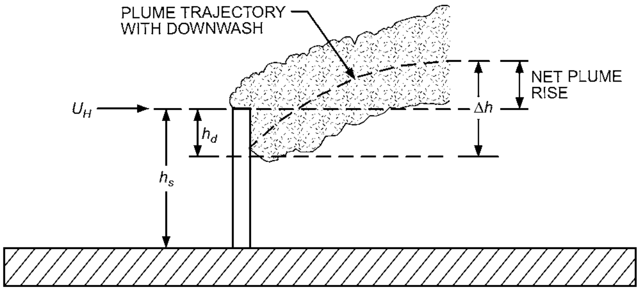

Fig. 3 Reduction of Effective Stack Height by Stack Wake Downwash

for buildings significantly higher than 10 m, using the power law rule described in Equation (4) and Table 1 of Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*.

Other Stack Design Standards

Minimum heights for chimneys and other flues are discussed in the *International Building Code* (ICC 2006). For laboratory fume hood exhausts, American Industrial Hygiene Association (AIHA) *Standard* Z9.5 recommends a minimum stack height of 3 m above the adjacent roof line, an exhaust velocity V_e of 15 m/s, and a stack height extending one stack diameter above any architectural screen; National Fire Protection Association (NFPA) *Standard* 45 specifies a minimum stack height of 3 m to protect rooftop workers. Toxic chemical emissions may also be regulated by federal, state, and local air quality agencies.

Contamination Sources

Some contamination sources that need consideration in stack and intake design include the following.

Toxic Stack Exhausts. Boilers, emergency generators, and laboratory fume hoods are some sources that can seriously affect building indoor air quality because of toxic air pollutants. These sources, especially diesel-fueled emergency generators, can also produce strong odors that may require administrative measures, such as generator testing during low building occupancy or temporarily closing the intakes.

Automobile and Truck Traffic. Heavily traveled roads and parking garages emit carbon monoxide, dust, and other pollutants. Diesel trucks and ambulances are common sources of odor complaints (Smeaton et al. 1991). Avoid placing intakes near vehicle loading zones. Overhead canopies on vehicle docks do not prevent hot vehicle exhaust from rising to intakes above the canopy. When the loading zone is in the flow recirculation region downwind from the building, vehicle exhaust may spread upwind over large sections of the building surface (Ratcliff et al. 1994). Garbage containers may also be a source of odors, and garbage trucks may emit diesel exhaust with strong odors.

Kitchen Cooking Hoods. Kitchen exhaust can be a source of odors and cause plugging and corrosion of heat exchangers. Grease hoods have stronger odors than other general kitchen exhausts. Grease and odor removal equipment beyond that for code requirements may be needed if air intakes cannot be placed an appropriate distance away.

Evaporative Cooling Towers. Outbreaks of Legionnaires' disease have been linked to bacteria in cooling tower drift droplets being drawn into the building through air intakes (Puckorius 1999). ASHRAE *Guideline* 12 gives advice on cooling tower maintenance for minimizing the risk of Legionnaires' disease, and suggests keeping cooling towers as far away as possible from intakes, operable windows, and outdoor public areas. No specific minimum separation distance is provided or available. Prevailing wind directions should also be considered to minimize risk. Evaporative cooling towers can have several other effects: water vapor can increase air-conditioning loads, condensing and freezing water vapor can damage equipment, and ice can block intake grilles and filters. Chemicals added to retard scaling and biological contamination may be emitted from the cooling tower, creating odors or health effects, as discussed by Vanderheyden and Schuyler (1994).

Building General Exhaust Air. General indoor air that is exhausted normally contains elevated concentrations of carbon dioxide, dust, copier toner, off-gassing from materials, cleaning agents, and body odors. General exhaust air should not be allowed to reenter the building without sufficient dilution.

Stagnant Water Bodies, Snow, and Leaves. Stagnant water bodies can be sources of objectionable odors and potentially harmful organisms. Avoid poor drainage on the roof or ground near the intake. Restricted airflow from snow drifts, fallen leaves, and other debris can be avoided in the design stage with elevated louvers above ground or roof level.

Rain and Fog. Direct intake of rain and fog can increase growth of microorganisms in the building. AMCA (2009) recommends selecting louvers and grilles with low rain penetration and installing drains just inside the louvers and grilles. In locations with chronic fog, some outdoor air treatment is recommended. One approach is to recirculate part of the indoor air to evaporate entrained water droplets, even during full air-side economizer operation (maximum outdoor air use).

Environmental Tobacco Smoke. Outdoor air intakes should not be placed close to outdoor smoking areas.

Plumbing Vents. Codes frequently require a minimum distance between plumbing vents and intakes to avoid odors.

Smoke from Fires. Smoke from fires is a significant safety hazard because of its direct health effects and from reduced visibility during evacuation. NFPA *Standard* 92A discusses the need for good air intake placement relative to smoke exhaust points.

Construction. Construction dust and equipment exhaust can be a significant nuisance over a long period. Temporary preconditioning of outdoor air is necessary in such situations, but is rarely provided. A simple solution is to provide room and access to the outdoor air duct for adding temporary air treatment filters or other devices, or a sufficient length of duct so that such equipment could be added when needed. Intake louvers and outdoor air ducts also require more frequent inspections and cleaning when construction occurs nearby.

Vandalism and Terrorism. Acts of vandalism and terrorism are of increasing concern. Louvers and grilles are potential points of illegal access to buildings, so their placement and construction are important. Intentional introduction of offensive or potentially harmful gaseous substances is also of concern. Some prudent initial design considerations might be elevating grilles and louvers away from easy pedestrian access and specifying security bars and other devices. Also, unlocked stair tower doors required for roof access during emergency evacuations may limit use of rooftop air intakes in sensitive applications because individuals would have ready access to the louvers. For more information, see ASHRAE's (2003) *Risk Management Guidance for Health, Safety, and Environmental Security under Extraordinary Incidents*.

General Guidance on Intake Placement

Carefully placed outdoor air intakes can reduce stack height requirements and help maintain acceptable indoor air quality. Rock and Moylan (1999) reviewed literature on air intake locations and design, and Petersen and LeCompte (2002) showed the benefit of placing air intakes on building sidewalls. ASHRAE *Standard* 62.1 highlights the need to locate makeup air inlets and exhaust outlets to avoid contamination.

Experience provides some general guidelines on air intake placement. Unless the appropriate dispersion modeling analysis is conducted, intakes should never be located in the same architectural screen enclosure as contaminated exhaust outlets. This is especially the case for low-momentum or capped exhausts (which tend to be trapped in the wind recirculation zone within the screen). For more information, see the section on Influence of Architectural Screens on Exhaust Dilution.

If exhaust is discharged from several locations on a roof, intakes should be sited to minimize contamination. Typically, this means maximizing separation distance. Where all exhausts of concern are emitted from a single, relatively tall stack or tight cluster of stacks, a possible intake location might be close to the base of this tall stack, if this location is not adversely affected by other exhaust locations or is not influenced by tall adjacent structures creating downwash. However, contaminant leakage from the side of the stack has been observed in positively pressurized areas between the exhaust fans and stack exit (Hitchings 1997; Knutson 1997), so air intakes should not be placed very close to highly toxic or odorous exhaust stacks regardless of stack height.

Intakes near vehicle loading zones should be avoided. Overhead canopies on vehicle docks do not effectively protect air intakes, and vehicle exhaust may spread over large sections of the building surface. Loading zones also may have garbage and solid waste receptacles that create odors; trucks that serve the receptacles also produce odors. Air intakes should also not be placed near traffic or truck waiting areas. General building exhausts should also not be placed near outdoor contamination sources because flow reversal and ingestion of air through exhaust outlets can occur under some conditions (Seem et al. 1998).

Examining airflow around a building can help determine air intake placement. When wind is perpendicular to the upwind wall, air flows up and down the wall, dividing at about two-thirds up the wall (Figures 4 and 5). The downward flow creates ground-level swirl (shown in Figure 4) that stirs up dust and debris. To take advantage of the natural separation of wind over the upper and lower halves of a building, toxic or nuisance exhausts should be located on the roof and intakes located on the lower one-third of the building, but high enough to avoid wind-blown dust, debris, and vehicle exhaust. If ground-level sources (e.g., wind-blown dust, vehicle exhaust) are major sources of contamination, rooftop intake is desirable.

Code Requirements for Air Intakes

Many model building codes exist, and local governments adopt and amend codes as needed. Architects and building systems designers need to be familiar with local and national codes applicable to each project. Mechanical and plumbing codes typically give minimum required separation distances for some situations; how-

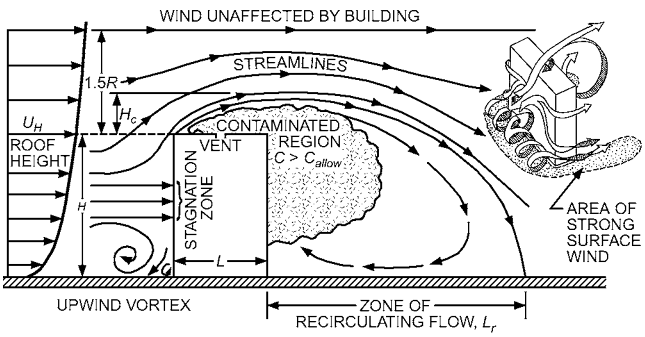

Fig. 4 Flow Patterns Around Rectangular Building

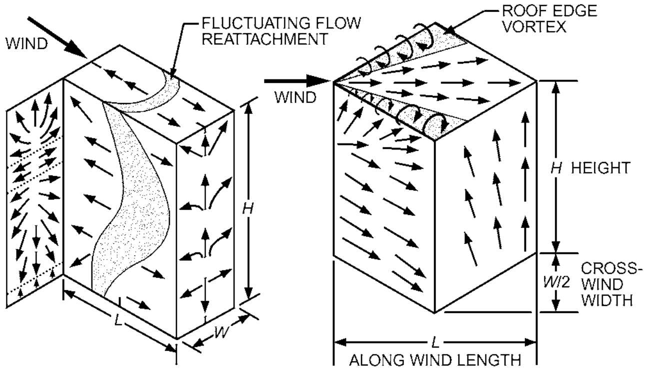

Fig. 5 Surface Flow Patterns and Building Dimensions

ever, maintaining these separation distances does not necessarily guarantee that intake contamination will not occur.

One example of a model building code is the *Uniform Mechanical Code* (UMC) (IAPMO 1997a), which has been widely adopted in the United States. The UMC requires that exhausts be at least 0.9 m from property lines and 0.9 m from openings into buildings. Makeup air intakes should be placed to avoid recirculation. Grease- and explosives-bearing ducts, combustion vents, and refrigeration equipment have special requirements: intakes should be at least 3 m from combustion or plumbing vents and exhaust air outlets, and be at least 3 m above a road. Cooling towers should be 1.5 m above or 6 m away from intakes.

The *Uniform Plumbing Code* (UPC) (IAPMO 1997b), requires that exhaust vents from domestic water heaters be 0.9 m or more above air inlets. Sanitary vents must be 3 m or more from or 0.9 m above air intakes. When UPC and UMC requirements conflict, the UPC provisions govern. However, local jurisdictions may modify codes, so the adopted versions may have significantly different requirements than the model codes.

Treatment and Control Strategies

When available intake/exhaust separation does not provide the desired dilution factor, or intakes must be placed in undesirable locations, ventilation air requires some degree of treatment, as discussed in Section 6.2.1 of ASHRAE *Standard* 62.1. Fibrous media, inertial collectors, and electrostatic air cleaners, if properly selected, installed, and maintained, can effectively treat airborne particles. Reducing gaseous pollutants requires scrubbing, absorptive, adsorptive, or incinerating techniques. Biological hazards require special methods such as using high-efficiency particulate air (HEPA) filters and ultraviolet light. Chapters 17, 29, and 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* describe these treatments in detail. One control approach that should be used with care is selective operation of intakes. If a sensor in the intake airstream detects an unacceptable level of some substance, the outdoor air dampers are closed until the condition passes. This strategy has been used for helicopter landing pads at hospitals and during emergency generator testing. The drawbacks are that pressurization is lost and ventilation air is not provided unless the recirculated air is heavily treated. In areas of chronically poor outdoor air quality, such as large urban areas with stagnant air, extensive and typically costly treatment of recirculated air may be the only effective option when outdoor air dampers are closed for extended periods.

Intake Locations for Heat-Rejection Devices

Cooling towers and similar heat-rejection devices are very sensitive to airflow around buildings. This equipment is frequently roof-mounted and has intakes close to the roof, where air can be

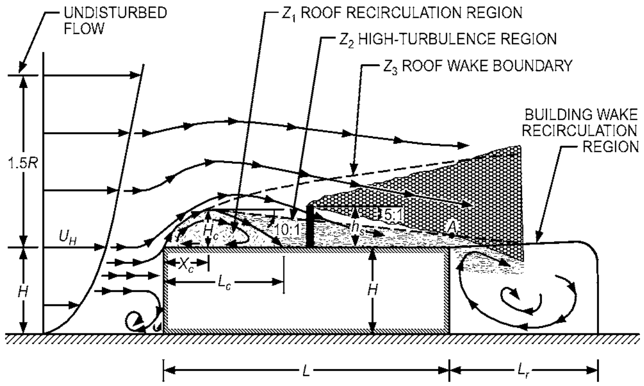

Fig. 6 Design Procedure for Required Stack Height to Avoid Contamination
(Wilson 1979)

considerably hotter and at a higher wet-bulb temperature than air that is not affected by the roof. This can reduce the capacity of cooling towers and air-cooled condensers.

Heat exchangers often take in air on one side and discharge heated, moist air horizontally from the other side. Obstructions immediately adjacent to these horizontal-flow cooling towers can drastically reduce equipment performance by reducing airflow. Furthermore, exhaust-to-intake recirculation can be an even more serious problem for this equipment: recirculation of warm, moist exhaust raises the inlet wet-bulb temperature, which reduces performance. Recirculation can be caused by adverse wind direction or local disturbance of airflow by an upwind obstruction, or by a close downwind obstruction. Vertical exhaust ducts may need to be extended to reduce recirculation and improve equipment effectiveness.

Wind Recirculation Zones on Flat-Roofed Buildings

Stack height design must begin by considering the wind recirculation regions (Figure 6). To avoid exhaust reentry, the stack plume must avoid rooftop air intakes and wind recirculation regions on the roof and in the wake downwind of the building. If stacks or exhaust vents discharge within this region, gases rapidly diffuse to the roof and may enter ventilation intakes or other openings. Figures 4 and 6 show that exhaust gas from an improperly designed stack is entrained into the recirculating flow zone behind the downwind face and is brought back into contact with the building.

Wilson (1979) found that, for a flat-roofed building, the upwind roof edge recirculation region height H_c at location X_c and its recirculation length L_c (shown in Figures 1 and 6) are proportional to the building size scale R:

$$H_c = 0.22R \tag{1}$$

$$X_c = 0.5R \tag{2}$$

$$L_c = 0.9R \tag{3}$$

and the wind recirculation cavity length L_r on the downwind side of the building is approximately

$$L_r = R \tag{4}$$

where R is the building scaling length:

$$R = B_s^{0.67} B_L^{0.33} \tag{5}$$

where B_s is the smaller of the building upwind face dimensions (height or width) and B_L is the larger. These equations are approximate but are recommended for use. The dimensions of flow recirculating zones depend on the amount of turbulence in the approaching wind. High levels of turbulence from upwind obstacles can decrease the coefficients in Equations (1) to (4) by up to a factor of two. Turbulence in the recirculation region and in the approaching wind also causes considerable fluctuation in the position of flow reattachment locations (Figures 5 and 6).

Rooftop obstacles such as penthouses, equipment housings, and architectural screens are accounted for in stack design by calculating the scale length R for each of these rooftop obstacles from Equation (5) using the upwind face dimensions of the obstacle. The recirculation regions for each obstacle are then calculated from Equations (1) to (4). When a rooftop obstacle is close to the upwind edge of a roof or another obstacle, the flow recirculation zones interact. Wilson (1979) gives methods for dealing with these situations.

Building-generated turbulence is confined to the roof wake region, whose upper boundary Z_3 in Figure 6 is

$$Z_3/R = 0.28(x/R)^{0.33} \tag{6}$$

where x is the distance from the upwind roof edge where the recirculation region forms. Building-generated turbulence decreases with increasing height above roof level. At the edge of rooftop wake boundary Z_3, turbulence intensity is close to the background level in the approach wind. The high levels of turbulence in the air below the boundary Z_2 in Figure 6 rapidly diffuse exhaust gases downward to contaminate roof-level intakes. As shown in Figure 6, the boundary Z_2 of this high-turbulence region downwind of a wind recirculation region is approximated by a straight line sloping at 10:1 downward from the top of the wind recirculation zone to the roof. The stack in Figure 6 may be inadequate because at point A the plume intersects the high turbulence boundary Z_2. The geometric method for stack height is discussed in more detail in the next section.

2. GEOMETRIC METHOD FOR ESTIMATING STACK HEIGHT

This section presents a method of specifying stack height h_s so that the lower edge of the exhaust plume lies above air intakes and wind recirculation zones on the roof and downwind of the emitting building, based on flow visualization studies (Wilson 1979). This method does not calculate exhaust dilution in the plume; instead, it estimates the size of recirculation and high turbulence zones, and the stack height to avoid contamination is calculated from the shape of the exhaust plume. High vertical exhaust velocity is accounted for with a plume rise calculation that shifts the plume upward. Low vertical exhaust velocity that allows stack wake downwash of the plume (see Figure 3) is accounted for by reducing the effective stack height.

This stack height should prevent reentry of exhaust gas into the emitting building most of the time, if no large buildings, structures, or terrain are nearby to disturb the approaching wind. The geometric method considers only intakes on the emitting building. Additional stack height or an exhaust-to-intake roof-level dilution calculation is often required if the exhaust plume can impinge on a nearby building (Wilson et al. 1998b). Dilution calculations should be used if this method produces an unsatisfactorily high stack, or if exhaust gases are highly toxic releases from fume hood exhaust.

Rooftop obstacles can significantly alter dispersion from exhaust stacks immediately downwind of, and of similar height to, the obstacles (Saathoff et al. 2002). The goal of the geometric stack method is to ensure that the exhaust plume is well above the recirculation zones associated with these obstacles.

Step 1. Use Equations (1) to (5) to calculate the height and location of flow recirculation zones 1 and 2 and the recirculation zone downwind of the building (see Figure 6). All zones associated with rooftop obstacles up- and downwind of the stack location should be included. Note that zone 3 is not used in the geometric design method.

Step 2. Draw the recirculation regions on the top and downwind sides of penthouses, equipment housings, architectural screens, and other rooftop obstacles up- and downwind of the stack location. If there are intakes on the downwind wall of the building, include the building recirculation region L_r on this wall. Now, calculate the height h_{sc} of a stack with a rain cap (i.e., no plume rise) and draw a line sloping down at 1:5 (11.3°) in the wind direction above the roof. Slide this line down toward the building as shown in Figure 1 until it contacts any one of the recirculation zones on any obstacle up- or downwind of the stack (or until the line contacts any portion of the building if there are no rooftop zones or sidewall intakes). With the line in this position, its height at the stack location is the smallest allowable plume height h_{sc} for that wind direction. Repeat for other wind directions to find the worst-case (highest) required plume height.

This estimated h_{sc} is based on an assumption that the plume spreads up and down from h_{sc} with a 1:5 slope (11.3°), as shown in Figure 6. (This slope represents a downward spread of approximately two standard deviations of a bell-curve Gaussian plume concentration distribution in the vertical direction.)

Step 3. Reduce the stack height to give credit for plume rise from uncapped stacks. Only jet momentum rise is used; buoyancy rise is neglected as a safety factor. For an uncapped stack of diameter d_e, plume rise h_r from the vertical jet momentum of the exhaust is estimated versus downwind distance from Briggs (1984) as

$$h_r = \min\{\beta h_x, \beta h_f\} \tag{7}$$

where the plume rise versus downwind distance, in m, is

$$h_x = \left\{\left(\frac{3F_m x}{\beta_j^2 U_H^2}\right)^{1/3}\right\}$$

momentum flux, in m^4/s^2, is

$$F_m = V_e^2\left(\frac{d_e^2}{4}\right)$$

the diameter of exhaust is

$$d_e = \sqrt{4A_e/\pi}$$

the jet entrainment coefficient is

$$\beta_j = \frac{1}{3} + \frac{U_H}{V_e}$$

the final plume rise, in m, is

$$h_f = \frac{0.9[F_m U_H/U_*]^{1/2}}{U_H \beta_j}$$

and the logarithmic wind profile equation is

$$U_H/U_* = 2.5 \ln(H/z_o)$$

where

β = stack capping factor: 1.0 without cap, 0 with cap
x = distance downwind of stack, m
V_e = stack exit velocity, m/s
A_e = area of exhaust
U_H = wind speed at building top, m/s
H = building height above ground level, m
U_* = friction velocity, m/s
z_o = surface roughness length, m

Table 1 Atmospheric Boundary Layer Parameters

Terrain Category	z_o, m	a	δ, m
Flat, water, desert	0.01	0.10	213
Flat, airport, grassland	0.05	0.14	274
Suburban	0.65	0.22	365
Urban	2.0	0.33	457

Table 1 describes various z_o values for a range of sites. For example if z_o equals 0.65 m and H = 15 m, substituting into the logarithmic wind profile equation gives $U_H/U_* = 7.9$.

For an uncapped stack, the capping factor is β = 1.0. For a capped stack, β = 0, so $h_r = 0$, and no credit is given for plume rise. U_H is the maximum design wind speed at roof height for which air intake contamination must be avoided. This maximum design speed must be at least as large as the hourly wind speed exceeded 1% of the time. This 1% design speed is listed for many cities in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* (on the CD-ROM and ASHRAE Handbook Online). For cities not on this list, set U_H equal to 2.5 times the annual average hourly wind speed as recommended in Table 2 of Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*.

The plume rise of Equation (7) plus the physical stack height should not be considered equivalent to an effective stack height. A real stack of that height has better performance for two reasons: the effective height is achieved immediately instead of somewhere downstream, and the plume is higher than the effective height because of exhaust momentum. Stack height plus plume rise are additive in the geometric method as a simplification, but there are other conservatisms built into the geometric method to offset this approach.

Step 4. Increase stack height, if necessary, to account for stack wake downwash caused by low exhaust velocity, as described in the section on Recommended Stack Exhaust Velocity. For a vertically directed jet from an uncapped stack (β = 1.0), Wilson et al. (1998b) recommend a stack wake downwash adjustment h_d of

$$h_d = d_e(3.0 - \beta V_e/U_H) \quad (8)$$

for $V_e/U_H < 3.0$. For $V_e/U_H > 3.0$, there is no downwash and $h_d = 0$. Rain caps and louvers are frequently used on stacks of gas- and oil-fired furnaces and packaged ventilation units, for which β = 0 and $h_d = 3.0d_e$.

The final adjusted stack height h_s recommended is

$$h_s = h_{sc} - h_r + h_d \quad (9)$$

The advantage of using an uncapped stack instead of a capped stack is considerable. If the minimum recommended exhaust velocity V_e of $1.5U_H$ is maintained for an uncapped stack (β = 1.0), plume downwash $h_d = 1.5d_e$ and $h_r = 4.5d_e$. For a capped stack (β = 0), $h_d = 3.0d_e$ and $h_r = 0$. Using these values in Equation (10), an uncapped stack can be made $6.0d_e$ shorter than a capped stack.

Example 1. The stack height h_s of the uncapped vertical exhaust on the building in Figure 1 must be specified to avoid excessive contamination of intakes A and B by stack gases. The stack has a diameter d_e of 0.5 m and an exhaust velocity V_e of 9.0 m/s. It is located 16 m from the upwind edge of the roof. The penthouse's upwind wall (with intake A) is located 30 m from the upwind edge of the roof, 4 m high, and 7 m long in the wind direction. The top of intake A is 2 m below the penthouse roof. The building has a height H of 15 m and a length of 62 m. The top of intake B is 6 m below roof level. The width (measured into the page) of the building is 50 m, and the penthouse is 9 m wide. The annual average hourly wind speed is 12.8 km/h at a nearby airport with an anemometer height H_{met} of 10 m. The building is in suburban terrain (see Table 1). Calculate the required stack height h_s by the geometrical method using the lowest allowable design wind speed.

Solution: The first step is to set the height h_{sc} of a capped stack by projecting lines with 1:5 slopes so that recirculation zones are covered, as shown in Figure 1. The only influence of intake location is that the downwind recirculation zone must be considered if there is an intake on the downwind wall, which is true for intake B in this example.

First, check the rooftop recirculation zone associated with the penthouse. To find the height of this recirculation zone, use Equation (5):

$$R = (4)^{0.67}(9.0)^{0.33} = 5.23 \text{ m}$$

Then use Equations (1) and (2):

$$H_c = (0.22)(5.23) = 1.15 \text{ m}$$

$$X_c = (0.5)(5.23) = 2.62 \text{ m}$$

With the 1:5 slope of the lower plume boundary shown in Figure 6, the capped stack height in Figure 1 (measured from the main roof) must be

$$h_{sc} = 0.2(30 - 16 + 2.62) + 1.15 + 4.0 = 8.5 \text{ m}$$

to avoid the recirculation zone above the penthouse.

Next, check the building wake recirculation zone downwind of the building. The plume must also avoid this region because intake B is located there. The length of this recirculation region is found using Equation (4):

$$L_r = (15)^{0.67}(50)^{0.33} = 22.3 \text{ m}$$

Projecting the downwind corner of this recirculation region upwind with a 1:5 slope to the stack location gives the required height of a no-downwash capped stack above the main roof level as

$$h_{sc} = 0.2(62 + 22.3 - 16) = 13.7 \text{ m}$$

for the plume to avoid the recirculation zone on the downwind side of the building.

The design stack height is set by the condition of avoiding contamination of the building wake, because avoiding the penthouse roof recirculation requires only a 8.5 m capped stack. Credit for plume rise h_r from the uncapped stack requires calculation of the building wind speed U_H at H = 15 m. The minimum allowable design wind speed is the speed that is exceeded 1% of the time at the meteorological station. In this case, for H_{met} = 10 m at the airport meteorological station, this 1% wind speed is U_{met} = 2.5(12.8) = 32 km/h = 9 m/s, using the relationship described in Table 2 of Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*. With the airport in open terrain (see Table 1), and the building in suburban terrain, the wind speed adjustment parameters are a_{met} = 0.14 and δ_{met} = 274 m at the airport, and a = 0.22 and δ = 365 m at the building. Using Equation (4) in Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*, with building height H = 15 m,

$$U_H = 9\left(\frac{274}{10}\right)^{0.14}\left(\frac{15}{365}\right)^{0.22} = 7.1 \text{ m/s}$$

Because V_e/U_H = 9.0/7.1 = 1.27 is less than 3.0, there is some plume downwash as shown in Figure 3. From Equation (9),

$$h_d = 0.5[3 - 1.0(1.27)] = 0.86 \text{ m}$$

Then, using Equation (7), the plume rise at the design wind speed and the distance to the closest intake A is calculated to be

x = 14.1 m
H = 15 m
d = 0.5 m
V_e = 9 m/s
U_H = 7 m/s
z_o = 0.65 m
F_m = 5.1 m^4/s^2
B_j = 1.11
h_x = 1.52 m
U_H/U_* = 7.9
h_f = 0.73 m
h_r = 0.73 m

Using these values in Equation (10), the uncapped height h_{sc} is, with the height reduction credit for the 1.92 m rise and the height addition to account for the 0.86 m downwash,

$$h_s = 13.7 - 0.74 + 0.86 = 13.82 \text{ m}$$

As shown in Figure 1, this stack height is measured above the main roof. If stack height is higher than desirable, an alternative is to use dilution calculations. The geometric method does not directly account for dilution within the plume.

3. EXHAUST-TO-INTAKE DILUTION OR CONCENTRATION CALCULATIONS

Worst-Case Critical Dilution or Maximum Concentration

The geometric stack design procedure does not give a quantitative estimate of the worst-case critical dilution factor D_{crit} at an air intake. If a required dilution can be specified with known stack emissions and required health limits, odor thresholds, or air quality regulations, computing critical dilutions is the preferred method for specifying stack heights. Petersen et al. (2002, 2004) and Smeaton et al. (1991) discuss use of emission information and formulation of dilution requirements in more detail. Exhaust from a single-source dedicated stack may require more atmospheric dilution than a single stack with the same exhausts combined, because emissions are diluted in the exhaust manifold.

This section describes the methods for computing outdoor dilution of exhausts emitted from a rooftop stack because of atmospheric dispersion processes. The resulting dilution can be converted to contaminant concentration for comparison to odor thresholds or health limits. Dispersion of pollutants from building exhaust depends on the combined effect of atmospheric turbulence in the wind approaching the building and turbulence generated by the building itself. This building-generated turbulence is most intense in and near the flow recirculation zones that occur on the upwind edges of the building (Figures 1 and 5). Dilution of exhaust gas is estimated using design procedures developed for tall isolated stacks (EPA 1995, 2004), with modifications to include the high turbulence levels experienced by a plume diffusing over a building roof in an urban area (Schulman et al. 2000). Halitsky (1982), Hosker (1984), Meroney (1982), and Wilson and Britter (1982) are good references regarding gas diffusion near buildings.

Dispersion models (including physical models) ranging from the simple to very complex are intended to help the designer investigate how pollutants will be distributed in the atmosphere, around the building, and around adjacent buildings and areas. These models identify potential problems that could result in too-high pollution concentrations by air intakes, entrances, or other sensitive areas that can fairly easily be corrected during design by changing design parameters such as exhaust exit velocity, stack location or height, etc. Identifying these problems during the design phase allows for a less expensive, more efficient solution than trying to correct a real problem after the building is completed, when, for example, changing the location and/or height of the stack can be very costly.

Dilution and Concentration Definitions

A building exhaust system releases a mixture of building air and pollutant gas at concentration C_e (mass of pollutant per volume of air) into the atmosphere through a stack or vent on the building. The exhaust mixes with atmospheric air to produce a pollutant concentration C, which may contaminate an air intake or receptor if the concentration is larger than some specified allowable value C_{allow} (see Figure 4). The dilution factor D between source and receptor mass concentrations is defined as

$$D = C_e/C \tag{10}$$

where

C_e = contaminant mass concentration in exhaust, kg/m³
C = contaminant mass concentration at receptor, kg/m³

The dilution increases with distance from the source, starting from its initial value of unity. If C is replaced by C_{allow} in Equation (11), the atmospheric dilution D_{req} required to meet the allowable concentration at the intake (receptor) is

$$D_{req} = C_e/C_{allow} \tag{11}$$

The exhaust (source) concentration is given by

$$C_e = \dot{m}/Q_e = \dot{m}/(A_e V_e) \tag{12}$$

where

$\dot{m}$ = contaminant mass release rate, kg/s
Q_e = $A_e V_e$ = total exhaust volumetric flow rate, m³/s
A_e = exhaust face area, m²
V_e = exhaust face velocity, m/s

The concentration units of mass per mixture volume are appropriate for gaseous pollutants, aerosols, dusts, and vapors. The concentration of gaseous pollutants is usually stated as a volume fraction f (contaminant volume/mixture volume), or as ppm (parts per million) if the volume fraction is multiplied by 10^6. The pollutant volume fraction f_e in the exhaust is

$$f_e = Q/Q_e \tag{13}$$

where Q is the volumetric release rate of the contaminant gas. Both Q and Q_e are calculated at exhaust temperature T_e.

The volume concentration dilution factor D_v is

$$D_v = f_e/f \tag{14}$$

where f is the contaminant volume fraction at the receptor. If the exhaust gas mixture has a relative molecular mass close to that of air, D_v may be calculated from the mass concentration dilution D by

$$D_v = (T_e/T_a)D \tag{15}$$

where

T_e = exhaust air absolute temperature, K
T_a = outdoor ambient air absolute temperature, K

Many building exhausts are close enough to ambient temperature that volume fraction and mass concentration dilutions D_v and D are equal.

Roof-Level Dilution Estimation Method

This section presents equations for predicting worst-case roof-level dilution of exhaust from a vertical stack on a roof. The equations assume a bell-shaped Gaussian concentration profile in both the vertical and cross-wind horizontal directions. Gaussian profiles have been used in many atmospheric dispersion models, such as those used by the U.S. Environmental Protection Agency. Considering their simplicity, bell-shaped Gaussian concentration profiles in the cross-wind y and vertical z directions at a given horizontal distance x represent atmospheric dispersion remarkably well (Brown et al. 1993).

The dilution equations predict the roof-level dilution D_r, which is the ratio of contaminant concentration C_e at the exit point of the exhaust to the maximum concentration C_r on the plume centerline at roof level, giving $D_r = C_e/C_r$. The centerline of the plume is defined in the x direction, with y the lateral (cross-wind) distance off the plume centerline (axis), and z the vertical. Dilution is affected by three processes:

- Wind carries the plume downwind. The higher the wind speed, the greater the dilution on the plume axis. Wind speed U_H carrying the plume is the wind speed in the undisturbed flow approaching the top of the building.
- Wind turbulence spreads the plume vertically and laterally (cross-wind). Plume spreads in the cross-wind y direction and the

vertical z direction are σ_y and σ_z. These plume spreads increase with downwind distance.

- The plume is carried vertically by the initial buoyancy and vertical momentum of the exhaust at the stack exit. The higher the plume, the greater the dilution at the roof surface. The stronger the wind, the less the plume rises, which may produce less dilution.

Thus, wind speed can have two effects: (1) at very low wind speed, the exhaust jet from an uncapped stack rises high above roof level, producing a large exhaust dilution D_r at a given intake location; and (2) at high wind speed, the plume rise is low but the dilution is large because of longitudinal stretching of the plume by the wind. Between these extremes is the critical wind speed $U_{H,crit}$, at which the smallest amount of dilution occurs for a given exhaust and intake location.

Before performing Gaussian dilution calculations on a rooftop, the effect of rooftop obstacles, wind recirculation zones, and intake location(s) must be considered. Dilution depends on the vertical separation ζ between the plume centerline h_{plume} and h_{top}, defined as the highest of the intake, all active obstacles (discussed later), and recirculation zones defined in Equation (1). Vertical separation ζ is defined as

$$\zeta = h_{plume} - h_{top}$$
$$= 0 \text{ if } h_{plume} < h_{top} \quad (16)$$

Plume centerline h_{plume} versus downwind distance defined as

$$h_{plume} = h_s + h_r - h_d \quad (17)$$

where h_s is the physical stack height above the roof, h_r is the plume rise versus downwind distance defined in Equation (7), and h_d is the stack wake downwash defined in Equation (9) (see Figure 1).

To determine which rooftop obstacles are considered active in defining h_{top}, start by drawing a line in plan view through the stack location and the intake of interest. All obstacles along this line or one obstacle width laterally (y-direction) from the line are considered active. Obstacles and recirculation zones upstream of the stack and downstream of the intake should also be considered. The value of h_{top} is the higher of the active obstacles, recirculation zones (including zones on top of active obstacles) defined in Equation (1), and the height of the intakes. All of these heights should be referenced to the same roof level used to determine h_s. Once h_{top} is defined and ζ is calculated, dilution at the intake is calculated from

$$D_r(x) = \frac{4U_H\sigma_y\sigma_z}{V_e d_e^2}\exp\left(\frac{\zeta^2}{2\sigma_z^2}\right) \quad (18)$$

When plume height is less than the height of intakes, active obstacles, and recirculation zones (i.e., $h_{plume} < h_{top}$), then $\zeta = 0$ and dilution should be calculated using Equation (23).

If exhaust gases are hot, buoyancy increases the rise of the exhaust gas mixture and produces lower concentrations (higher dilutions) at roof level. For all exhausts except very hot flue gases from combustion appliances, it is recommended that plume rise from buoyancy be neglected in dilution calculations and stack design on buildings. By neglecting buoyant plume rise, the predicted dilution has an inherent safety factor, particularly at low wind speed, where buoyancy rise is significant.

Cross-Wind and Vertical Plume Spreads for Dilution Calculations

Close to the stack, dispersion is governed by mechanical mixing, and the following equations for lateral and vertical plume spread can used (Cimorelli et al. 2005):

$$\sigma_y = (i_y^2 x^2 + \sigma_o^2)^{1/2} \quad (19)$$

$$\sigma_z = (i_z^2 x^2 + \sigma_o^2)^{1/2} \quad (20)$$

where i_y is lateral turbulence intensity, i_z is vertical turbulence intensity, x is distance downwind from the stack, and σ_o is initial source size, normally set equal to $0.35d_e$. The lateral and vertical turbulence intensity can be calculated using the following equations:

$$i_y = 0.75 i_x; \quad i_z = 0.5 i_x \quad (21)$$

where

$$i_x = n \ln\left(\frac{30}{z_o}\right) / \ln\left(\frac{z}{z_o}\right)$$

$$n = 0.24 + 0.096 \log_{10} z_o + 0.016(\log_{10} z_o)^2$$

where inputs z and z_o are in metres.

The averaging time over which exhaust gas concentration exposures are predicted is important in determining roof-level dilution. The preceding equations provide dilution estimates for a 10 to 15 min averaging time, which corresponds to the averaging time for ACGIH short-term exposure limits. If odors are a concern, peak minimum dilution may be needed; dilution for shorter averaging times can be estimated as

$$(D_r)_s = (D_r)_{15} \times \left(\frac{t_s}{15}\right)^{0.2}$$

where $(D_r)_s$ is the estimate for a shorter averaging time t_s and $(D_r)_{15}$ is the estimate for the 15 min averaging time. For example, assume a predicted dilution of $(D_r)_{15} = 100$. The dilution for a 1 min averaging time would be $100 \times (1/15)^{0.2} = 58$. If estimates for longer averaging times are needed, the preceding estimates should be assumed to be hourly averages and the following conservative multiplication factors (EPA 1992) should be used to obtain the estimated maximum concentrations for 3 h, 8 h, 24 h, or annual averaging times:

Averaging Time	Scaling or Multiplying Factors
3 h	1.1
8 h	1.4
24 h	2.5
Annual	12.5

Equations (17), (18), (19), and (20) imply that dilution does not depend on the location of either the exhaust or intake, only on the horizontal distance x between them and the vertical separation ζ. This is reasonable when both exhaust and intake locations are on the same building wall or on the roof. Dilution can increase if the intake is below roof level on the sidewall of a building and the exhaust stack is located on the roof. Petersen et al. (2004) provide methods for estimating the increased dilution on sidewalls.

Stack Design Using Dilution Calculations

Example 2. In general, a spreadsheet should be designed using the preceding equations to calculate dilution from an exhaust at any specified location on the roof. This example shows the results for a calculation at intake A using the information provided in Example 1. The distance from stack to intake is 14.1 m, and highest point on intake A is 2 m above the roof. Assume a 6.1 m stack height above the roof. Figure 7 provides the calculated dilution versus wind speed. The recommended method involves the following steps: (1) specify the site conditions using Table 1; (2) carry out the calculations outlined in Figure 7 using surface roughness in Table 1 for range of wind speeds; (3) repeat the calculations using a surface roughness half this value and 1.5 times this value; (4) find the lowest dilution for the range of wind speeds of interest for each surface roughness; and (5) determine the overall minimum

dilution and use this value to determine the acceptability of the exhaust design.

Dilution from Flush Exhaust Vents with No Stack

For exhaust grilles and louvers on the roof or walls of a building or penthouse, vertical separation $\zeta = 0$ in Equation (19). Combining Equations (19), (20), and (21) gives

$$D_s(x) = \frac{4U_H\sigma_y\sigma_z}{V_e d_e^2} \tag{22}$$

The subscript s in the dilution D_s from a surface exhaust distinguishes it from the roof-level dilution D_r from a stack [Equation (19)].

Minimum critical dilutions for flush exhausts can be calculated using the approximate value $U_{H,crit} = 2$ m/s based on the observation that, for wind speeds less than 2 m/s) at roof height, the atmosphere tends to develop high levels of turbulence that increase exhaust-to-intake dilution. For flush roof exhausts with no stack, and for wall intakes, the experiments of Petersen et al. (2004) suggest that D_s at the intake is at least a factor of 2 larger than the dilution at a roof-level intake at the same stretched-string distance S from the stack.

Example 3. The exhaust flow of $Q_e = 1.76$ m^3/s in Example 1 comes from a louvered grille at location A. The exhaust grille is 0.7 m high and 0.7 m wide. What is the critical exhaust-to-intake dilution factor at intake B on the downwind wall of the building for an averaging time of 15 min?

Solution: Exhaust grille A has a face area of A_e = 0.49 m^2 and an exhaust velocity V_e of 707 fpm (3.59 m/s). From Equation (8), the effective exhaust diameter is $d_e = [(4)(0.49)/\pi]^{0.5} = 0.79$ m. The stretched-string distance S from exhaust A to intake B is the sum of the 2 m from the top of A to the top of the penthouse, plus the 7 m length of the penthouse, plus the sloped line of horizontal length 24.9 m from the downwind edge of the penthouse roof, and a vertical drop of 4 m to the roof, plus the 6 m to intake B:

$$S = 2 + 7 + \sqrt{24.9^2 + (4+6)^2} = 35.8 \text{ m}$$

The critical wind speed is assumed to be $U_{H,crit}$ = 2 m/s for capped stacks and flush vents. The critical dilution of exhaust from A at intake B is calculated from Equation (23). Using a similar method as outlined in Example 2, Figure 8 shows the calculation table results where S and x are assumed equal.

These are conservative estimates because they represent the dilution at a low critical wind speed of 2 m/s.

Dilution at a Building Sidewall (Hidden) Intakes

Petersen et al. (2004) provided results of an ASHRAE research study that outlined methods for estimating dilution or concentration for visible versus hidden intakes. A hidden intake is typically on a building side wall or on the side wall of a roof obstruction opposite the exhaust source. A visible intake is at roof level or on top of an obstruction, directly above the exhaust source. The basic approach starts following the method for estimating dilution at a rooftop intake. Dilution is calculated at the rooftop location above the side-wall receptor; dilution at this distance is then increased by the factors given in Petersen et al. (2004). A conservative dilution increase factor for most building configurations is 2.0.

EPA Models

In late 2005, the EPA recommended that the AERMOD modeling system (Cimorelli et al. 2005) be used instead of the previously preferred industrial source complex (ISC3) model (EPA 1995). The new model includes state-of-the-art boundary layer parameterization techniques, convective dispersion, plume rise formulations, and complex terrain/plume interactions, as well as a building downwash algorithm. AERMOD can be used to calculate short-term (hourly) exposure and long-term (monthly and annual) exposure. Both the short- and long-term models are divided into three source classifications: (1) point source, (2) line source, and (3) area source. For exhaust stack design, the point source is the model of interest. The EPA (2006) guideline also describes a short- and a long-term dry deposition model. AERMOD uses the Gaussian equation to calculate the concentration of the contaminant concentration downwind of the source. The models consider the wind speed profile, use plume rise formulas, calculate dispersions factors (which take into consideration different landscapes, building wakes and downwash, and buoyancy), calculate the vertical distribution, and consider decay of the contaminant. More information on AERMOD and other EPA models can be found at www.epa.gov/scram. Remember that the EPA models are primarily designed to predict concentration (or dilution) values downwind of the building on which the exhausts are located. For predicting effects at building intakes, operable windows, and entrances, alternative modeling methods are required.

Wind Tunnel Modeling

Wind tunnel modeling is often the preferred method for predicting maximum concentrations for stack designs and locations of interest when energy and equipment optimization is desired. It is the recommended approach because it gives the most accurate estimates of concentration levels in complex building environments. A wind tunnel modeling study is like a full-scale field study, except it is conducted before a project is built. Typically, a scale model of the building under evaluation, along with the surrounding buildings and terrain within a 300 m radius, is placed in an atmospheric boundary layer wind tunnel. A tracer gas is released from the exhaust sources of interest, and concentration levels of this gas are then measured at receptor locations of interest (e.g., air intakes, operable windows) and converted to full-scale concentration values. Next, these values are compared against the appropriate health or odor design criteria to evaluate the acceptability of the exhaust design. Petersen and Cochran (2008) and Snyder (1981) provide more information on scale-model simulation and testing methods. Scale modeling is also discussed in Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*.

Wind-tunnel studies are highly technical, so care should be taken when selecting a dispersion modeling consultant. Factors such as past experience and staff technical qualifications are extremely important.

Computer Simulations Using Computational Fluid Dynamics (CFD)

CFD models are used successfully to model internal flow paths in areas such as vivariums and atriums, as well as in external aerodynamics for the aerospace industry. Aerospace CFD turbulence models, however, are ill suited for modeling atmospheric turbulence in complex full-scale building environments because of the differing geometric scales. More information on CFD modeling is in Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*.

Based on the current state of the art, CFD models should be used with extreme caution when modeling exhaust plumes from laboratory pollutant sources. Currently, CFD models can both over- and underpredict concentration levels by orders of magnitude, leading to potentially unsafe designs. If a CFD study is conducted for such an application, supporting full-scale or wind tunnel validation studies should be carried out. Various commercial software packages are available for CFD-driven airflow analysis. Most have advanced user interfaces and resulting visualization capabilities, as well as sophisticated physical models and solver options. Usually, commercial software includes advanced technical user support provided by vendor specialists. Several open-source research codes are available, as well, but require a much greater user insight into the underlying solution methods and hardware platforms. Normally, no user support or problem-specific validation data are available. Regardless of the software package choice, obtaining an accurate numerical solution requires expertise, training, and understanding of the fundamental aspects of CFD algorithm construction and implementation.

4. OTHER CONSIDERATIONS

Annual Hours of Occurrence of Highest Intake Contamination

To assess the severity of the hazard caused by intake contamination, it is useful to know the number of hours per year that exhaust-to-intake dilution is likely to be lower than some allowable minimum dilution. The first step in making a frequency-of-occurrence estimate is to use the method outlined in Examples 2 and 3 to estimate the minimum dilution versus wind speed at the intake or receptor location of interest. Next, specify the wind speed range at which the dilution is unacceptable. Weather data are then used to calculate the number of hours per year that wind speeds fall in this range for the 22.5° wind direction sector centered on a line joining the exhaust and intake.

Combined Exhausts

When exhaust from several collecting stations is combined in a single vent (as recommended in the section on Exhaust Stack and Air Intake Design Strategies), the plume rise increases because of the higher mass flow in the combined jet and results in significantly lower roof-level intake concentration C_r compared to that from separate exhausts. Where possible, exhausts should be combined before release to take advantage of this increase in overall dilution. For example, consider a single fume hood exhaust stack at 0.5 m^3/s with a 15.24 m/s exit velocity (A_e = 0.1 m) versus 10 such fume hoods combined into a single stack at 5 m^3/s and 15.24 m/s (A_e = 1 m). The F_m term in Equation (7) is proportional to the exhaust velocity times the exhaust area. For this example, F_m would increase by a factor of 10. Based on Equation (7), the plume rise would increase by a factor of $(10)^{0.33}$, or 2.1.

Ganged Exhausts

Greater plume rise and dilution can be achieved by grouping individual stacks close together. Petersen and Reifschneider (2008) summarized ASHRAE research project RP-1167 on this topic and provided a method for calculating the plume rise and subsequent dilution for ganged stacks, to optimize stack arrangements. They found that, when stacks are nearly touching, the momentum terms for the individual stacks can add together and Equation (7) can be used to compute plume rise for ganged arrangements. If stacks are situated up- and downwind of each other, the F_m terms can also be added for quite large separation distances. If the stacks are not up- or downwind of each other, the paper presents an equation that can used to estimate the fraction of the momentum that can be added. This is a particularly advantageous strategy when a dedicated low-flow exhaust is needed that has toxic chemicals. This stack can be placed next to any high-flow stack and achieve the same plume rise and resulting high dilution.

Influence of Architectural Screens on Exhaust Dilution

Architectural screens are often placed around rooftop equipment to reduce noise or hide equipment. Unfortunately, these screens interact with windflow patterns on the roof and can adversely affect exhaust dilution and thermal efficiency of equipment inside the screen. This section describes a method to account for these screens by modifying the physical stack height h. Architectural screens generate flow recirculation regions similar to those shown downwind of the building and penthouse in Figure 1. These screens are often made of porous materials with mesh or louvers, which influence the height of the recirculation cavity above the screens.

To incorporate the effect of architectural screens into existing dilution prediction equations, use the stack height reduction factor F_h. Stack height h_s above the roof must be multiplied by F_h when the stack is enclosed within a screen (Petersen et al. 1999). Effective stack height $h_{s,eff}$ measured above roof level is

$$h_{s,eff} = F_h h_s \tag{23}$$

The stack height reduction factor F_h is directly related to screen porosity P_s. For stack heights above the top of the screen that are less than 2.5 times the height of the screen,

$$F_h = 0.81 P_s + 0.20 \tag{24}$$

where porosity is

$$P_s = \frac{\text{Open area}}{\text{Total area}} \tag{25}$$

F_h is applied directly to h_s after the required stack height has been calculated, and should be included where the physical stack height is less than 2.5 times the height of the architectural screen.

Example 4. Calculate the required stack height for an uncapped stack with a height of 4.7 m above roof level, surrounded by a 3 m high, 50% porous architectural screen.

Solution: To determine the effect of the 50% porous screen, use Equation (25) with $P_s = 0.5$

$$F_h = 0.81(0.5) + 0.2 = 0.605$$

The screen has reduced the effective stack height from its actual height of 4.7 m to

$$h_{s,eff} = 0.605(4.7) = 2.84 \text{ m}$$

When the effect of the 50% porous screen is added, the 4.7 m stack height is found to behave like a 2.86 m stack. The actual stack height h_s must be increased to account for the screen's effect. This is most easily done by dividing h_s by the stack height reduction factor:

$$h_{s,\,corrected} = \frac{h_s}{F_h} = \frac{4.7}{0.605} = 7.8 \text{ m}$$

The corrected 7.8 m high stack effectively behaves like a 4.7 m tall stack, and should produce the same dilution at downwind air intakes. The correct height should be used for input when estimating dilution.

Emissions Characterization

Typical exhaust sources of concern are fume hoods, emergency generators, kitchens, vivariums, loading docks, traffic, cooling towers, and boilers. Chemical emissions from each source should be characterized to determine a design criterion, or critical concentration. Three types of information are needed to characterize the emissions: (1) a list of the toxic or odorous substances that may be emitted, (2) the health limits and odor thresholds for each emitted substance, and (3) the maximum potential emission rate for each substance.

Recommended health limits C_{health} are based on AIHA *Standard* Z9.5, which specifies air intake concentrations no higher than 20% of acceptable indoor concentrations for routine emission and 100% of acceptable indoor concentrations for accidental releases. Acceptable indoor concentrations are frequently taken to be the minimum short-term exposure limits (STEL) from the American Conference of Governmental Industrial Hygienists (ACGIH), the Occupational Safety and Health Administration (OSHA), and the National Institute of Occupational Safety and Health (NIOSH), as listed in ACGIH. ACGIH also provides odor thresholds.

For laboratories, emission rates are typically based on small-scale accidental releases in fume hoods or in room, either liquid spills or emptying of a lecture bottle of compressed gas. Evaporation from liquid spills is computed from equations in EPA (1992) based on a worst-case spill in a fume hood or a room. Compressed gas leaks typically assume a fractured lecture bottle empties in one minute. For other sources, such as emergency generators, boilers, and vehicles, chemical emissions rates are often available from the manufacturer.

For general laboratory design purposes, Chapter 17 provides an example emission characterization (i.e., design criterion). A 7.5 L/s chemical emission rate (e.g., from a liquid spill or lecture bottle fracture) is assumed, along with a limiting concentration of 3 mg/kg or less at an intake. For dispersion modeling purposes, the emission characterization can be expressed in SI units as 400 μg/m^3 per g/s, or in dilution units of 1:5000 per 500 L/s of exhaust flow. Chapter 17 includes the following disclaimers regarding this design criterion: (1) laboratories using extremely hazardous substances should conduct a chemical-specific analysis based on published health limits, (2) a more lenient limit may be justified for laboratories with low levels of chemical usage, and (3) project-specific requirements must be developed in consultation with the safety officer.

Chapter 17's criterion may be put into perspective by considering the as-manufactured and as-installed chemical hood containment requirements outlined in ANSI/AIHA *Standard* Z9.5-2003 (i.e., a concentration at a manikin outside the chemical hood of 0.05 ppm or less for as-manufactured, and 0.10 ppm or less for as-installed, with a 0.07 L/s accidental release in the hood as measured using the ASHRAE *Standard* 110-2016 test method). The as-manufactured requirement is equivalent to a design criterion of 750 μg/m^3 per g/s, and the as-installed requirement is equivalent to a design criterion of 1500 μg/m^3 per g/s. Hence, the ASHRAE criterion for a manikin representing a worker outside the chemical hood is 1.9 to 3.8 times less restrictive than that for the air intake or other outdoor locations. It seems reasonable that the air intake has more strict criteria, because the worker at the chemical hood can shut the hood or walk away to avoid adverse exposure. Also, the ASHRAE *Standard* 110-2016 test is not necessarily a worst-case exposure scenario for the worker.

SYMBOLS

A_e = stack or exhaust exit face area, m^2
B_L = larger of two upwind building face dimensions H and W, m
B_s = smaller of two upwind building face dimensions H and W, m
C = contaminant mass concentration at receptor at ambient air temperature T_e, Equation (11), kg/m^3
C_{allow} = allowable concentration of contaminant at receptor, Equation (12)
C_e = contaminant mass concentration in exhaust at exhaust temperature T_e, Equation (11), kg/m^3
C_r = maximum mass concentration, kg/m^3
D = dilution factor between source and receptor mass concentrations, Equation (11)
D_{crit} = critical dilution factor at roof level for uncapped vertical exhaust at critical wind speed $U_{H,crit}$ that produces smallest value of D_r for given exhaust-to-intake distance S and stack height h_s
D_r = roof-level dilution factor D at given wind speed for all exhaust locations at same fixed distance S from intake, Equation (19)
D_{req} = atmospheric dilution required to meet allowable concentration of contaminant C_{allow}, Equation (12)
D_s = dilution at a wall or roof intake from a flush exhaust grille or louvered exhaust, Equation (23)
D_v = dilution factor between source and receptor using volume fraction concentrations, Equation (15)
d_e = effective exhaust stack diameter, Equation (8), m
F_h = stack height adjustment factor to adjust existing stack height above screen for influence of screen of exhaust gas dilution, Equation (25)
F_m = momentum flux, m^4/s^2
f = contaminant volume concentration fraction at receptor; ratio of contaminant gas volume to total mixture volume, Equation (15), ppm × 10^{-6}
f_e = contaminant volume concentration fraction in exhaust gas; ratio of contaminant gas volume to total mixture volume, Equation (14), ppm × 10^{-6}
H = building height above ground level, m
H_c = maximum height above roof level of upwind roof edge flow recirculation zone, Equation (1), m
H_{met} = anemometer height, m
h_d = downwash correction to be subtracted from stack height, Equation (9), m
h_f = final plume rise, m
h_{plume} = final plume height, Equation (18), m
h_r = plume rise of uncapped vertical exhaust jet, Equation (7), m
h_s = physical exhaust stack height (typically above roof unless otherwise specified), m
h_{sc} = required height of capped exhaust stack to avoid excessive intake contamination, Equation (10), m
$h_{s,eff}$ = effective exhaust stack height above roof on which it is located, corrected for an architectural screen surrounding the stack, Equation (24), m
h_{top} = height of highest of intake, active obstacle, or recirculation zone on a rooftop between the stack and intake, Equation (17), m
h_x = plume rise at downwind distance x, m
i_y = lateral turbulence intensity
i_z = vertical turbulence intensity
L = length of building in wind direction, Figure 5, m
L_c = length of upwind roof edge recirculation zone, Equation (3), m
L_r = length of flow recirculation zone behind rooftop obstacle or building, Equation (4), m
$\dot{m}$ = contaminant mass release rate, Equation (13), kg/s
P_s = porosity of an architectural screen near a stack, Equation (26)
Q = contaminant volumetric release rate, Equation (14), m^3/s
Q_e = total exhaust volumetric flow rate, Equation (13), m^3/s
R = scaling length for roof flow patterns, Equation (5), m
S = stretched string distance from exhaust to intake, m
T_a = outdoor ambient air absolute temperature, Equation (16), K
T_e = exhaust air mixture absolute temperature, Equation (16), K
U_* = friction velocity, m/s
U_H = mean wind speed at height H of upwind wall in undisturbed flow approaching building, Equation (7), m/s
$U_{H,crit}$ = critical wind speed that produces smallest roof-level dilution factor D_{crit} for uncapped vertical exhaust at given X and h_s, m/s
V_e = exhaust gas velocity, Equation (13), m/s
W = width of upwind building face, m
X_c = distance from upwind roof edge to H_c, Equation (2), m
x = horizontal distance from upwind roof edge where recirculation region forms in direction of wind, m
x = downwind horizontal distance from center of stack, Equations (20) and (21), m
y = cross-wind distance off the plume centerline, m
z = vertical distance, m
z_o = surface roughness length, m
Z_1 = height of flow recirculation zone boundary above roof, Figure 6, m
Z_2 = height of high-turbulence zone boundary above roof, Figure 6, m
Z_3 = height of roof edge wake boundary above the roof, Equation (6) and Figure 6, m

Greek

β = capping factor; 1.0 for vertical uncapped roof exhaust; 0 for capped, louvered, or downward-facing exhaust
β_j = jet entrainment coefficient
ζ = vertical separation above h_{top}, Equation (17), m
σ_o = standard deviation of initial plume spread at the exhaust used to account for initial dilution, Equation (20), m
σ_y = standard deviation of cross-wind plume spread, Equation (20), m
σ_z = standard deviation of vertical plume spread, Equation (21), m

CHAPTER 47

AIR CLEANERS FOR GASEOUS CONTAMINANTS

Terminology 47.1
Gaseous Contaminants 47.3
Problem Assessment 47.7
Contaminant Reduction Strategies 47.8
Contaminant Removal by Ventilation Air Cleaning 47.8
Equipment 47.11
Air Cleaner System Design 47.12
Safety 47.17
Installation, Start-Up, and Commissioning 47.18
Operation and Maintenance 47.18
Environmental Influences on Air Cleaners 47.19
Testing Media, Equipment, and Systems 47.19

THE purpose of gas-phase (molecular) filtration is to remove air contaminants that could adversely affect the occupants, processes, or contents of a space. The effects are problematic at different concentration levels for different contaminants. There are four categories of harmful effects: toxicity, odor, irritation, and material damage. In most cases, contaminants become annoying through irritation or odor before they reach levels toxic to humans, but this is not always true. For example, the potentially deadly contaminant carbon monoxide has no odor. More information on gaseous contaminants and odors can be found in Chapters 11 and 12 of the 2017 *ASHRAE Handbook—Fundamentals.*

Indoor gaseous contaminant levels can sometimes be reduced with ventilation air drawn from outdoors, diluting the contaminants to acceptable levels. However, available outdoor air itself may contain undesirable gaseous contaminants at unacceptable concentrations. If so, it requires treatment by gaseous contaminant removal equipment before being used for ventilation. In addition, minimizing outdoor airflow, as specified in ASHRAE *Standard* 62.1's IAQ procedure, by using a high recirculation rate and filtration is an attractive means of energy conservation. However, recirculated air cannot be made equivalent to fresh outdoor air by removing only particulate contaminants. Noxious, odorous, and toxic contaminants must also be removed by gaseous contaminant removal equipment, which is frequently different from particulate filtration equipment.

This chapter covers design procedures for gaseous contaminant air-cleaning systems for occupied spaces only. Procedures discussed are appropriate to address odors and gaseous irritants. Removal of contaminants for the express purpose of protecting building occupants (whether against deliberate attack or industrial accidents) or to protect artifacts (e.g., in museums) requires application of the same design principles, but applied more rigorously and with great emphasis on having specific design and performance data, providing redundancy, and added engineering safety factors. Design for protection is not a focus of this chapter, although published design guidance is included and referenced; for more detail, see Chapter 61. Aspects of air-cleaning design for museums, libraries, and archives are included in Chapter 24, and removal of gaseous contaminants from industrial processes and stack gases is covered in Chapter 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. TERMINOLOGY

In particular, gaseous contaminant control technology performance is a function of (1) the specific contaminant, (2) its concentration, (3) airflow rate, and (4) environmental conditions. The terminology related to gaseous contaminant air-cleaning equipment is specific to the field, and some terms that are familiar from particle filtration differ slightly in this context.

Absorption. Transport and dissolution of a sorbate into an absorbent to form a homogeneous mixture having the characteristics of a solution. It is important to distinguish absorption from the surface phenomenon of **adsorption**, which is one of the most important processes in operation of air cleaners that remove gaseous contaminants.

Activated Carbon. Carbon, usually in the form of granules, treated to enhance its surface area and consequent ability to adsorb gases through a highly developed pore structure.

Activity. Mass of contaminant contained in a physical adsorbent at saturation, expressed as a percentage or fraction of the adsorbent mass (i.e., grams contaminant/grams adsorbent). Activity is an equilibrium property under particular challenge conditions, and is not a function of airflow. (In most cases, commercial bed filters are changed for efficiency reasons well before the adsorbent is saturated.) If a saturated adsorbent bed is then exposed to clean air, some of the adsorbed contaminant will desorb. Activity is generally greater than receptivity.

Adsorbent. Any solid having the ability to concentrate significant quantities of other substances on its surface.

Adsorption. Process in which the molecules of a gas or vapor adhere by physical or chemical processes to the exposed surface of solid substances (both the outer surface and inner pore surface) with which they come into contact.

Adsorption, Chemical (Chemisorption). Binding of a contaminant to the surface of an adsorbent by forces with energy levels approximately those of a chemical bond. Chemisorption is an irreversible process.

Adsorption, Physical. Attraction of a contaminant to the surface, both outer surface and inner pore surface, of adsorbent media by physical forces (Van der Waals forces). Physical adsorption is a reversible process.

Adsorption Capacity. The amount (mass or moles) of a selected contaminant that can be contained in the media of a gas-phase air-cleaning device under given test conditions and end point.

Adsorbent, Regenerated. Adsorbent material which, after saturation, may be treated to recover its adsorption properties and thereby enabled for reuse.

Adsorption Isotherm. A curve obtained by plotting, at constant temperature, the quantity of adsorbate against the concentration of the substance in the original gas or solution.

Breakthrough. Point in the operating cycle of a gas-phase air-cleaning device at which the effluent contaminant concentration becomes measurable. Thereafter, the effluent concentration may rise rapidly.

Breakthrough Curve. Plot of contaminant penetration through the air cleaner versus time for a particular challenge concentration and airflow.

Breakthrough Time. Operating time (at constant operating conditions) before a certain penetration is achieved. For instance, the 10% breakthrough time is the time between beginning to challenge a physical adsorbent or chemisorbent and the time at which air

The preparation of this chapter is assigned to TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment.

discharged contains 10% of the contaminant feed concentration. Continued operation leads to 50% and eventually to 100% breakthrough, at which point a physical adsorbent is saturated. For a chemisorbent, the media is exhausted. (Some commercial devices are designed to allow some of the challenge gas to bypass the adsorbent. These devices break through immediately, and breakthrough time, as defined here, does not apply.)

Capacity. See **Adsorption Capacity**.

CAS Number. An identification number unique to each individual chemical, specified by the Chemical Abstracts Service (CAS), a division of the American Chemical Society (ACS).

Catalyst. Any substance that, when present in a small quantity, significantly affects the rate of a chemical reaction without itself being consumed or undergoing a chemical change. Most catalysts accelerate reactions, but a few retard them (negative catalysts, or inhibitors).

Channeling. The disproportionate or uneven flow of fluid (gas or liquid) through passages of lower resistance that can occur in fixed beds or columns of granular media because of nonuniform packing, irregular sizes and shapes of media, gas pockets, wall effects, and other causes.

Challenge (Air) Stream. Test contaminant(s) of interest diluted to the specific concentration(s) of the test prior to filtration.

Chemisorbent Media. Media formed when an adsorbent such as activated alumina, zeolite, or activated carbon is treated with a chemical reagent such as potassium permanganate, potassium hydroxide, or phosphoric acid. Adsorbates are removed by a reaction with the chemical reagent.

Concentration. Quantity of one substance dispersed in a defined amount of another. Concentrations of contaminants in air are usually expressed as parts per million by volume (ppmv) or as milligrams of contaminant per cubic metre of air (mg/m^3).

Density, Apparent (Bulk Density). Mass under specified conditions of a unit volume of a solid physical adsorbent or chemisorbent, including its pore volume and interparticle voids.

Desorption. Process by which adsorbed molecules leave the surface of a physical adsorbent and reenter the fluid stream. This process is the opposite of adsorption.

Efficiency. See **Removal Efficiency**.

Efficiency Curve. Plot of contaminant removal efficiency against time for a particular challenge concentration and airflow.

Equilibrium Capacity. See **Adsorption Capacity**.

HEPA Filter. High-efficiency particle air filter that has performance compliant with requirements of filter class ISO 35H to ISO 45H (per ISO 29463-1).

Mass Transfer Zone. Depth of physical adsorption or chemisorption media required to remove essentially all of an incoming contaminant; dependent on type of media, media granule size, contaminant nature, contaminant inlet concentration, and environmental conditions.

Mean Particle Diameter. Weighted average particle size, in millimeters, of a granular adsorbent; computed by multiplying the percent retained in a size fraction by the respective mean sieve openings, summing these values, and dividing by 100.

Media. Granular or pelletized physical adsorbent (or chemisorbent) used in gaseous contaminant air-cleaning equipment. Also used to refer to a material (e.g., a nonwoven) that contains a physical adsorbent or chemisorbent.

Penetration. Ratio of contaminant concentration downstream of the media bed to the upstream (challenge) concentration, sometimes expressed as a percentage. Related to fractional efficiency by the expression Efficiency = (1 – Penetration). Unlike particulate filters, physical adsorbents and chemisorbents both decline in efficiency as they load. The decline can be very sudden, and is usually not linear with time.

Pressure Drop. Difference in absolute (static) pressure between two points in an airflow system, caused by frictional resistance to airflow in a duct, filter, or other system component such as a media bed or air-cleaning device.

Reactivation. Treatment of carbon with elevated temperature and steam to remove the volatiles that have been adsorbed on the carbon, so that the adsorbent can be reused.

Regeneration. The process of treating carbon thermally or chemically to extend its life.

Removal Efficiency. Fraction or percentage of a challenge contaminant that is removed by the air-cleaner media bed at a given time. Removal efficiency is also known simply as "efficiency."

Residence Time. Theoretical time period that a contaminant molecule is within the boundaries of the media bed of a physical adsorbent or chemisorbent. The longer the residence time, the higher the efficiency. For gaseous contaminant removal equipment, residence time is computed as

$$\text{Residence time (s)} = \frac{\text{Bed area exposed to airflow} \times \text{Bed depth}}{\text{Airflow rate}} \quad (1)$$

For commercial gaseous contaminant air cleaners, residence time computation neglects the fact that a significant fraction of the volume of the bed is occupied by the media. For example, a unitary adsorber containing trays totaling 4 m^2 media in a 25 mm deep bed, challenged at 1 m^3/s, has a residence time of 0.1 s. Given this definition, a deeper media bed, lower airflow rate, or media beds in series increase residence time and thus performance. Because gaseous contaminant air cleaners all tend to have approximately the same granule size, residence time is a generally useful indicator of performance. In some engineering disciplines, the media volume is subtracted from the nominal volume of packed beds when calculating residence time. This gives a shorter residence time value and is not normally used for HVAC. A minimum 0.07 s residence time for physical adsorbents, and 0.1 s for chemisorbents, provides for a minimum 95% contact time.

Different ways of arranging the media, different media, or different media granule sizes all can change the effective residence time because of their effect on the volume of the bed occupied by the media. The geometry and packaging of some technologies makes computation of residence time difficult. For example, the flow pattern in pleated fiber-carbon composite media is difficult to specify, making residence time computation uncertain. Therefore, although residence times can be computed for partial-bypass filters, fiber-adsorbent composite filters, or fiber-bonded filters, they cannot be compared directly and may serve more as a rating than as an actual residence time. Manufacturers might publish equivalent residence time values that say that a particular physical adsorbent or chemisorbent performs the same as a traditional deep-bed air cleaner, but no standard test exists to verify such a rating.

Retentivity. Measure of the ability of a physical adsorbent or gas-phase air-cleaning (GPAC) device to resist desorption of an adsorbate. It is usually stated as a percentage or fraction of the adsorbent mass and calculated as the residual capacity (fraction remaining) after purging the adsorbent with clean, conditioned air, following the challenge breakthrough. Retentivity is generally less than activity.

Sorbate. A material that has been or is capable of being taken up by another substance through either absorption or adsorption.

Saturation. State of a physical adsorbent when it contains all the contaminant it can hold at the challenge concentration, temperature, and humidity of operation.

Vapor (Vapor-Phase Contaminant). Substance whose vapor pressure is less than the ambient pressure at ambient temperature but is present in the gas phase by evaporation or sublimation.

Volatile Organic Compound (VOC). Chemical belonging to the medium-volatility subset of the organic compounds that can be

present in indoor air under normal indoor atmospheric conditions of temperature and pressure; specifically, an organic compound with a saturation vapor pressure greater than 10^{-2} kPa at 25°C.

2. GASEOUS CONTAMINANTS

Ambient air contains nearly constant amounts of nitrogen (78% by volume), oxygen (21%), and argon (0.9%), with varying amounts of carbon dioxide (about 0.04%) and water vapor (up to 3.5%). In addition, trace quantities of inert gases (neon, xenon, krypton, helium, etc.) are always present.

Gases and vapors other than these natural constituents of air are usually considered to be gaseous contaminants. Their concentrations are almost always small, but they may have serious effects on building occupants, construction materials, or contents. Removing these gaseous contaminants is often desirable or necessary.

Sources of nonindustrial contaminants are discussed in Chapter 11 in the 2017 *ASHRAE Handbook—Fundamentals*. However, for convenience, data on some of the contaminants in cigarette smoke (Table 1), and some common contaminants emitted by building materials (Table 2), indoor combustion appliances (Table 3), office equipment (Table 4), and occupants (Table 5) are provided here.

Table 6 gives typical outdoor concentrations for gaseous contaminants at urban sites; however, these values may be exceeded if the building under consideration is located near a fossil fuel power plant, refinery, chemical production facility, sewage treatment plant, municipal refuse dump or incinerator, animal feed lot, or other major source of gaseous contaminants. If such sources have a significant influence on the intake air, a field survey or dispersion model must be run. Many computer programs have been developed to expedite such calculations.

Using Source Data to Predict Indoor Concentrations

Source data such as those in Tables 1 to 5 provide the type of raw information on which air-cleaning system designs can be based in addition to indicating which parameters to measure. Outdoor air contaminants enter buildings through the outdoor air intake and through infiltration. The indoor sources enter the occupied space air and are distributed through the ventilation system. If measurements are not available, source data can be used to predict the contaminant challenge to air-cleaning systems using building air quality models. The following relatively simple published model is intended as an introduction to the topic.

Meckler and Janssen (1988) described a model for calculating the effect of outdoor pollution on indoor air quality, which is outlined in this section and provided in the appendix of ASHRAE *Standard* 62.1 and 62.2.

A recirculating air-handling schematic is shown in Figure 1. In this case, mixing is not perfect; the horizontal dashed line represents the boundary of the region close to the ceiling through which air passes directly from the inlet diffuser to the return air intake. Ventilation effectiveness E_v is the fraction of total air supplied to the space that mixes with room air and does not bypass the room along the ceiling. Meckler and Janssen suggest a value of 0.8 for E_v. Any people in the space are additional sources and sinks for gaseous contaminants. In the ventilated space, the steady-state contaminant concentration results from the summation of all processes adding contaminants a to the space divided by the summation of ventilation and other processes removing contaminants b. The steady-state concentration C_{ss} for a single component can be expressed as (Meckler and Janssen 1988)

$$C_{ss} = a/b = \frac{\text{Contaminant insertion into space}}{\text{Contaminant removal from space}} \quad (2)$$

where

C_{ss} = steady-state contaminant concentration, µg/m^3
a = contaminants inserted into space, µg/s
b = contaminants removed from space, µg/s

For the occupied space, the parameters for insertion of the contaminant into the occupied space are

$$a = NG_O + Q_iC_x + G + (E_vPQ_vC_x)/f - k_nA \quad (3)$$

where

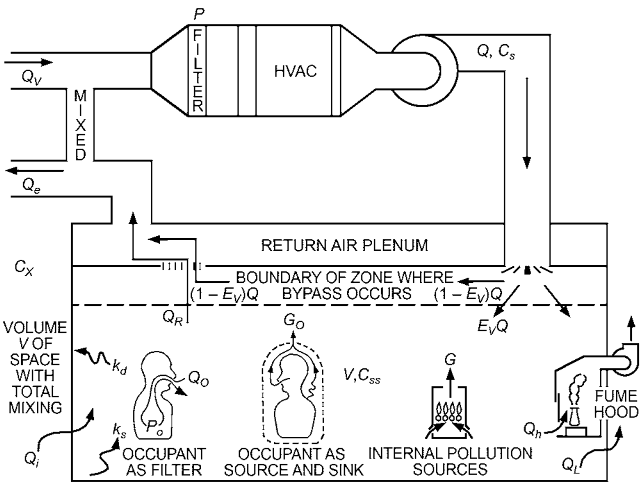
N = number of occupants
G_O = generation rate of contaminant by an occupant, μg/(s·person)
Q_i = infiltration flow, m³/s
C_x = outdoor concentration of contaminant, μg/m³
G = generation rate of contaminant by nonoccupant sources, μg/s
E_v = ventilation effectiveness (fraction of supply air passing through bypass boundary zone into occupied space)
P = HVAC filter penetration by contaminant, fraction
Q_v = ventilation airflow, m³/s
f = $1 - P(1 - E_v)$ = factor arising from mixing outdoor and recirculated air in the air-handling unit, fraction
k_n = difference of k_d and k_s= net deposition on surfaces for the contaminant, μg/h·m²
A = surface area inside the occupied space on which contaminant can be adsorbed or desorbed, m²

The parameters associated with removal of contaminant from the space are

$$b = Q_L + Q_h + NQ_O(1 - P_O) + (E_vQ - Q_v)(1 - P)/f + Q_e \quad (4)$$

where

Q_L = leakage (exfiltration) flow, m³/s



A = surface area inside occupied space on which contaminant can be adsorbed or desorbed, m²
V = volume of occupied zone, m³
C_{ss} = steady state contaminant concentration in occupied zone, μg/m³
C_s = concentration of contaminant in supply air, μg/m³
C_x = outdoor concentration of contaminant, μg/m³
G = generation rate for contaminant by nonoccupant sources, μg/s
G_O = generation rate for contaminant by an occupant, μg/(s·person)
N = number of occupants
E_v = ventilation effectiveness (fraction of supply air passing through bypass boundary zone into occupied space), fraction
f = $1 - P(1 - E_v)$ = factor arising from mixing of outdoor and recirculated air in air-handling unit, fraction
k_s = contaminant emission rate for occupied zone surfaces, μg/h·m²
k_d = contaminant deposition rate for occupied zone surfaces, μg/h·m²
k_n = difference of k_d and k_s = net deposition on surfaces for contaminant, μg/h·m²
P = HVAC filter penetration by contaminant, fraction
P_O = fraction of contaminant exhaled from human lung, fraction
Q = total supply airflow, m³/s
Q_e = exhaust airflow, m³/s
Q_v = ventilation airflow, m³/s
Q_h = hood airflow, m³/s
Q_i = infiltration airflow, m³/s
Q_L = leakage (exfiltration) airflow, m³/s
Q_O = average respiratory airflow for single occupant, m³/s

Fig. 1 Recirculatory Air-Handling System with Gaseous Contaminant Modifiers

Q_h = hood flow, m³/s
N = number of occupants
Q_O = average respiratory flow for single occupant, m³/s
P_O = penetration of contaminant through human lung, fraction
Q = total flow, m³/s
Q_v = ventilation (makeup) airflow, m³/s
P = filter penetration for contaminant, fraction
Q_e = exhaust airflow, m³/s

The steady-state contaminant concentration is of interest for both system design and filter sizing. Laying out the equation for the steady-state concentration with all of the parameters, Equation (2), with substitutions of Equations (3) and (4), becomes

$$C_{ss} = \frac{NG_O + Q_iC_x + G + (E_vPQ_vC_x)/f - k_nA}{Q_L + Q_h + NQ_O(1 - P_O) + (E_vQ - Q_v)(1 - P)/f + Q_e} \quad (5)$$

The following assumptions are made for this model:

- No removal of contaminant by HVAC system elements (with the exception of the filter) and ductwork
- No contaminant interactions in the air
- No removal of contaminants by occupants other than through breathing
- Occupied space is perfectly mixed

The parameters for this model must be evaluated carefully so that nothing significant is ignored. Leakage flow Q_L, for example, may include flow up chimneys or toilet vents.

It may also help to know how rapidly concentration changes when conditions change suddenly. The dynamic equation for the building in Figure 1 is

$$C_\theta = C_{ss} + (C_0 - C_{ss})e^{-b\theta/V} \quad (6)$$

where

C_θ = concentration in space θ minutes after a change of conditions
C_0 = concentration in space at time θ = 0
V = volume of the ventilated space, m³
b = volume per unit time
θ = time

with C_{ss} given by Equation (2), and b by Equation (4).

Reducing air infiltration, leakage, and ventilation air to reduce energy consumption raises concerns about indoor contaminant buildup. A low-leakage scenario may be simulated by letting $Q_i = Q_L = Q_h = 0$. Then the steady-state concentration becomes

$$C_{ss} = \frac{NG_O + G + [(E_vPQ_vC_x)/f] + k_nA}{NQ_O(1 - P_O) + [(E_vQ - Q_v)(1 - P)/f] + Q_e} \quad (7)$$

Even if there is no ventilation airflow ($Q_v = 0$), a low-penetration (high-efficiency) gaseous contaminant filter and a high recirculation rate help lower the internal contaminant concentration. In most structures infiltration and exfiltration are never zero. The only inhabited spaces operating on 100% recirculated air are space capsules, undersea structures and vehicles, and structures with life support (to eliminate carbon dioxide and carbon monoxide and supply oxygen).

Outdoor air contaminant concentrations and the emission rates of the internal sources are generally unsteady in nature. Buildings may also have multiple rooms within a building zone, with multiple and varying sources of gaseous contaminants and complex room-to-room air changes. In addition, mechanisms other than adsorption may eliminate gaseous contaminants on building interior surfaces. Nazaroff and Cass (1986) provide estimates for contaminant deposition and emission velocities k_d and k_s that range from 3 to 600 μm/s for surface adsorption only. A worst-case analysis, yielding the highest estimate of indoor concentration, is obtained by setting the deposition velocity on surfaces to zero. EPA at www.epa.gov/air-research/simulation-tool-kit-indoor-air-quality-and-inhalation-exposure-iaqx) are available to handle these calculations. Details on multizone modeling and computational fluid dynamics (CFD) modeling can also be found in Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*.

The assumption of bypass and mixing used in the model presented here can be used to approximate the multiple-room case, because gaseous contaminants are readily dispersed by airflow. Also, a gaseous contaminant diffuses from a location of high concentration to one of low concentration, even with low rates of turbulent mixing.

Quantities appropriate for the flows in Equations (2) to (5) are discussed in the Local Source Management and Dilution Through General Ventilation sections. Infiltration flow can be approximated by the techniques described in Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals* or, for existing buildings, by tracer or blower-door measurements. ASTM *Standard* E741 defines procedures for tracer-decay measurements. Tracer and blower-door techniques are given in ASTM (2017); DeFrees and Amberger (1987) describe a variation on the blower-door technique useful for large structures.

To assist in understanding how the equations can be applied, an example is included for the steady-state concentration C_{ss}, in this

case, toluene. The example conditions are for an occupied conference room of $6.096 \times 12.192 \times 3.048$ m containing 100 people (the bypass zone above is of undetermined height and does not need to be specified further). The following parameters are used, and the calculation is performed in SI units:

A = surface area inside ventilated space on which contaminant can be adsorbed, 260.13 m^2
E_v = ventilation effectiveness = 0.8
G = generation rate for contaminant by nonoccupant sources, 0.0 μg/s
G_O = generation rate for contaminant by an occupant, 0.00639 μg/(s·person)
k_n = deposition velocity on a for contaminant, 3 μg/h·m^2
N = number of occupants, 100
C_x = outdoor concentration of contaminant, 20 μg/m^3
P = filter penetration for contaminant, 0.75
P_O = penetration of contaminant through human lung, 0.5
Q = total flow, 0.8 m^3/s
Q_O = average respiratory flow for a single occupant, 8 L/min = 1.33×10^{-4} m^3/s
Q_v = ventilation (makeup) airflow, 8 L/s·person = 0.008 m^3/s; for 100 people, Q_v = 0.8 m^3/s

Using these parameters, the steady-state concentration from Equation (7) becomes

Table 6 Typical U.S. Outdoor Concentration of Selected Gaseous Air Contaminants

[a]*Source*: EPA (2009). Note that only statistically viable datasets were used to calculate the national average concentrations, so the numbers may not be fully representative.
[b]*Source*: EPA (2016b).

$$C_{ss} = \frac{(100)(0.00639) + [(0.8 \times 0.75 \times 0.8 \times 20)/0.85]}{(100)(0.0001333)(0.5) + [(0.8 \times 0.8 - 0.8)(0.25)]/0.85 + 0.8} = \frac{11.933}{0.759} = 15.7\ \mu g/m^3$$

These calculations can help in determining the space concentration of the contaminant but can also be used in determining changes in filtration to modify that concentration.

3. PROBLEM ASSESSMENT

Consensus design criteria (allowable upper limit for any contaminant) do not exist for most nontoxic chemicals. Chapter 10 of the 2017 *ASHRAE Handbook—Fundamentals* discusses health effects of gaseous contaminants and explains the various exposure limits used to protect industrial workers indoors. It also provides limited guidance on acceptable indoor air concentrations in commercial buildings and residences. Chapter 11 of that volume discusses the nature and non-health-related effects of gaseous contaminants, as well as providing some guidance on measuring their concentrations.

Ideally, design for reduction of exposure to gaseous contaminants is based on accurate knowledge of the identity and concentration (as a function of time) of the contaminants and other chemical species that are present, as well as the sources of each contaminant and behavior of the contaminant in the space. This knowledge may come from estimates of source strength, modeling, direct measurement of the sources, or from direct measurements of the contaminant levels in the indoor air. Unfortunately, definitive assessment is seldom possible, so often careful observation, experience, and judgment must supplement data as the basis for design. For instance, certain molecular contaminants may have distinctive odor levels, or have known sources in different geographical regions.

Two general design cases exist: (1) ventilation systems in newly constructed buildings for which contaminant loads must be estimated or measured, and (2) modification of existing ventilation systems to solve particular problems. For the first case, models, such as described in the section on Gaseous Contaminants, must be used. To estimate the contaminants, identify contaminant-generating activities, estimate and sum the building sources, and identify outdoor air contaminants. Gaps in measured contaminant load data must be filled with estimates or additional measurements. Once contaminant loads are identified, design can begin.

To address a particular problem in an existing system, special measurements may also be required to identify the contaminant. Assessing the problem can become an indoor air quality investigation, which may include building inspection, occupant questionnaires, and local sampling and analysis. The *Building Air Quality Guide* (EPA 1991) is a useful basic guide for such investigations. Once the contaminant loads are understood, design can begin.

Contaminant Load Estimates

Valuable guidance on estimating contaminant loads in industrial situations is given by Burton (2003). In the 2017 *ASHRAE Handbook—Fundamentals*, Chapter 11 discusses sampling and measurement techniques for industrial and nonindustrial environments, and Chapter 12 covers evaluating odor levels.

Results of sampling and analysis identify contaminants and their concentrations at particular places and times or over known periods. Several measurements, which may overlap or have gaps in the contaminants analyzed and times of measurement, are usually used to estimate the overall contaminant load. Measurements are used to develop a time-dependent estimate of contamination in the building, either formally through material balance or informally through experience with similar buildings and contaminates. The degree of formality applied depends on the perceived severity of potential effects.

4. CONTAMINANT REDUCTION STRATEGIES

Four contaminant reduction strategies may be used to improve the indoor air quality in a building: (1) elimination of sources or reduction of their emissions, (2) local hood usage with exhaust or recirculated air cleaning, (3) dilution with increased general ventilation, and (4) general ventilation air cleaning with or without increased ventilation rates. For indoor contaminant sources, the first three are usually favored because of cost considerations. Reducing concentrations by general air cleaning is more difficult, because it is applied after the contaminants are fully dispersed and at their lowest concentration. the section on Contaminant Removal by Ventilation Air Cleaning discusses the fourth strategy of general ventilation air cleaning in more detail, so it will not be addressed in this section.

Elimination or Reduction of Emissions

This strategy is the most effective and often the least expensive. For instance, prohibiting smoking in a building or isolating it to limited areas greatly reduces indoor pollution, even when rules are poorly enforced (Elliott and Rowe 1975; Lee et al. 1986). Radon gas levels can be reduced by installing traps in sewage drains, sealing, and subsurface ventilation to prevent entry of the gas (EPA 1987, 1993). Using waterborne materials instead of those requiring organic solvents may reduce VOCs, although Girman et al. (1984) show that the reverse is sometimes true. Substituting carbon dioxide for halocarbons in spray-can propellants is an example of using a relatively innocuous contaminant in place of a more troublesome one. Growth of mildew and other organisms that emit odorous contaminants can be restrained by eliminating or reducing condensation and applying fungicides and bactericides, provided they are registered for the use and carefully chosen to have low offgassing potential.

Local Source Management

Local source management is more effective than using general ventilation when discrete sources in a building generate substantial amounts of gaseous contaminants. If these contaminants are toxic, irritating, or strongly odorous, local capture and outdoor exhaust is essential. Bathrooms and kitchens are the most common examples. Some office equipment benefits from direct exhaust. Exhaust rates are sometimes set by local codes. The minimum transport velocity required for capturing large particles is larger than that required for gaseous contaminants; otherwise, the problems of capture are the same for both gases and particles.

Capture hoods are normally provided with exhaust fans and stacks that vent to the outdoors. Hoods use large quantities of tempered makeup air, which requires a great deal of fan energy, so hoods waste heating and cooling energy. Makeup for air exhausted by a hood should be supplied so that the general ventilation balance is not upset when a hood exhaust fan is turned on. Back diffusion from an open hood to the general work space can be eliminated by surrounding the work space near the hood with an isolation enclosure, which not only isolates the contaminants, but also keeps unnecessary personnel out of the area. Glass walls for the enclosure decrease the claustrophobic effect of working in a small space.

Increasingly, codes require filtration of hood exhausts to prevent toxic releases to the outdoors. Hoods should be equipped with controls that decrease their flow when maximum protection is not needed. Hoods are sometimes arranged to exhaust air back into the occupied space, saving heating and cooling of outdoor air. This practice must be limited to hoods exhausting the most innocuous contaminants because of the risk of filter failure. Design of effective hoods is described in ACGIH (2013) and in Chapter 33 of this volume.

Dilution Through General Ventilation

In residential and commercial buildings, the chief use of local source hooding and exhaust occurs in kitchens, bathrooms, and occasionally around specific point sources such as diazo printers. Where there is no local removal of contaminants, the general ventilation distribution system can sometimes provide contaminant concentration reduction through dilution. These systems must meet both thermal load requirements and contaminant concentration standards. Complete mixing and a relatively uniform air supply per occupant are desirable for both purposes. The air distribution guidelines in Chapters 16, 20, and 21 of the 2017 *ASHRAE Handbook—Fundamentals* are appropriate for contamination reduction by general ventilation. Airflow requirements set by ASHRAE *Standard* 62.1 must be met.

When local exhaust is combined with general ventilation, a proper supply of makeup air must balance the exhaust flow for any hoods present to maintain the desired over or underpressure in the building or in specific rooms. Supply fans may be needed to provide enough pressure to maintain flow balance. For instance, clean spaces are designed so that static pressure forces air to flow from cleaner to less clean spaces, and the effects of doors opening and wind pressure, etc., dictate the need for backdraft dampers. Chapter 19 covers clean spaces in detail.

5. CONTAMINANT REMOVAL BY VENTILATION AIR CLEANING

If eliminating sources, local hooding, or dilution cannot reduce contaminant concentrations to desired levels, or are only partially effective, the air must be cleaned. Designing an air-cleaning system requires understanding of the capabilities and limitations of the processes involved.

Complete and permanent removal of every contaminant is often not necessary. Intermittent nuisance odors, for instance, can often be managed satisfactorily and economically using a design that shaves the peak to below the odor threshold and then slowly releases the contaminant back into the air, still below the odor threshold. On the other hand, such an approach would be inappropriate for a contaminant that affected occupants' health. Design goals are discussed at greater length in the section on Air Cleaner System Design.

Gaseous Contaminant Removal Processes

Many chemical and physical processes remove gases or vapors from air, but those of highest current commercial interest to the HVAC engineer are physical adsorption and chemisorption. The operational parameters of greatest interest are removal efficiency,

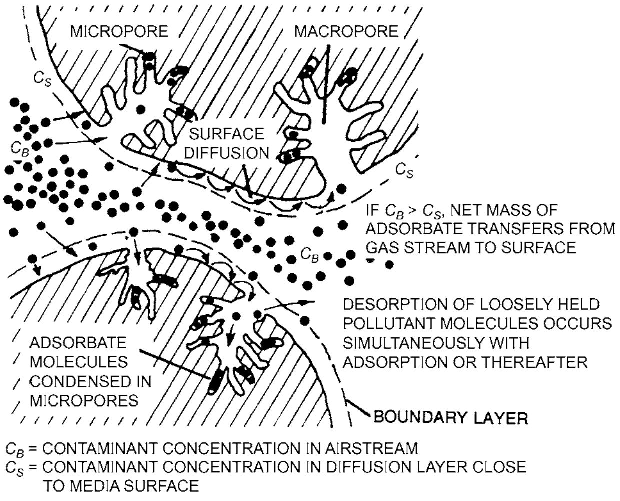

Fig. 2 Steps in Contaminant Adsorption

pressure drop, operational lifetime, first cost, and operating and maintenance cost. Other removal processes have been proposed, but currently have limited application in HVAC work, and are only briefly discussed.

Physical Adsorption. Physical adsorption is a surface phenomenon similar in many ways to condensation. Contaminant gas molecules strike a surface and remain bound to it (adsorbed) for an appreciable time by molecular attraction (van der Waals forces). Therefore, high surface area is crucial for effective adsorbents. Surfaces of gaseous contamination adsorption media are expanded in two ways to enhance adsorption. First, the media are provided in granular, pelletized, or fibrous form to increase the gross surface exposed to an airstream. Second, the media's surface is treated or activated to develop microscopic pores, greatly increasing the area available for molecular contact. These internal pores account for the majority of available surface area in most commercially available adsorbents. Typical activated alumina has a surface area of 200 to 330 m^2 per gram; typical activated carbon has a surface area from 800 to 1600 m^2/g. Pores of various microscopic sizes and shapes form minute traps that can fill with condensed contaminant molecules.

The most common adsorbent granules are millimeter-sized, and the granules are used in the form of packed beds. In general, packed beds composed of larger beaded or pelletized media have slightly lower pressure drops per unit depth of sorbent than those composed of granular or flaked media. On the other hand, the surface area with smaller particles of the adsorbent is more accessible to the contaminant.

Several steps must occur in physical adsorption of a molecule (Figure 2):

1. The molecule is transported from the carrier gas stream across the boundary layer surrounding the adsorbent granule. This occurs randomly, with molecular movement both to and from the surface; the net flow of molecules is toward the surface when the concentration of contaminant in the gas flow is greater than at the granule surface. For this reason, adsorption decreases as contaminant load on the adsorbent surface increases. Very low concentrations in the gas flow also result in low adsorption rates or even reemission of collected contaminants.
2. The molecules of the contaminant diffuse into the pores to occupy that portion of the surface. Diffusion distances are lower and adsorption rates higher for smaller particles of adsorbent.
3. The contaminant molecules are bound to the surface.

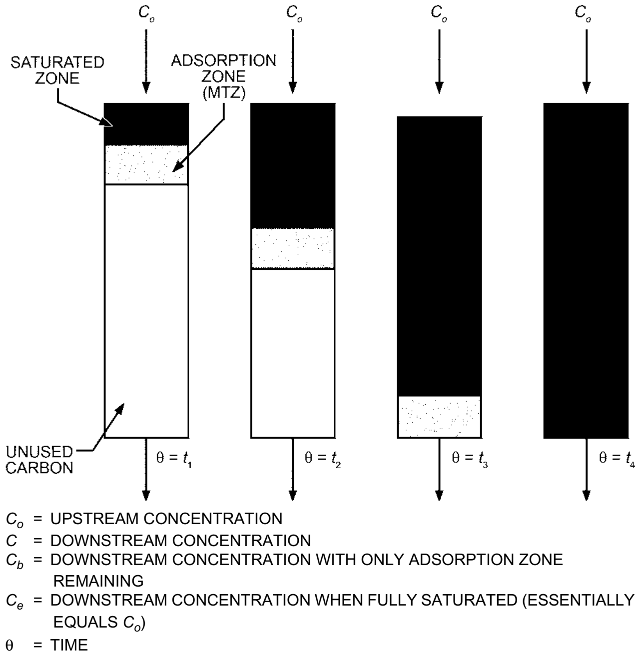

Fig. 3 Dependence of Contaminant Concentration on Bed Depth and Exposure Time

Any of these steps may determine the rate at which adsorption occurs. In general, step 3 is very fast for physical adsorption, but reversible: adsorbed molecules can be desorbed later, either when cleaner air passes through the adsorbent bed or when another contaminant arrives that either binds more tightly to the adsorbent surface or is present at a much higher concentration. Complete desorption usually requires adding thermal energy to the bed.

Providing a sufficient depth of adsorbent and contact time is very important in achieving efficient contaminant removal. When a contaminant is fed at constant concentration and constant gas flow rate through an adsorbent bed of sufficient depth, the gas stream concentration within the bed varies with time θ and bed depth, as shown in Figure 3. In fixed-bed adsorption, at any given time, the bed can be divided into three zones: (1) the saturated zone containing adsorbent nearly saturated (spent) with the contaminants, (2) the adsorption zone, and (3) a zone with unused adsorbent. Distribution of contaminant in an adsorbent bed is often described in terms of an idealized **mass transfer zone (MTZ)**. Conceptually, all contaminant adsorption takes place in the MTZ. Upstream, the adsorbent is spent and the concentration is equal to the inlet concentration. Downstream of the MTZ, all contaminant has already been adsorbed. The movement of the MTZ through the media bed is known as the **adsorption wave**. Though in actuality the front and back of the zone are not sharply defined, for many media/contaminant combinations the MTZ provides a very useful picture of media performance.

The minimum bed depth is based primarily on the length of the **mass transfer zone (MTZ)**, which, at fixed conditions such as temperature, partial pressure, and flow rate, is related to the rate of adsorption. The movement of the MTZ through the adsorbent bed can also be graphically represented as a **breakthrough curve** (Figure 4). When the leading edge of the MTZ reaches the outlet of the bed, the concentration of the contaminant suddenly begins to rise. This is referred to as the **breakthrough point**. Past the breakthrough point, the downstream concentration is at less than 0.1% of the upstream, just as the slope of the curve increases until it reaches an exhaustion point where the bed becomes fully saturated. If the

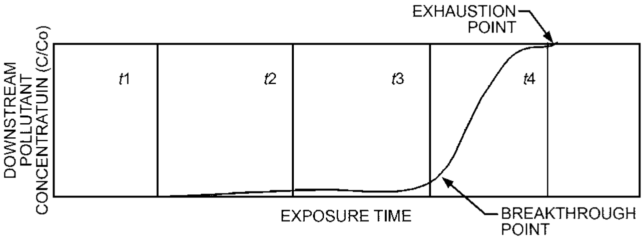

Fig. 4 Breakthrough Characteristics of Fixed-Bed Adsorbents

adsorbent bed depth is shorter than the required MTZ, breakthrough will occur almost immediately, rendering the system ineffective. For protection purposes, any contaminant downstream might be too much; for nuisance odors, staying below the odor threshold might be adequate. The interval between these various breakthrough times could be very short, or more significant, depending on contaminant and media. However, not all adsorbent/contaminant combinations show as sharp a breakthrough as in Figure 4. Breakthrough curves can be used to calculate a number of different properties of the adsorbent system such as breakthrough capacity, degree of utilization, usage rate etc.

Multiple contaminants produce more complicated penetration patterns: individually, each contaminant might behave as shown in Figure 4, but each has its own time scale. The better-adsorbing contaminants are captured in the upstream part of the bed, and the poorer-absorbing are adsorbed further downstream. As the challenge continues, the better-adsorbing compound progressively displaces the other, meaning the displaced component can leave the adsorbent bed at a higher concentration than it entered.

Underhill et al. (1988) and Yoon and Nelson (1988) discuss the effect of relative humidity on physical adsorption. Water vapor acts as a second contaminant, generally present at much higher concentrations than typical indoor contaminants, altering adsorption parameters by reducing the amount of the first contaminant that can be held by the bed and shortening breakthrough times. For solvent-soluble VOCs adsorbed on carbon, relative humidity's effect is modest up to about 50%, and greater at higher percentages. On the other hand, chemicals that dissolve in water may experience increased adsorption into the water layer at high relative humidities.

Chemisorption. The three steps described for physical adsorbents also apply to chemisorption. However, the third step in chemisorption involves chemical reactions with electron exchange between the contaminant molecule and the chemisorbent. This action differs in the following ways from physical adsorption:

- Chemisorption is highly specific; only certain contaminant compounds will react with a particular chemisorbent.
- Chemisorption is not reversible. Once the adsorbed contaminant has reacted, it is not desorbed. However, one or more reaction products, different from the original contaminant, may be formed in the process, and these reaction products may enter the air as new contaminants.
- Water vapor often helps chemisorption or is necessary for it, whereas it usually hinders physical adsorption.
- Chemisorption per se is a monomolecular layer phenomenon; the pore-filling effect that takes place in physical adsorption does not occur, except where adsorbed water condensed in the pores forms a reactive liquid.

Most chemisorbent media are formed by coating or impregnating a highly porous, nonreactive substrate (e.g., activated alumina, zeolite, or carbon) with a chemical reactant (e.g., acids, bases, or

Table 7 Comparison of Physical Adsorption and Chemisorption

Physical Adsorption	Chemisorption
Forces operating are weak van der Waal's forces.	Forces operating are similar to those of a chemical bond.
Heat of adsorption is low (about 20 to 40 kJ mol^{-1}).	Heat of adsorption is high (about 40 to 400 kJ mol^{-1}).
No compound formation takes place.	Surface compounds are formed.
Process is reversible; desorption of gas occurs by increasing temperature or decreasing pressure.	Process is irreversible.
Process does not require any activation energy.	Process requires activation energy.
Adsorption decreases with increase of temperature.	Adsorption increases with increasing temperature.
Process is not specific in nature: all gases are adsorbed on all solids to some extent, though some compounds are adsorbed better than others.	Process is semispecific in nature and occurs only when there is some possibility of compound formation between the gas being adsorbed and the solid adsorbent.
Process forms a multimolecular layer.	Process forms a unimolecular layer.

Adapted from www.thebigger.com/chemistry/surface-chemistry/distinguish-between-physical-adsorption-and-chemisorption/

oxidizing chemicals). The reactant will eventually become exhausted, but the substrate may have physical adsorption ability that remains active when chemisorption ceases.

General Considerations. Physical adsorption and chemisorption are the removal processes most commonly used in gaseous contaminant filtration. In most cases, the processes for both involve media supplied as granules, flakes, or pellets, which are held in a retaining structure that allows air being treated to pass through the media with an acceptable pressure drop at the operating airflow. Granular media are traditionally a few millimetres in all dimensions, typically on the order of 4 × 6 or 4 × 8 U.S. mesh pellets or flakes. Table 7 summarizes the differences between physical adsorption and chemisorption.

Other Processes. Although physical adsorption and chemisorption are the most frequently used, the following processes are used in some applications.

Liquid absorption devices (scrubbers) and **combustion devices** are used to clean exhaust stack gases and process gas effluent. They are not commonly applied to indoor air cleanup. Additional information may be found in Chapter 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Catalysts can clean air by stimulating a chemical reaction on the surface of the media. **Catalytic combustion** or **catalytic oxidation (CatOx)** oxidizes moderate concentrations of unburned hydrocarbons in air. In general, the goal with catalytic oxidation is to achieve an adequate reaction rate (contaminant destruction rate) at ambient temperature. Reaction products are a concern, because oxidation of VOCs other than hydrocarbons or other reactions can produce undesirable by-products such as nitrogen-, sulfur-, and chlorine-containing gases. This technology has been used industrially for years, but its potential use for indoor air cleaning is relatively new. Equipped with custom catalysts and operated at elevated pressures and temperatures, CatOx can be extremely effective at the removal of indoor contaminants, but is not currently cost-competitive in commercial indoor air or HVAC applications, especially if removal of undesirable by-products is required. Availability of waste heat significantly improves CatOx cost competitiveness. CatOx systems have potential application in security and protection applications.

Photocatalysis (or **photocatalytic oxidation [PCO]**) uses light (usually ultraviolet [UV]) and a photocatalyst to perform **reduction-oxidation (redox)** chemistry on the catalyst's surface as first observed and reported by Fujishima and Honda (1972). The photocatalyst can be granular, bulk, or unsupported, or it can be supported as a thin film on media such as glass, polymer, ceramic, or metal. However, supported photocatalysts are generally used for air treatment. The light sources must emit photons of energy greater than that of the intrinsic band-gap energy E_g of the photocatalyst. For example, the photocatalyst titanium dioxide (TiO_2) has band-gap energy of 3.1 eV. For this material, ultraviolet light with wavelengths less than 380 nm has sufficient energy to overcome the E_g of TiO_2.The characteristic chemistry consists of reactant gases adsorbing onto the photocatalyst, followed by reaction, product formation, and desorption. With appropriate light intensity and sufficiently long residence time, photocatalysis can almost completely oxidize a wide variety of organic compounds such that the exit gas stream contains mostly carbon dioxide and water (Obee and Brown 1995; Obee and Hay 1999; Peral and Ollis 1992; Peral et al. 1997; Tompkins et al. 2005a). In cases of incomplete oxidation, particularly when chlorinated compounds are present as reactants, multiple by-products may be formed (d'Hennezel et al. 1998; Farhanian and Haghighat 2014). ASHRAE research project RP-1134 exhaustively reviewed the literature on UV photocatalysis (Tompkins et al. 2005a, 2005b).

Currently, with recent catalyst, lamp, and reactor design developments, UV-PCO can be used as a gas-contaminant removal technology (Chen et al. 2005). A study conducted for an in-duct UV-PCO system utilizing honeycomb monoliths with VOC mixtures found in indoor air showed single pass VOC removal efficiencies ranging from 19 to 85%, with the oxidation rates approximately following: alcohols and glycol ethers > aldehydes, ketones, and terpene hydrocarbons > aromatic and alkane hydrocarbons > halogenated aliphatic hydrocarbons (Hodgson et al. 2005). A time dependent mathematical model has recently been developed to predict the performance of an in-duct PCO air cleaner under realistic indoor conditions (Zhong et al. 2013). In most residential and commercial building applications, reduction of levels is likely to be most effective when the air contaminants can be passed through the UV-PCO filters multiple times. In an HVAC application, the preferred location for a UV-PCO filter is in the return or mixed air, where gas contaminants pass through the filter many times in a given time period. UV-PCO can be an attractive because of its promise of reduced maintenance (no filters and/or adsorption media to maintain and dispose of periodically) and ability to treat a wide variety of airborne chemicals.

Sometimes, the UV-PCO unit is followed by a gas-phase media section that can adsorb any partially oxidized molecules to prevent them from recirculating back into the occupied space (Hodgson et al. 2007). A further extension of UV-PCO being studied is use of UVV (i.e., low-energy UV light with wavelength close to the visible limit of 400 nm) along with UVC (short-wavelength UV light; wavelength of 100 to 280 nm) to generate radicals such as ozone, hydroxyls, and peroxides, which increase contaminant destruction efficiency and hence air-cleaner single-pass efficiency. A downstream gas-phase media section is necessary in this case to destroy these radicals and prevent them from passing into occupied spaces.

Air ionizers (ion generators) may be effective under some circumstances for particulate, VOC, and odor removal. Most ionization technologies are based on the principle of corona discharge (or nonthermal plasma) and can be classified into three categories: needlepoint ionization, bipolar ionization, and ozone generators. Air ionization involves the electronically induced formation of positive and/or negative ions, including reactive oxygen species (ROS) that react rapidly with airborne VOCs and particulate species. Manufacturers of these systems suggest that reactive oxygen species can be present as oxygen radicals, activated oxygen, superoxide or diatomic oxygen, trivalent oxygen, or oxygen cluster ions. Most ionization systems are prone to generate NO_x and ozone, which is harmful to humans, and require control systems to maintain ozone levels below safe limits or should be avoided (ASHRAE 2015). There are limited peer-reviewed studies on the effectiveness of ionization systems to remove VOCs and odors in a single pass moving air stream.

Ozone is sometimes touted as a panacea for removing gas-phase contaminants from indoor air. However, considerable controversy surrounds its use in indoor air. Ozone is a criteria pollutant and its maximum allowable concentration (8 h time-weighted average [TWA]) is regulated in both indoor (OSHA 1994) and outdoor air (EPA 2016a). Some ozone generators can quickly produce hazardous levels of ozone (Shaughnessy and Oatman 1991). Furthermore, the efficacy of ozone at low concentrations for removing gaseous pollutants has not been documented in the literature (Boeniger 1995). Human sensory results obtained in conjunction with a study by Nelson et al. (1993) showed that an ozone/negative ion generator used in a tobacco-smoke environment (1) produced unacceptable ozone levels at the manufacturer's recommended settings, and (2) when adjusted to produce acceptable ozone levels, produced more odor and eye irritation over time than environmental tobacco smoke (ETS). Other work by Nelson (unpublished) has shown the rapid oxidation of NO to NO_2 by ozone and only a minor decrease in nicotine concentrations when ozone is used to "clean" the air. In light of the potential for generating hazardous ozone levels indoors and the lack of scientific data supporting its efficacy, using ozone to combat ETS in indoor air is not recommended. In addition, reaction of ozone with both indoor contaminants and building and HVAC surfaces can produce secondary contaminants such as small particles and aldehydes (Morrison et al. 1998; Vartiainen et al. 2006; Wang and Morrison 2006).

Biofiltration is effective for low concentrations of many VOCs found in buildings (Janni et al. 2001). It is suitable for exhaust air cleaning and is used in a variety of applications including plastics, paper, and agricultural industries and sewage treatment plants. Operating costs are low, and installation is cost-competitive. However, concerns over using uncharacterized mixtures of bacteria in the filter, possible downstream emissions of microbials or chemicals, and the risk of unexpected or undetected failure make it unsuitable for cleaning air circulated to people.

Odor counteractants and **odor masking products** do not remove the contaminant(s) responsible for problem odors from the air; they may apply only to specific odors and have limited effectiveness. They also add potential contaminants to the air.

6. EQUIPMENT

The purpose of gas-phase filtration equipment is to expose the chosen filtration media or device to the air to be filtered. In most cases, the filtration method uses granular media material, supplied either in bulk, or incorporated into a filter device that can be refillable or disposable. Typically, the gas filter has a particulate prefilter and afterfilter.

The most common retaining structure places the granular media between perforated retaining sheets or screens, as shown in Figures 5A, 5B, 5C, 5D, 5F, and 5H. The perforated retainers or screens must have holes smaller than the smallest particle of the media, and are typically made of aluminum; stainless, painted, plated, or coated steel; plastics; and kraftboard. Figure 5I represents a bonded flat panel filter.

Media may also be retained in fibrous filter or other porous support structures, and very fine media can be attached to the surface or within the structure of some particulate filter media, as shown in Figures 5E and 5G.

Effect of Media Size. Filtration devices that use small-diameter media generally have higher initial efficiency than the same media in larger particles, because of the larger exposed surface area. Devices that use larger-diameter media generally provide more overall filtration capacity because of the greater mass of media exposed to the air to be filtered.

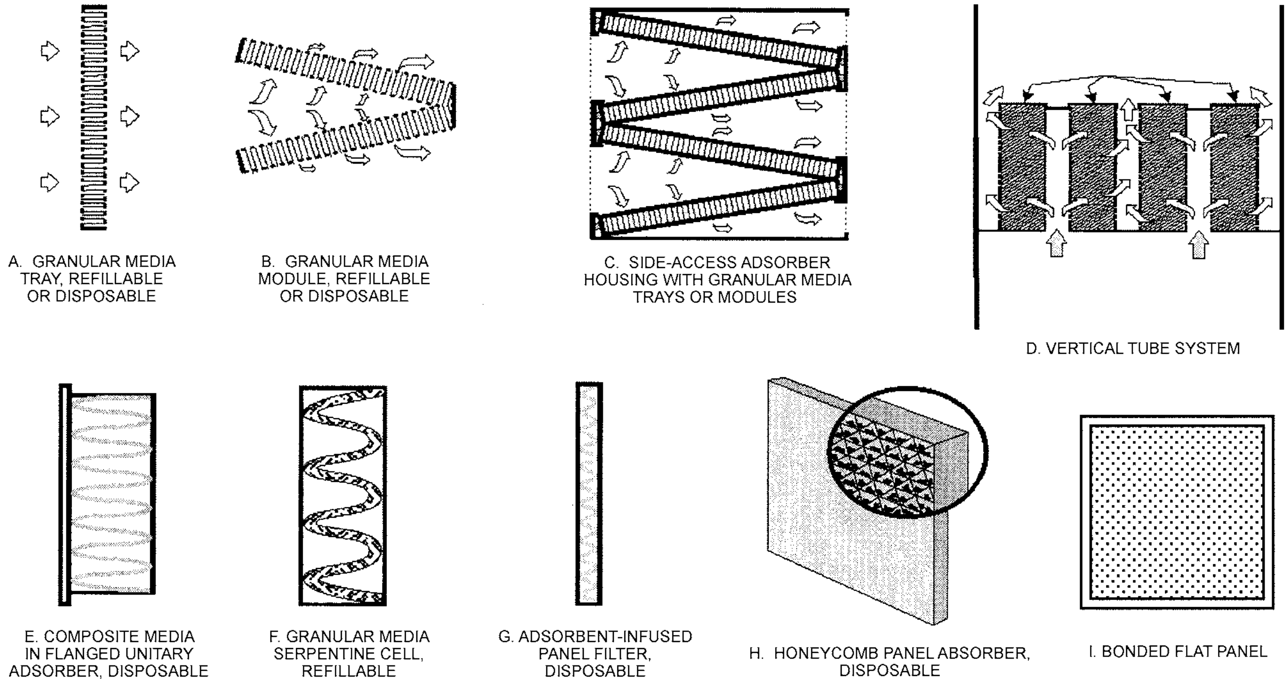

Fig. 5 Sectional and Schematic Views of Typical Physical Adsorbent and Chemisorbent Configurations

Equipment Configurations. The typical media-holding devices shown in Figure 5 vary in thickness from 16 mm to as much as 150 mm. Though they can be mounted perpendicular to the airflow (Figure 5A), they more often hold the media at an angle to the airstream (Figures 5B to 5F) to increase the face area and thereby reduce pressure drop and increase residence time.

The honeycomb panels in Figure 5H hold the media in small channels formed by a corrugated spacer material, faced with a plastic mesh material. Though they usually have a low pressure drop, these are often in a holding frame configured at an angle to the airflow, as in Figure 5C.

Most of these devices are removed from the airstream, to either be refilled, or replaced. An exception is the vertical tube system, shown in Figure 5D. It is filled with bulk media, usually from plastic pails or large bags, fed in through top-access hatch(es). Expended media is removed by vacuuming from the same hatches, or from bottom hatches or hoppers.

Bypass. Performance of any air cleaner installation is limited by the airflow integrity of the total installation. A 100% efficient filter mounted in a housing that allows unintentional bypass is not truly a 100% efficient filter. Designers should consider the desired overall efficiency and ensure that the housing and filter together meet performance goals. One method of detecting significant unintentional bypass is to measure whether the filter achieves its rated pressure drop at full flow; if the pressure drop is low, bypass is likely.

7. AIR CLEANER SYSTEM DESIGN

Air cleaner system design consists of determining and sizing the air cleaning technology to be applied, and then choosing equipment with characteristics (size and pressure drop) that can be incorporated into the overall mechanical design. The overall mechanical design may be carried out according to ASHRAE *Standard* 62.1's IAQ procedure rather than using the ventilation procedure.

The gaseous contaminant air-cleaning system designer ideally should have the following information:

- A clear goal concerning what level of air cleaning is needed based on the application
- Exact chemical identity of the contaminants present in significant concentrations (not just the ones of concern)
- Rates at which contaminants are generated in the space and are transported to air cleaner system.
- Rates at which contaminants are brought into the space with outdoor air
- Time-dependent performance of the proposed air cleaner for the contaminant mixture at concentration and environmental conditions to be encountered

This information is usually difficult to obtain, though *Standard* 62.1's IAQ procedure provides some guidance. The first three items can be obtained by sampling and analysis, but funding is usually not sufficient to carry out adequate sampling except in very simple contamination cases. Designers must often make do with a chemical family (e.g., aldehydes). Investigation may allow a rough estimate of contaminant generation rate based on quantity of product used daily or weekly. Experience with the particular application or published guidance (e.g., Rock [2006] for environmental tobacco smoke) can be very helpful.

Experimental measurements of air cleaner performance can now be carried out using ASHRAE *Standard* 145.2 for individual contaminant gases. Alternatively, performance can be estimated, using Equations (2) to (7), when the exact chemical identity of a contaminant is known. The chemical and physical properties influencing a contaminant's removal by air-cleaning devices can usually be obtained from handbooks and technical publications. Contaminant properties of special importance are relative molecular mass, normal boiling point at standard temperature and pressure (STP), heat of vaporization, polarity, chemical reactivity, and diffusivity.

Air cleaner performance with mixtures of chemically dissimilar compounds is very difficult to predict. Some gaseous contaminants, including ozone, radon, and sulfur trioxide, have unique properties that require design judgment and experience.

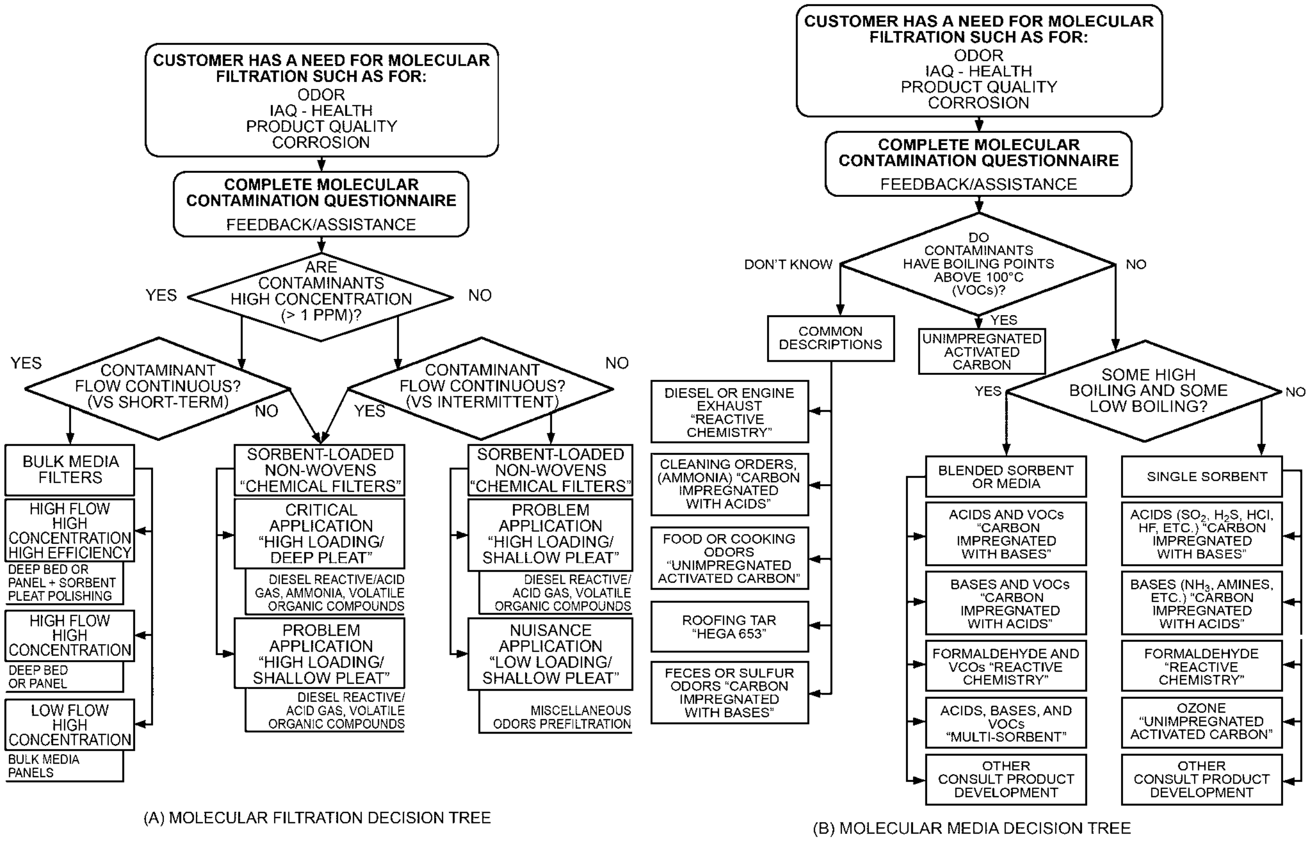

Fig. 6 Filtration and Media Selection Methods

Finally, design goals must be considered. For a museum or archive, the ideal design goal is total removal of the target contaminants with no subsequent desorption or release of by-products. For any chemical that may affect health, the design goal is to reduce the concentration to below the level of health concerns. Again, desorption back into the space must be minimized. For odor management, however, 100% removal may be unnecessary, and desorption back into the space at a later time with a lower concentration may be economical and acceptable.

The first step in design is selecting an appropriate physical or chemical adsorption medium. Next, the air cleaner's location in the HVAC system must be decided and any HVAC concerns addressed. Then the air cleaner must be sized so that sufficient media is used to achieve design efficiency and capacity goals and to estimate media replacement requirements. Finally, commercial equipment that most economically meets the needs of the application can be selected. These steps are not completely independent.

Media Selection

Media selection is clear for many general applications; however, some complex gas mixtures in critical applications may require bench testing to determine if capacity and efficiency values are suitable for the application. In general, gaseous contaminants that have boiling points greater than 48.9ºC and molecular weights over 50 can be removed by physical adsorption using standard activated carbon. Those with a lower boiling points and molecular weights usually require chemisorption or addition of a catalyst for complete removal. Figure 6 shows the media and filtration selection process.

In practice, different uses of the same application may be served well by somewhat different media selections. Any guidance must be tempered by consideration of the specifics of a particular location, and guidance given by different manufacturers may differ somewhat. Table 8 consolidates general guidance for numerous commercial applications from multiple manufacturers. Within each media group, the applications are listed alphabetically; similar applications appear in more than one list, because some applications may be well served with either a single medium or by a blend, with the best choice determined by the specific contaminants present (both chemical identity and concentration). Acceptability may hinge on a specific, hard-to-remove chemical that is present at one site but not at another. Adsorption capacity for a particular chemical or application may vary from these guidelines with changes in

- **Competitive adsorption.** Multiple contaminants confound performance estimates, particularly for physical orbents and permanganate media.
- **Temperature.** A temperature increase decreases adsorption in a physical adsorbent, whereas it increases the reaction rates of chemisorbents.
- **Humidity.** For physical adsorbents, the effect of humidity (generally for > 50% rh) depends on the contaminant. Carbon capacity for water-miscible solvents increases; capacity for immiscible or partially miscible solvents decreases. Some humidity is usually required for effective operation of chemisorbents.
- **Concentration.** Increased contaminant concentration improves adsorption for both physical and chemical adsorbents.

Table 9 provides a general guide to selecting media commonly used to remove particular chemicals or types of chemicals. The media covered are permanganate-impregnated media (PIM), activated carbon (AC), acid-impregnated carbon (AIC), and base-

Table 8 Typical Contaminants in Commercial Applications

Commercial Application	Contaminants/Species
Activated Carbon or Carbon/Permanganate-Impregnated Media Blend	
Airport terminals (air side and non-air side), art studios, athletic clubs, auditoriums, banks (customer area), banquet rooms, beauty salons, bus terminals, clinics, darkrooms, decal application, dentists'/doctors' offices, dry cleaners (dust area), factories (office area), florists, grocery stores, kitchen exhausts, locker rooms, office buildings, painted rooms, pharmacies, photo stores, photographic studios, physiotherapy, recreation halls, rendering plants, stores	Multiple volatile organic gases/solvent vapors and inorganic gases; possibly some gases poorly adsorbed by carbon Multiple organics and inorganics, fumes, food odors, body odors, perfumes, floral scents, odorous fumes, moldy odors, paint fumes, furniture, ETS, NO_x, SO_x, O_3, mercaptans, valeric acid, formaldehyde
Activated Carbon/Permanganate-Impregnated Media Blend	
Bars, bingo halls, brasseries, cafeterias, casinos, cocktail lounges, conference rooms, correctional facilities, funeral homes, geriatrics, hospitals, hotels (smoking, renovation), ICUs, libraries, lounges, lunch rooms, motels, museums, night clubs, nurseries, paint shops (office), penal institutions, projection booths, psychiatric institutions and wards, public toilets, restaurants, segregated smoking rooms, storage rooms, theaters, waiting rooms	Mixed gases/ETS; good possibility of volatile organic gases and/or solvent vapors ETS, body odors, urine, excreta, perfume, multiple odors, food odors, kitchen fumes, food, furniture/furnishings offgassing, multiple organics and inorganics, paint
Activated Carbon or Permanganate-Impregnated Media	
Barber shops, dining rooms	Mixed gases, ETS, food odors
Carbon/Permanganate Blend or Permanganate-Impregnated Media	
Embalming rooms, fruit/vegetable storage, greenhouses	Multiple organics; organic gases poorly sorbed by activated carbon Multiple organics, formaldehyde, ethylene
Activated Carbon or Permanganate-Impregnated Media/Acid-Impregnated Carbon Blend	
Garbage disposal areas	Mixture of volatile organics and inorganics with ammonia
Permanganate-Impregnated Media	
Autopsy rooms, banks (vault area), fish markets, hospitals (autopsy), morgues	Volatile organic gases poorly adsorbed by activated carbon Formaldehyde, trimethyl amine
Permanganate-Impregnated Media/Acid-Impregnated Carbon Blend	
Pet shops, animal holding rooms, veterinary hospitals	Mixed organic gases with significant ammonia urine, excreta, animal odors
Activated Carbon/Acid-Impregnated Carbon Blend	
Printing plants	Mixed hydrocarbons and ammonia
Acid-Impregnated Carbon	
Fertilizer plants (office)	Largely ammonia

Notes: Permanganate impregnant is potassium permanganate. Acid impregnants vary. ETS = environmental tobacco smoke

impregnated carbon (BIC). The numeral 1 indicates the best media to use, and 2 the second choice. As was true of Table 6, some difference in opinion exists as to which media is best, and chemicals for which there is disagreement are tagged with an exclamation point. Where information is unavailable, media can be evaluated for their ability to remove specific gases using ASHRAE *Standard* 145.1.

Air Cleaner Location and Other HVAC Concerns

Outdoor Air Intakes. Proper location of the outdoor air intake is especially important for applications requiring gaseous contaminant filters because outdoor contaminants can load the filters and reduce their operating lifetime. Outdoor air should not be drawn from areas where point sources of gaseous contaminants are likely: building exhaust discharge points, roads, loading docks, parking decks and spaces, etc. See Chapter 46 for more information on air inlets.

To further help reduce the amount of contaminants from outdoor air, at least on days of high ambient pollution levels, the quantity of outdoor air should be minimized.

Air Cleaner Usage. The three principal uses for gaseous contaminant removal equipment in an HVAC system are as follows:

- *Outdoor air treatment.* Air-cleaning equipment can be located at the outdoor air intake to treat outdoor air only. This treatment is used principally when indoor gaseous contaminant concentrations are adequately reduced by outdoor air ventilation, but the outdoor air needs to be cleaned to achieve satisfactory indoor air quality. Note that air-cleaning media performance is a function of the temperature and relative humidity of the incoming air. Problems may arise when outdoor air temperature and relative humidity are either very low or very high. Consult the supplier for advice if the installation is in an extreme climate region.
- *Bypass or partial supply air treatment.* Intentional bypass can be achieved with a bypass duct and control damper or by installing an air cleaner in a manner that allows substantial bypass. Partial supply air treatment may be appropriate where a specific threshold contamination level is targeted, when outdoor and indoor contamination rates are known, and the required level of reduction is small to moderate.
- *Full supply air treatment.* Full treatment achieves the best contaminant concentration reduction, but with the highest cost and largest equipment volume. This approach is most often used in ventilation strategies that reduce outdoor air while maintaining good indoor air quality.

When outdoor air quality is adequate, treatment of recirculated ventilation air alone may be adequate to keep indoor contaminants such as bioeffluents at low levels. Full or bypass treatment of the supply air may be appropriate, depending on the source strength.

Sizing Gaseous Contaminant Removal Equipment

A number of issues need to be taken into account during equipment sizing. These include

- Nature of contaminant(s) to be removed
- Average and peak concentrations of contaminant(s)
- Efficiency of the media used
- HVAC considerations, including layout and space available for equipment installation; equipment location; whether air is indoor, outdoor, or supply; and volume airflow and air velocity through the section

Table 9 Media Selection by Contaminant

Gaseous Contaminant	PIM	AC	AIC	BIC	Gaseous Contaminant	PIM	AC	AIC	BIC	Gaseous Contaminant	PIM	AC	AIC	BIC
Acetaldehyde	1	2			Dichlorofluoromethane		1			Methyl formate	2	1

1 = primary media selection for contaminant; 2 = secondary media selection.
PIM = permanganate-impregnated media; AC = activated carbon;
AIC = acid-impregnated carbon; BIC = base-impregnated carbon
R-114 is dichlorotetrafluoroethane; R-11 is trichlorofluoromethane.

Comments: Some contaminant molecules have isomers that, because they have different physical properties (boiling point, vapor pressures), require different treatment methods. For some contaminants, preferred treatment is ion exchange or another (nonlisted) impregnated carbon. For some contaminants, manufacturer recommendations differ. "!" is used to identify these cases.

The more undesirable the contaminant of concern, and the greater its concentration, the greater the quantity of media required for removal, and the larger the air cleaner installation. Media efficiency depends on the residence time of contaminant(s) in the air cleaner, which in turn depends on media bed depth and HVAC air velocity.

There are two common sizing approaches: testing and calculations with Equations (2) to (7), or following manufacturers' guidance.

Available Test Methods and Equations. ASHRAE *Standard* 145.1 provides a method for testing granular media at small scale in a laboratory, and can be used to compare media performances against specific contaminants. ASHRAE *Standard* 145.2 provides a method of testing a 0.6 × 0.6 m filter under laboratory conditions and can supply more direct evaluation of potential air cleaning installations. Equations (2) to (7) can be used to size equipment, though the contaminant concentration data required to use the equations effectively may be difficult to obtain.

General procedures for developing a specification for an air cleaner installation are as follows:

1. Choose a physical or chemical adsorbent suited to the contaminant(s) using testing or taking guidance from Tables 6 and 7.
2. Pick an appropriate efficiency for the adsorbent (complete removal or partial bypass), depending on the contaminant(s).
3. Choose a desired operating adsorbent end point of 10%, 50%, or other breakthrough, depending on the application and allowable steady-state concentration. A building ventilation performance model, with the adsorber appropriately positioned, allows calculation of the expected indoor concentration at various breakthroughs and efficiencies.

4. Obtain a measurement or estimate of breakthrough time at adsorbent use conditions as developed in step 3.
5. Determine the change-out rate for the adsorbent as set by the breakthrough time.
6. Match the computed design requirements to available air cleaning equipment and specify.

Manufacturers' Design Guidance. Most manufacturers of air-cleaning system components offer selection guidance. Some of the approaches for traditional granular beds are summarized here. Note that inclusion of this information or exclusion of other approaches does not imply acceptance or endorsement by ASHRAE, but is meant to be an abbreviated overview of present-day practice. The general expectation is of an HVAC application service life of 9 to 18 months for a 3120 h air-conditioning year. These values are simply a summary of conventional wisdom directed at meeting that goal, and they can be substantially in error.

Manufacturers with laboratory testing facilities may evaluate and specify filters by measuring the initial removal efficiency of the whole filter installed in its frame (similar to the ASHRAE *Standard* 145.2 test), and measure the amount of contaminant removed as adsorbent capacity is consumed during the test. Curves of efficiency versus capacity are used to guide the customer through the selection process.

In situations where multiple contaminants at low concentrations occur, such as in most IAQ investigative work and applications, neither the total load nor specific contaminant can typically be determined. In these cases, a broad-based air-cleaner design approach is usually recommended, consisting of two media banks: activated carbon, followed by permanganate-impregnated media. Sometimes these two media are combined into one bank because of space or pressure drop limitations.

- For light-duty applications, the recommendation is to use particulate filter media infused with carbon and/or permanganate media and pleated into a traditional filter design.
- For medium-duty applications, granular media are used in 25 to 75 mm deep refillable or disposable bulk-fill modules for increased efficiency and service life.

A useful approach for carbon-based air cleaners divides HVAC and IAQ applications into three categories and recommends specific equipment selection based on efficiency and activated carbon mass, as follows:

1. Heavy-duty outdoor air or mixed air IAQ applications with a relatively constant VOC generation rate and relatively constant moderate to severe outdoor air pollution:
   - For cleaned-air-equivalent air quality (i.e., air cleaned well enough to substitute for outdoor air), use equipment with >90% efficiency and 34 to 45 kg of high-grade carbon per 0.94 m^3/s. For a 25 mm bed in common commercial unitary adsorbers, this corresponds to a 0.1 s residence time.
   - With severe outdoor air pollution from nearby sources, it may be necessary to size equipment at 41 kg of carbon per 0.47 to 0.66 m^3/s, which corresponds to 0.14 to 0.2 s residence time.
2. For medium-duty return or mixed-air IAQ applications with constant low to moderate VOC generation and cleaned-air-equivalent air quality, use equipment efficiencies of 20 to 90% and 4 to 34 kg of carbon per 0.94 m^3/s. This corresponds to partial bypass equipment at the low-efficiency end and ranges up to about 0.08 s residence time at the high-efficiency end.
3. For light-duty mixed-air IAQ applications with intermittent low to high VOC generation and an intermittent low to high outdoor air pollution load, use equipment efficiencies of >75% for odor management, which corresponds to a partial bypass design.

Table 10 Suggested Mesh 4.8 × 3.4 or 4.8 × 2.4 mm Coconut Shell Carbon Residence Time Ranges

Application	Residence Time,[a] s
HVAC odor management applications for indoor air quality	
Light duty recirculation	0.03 to 0.07
Light duty – medium duty	0.07 to 0.10
Heavy duty	0.06 to 0.14
Cleanroom corrosion reduction	
Recirculation	0.03 to 0.07
Intakes	0.03 to 0.14
Industrial corrosion reduction (refineries, wastewater, pulp, etc.)	0.12 to 0.28+
Corrosive/reactive low-level exhaust applications	0.12 to 0.28+
Toxic gas removal	Not applicable
Museums	
Standard applications	0.07 to 0.12
Recirculation applications	0.06 to 0.10
Critical air intake	0.28+
Critical recirculation application	0.12 to 0.28+
Nuclear applications[b]	0.12 to 0.28+

Notes: [a]All residence times given are rules of thumb using 4.8 × 3.4 or 4.8 × 2.4 mm mesh carbon in granular beds for the application indicated. Other carbon packages, such as pleated filters containing finely divided carbon, may be dramatically different. Particularly at low (μL/m^3) contaminant concentrations, well-designed pleated carbon filters can be very efficient and have adequate capacity.
[b]Nuclear Grade Carbons are most often an 8 × 16 mesh
Source: Data from ©1992 Extraction Systems, Inc.

Another form of manufacturer's guidance of activated carbons is shown in Table 10, which gives suggested packed-bed residence time ranges, developed for the 4.8 × 3.4 or 4.8 × 2.4 mm mesh coconut shell carbon typically used in packed beds, for various applications. Mesh size is frequently used to specify granular media. The mesh size is closely related to the U.S. sieve size (the smallest sieve that the granule will pass through), and inversely related to the dimensions of the granule. A table with more information can be found in Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals*. Residence times in Table 9 are appropriate for moderate to thick beds of large-particle carbons, but do not apply universally to commercial adsorbents. Different ways of arranging the carbon, different adsorbents, or different carbon granule sizes change the residence time required to get a particular result. This is especially true of very finely dispersed activated carbon, which has very fast adsorption kinetics. In addition, the geometry and packaging of some adsorbent technologies make computation of residence time difficult. For instance, cylindrical beds with radial flow have air velocities that decrease from the center to the periphery, so special computational techniques are needed to put residence time on the same basis as for a flat bed. Similarly, the flow pattern in pleated fiber/carbon composite media is difficult to specify, making residence time computation uncertain. Therefore, although residence times can be computed for partial-bypass filters, fiber-adsorbent composite filters, or fiber-bonded filters, they cannot be compared directly with those in Table 9, and serve more as a rating than as an actual residence time. By applying residence time as a rating, manufacturers may publish equivalent residence time values that say, in effect, that this adsorber performs the same as a traditional deep bed adsorber. No standard test exists to verify such a rating. A test can be performed per ASHRAE *Standard* 145.1 to compare filters (e.g., fiber-bonded filters to a granular adsorber) and determine what is best suited for an application.

Special Cases

Ozone reaches an equilibrium concentration in a ventilated space without a filtration device. It does so partly because ozone molecules react in air to form oxygen, but also because of reactions with people, plants, ductwork, and materials in the space. This oxidation is harmful to all four things, and therefore natural ozone decay is not a satisfactory way to remove ozone, except possibly at low concentrations (<0.2 mg/m^3). Fortunately, activated carbon adsorbs ozone readily, both reacting with it and catalyzing its conversion to oxygen.

Radon is a radioactive gas that decays by alpha-particle emission, eventually yielding individual atoms of polonium, bismuth, and lead. These atoms form ions, called radon daughters or radon progeny, which are also radioactive; they are especially toxic, lodging deep in the lung when radon is inhaled, where they emit alpha and beta particles that are potentially cancer causing. Radon progeny, both attached to larger aerosol particles and unattached, can be captured by particulate air filters. Radon gas itself may be removed with activated carbon, but in HVAC systems this method costs too much for the benefit derived. Reduction of radon emission at the source by sealing entry points or depressurizing the source location like subslab ventilation are the accepted methods of reducing exposure to radon.

Museums, libraries, archives, and similar applications are special cases of air cleaner design for protection, and may require very efficient air cleaning; see Chapter 24 for specifics.

Building protection applications, whether to protect occupants against industrial accidents or deliberate acts, cannot reasonably stand alone. It makes little sense to design a complex system that can be easily overcome by physical acts. Air cleaner design alone is not enough. Air cleaning must be part of a complete and in-depth IAQ program. The designer must have a scenario or series of scenarios against which to design protective systems.

Because a given air-cleaning technology may not protect against all challenges, protection against deliberate acts requires a robust design. The air-cleaning technology can be chosen to protect against the most challenging contaminant. Once the challenge contaminants are identified, a more rigorous application of the design method described previously is applied. Military specification hardware is generally suitable, although high-end commercial designs can provide significant protection. Testing of the installed filters is generally required, maintenance costs are significant, and the cost in space allocated to the installation, energy, and capital is high.

U.S. government guidance for the designer is available online (FEMA 2003a, 2003b; NIOSH 2002, 2003). The FEMA web site also includes a number of other applicable documents. For additional guidance, see Chapter 60.

Energy Concerns

Pressure drop across the contaminant filter directly affects energy use. Data on the resistance of the filter as a function of airflow and on the resistance of the heating/cooling coils must be provided by the manufacturer. If no information is available, ASHRAE *Standard* 145.2 provides a procedure for measuring pressure drop across a full-scale gaseous air cleaner in a laboratory setting. In addition to the gaseous contaminant filter itself, pressure drop through the housing, any added duct elements, and any particulate filters required up- and/or downstream of the gaseous contaminant filter must be included in the energy analysis.

Choosing between using outdoor air only and outdoor air plus filtered recirculated air is complex, but can be based on technical or maintenance factors, convenience, economics, or a combination of these. An energy-consumption calculation is useful. Replacing outdoor air with filtered indoor air reduces the amount of air that must be conditioned at an added expense in recirculation pressure drop. Outdoor air or filtered recirculated air may be used in any ratio, provided the air quality level is maintained. Janssen (1989) discusses the logic of these requirements.

Where building habitability can be maintained with ventilation alone, an economizer cycle is feasible under appropriate outdoor conditions. However, economizer mode may not be feasible at high humidity, because high humidity degrades the performance of carbon adsorbents.

Table 11 Items Included in Economic Comparisons Between Competing Gaseous Contaminant Removal Systems

Capital Costs	Operating Costs
Added filtration equipment	Replacement or reactivation of gaseous contaminant filter media
Fan	
Motor	Disposal of spent gaseous contaminant filter media
Sensors and controls	
Plenum	Added electric power
Spare media holding units	Maintenance labor
Floor or duct space	

Economic Considerations

Capital and operating costs for each competing system should be identified. Chapter 38 provides general information on performing an economic analysis. Table 11 is a checklist of filtration items to be considered in such an analysis. It is important that the fan maintain adequate flow and overcome the pressure drop with an in-line air cleaner in place. If a larger blower is required, space must be available. Modifying unitary equipment that was not designed to handle the additional pressure drop through air-cleaning equipment can be expensive. With built-up designs, the added initial cost of providing air cleaners and their pressure drop can be much less because the increases may be only a small fraction of the total.

The life of the adsorbent media is very important. The economic benefits of regenerating spent carbon should be evaluated in light of the cost and generally reduced activity levels of regenerated material. Regeneration of impregnated carbon or any carbon containing hazardous contaminants is never permitted. Spent alumina- or zeolite-based adsorbents also cannot be regenerated.

8. SAFETY

Gaseous contaminant removal equipment generally has a low hazard potential. Contaminant concentrations are low, temperature is moderate, and the equipment is normally not closed in. Alumina- or zeolite-based media do not support combustion, but carbon filter banks have been known to catch fire, usually from an external source such as a welder's torch. Check local codes and fire authorities for regulations on carbon. One authority requires automatic sprinklers in the duct upstream and downstream of carbon filter banks. As a minimum, a smoke detector should be installed downstream of the filter bank to shut down the fan and sound an alarm in case of fire.

Access for safe maintenance and change-out of adsorbent beds must be provided. Physical and chemical adsorbent filters are both much heavier than particulate filters. Suitable lifting equipment must be available during installation and removal to prevent injury.

At some point, granular activated carbon (GAC) becomes exhausted, and it is necessary to rebed the media. Depending on how the GAC was used, it may be considered nonhazardous and can be removed by the user or a service company. Hazardous media may be toxic, ignitable, corrosive, or reactive; see guidelines in 40 CFR 261 (2012; www.ecfr.gov).

It is the responsibility of the generator to determine the nature of the spent carbon waste. A carbon profile should be performed to characterize it as either hazardous or nonhazardous. A spent carbon profile is required to ensure that the spent carbon is safely recycled or disposed of in compliance with federal, state, and local regulations. Disposal of hazardous waste is governed by Resource Conservation and Recovery Act (RCRA; www.epa.gov/rcra).

If adsorbent trays are to be refilled on site, safety equipment must be provided to deal with the dust this generates. Hood usage, dust masks, and gloves are all required to refill adsorbent trays from bulk containers.

9. INSTALLATION, START-UP, AND COMMISSIONING

This section provides general guidance on installing gaseous contaminant removal equipment. Manufacturers can provide complete installation details and drawings. Following the manufacturer's instructions will ensure that the equipment is installed properly and that it operates as designed.

Particulate Filters. Physical adsorbents and chemisorbents cannot function properly if their surfaces are covered and their pores clogged with particulate matter. UV-PCO system performance is also degraded unless protected by prefilters. A particulate filter with a minimum efficiency reporting value (MERV) of at least 8 (per ASHRAE *Standard* 52.2) should be installed ahead of the adsorbent bed to capture dirt and dust and to allow the adsorbent to capture gas-phase contaminants. Weschler et al. (1994) reported that carbon service life for ozone removal was lengthened by using an improved prefiltration. A secondary, higher-efficiency particulate filter is often desirable in critical and dusty installations. If the air is extremely dirty (e.g., from diesel exhaust or fumes), the filter should have a much higher efficiency rating. A minimum of a MERV 14 particulate filter is recommended for such applications.

Final filters downstream of the installation are often used in critical applications where dust from media at start-up is likely, or where vibration of the adsorbent bed may cause granular media to shed particles. These filters should have a minimum MERV 8 rating, but as noted, a secondary and/or higher-efficiency filter may be needed in some applications. Consult the equipment manufacturer for their recommendation.

Equipment Mass. Physical and chemical adsorption equipment is much heavier than particulate filtration equipment, so supporting structures and frames must be designed accordingly. A typical filter with a face area of 610 by 610 mm consisting of a permanent holding frame and sorbent media can have an installed mass of approximately 14 to 182 kg, depending on its depth and configuration. The manufacturer can provide system weights for the selected equipment.

Minimize or Eliminate Unintentional Bypass. Unintentional bypass can degrade the installed performance of a gas filter. Adsorbent beds and ducts must be tightly sealed to prevent bypass of contaminants. Before installation, and periodically during operation, visually inspect filters and replace any that are damaged. Install the filter according to the airflow direction indicated. Check to be sure that filters are properly seated and to ensure that the bank of filter frames is rigid and reinforced to avoid collapse. It is good practice to caulk all seams between individual holding frames. Granular media settles and compacts over time, and trays or modules must be loaded with media and installed following manufacturers' recommendations to eliminate bypass through the media bed. In addition, ensure that all doors, seams, and joints downstream of the adsorbent bed are properly sealed to prevent contaminated air from entering the system.

When to Install Media. Proper timing for installing adsorbent beds in their holding frames depends on building circumstances. If they are installed at the same time as their holding frames and if the HVAC is turned on during the latter phases of construction, the adsorbents will adsorb paint and solvent vapors and other contaminants before the building is ready for occupancy. In some situations, adsorption of vapors and gases in the ventilation system before official start-up may be desired or needed. However, adsorbent life will be reduced correspondingly. If sorbent media are not used until the building is ready for occupancy, the unremoved contaminants may seriously reduce the initial indoor air quality of the building and the usable life of the bed. Thus, shortened life is an acceptable trade-off for the quality of air at the time of occupancy (NAFA 2012). If the media is not in place during fan testing, the test and balance contractor must be instructed to place blank-offs or restrictions in the frames to simulate adsorbent bed pressure drop. Gas-phase adsorbents typically can have significant pressure drop, and failing to account for this detail will negatively affect fan airflow. The specifications should clearly state when media are to be installed.

Pressure Gages. If upstream filtration is adequate, adsorbent pressure drop will not increase during normal operation, unless media settling and compacting occurs. A pressure gage is therefore not normally needed for a particulate filter bank. However, a gage can be useful to detect fouling or unintentional bypass. If the prefilters or final filters are installed immediately adjacent to the adsorbents, it may be more feasible to install the gage across the entire assembly.

Provision for Testing. At any time after installation of new media, determining the remaining adsorbent capacity or operating life may be required. (See the section on When to Change Media in under Operation and Maintenance.) The installation should provide access ports to the fully mixed airstream both up- and downstream of the air cleaner. If media samples will be removed to determine remaining life of the gas filter, access must be provided to obtain those samples.

Start-Up and Commissioning

Special procedures are not required during start-up of an air handler with installed gaseous contaminant air cleaners. The testing and balancing contractor normally is required to measure and record resistance of all installed filter banks, including adsorbers, for comparison with design conditions. Refer to manufacturers' instructions.

The commissioning authority may require an activity test on a random sample of media to determine if the new media meets specifications or suffered prior exposure that reduced its life. An in situ air sampling test may also be required on the adsorbent; however, no standard method for this test exists. See Chapter 44 for more on commissioning.

10. OPERATION AND MAINTENANCE

Bypass units and filters with adsorbent-infused fibrous media require frequent changing to maintain even low efficiency, but frequent maintenance is not required for complete removal units. Complete removal media units usually have a replaceable cell that cannot be regenerated or reactivated. This section covers maintenance of complete removal equipment with refillable trays or modules only.

When to Change Media

The changeout point of physical and chemical adsorbent is difficult to determine. Sometimes media are changed when breakthrough occurs and occupants complain; but if the application is sensitive, tests for estimated residual activity may be made periodically. A sample of the media in use is pulled from the adsorbent bed or from a pilot cell placed in front of the bed. The sample is sent to the manufacturer or an independent test laboratory for analysis, and the changeout time is estimated knowing the time in service and the life remaining in the sample.

In corrosion control installations, specially prepared copper or silver coupons are placed in the space being protected by the adsorbent. After some time, usually a month, the coupons are sent to an analytical lab for measurement of corrosion thickness, which indicates the effectiveness of the gaseous contaminant removal and provides an indication of system life. A standardized methodology for these tests is described in Instrument Society of America (ISA) *Standard* 71.04.

Replacement and Reactivation

Regeneration of granular media is not the same as reactivation (regeneration), which is the process of restoring spent activated carbon media to its original efficiency (or close to it). In some unit operations, in some industrial applications (e.g., pressure swing adsorption), spent carbon is regenerated in special high-temperature vessels in the absence of oxygen to drive off contaminants. Chemisorber modules can be replaced (or media changed), however chemisorber media cannot be regenerated.

Building operating personnel may choose to dump and refill trays and modules at the site after replacing those removed with a spare set already loaded with fresh media. They may also choose to dump the trays locally and send the empty trays to a filter service company for refilling, or they may simply exchange their spent trays for fresh ones. Disposing of spent sorbent by dumping must be limited to building air quality applications where no identifiable hazardous chemicals have been collected.

11. ENVIRONMENTAL INFLUENCES ON AIR CLEANERS

Environmental conditions, particularly temperature and humidity, affect the performance of most gaseous contaminant removal equipment. Physical adsorbents such as activated carbon are particularly susceptible. The user should confirm performance for any air-cleaning device at the expected normal environmental conditions as well as at extremes that might be encountered during equipment outages. The following information is an overview.

High relative humidity in the treated airstream lowers efficiency of physical adsorbers, such as carbon, because of competition for adsorption sites from the much more numerous water molecules. Often, performance is relatively stable up to 40 to 50% rh, but some compounds can degrade at higher humidities. Both the chemical nature of the contaminant(s) and the concentration affect performance degradation as a function of relative humidity. On the other hand, very low relative humidities may make some chemisorption impossible. Therefore, media performance must be evaluated over the expected range of operation, and the relative humidity and temperature of the gaseous contaminant removal system should be held within design limits.

The effect of relative humidity swings can be better understood by considering a hypothetical physical adsorbent with a saturation capacity for a contaminant of 10% at 50% rh and 5% at 70% rh. Over an extended period at its normal operating condition of 50% rh, the sorbent might reach a loading of 2%. At this point a humidity swing to 70% rh would not cause a problem, and the adsorbent could load up to 5% capacity. Should the humidity then swing back to 50%, the adsorbent could continue to adsorb up to 10% by mass of the contaminant. However, if the adsorbent were loaded to 8% by mass at 50% rh and the humidity rose to 70% rh, the carbon would be above its equilibrium capacity and desorption would occur until equilibrium was reached.

Similarly, swings in temperature and contaminant concentration can affect physical adsorbent performance. Increasing temperature reduces capacity, and increasing concentration increases capacity. Additionally, changes in the identity of the contaminant in the airstream can affect overall performance, as strongly adsorbed contaminants displace weakly held contaminants.

All physical and chemical adsorption media have an ability to capture dust particles and lint, which eventually plug the openings in and between media granules and cause a rapid rise in the pressure drop across the media or a decrease in airflow. All granular gaseous adsorption beds need to be protected against particle buildup by installing particulate filters upstream. A prefilter with a minimum ASHRAE *Standard* 52.2 MERV of 7 is recommended.

Vibration breaks up the granules to some degree, depending on the granule hardness, and causes media settling in some activated carbon filters. ASTM *Standard* D3802 describes a test for measuring the resistance of activated carbon to his abrasion. Critical systems using activated carbon require hardness above 92%, as described by *Standard* D3802.

Physical adsorption and chemisorption media sometimes accelerate corrosion of metals they come into contact with. Consequently, media holding cells, trays, and modules should not be constructed of uncoated aluminum or steel. Painted steel or acrylonitrile butadiene styrene (ABS) plastic are common and exhibit good material service lives in many applications. Coated or stainless steel components may be required in more aggressive environments.

12. TESTING MEDIA, EQUIPMENT, AND SYSTEMS

Testing may be conducted in the laboratory with small-scale media beds or small pieces of treated fabric or composite material. It may be done on full-scale air cleaners in a laboratory test rig capable of generating the test atmosphere or in the field. Laboratory tests with specific challenge gases are generally intended to evaluate media for developmental, acceptance, or comparative purposes. Full-scale tests using specific challenge contaminants are required to evaluate a complete adsorber as constructed and sold, and are ultimately needed to validate performance claims. Field tests under actual conditions are used to ensure that the air cleaners were also properly installed and to evaluate remaining media life.

Laboratory Tests of Media and Complete Air Cleaners

Small granular media samples have been tested in laboratories for many years, and most manufacturers have developed their own methods. ASTM *Standard* D5228 describes a test method, but it is not entirely applicable to HVAC work because indoor air tends to have a wide range of contaminants, and the contaminant concentrations are several orders of magnitude lower than those used in the testing.

Testing for Fundamental Media Properties. The test used to evaluate fundamental properties of physical adsorption media, measurement of the adsorption isotherm, is static. In this test, a small sample of the adsorbent media is exposed to the pollutant vapor at successively increasing pressures, and the mass of pollutant adsorbed at each pressure is measured. The low-pressure section of an isotherm can then be used to predict kinetic behavior, although the calculation is not simple. For many years, the test outlined in ASTM *Standard* D3467, which measured a single point on the isotherm of an activated carbon using carbon tetrachloride (CCl_4) vapor, was widely used for specifying performance of activated carbon. The test has been replaced by one described in ASTM *Standard* D5228, which uses butane as a test contaminant, because of carbon tetrachloride's toxicity.

A correlation has been developed between the results of the two test procedures so that users accustomed to $CC1_4$ numbers can recognize the performance levels given by ASTM D5228.

It is a qualitative measure of performance at other conditions, and a useful quality control procedure.

Another qualitative measure of performance is the Brunauer-Emmett-Teller (BET) method (ASTM *Standard* D4567), in which the surface area is determined by measuring the mass of an adsorbed monolayer of nitrogen. The results of this test are reported in square metres per gram of sorbent or catalyst. This number is often used as an index of media quality, with high numbers indicating high sorption.

Small-Scale Dynamic Media Testing. ASHRAE *Standard* 145.1-2015 provides a flow-through test of physical and chemical adsorption media at small scale (about 50 mm diameter test bed) and relatively high concentration (100 ppm). The test is intended to provide data for meaningful comparisons of media, provided that the same contaminant challenge gas is used for each test. *Standard* 145.1 was developed based on several publications describing similar test procedures. Steady concentrations of a single contaminant are fed to a media bed, and the downstream concentration is determined as a function of the total contaminant captured by the filter (ASTM *Standard* D3467; Mahajan 1987, 1989; Nelson and Correia 1976).

Because physical adsorbent performance is a function of concentration, testing at high concentrations does not directly predict performance at low concentrations. The corrections described in the section on Physical Adsorption must be applied. If attempts are made to speed the test by high-concentration loading, pollutant desorption from the filter may confuse the results (Ostojic 1985). An adsorber cannot be tested for every pollutant, and there is no general agreement on which contaminants should be considered typical. Nevertheless, tests run according to the previously mentioned references do give a useful measure of filter performance on a single contaminant, and they do give a basis for estimates of filter penetrations and filter lives. Filter penetration data thus obtained can be used to estimate steady-state indoor concentrations in the preceding equations.

VanOsdell et al. (2006) presented data from ASHRAE research project RP-792 showing that, for a particular VOC adsorbed on activated carbon, tests at high concentration could be extrapolated to indoor levels. In addition, tests of a carbon with one chemical, toluene, were used to predict breakthough times for four other chemicals with modest success. The breakthrough times correlated well on a log-log plot of breakthrough time versus challenge concentration, and the predictions, based only on chemical properties and toluene and carbon performance data, were within approximately 100% of measured values.

A more recent ASHRAE research project, RP-1557 (Han et al. 2013), tested several physical and chemical adsorbent media against toluene, formaldehyde, ozone, and nitrogen dioxide. It found that relative performance at high-challenge-gas concentration corresponded with performance at low concentration. Some progress was also made in developing a mechanistic model for predicting low-concentration behavior for physical adsorbers.

Because physical adsorbers, chemisorbers, and catalysts are affected by the temperature and relative humidity of the carrier gas and the moisture content of the filter bed, they should be tested over the range of conditions expected in the application. Contaminant capture and reaction product generation need to be evaluated by exposing the test filter to unpolluted air and measuring downstream concentrations. Reaction products may be as toxic, odorous, or corrosive as captured pollutants.

Full-Scale Laboratory Tests of Complete Air Cleaners. Full-scale tests of in-duct air cleaners are the system test analogs of the media tests described previously. ASHRAE *Standard* 145.2-2016 details a full-scale performance test for in-duct air cleaners in a laboratory setting. In critical applications, such as chemical warfare protective devices and nuclear safety applications, sorption media are evaluated in a small canister, using the same carrier gas velocity as in the full-scale unit. The full-scale unit is then checked for leakage through gaskets, structural member joints, and thin spots or gross open passages in the sorption media by feeding a readily adsorbed contaminant to the filter and probing for its presence downstream (ASME *Standard* AG-1). Some HVAC filter manufacturers perform full-scale laboratory testing routinely for development and testing.

Chamber Decay Laboratory Tests of Complete Air Cleaners. Gaseous contaminant removal devices can be tested in sealed chambers by recirculating contaminated air through them and measuring the decay of an initial contaminant concentration over time. Chamber decay tests are generally used for devices that physically cannot be tested in a duct, or that have single-pass efficiencies so low that they cannot be reliably measured using up- and downstream measurements. The procedures used are gaseous contaminant analogs to the Association of Home Appliance Manufacturers (AHAM) particulate air cleaner test method, but no consensus test standard exists and test methods vary between laboratories. Decay tests can provide valuable data, but the results are affected by factors extraneous to the air cleaner itself, such as errors introduced by adsorption on the chamber surfaces, leaks in the chamber, and the drawing of test samples. Robust test quality assurance and quality control are required to obtain meaningful data. Daisey and Hodgson (1989) compared the pollutant decay rate with and without the contaminant removal device to examine these uncertainties.

A useful quantity that can be calculated from data obtained during air-cleaner testing is the **clean air delivery rate (CADR)**. Most air cleaners do not remove 100% of the contaminant(s) that they are intended to mitigate. The CADR expresses this incomplete removal as delivery of a lesser amount of fully cleaned air. For an in-duct test, the CADR is calculated as the product of the single-pass efficiency and the airflow rate through the device. For a chamber test, the CADR is calculated as the product of the decay rate constant due to action of the air cleaner and the volume of the chamber. Units are those of airflow rate (i.e., m^3/s), allowing direct comparison between the impact of the air cleaner and use of ventilation air. Note that the CADR may be different for each of the gaseous contaminants that the air cleaner removes.

Field Tests of Installed Air Cleaners

Gaseous contaminant air cleaners are expensive enough to place a premium on using their full capacity (service life). For odor management applications, the most reliable measure of the continued usefulness of gaseous contaminant air cleaners may be a lack of complaints because of the low concentrations, and complaints often serve as early indicators of exhausted granular beds. This approach is not acceptable for toxic contaminants, for which more formal procedures must be used. Unfortunately, and despite significant effort, there is not a simple, accepted standard for field-testing the capacity of gaseous air-cleaning equipment. Two approaches have been used: (1) laboratory testing of samples of media removed from the field and (2) in situ upstream/downstream gas measurements using the ambient contaminant(s) as the challenge.

The classic, and still widely used, technique of evaluating the status of a granular air cleaner in the field is to remove a small sample and ship it to a laboratory. Media manufacturers offer this service. The sample needs to be representative of the air cleaner, so should be obtained from near the center of the air cleaner. Consolidated multiple small samples taken over the filter area are more representative of the air cleaner than one larger sample. The sample needs to be handled and shipped carefully so that it remains representative of the in-place filter when it reaches the laboratory; laboratories can suggest procedures. Given a representative sample and good handling, sampled media test results give a good indication of the state of a media bed.

Unfortunately, media sampling as a field-testing procedure has disadvantages. First, it applies only to granular media that can be sampled; cutting a hole in a bonded or pleated media product to obtain a sample destroys the filter. In addition, opening a granular media air cleaner to obtain samples is sufficiently disagreeable to prevent its frequent application.

These disadvantages have led to attempts to find more convenient ways to evaluate filters in the field. The most widely used alternative approach is to sample the air up- and downstream of the filter and use the ratio to estimate the remaining filter capacity.

Field tests of gaseous contaminant air cleaners are conducted using the same general techniques discussed under contaminant measurement and analysis. Depending on the contaminant, type of air cleaner, and application, field testing can be accomplished with active or passive sampling techniques. Liu (1998) discussed the relative merits of the various techniques. Each has the potential to be superior in a given case. For indoor air applications with relatively constant contaminant sources, passive samplers are advantageous because they capture an integrated sample and are more economical. (Real-time samplers are used infrequently in this role.)

Up- and downstream measurements are evaluated by converting them to efficiency or fractional penetration and comparing them to measurements made at the time of installation. Because gaseous challenge contaminants cannot be injected into the HVAC system in occupied buildings, the up- and downstream samplers are exposed only to the ambient contaminants, which usually vary in nature and concentration. This complicates interpretation of the data, because air cleaner efficiency varies with concentration and nature of the contaminant. Measurement of efficiency using field samples is most directly interpreted if there is a single contaminant (or relatively consistent group of contaminants [evaluated as TVOC]) with a relatively constant challenge concentration. For multiple contaminants at multiple concentrations, judgment and experience are needed to interpret downstream measurements. Bayer and Hendry (2005) attempted to use single-component analyses to evaluate air cleaners in the field. The up- and downstream samples were analyzed not for TVOC, but for particular chemicals (heptane, toluene, ethyl benzene, and formaldehyde). Bayer and Hendry found that the time variations of the challenge made the efficiency determinations so variable that the procedure could not be used reliably.

CHAPTER 48

DESIGN AND APPLICATION OF CONTROLS

System Types 48.1
Heating Systems 48.1
Cooling Systems 48.4
Air Systems 48.8
Special Applications 48.18
Design Considerations and Principles 48.19
Control Principles for Energy Conservation 48.20

AUTOMATIC control of HVAC systems and equipment usually includes control of temperature, humidity, pressure, and flow rates of air and water. Automatic controls can sequence equipment operation to meet load requirements and to provide safe equipment operation using direct digital control (DDC), electronic, electrical, mechanical, and/or pneumatic devices. Automatic controls are only fully effective when applied to well-designed mechanical systems; they cannot compensate for misapplied systems, excessive under- or oversizing, or highly nonlinear processes.

This chapter addresses control of typical HVAC systems, design of controls for system coordination and for energy conservation, and control system commissioning. Chapter 7 of the 2017 *ASHRAE Handbook—Fundamentals* covers details of component hardware and the basics of control.

1. SYSTEM TYPES

A building automation system (BAS) with direct digital, electronic, or pneumatic controls has several physical control loops, with each loop including a controlled variable (e.g., temperature), controlled device (e.g., actuator), and the process to be controlled (e.g., heating system). A BAS with DDC controllers can share sensor values with several control loops or have multiple control loops selectively activate an actuator.

A BAS with DDC controllers allows information such as system status or alarms to be shared through a common communication protocol, between HVAC systems or within building systems and services, thereby enabling advanced, energy-saving, system-level applications. ASHRAE *Guideline* 13 and *Standard* 135 have more detailed discussions of networking and interoperability.

2. HEATING SYSTEMS

Heating systems include boilers, fired by either fuel combustion or electric resistance, furnaces, electric resistance air heaters, and heat pumps. Systems involving combustion require multiple safeties, which should always follow local codes and manufacturers' guidelines. Load affects the required rate of heat input to a heating system. The rate is controlled by cycling a fixed-intensity energy source on and off, or by modulating the intensity of the heating process. Heating systems may come with factory-mounted controls capable of handling safeties, cycling, and modulation. In addition, a BAS can be used to interface with the heating system or to control it directly. The designer decides under what circumstances to turn equipment on and off in sequence and at what temperature set point to maintain the supply air or water.

Hot-Water and Steam Boilers

Hot-water distribution control includes temperature control at hot-water boilers or the converter, reset of heating water temperature, and control of pumps and distribution systems. Other controls to be considered include (1) minimum water flow through boilers, (2) protecting boilers from temperature shock and condensation on the heat exchanger, and (3) coil low-temperature detection. If multiple or alternative heating sources (e.g., condenser heat recovery, solar storage) are used, the control strategy must also include a way to sequence hot-water sources or select the most economical source.

Figure 1 shows a system for load control of a fossil-fuel-fired boiler. Boiler safety controls, usually factory installed with the boiler, include flame-failure, high-temperature, and other cutouts. ASME *Standard* CSD-1-2012 requires a manually operated remote shutdown switch located just outside the boiler room door for boilers with fuel input ratings less than 3633 kW. Field-installed operating controls must allow safety controls to function in all modes of operation. In most cases, energy savings can be significant if the boiler is controlled to reset the water temperature based on heating load or a proxy such as outdoor air temperature. If the boiler is also used for domestic water heating, the reset range will be limited because minimum temperatures required to kill bacteria must be maintained. A typical outdoor air reset schedule is shown in Figure 1. With DDC devices, reset can be controlled from zone demand, which can improve energy performance and ensure all zones are satisfied. To minimize condensation of flue gases and boiler damage in noncondensing boilers, water temperature should not be reset below that recommended by the manufacturer, typically 60°C entering water temperature, or condensation may occur and lead to corrosion-related failure. Condensing boilers are specifically designed to allow flue gases to condense and should operate at lower water temperatures to harness latent energy in the flue gas. Aggressive reset of hot-water temperatures improves the efficiency of condensing boilers, because efficiency is a strong function of boiler entering water temperature. Additional energy savings are achieved using variable-speed pumps controlled to reduce distribution pump capacity to match the load, as allowed by the boiler's maximum flow.

Hot-water heat exchangers or steam-to-water converters are sometimes used instead of boilers as hot-water generators. Converters

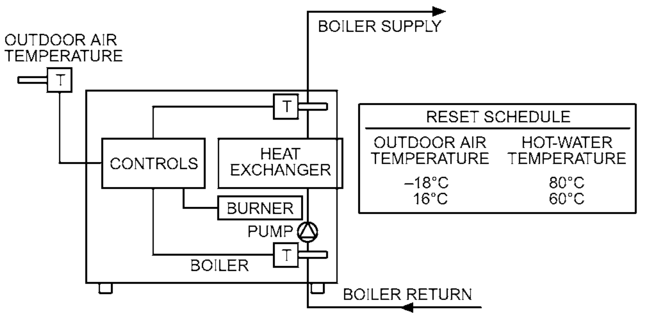

Fig. 1 Boiler Control

The preparation of this chapter is assigned to TC 1.4, Control Theory and Application.

typically do not include a control package; therefore, the engineer must design the control scheme. The schematic in Figure 2 can be used with either low-pressure steam or boiler water from 93 to 180°C. The supply water temperature sensor typically controls two modulating two-way valves in a 1/3 and 2/3 arrangement (because of poor turndown of steam valves) in a steam or high-temperature hot-water supply line. An outdoor temperature sensor (or zone demand, for higher efficiency) can be used to reset the supply water temperature downward as load decreases to improve the controllability of heating valves at low load and to reduce heat losses. A flow or differential pressure switch interlock should close the two-way valve when the hot-water pump is not operating. Ensure that the flow switch operates as expected at minimum flow rate on variable-flow systems. With a BAS, feedback from zone heating valves can be used to control starting and stopping of the hot-water pumps. When shutting down a steam converter or high-temperature hot-water system, close the steam valves and allow the water to circulate long enough to remove residual heat in the converter and prevent the pressure relief valve from opening.

Hot-Water Distribution Systems

Hot water is distributed using variable flow (primarily two-way valves at coils) or constant flow (three-way valves at coils). An example constant flow system is shown in Figure 3. Variable-flow systems are similar to the chilled-water distribution systems shown in Figures 10 and 11. Some boilers require constant flow or very high minimum flow rates. They typically are piped using a primary/secondary system (see Figure 11). These boilers are usually required by their listing to have flow switches to enable the boiler only when flow is proven. Boilers that require small (or zero) minimum flow rates are usually piped in a primary-only configuration with a bypass

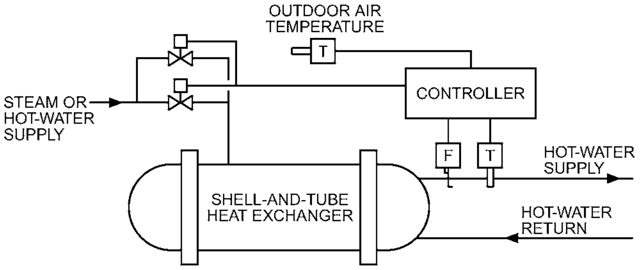

Fig. 2 Steam-to-Water Heat Exchanger Control

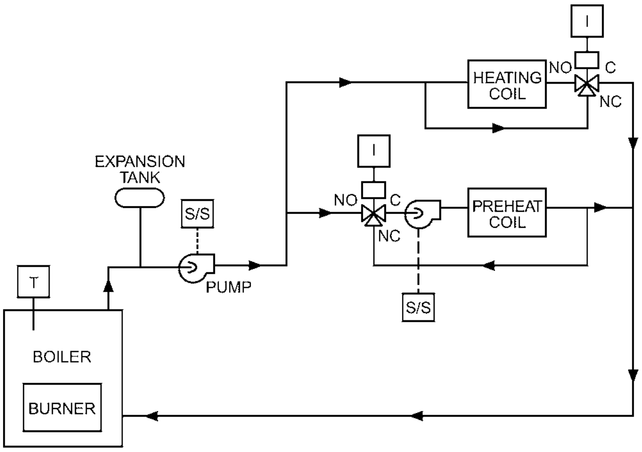

Fig. 3 Load and Zone Control in Constant Flow System

to maintain minimum flow (see Figure 10). A flow meter in the boiler circuit is usually installed to control the bypass valve. The bypass can also be controlled to maintain minimum boiler entering water temperatures for noncondensing boilers.

Heating Coils

Heating coils that are not subject to freezing can be controlled by simple two- or three-way modulating valves (Figure 4). (For information on the air side of coils, see the section on Air Systems.) The modulating valve is controlled by coil discharge air temperature or by space temperature, depending on the HVAC system. In cold regions, valves are set to normally open to allow heating if control power fails. In many systems, the supply air temperature set point is reset based on the outdoor air temperature, zone damper positions, return air temperature, or some other load proxy.

Heating coils in central air-handling units preheat, reheat, or heat, depending on the climate and the amount of minimum outdoor air needed. They can also provide morning warm-up on systems with limited zone heating capacity.

The equipment heating coil that first receives the outdoor air intake, even if mixed with indoor air, must have protection against freezing in cold climates, unless (1) the minimum outdoor air quantity is small enough to keep the mixed air temperature above freezing in all expected operating conditions and (2) enough mixing occurs to prevent stratification. Even when the average mixed-air temperature is above freezing, inadequate air mixing may allow freezing air to impinge on small areas of the coil, causing localized freezing. This blocks flow and, without a heat source, the rest of the coil and equipment downstream is at risk. Preheating coils that heat 100% outdoor air always need (1) protection against freezing and (2) constant water or steam flow in cold climates.

Steam preheat coils should have two-position valves and vacuum breakers to prevent condensate build-up in the coil. The valve should be fully open when outdoor (or mixed) air temperature is below freezing. This causes unacceptably high coil discharge temperatures at times, necessitating face-and-bypass dampers for final temperature control (Figure 5). The bypass damper should be sized to provide the same pressure drop at full bypass airflow as the combination of face damper and coil does at full airflow. When the outdoor air temperature is safely above freezing (roughly 1.7°C), the bypass damper is full open to the coil face and the coil valve can be modulated to improve controllability.

Hot-water coils must maintain a minimum water velocity in the tubes (on the order of 0.9 m/s) to avoid stratification and ensure proper heat transfer by maintaining turbulent flow. A two-position valve combined with face-and-bypass dampers (Figure 5) or a coil pump can be used. There are many coil pump piping schemes; the most common are shown in Figures 6 and 7. In each scheme, the control valve modulates to maintain the desired coil air discharge temperature and the pump maintains the minimum tube water velocity needed when the outdoor air is below freezing. Pumped coils can still

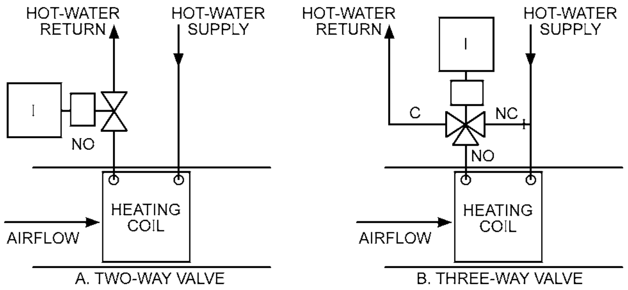

Fig. 4 Control of Hot-Water Coils

freeze in very cold regions, so additional low-temperature protection measures such as freezestats, glycol-based fluids, and default-to-open valves should be used.

A low-temperature detector (commonly called a **freezestat**), is a long, refrigerant-filled capillary tube used as a low-temperature sensing switch. If any short section of the tube is exposed to a low temperature (typically 3.3°C), it can provide an alarm or a hardwired

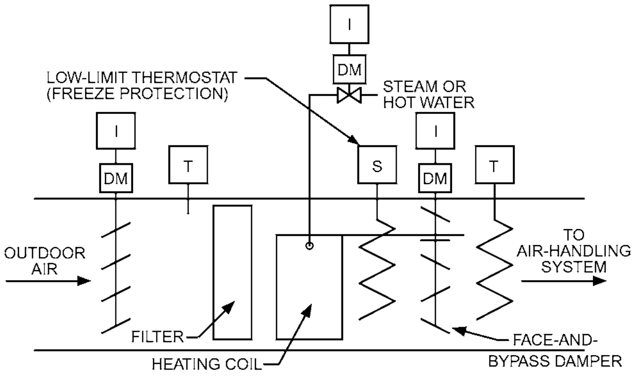

Fig. 5 Preheat with Face-and-Bypass Dampers

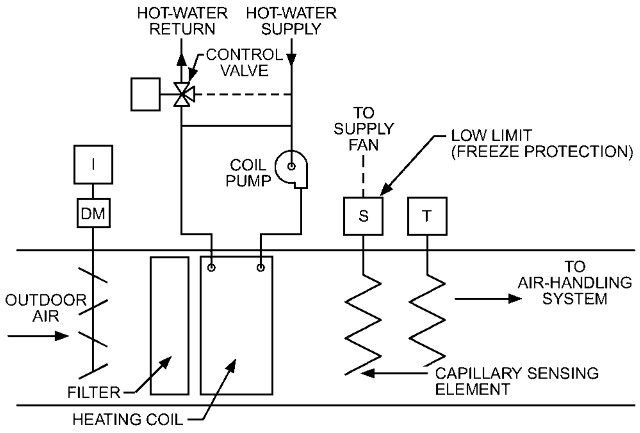

Fig. 6 Coil Pump Piped Primary/Secondary

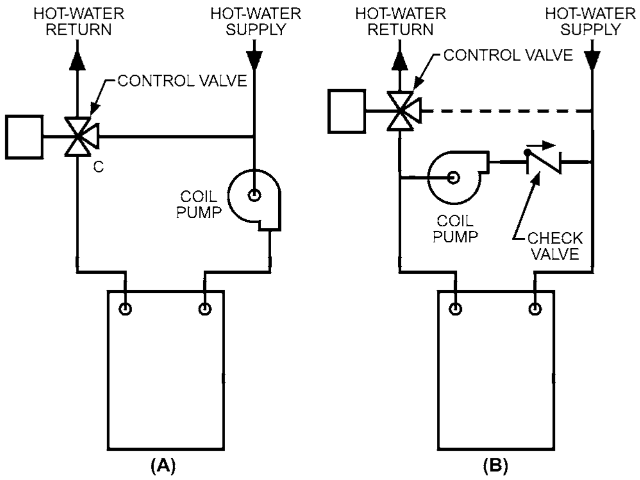

Fig. 7 Pumped Hot-Water Coil Variations: (A) Series and (B) Parallel

interlock to shut the outdoor damper and open the return damper, or shut down the fan.

Figure 6 shows the conventional primary/secondary (or secondary/tertiary) arrangement where the coil pump and the pumps feeding the coil are hydraulically independent. It results in constant flow through the coil and in either variable flow through the primary loop, if a two-way valve is used, or in constant flow through the primary loop, if a three-way valve is used (shown dashed in the figure).

In Figure 7A, the coil pump is in series with the primary pumps; this results in variable primary flow, which can affect flow through parallel coils that do not have pumps when the three-way valve moves, unless the primary system has variable-speed pumps and proper pressure control. The pump is decoupled when the three-way valve is closed to the system. The three-way valve must be oriented with the common port connected to the coil so its flow is not affected by the valve position.

Figure 7B shows the coil pump piped in parallel with the primary pumps. This design has the advantage that hot-water flow can be achieved through the coil if the coil pump fails. This design results in coil flow that varies from the pump design flow rate (when the control valve is closed) up through the sum of the pump flow rate plus the primary system flow rate (when the valve is wide open). Unlike the options in the previous two figures, the primary pump must be sized for the pressure drop through the coil at this high flow rate. Similarly, the coil pump must be sized for that pressure drop and not only for the flow it supplies. Flow through the primary circuit may be variable, if a two-way valve is used, or constant, if a three-way valve is used.

Some systems may use a glycol solution in combination with any of these methods; however, glycol affects control valve sizing (see Chapter 47 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*) and requires additional maintenance and careful handling.

Steam Coils. Modulating steam coils are controlled in much the same way as water coils. Control valve size and characteristics are important to achieve proper control (see Chapter 47 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*). Because the entering steam is hotter than the entering temperature of most water coils, a steam coil typically responds more rapidly and is smaller than a comparable water coil. In low-temperature applications, two-position control should be used, as discussed previously. For applications that require precise control at low loads, valves should be in a 1/3 and 2/3 arrangement.

Electric heating coils (duct heaters) are controlled in either two-position or modulating mode. Two-position operation uses power relays with contacts sized to handle the amperage of the heating coil. Step controllers can provide sequencing control of multiple stages of electric heat. Each stage may require a contactor, depending on the step controller contact rating. Timed two-position control requires a timer and contactors. The timer can be electromechanical, but it is usually electronic and provides a time base of 1 to 5 min. Thermostat demand determines the percentage of on-time. Because rapid cycling of mechanical or mercury contactors can cause maintenance problems, solid-state controllers are preferred. These devices may make cycling so rapid that control appears proportional; therefore, face-and-bypass dampers are not used. Use of electric heating coils is restricted in some areas by energy standards; check code compliance before using this application. A system with a solid-state controller and safeties is shown in Figure 8.

Current in individual elements of electric duct heaters is normally limited to a maximum safe value established by the *National Electrical Code*® (NFPA *Standard* 70) or local codes. An electric heater must have a minimum airflow switch and two high-temperature limit sensors: one with manual reset and one with automatic reset (Figure 9). The automatic reset high-limit thermostat

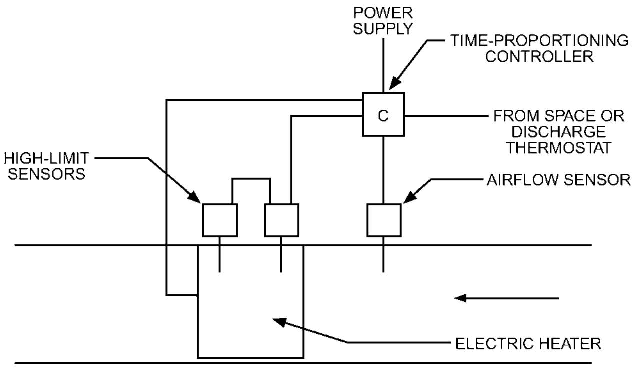

Fig. 8 Electric Heat: Solid-State Controller

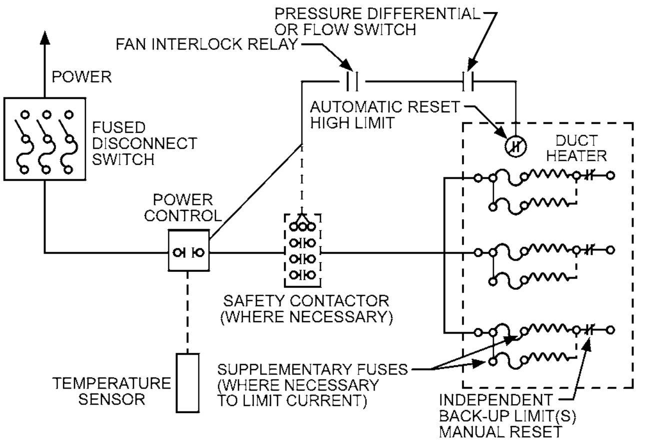

Fig. 9 Duct Heater Control

normally turns off the control circuit when temperatures exceed safe operating levels. If the control circuit has an inherent time delay or uses solid-state switching devices, a separate safety contactor may be desirable. The manual reset back-up high-limit thermostat is generally set independently to interrupt all current to the heater if other control devices fail. If still energized, electric coils and heaters can be damaged through overheating and potentially start a fire when air stops flowing around them. Control and power circuits must interlock with the associated fan to shut off electrical energy when it shuts down. Flow or differential pressure switches may be used for this purpose; however, they should be calibrated to energize only when there is airflow. This precaution shuts off power if a fire damper closes or duct lining blocks the air passage. The switch contact should also be calibrated to avoid chattering, which can damage mechanical or mercury contacts.

Radiant Heating and Cooling

Radiators (more accurately called **convectors**) can be used either alone or to supplement another heat source. The control strategy depends on the function performed. For a radiation-only heating application, rooms are usually controlled individually; each radiator and convector is equipped with an automatic control valve. Depending on room size, one thermostat may control one valve or several valves in unison. Unit-mounted thermostats and packaged controls allow lower component cost, better assembly quality, and avoid the cost and coordination of a second trade for remote sensor installation. Wall-mounted thermostats give the best results when controlling the space for the comfort of seated occupants.

For supplemental heating applications, where perimeter radiation is used to offset perimeter heat losses (the zone or space load is handled separately by a zone air system), sequence the radiation control with the main zone system to ensure there is no simultaneous heating and cooling. In the past, it was common to control the radiant system based on outdoor air temperature reset of the water temperature perhaps zoned by exposure with a solar compensating outdoor sensor, but this can result in “fighting” between the radiator and the main zone system and is disallowed by energy standards such as ASHRAE *Standard* 90.1.

Radiant panels combine controlled-temperature room surfaces with central air conditioning and ventilation. The radiant panel can be in the floor, walls, or ceiling. Panel temperature is maintained by circulating water or air, or by electric resistance. The central air system can be a basic one-zone, constant-temperature, constant-volume system, with the radiant panel operated by individual room control thermostats, or it can include some or all the features of dual-duct, reheat, multizone, or variable-air-volume (VAV) systems, with the radiant panel operated as a one-zone, constant-temperature system. Where hydronic tubing or electric heating elements are embedded in concrete, the rate of slab temperature change must be limited to prevent thermal expansion from cracking the concrete.

Radiant panels for both heating and cooling require controls similar to those for a four-pipe heating/cooling fan-coil. To prevent condensation, ventilation air supplied to the space during the cooling cycle should have a dew point below that of the radiant panel surface. The dew point should be actively controlled to prevent condensation. Outdoor air intake dehumidification and a tight building envelope or positive pressure are required. When internal latent loads increase, the chilled-water temperature for the radiant cooling panels should be reset upward if the dew point becomes too high.

3. COOLING SYSTEMS

Chillers

Manufacturers almost always supply chillers with an automatic control package installed. Their control functions fall into two categories: capacity and safety.

Because of the wide variety of chiller types, sizes, drives, manufacturers, piping configurations, pumps, cooling towers, distribution systems, and loads, most central chiller plants, including their controls, are custom designed. In the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, Chapter 43 describes various chillers (e.g., centrifugal, reciprocating, screw, scroll), and Chapter 13 covers variations in piping configurations and some associated control concepts. Chiller control strategies should always include an understanding of the chiller limits for minimum flow, minimum temperature, and acceptable rate of change for both.

Chiller plants are generally one of two types: variable flow (Figures 10 and 11) or constant flow (Figure 12). The figures show a parallel-flow piping configuration. Series-flow chiller configurations are often used in variable-primary-flow applications (Figure 10). The higher design water pressure drop of a series configuration is less of a concern in a variable-primary-flow application, because little time is spent at the maximum design flow operating condition. In Figures 10 and 11, the bypass line ensures minimum flow through the chiller(s). In Figure 10, flow is measured by the flow meter, and the BAS modulates the bypass valve as needed to maintain the minimum flow required by the operating chillers.

Control of the remote load determines which system type should be used. Throttling two-way coil valves vary flow in response to load, and are used with variable-flow systems.

Variable primary-only systems require greater care in design of the control system and control sequences than primary-secondary systems (Taylor 2002, 2011) but are usually more efficient. Selecting the bypass control valve and tuning the control loop is sometimes difficult because of the widely ranging differential pressure across the valve caused by its location near the pumps.

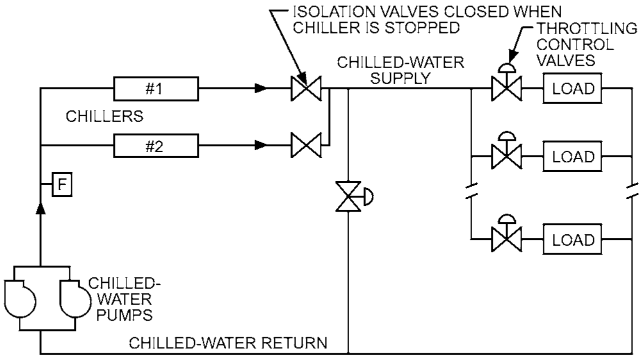

Fig. 10 Variable-Flow Chilled-Water System (Primary Only)

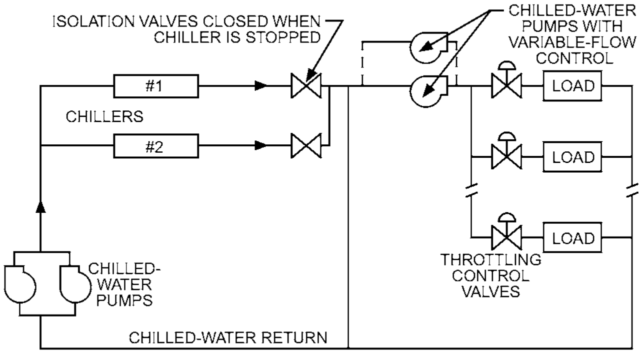

Fig. 11 Variable-Flow Chilled-Water System (Primary/Secondary)

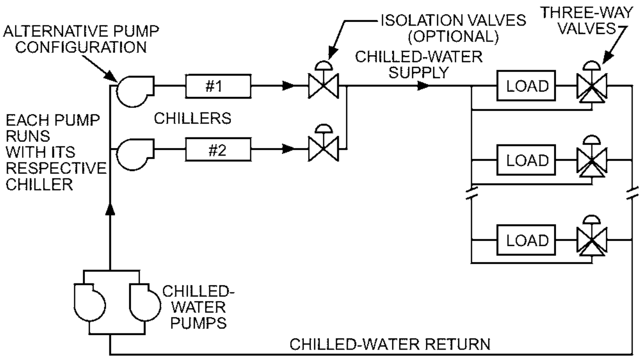

Fig. 12 Constant-Flow Chilled-Water System (Primary Only)

The valve must be large enough to bypass the minimum chiller flow through it with a pressure drop as low as the differential pressure set point used to control chilled-water (CHW) pump variable-frequency drives (VFDs). This is necessary because, if only a few valves are open in the system, the pressure at the differential pressure sensor location will be nearly equal to the differential pressure at the plant, because there is little pressure drop between these two points due to the low flow rate. This constraint makes the valve oversized for other flow scenarios that can occur, so tuning can be difficult. If the control loop is unstable, cold CHW supply can be fed back into the return intermittently and cause chillers to cycle off because of low load or cold supply water temperatures. However, if the loop is too slow, it may not respond quickly enough to sudden changes in flow (e.g., when a large number of air-handling units [AHUs] shut off at the same time), resulting in insufficient flow through the chillers and causing them to trip on low flow or low temperature.

The decision to reset the chilled-water supply temperature set point should be based on facility requirements. Chilled-water reset may not be appropriate in systems with tight space temperature and humidity requirements (e.g., hospitals, computer data centers, museums, some manufacturing facilities). Resetting the CHW temperature set point upward when loads are low is always an effective energy-saving strategy for constant-flow systems. In variable-flow systems, reset may or may not save energy, depending on plant design. High CHW temperature reduces coil performance, so coils in two-way valve systems demand more chilled water for the same load, degrading ΔT and increasing flow and pump energy requirements. Whether the net energy savings (chiller energy decrease minus pump energy increase) is positive and sufficient to offset the cost of implementing the reset strategy depends on chiller performance characteristics and the nature of coil loads. Resetting the CHW temperature set point also prevents unstable operation of control valves under very low loads. To ensure that no loads are starved, the chilled-water set point should be reset from the zone or system valve with the greatest load (load reset) (Taylor 2011).

The constant-flow system (Figure 12) is only constant flow under each combination of chillers on line; chillers and pumps can be staged if all loads experience similar loads at all times. If that is the case, the plant can supply about 80% of the design flow with just one of the headered pumps, and the chillers can be sequenced based on return temperature. Both pumps would run simultaneously only under peak demand. Staging may be prevented even at low plant loads if some coils are at high load while others are at low load, causing the chillers to operate at low loads, reducing plant efficiency. Use of constant-flow systems may be limited to smaller systems by energy codes.

Chiller Plant Operation Optimization

Chapter 42 discusses optimized control of chiller plants and details the control strategies that can be applied. This section highlights the general conclusions that can be drawn from the specific optimization strategy in the section on Sequencing and Loading of Multiple Chillers of that chapter.

Multiple chillers of different characteristics should be operated at a point that minimizes overall plant power consumption, considering the power consumption of the auxiliary chilled- and condenser water pumps and cooling tower fans as well as the consumption of the chillers and the load fans (Hartman 2005). For the general case of chillers with different part-load characteristics, operate multiple chillers at identical supply temperatures but different flows to achieve equal partial derivatives of the individual chillers' power consumption with respect to their loads. That is, the ratio of the incremental change in thermal load to the incremental change in input power should be identical for each online chiller. For identical chillers, this is achieved by loading them equally.

For constant-speed-drive chillers, sequencing is straightforward. It is best to run one chiller until fully loaded before bringing on a second machine. This dynamic changes for chillers with variable-speed drives, or if the chilled-water pumps are piped in a parallel (headered) arrangement or do not have variable-speed drives; for plants of this configuration, often overall plant power consumption is minimized when more chillers are operating at reduced load compared to fewer chillers operating at higher loads.

To meet any given plant load, many possible combinations exist for operating points of system equipment (e.g., chillers, pumps, cooling tower fans, air handler fans). When any given piece of equipment's operation point is changed, the operating point of at least one other piece of equipment must be changed to compensate. This results in one component reducing its power use and the other increasing it. Depending on how much each changes, total power use may increase or decrease. The combination of component operating points that results in minimum plant power consumption occurs when all the equipment in each subset that affect a variable (e.g., temperature, load, flow) operate at points where the power consumption partial derivative to the affected variable for each piece of equipment is equal.

A practical method to obtain the highest possible plant efficiency for current weather and load conditions uses a mathematical plant energy performance model and minimization to find the most efficient set of set points and commands. Alternatively, the most efficient configuration is precalculated for all foreseeable conditions and the control commands are then obtained from a lookup table (Nelson 2012).

When detailed information about the plant components' part-load energy performance for multiple scenarios is unavailable, or when sophisticated controls are beyond budget, use the following strategies. In most cases, they increase energy performance and are relatively easy to implement. However, return-on-investment analysis of controls of different sophistication levels is recommended, because the energy savings tend to quickly pay for the additional cost.

Cooling Tower Relief. Lowering the condenser water temperature by operating the tower fans at a higher speed reduces the compressor lift and the energy consumed by the chillers. Lowering the lift too much, however, may cause the fans to consume more energy than is saved by the chillers. A condenser temperature set point reset (to maintain constant tower approach [when the outdoor wet-bulb temperature is available] or proportional to the heat rejected or based on outdoor air temperature, and limited to the minimum chiller lift as recommended by the chiller's manufacturer), results in chiller energy savings of 1 to 3% for each 1 K reduction in water temperature for constant-speed chillers, and 2 to 5% for each 1 K reduction for variable-speed chillers. Chiller lift is defined as the difference between the chillers' leaving condenser water temperature and leaving evaporator temperature.

Supply Chilled-Water Temperature Reset. Increasing the supply temperature also reduces the chiller lift with similar savings per degree. Consider the effect on the loads and distribution pumps, because variable-speed pumps always (and fans sometimes) need to run harder, offsetting some or all the chiller energy savings. Also, some loads may not get enough cooling and be unable to maintain room temperature. Dehumidification requirements further limit the range of allowed supply temperature increase. As a first approach, the supply temperature set point can be reset between design value and 27 K proportional to the heat load or outdoor air temperature, or to maintain the most open cooling valve in the loads close to full open.

Maximize the Number of Variable-Speed Cooling Towers Used. Depending on the minimum flow needed by the cooling towers, more than one tower per chiller may be used. For example, two variable-speed towers can dissipate the same amount of heat as one tower by running at half the speed, and use about 1/8 of the energy.

Optimize the Number of Chillers Running. If the chillers' performance improves at part load (e.g., variable-speed centrifugal chillers), adding chillers before they are fully loaded results in more efficient configurations. Use the amount of heat removed or the kilowatts consumed by the chillers and, as a first approach, add a chiller when the operating chiller(s) are at 80% of capacity and shed one when they reach 35%.

Maximize (Return Temperature – Supply Temperature). Constant-flow chilled-water systems and constant-speed primary pumps result in more flow than needed for the amount of heat transported. The excess flow causes unnecessary pump energy use and increased compressor lift, which reduces chiller efficiency. Variable primary systems with two-way valves on all loads are the most efficient, but require a system bypass valve and careful control to prevent tripping the chillers (and potentially freezing them) because of low flow, when the load valves close, or when adding chillers. Systems with variable primary and variable secondary pumps and an open decoupler line are the next best in efficiency; they can be controlled to match the primary flow with the secondary, except to maintain the chillers' minimum flow. Next in efficiency are systems with constant primary and variable secondary pumps; these systems are robust and significantly simpler to control, not even requiring flow meters (hence their popularity). Constant-flow systems, which operate at part load most of the time, have the worst energy efficiency in most HVAC systems.

Performance Monitoring. Research (Deng and Burnett 1997; Erpelding 2007; Hartman 2012) shows that chiller plant performance begins to degrade soon after chillers are commissioned unless some form of ongoing commissioning is in place. The cause is usually equipment malfunction, poor maintenance, and/or inappropriate operation, which is difficult to detect in the complexity of plant operation. A performance-monitoring and -diagnosing system, especially an automated one, identifies deviations from expected operation and provides insights into their causes as well as suggesting improvements, thus prompting action and greatly contributing towards plant energy savings throughout its life cycle.

Cooling Tower

Cooling tower fans are typically controlled to maintain condenser water supply (CWS) temperature set point, as described previously. The CWS set point may be reset based on chiller load or, in the case of hydronic free cooling, space conditions. Figure 13 shows a typical cooling tower control schematic.

When the system includes large condenser water sumps, the temperature sensor's location must be considered. Large sumps introduce significant time delays into the system that must be accounted for in system design and operation. Often, condenser water supply piping does not run full at all times, particularly when draining to a sump. In this case, placing the temperature sensor so that is in contact with the water is important. This may necessitate locating the sensor on the bottom of an elbow or angled into the lower half of the pipe (to avoid mounting at the pipe bottom, where it could be susceptible to moisture collection).

Two-speed motors or variable-speed drives can reduce fan power consumption at part-load conditions and stabilize condenser water

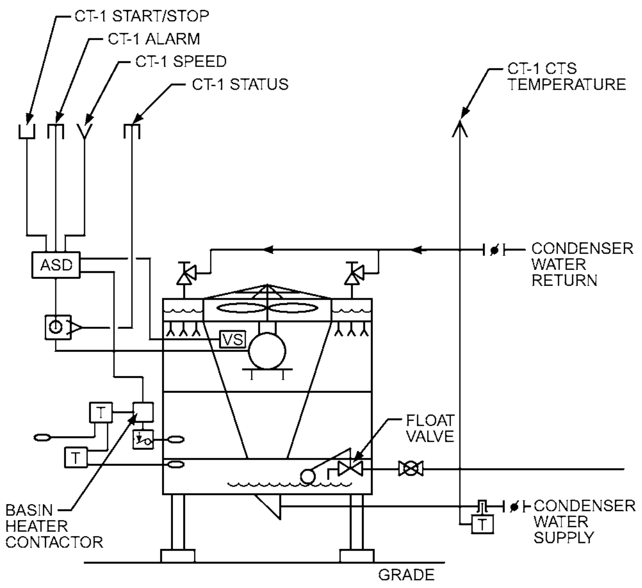

Fig. 13 Cooling Tower

temperature. Variable-speed drives (VSDs) improve control because fan speed can be better matched to the cooling load. When there are multiple towers, efficiency is maximized when as many cells as possible are active, which increases mass transfer area and reduces required fan speed. It may be necessary, however, to shut off flow to some cells to maintain minimum tower flow rate, as recommended by the tower manufacturer to minimize scaling. Fan speed should be controlled as follows.

Two-Speed Motors. The lowest fan speed should be used. For three two-speed towers, staging should be as follows:

Tower	Stage 1	Stage 2	Stage 3	Stage 4	Stage 5	Stage 6	Stage 7
1	Off	Low	Low	Low	High	High	High
2	Off	Off	Low	Low	Low	High	High
3	Off	Off	Off	Low	Low	Low	High

Provisions should be made to decelerate the fan when switching from high to low speeds.

Variable-Speed Drives. All of the operating tower fans should operate at the same speed.

Tower fans should also have a vibration switch hard wired to shut down the fan if excessive vibration is sensed.

Most tower manufacturers do not recommend bypassing water around the tower as a normal temperature control function, because this causes localized drying of the tower media and spot scaling. Bypass valves may be required for some low-temperature operations or hydronic economizer operations. Check with the tower manufacturer for bypass valve applications.

Where year-round tower operation is required in cold regions, cooling towers may require sump heating and/or continuous full flow over the tower to prevent ice formation, and may also require deicing. The cooling tower sump thermostat controls an electric heating element or hot-water or steam valve to keep water in the sump from freezing. Typically, sump heating is locked out during tower operation and when outdoor air temperatures are above freezing. When operating the tower in cold weather, full water flow is needed to prevent localized ice formation. If towers build up ice, reversing the fan rotation and sending air backward through the tower can deice them, either manually or automatically. Many operating personnel prefer to do this operation manually so they can observe the towers while deicing is under way. If deicing cycles are needed, the fan starter or VSD must be able to reverse the fan direction. There should be deceleration time interlocks so that the fans spin to a stop before engaging reverse operation. Automatic deicing control strategies are available from tower manufacturers.

Towers that have internal balancing piping or chambers must be allowed to drain into the basin when the tower is not operating in cold weather.

Auxiliary Control Functions. The control system may be required to cycle a fill valve to maintain sump level, or to monitor water consumption or water treatment systems. If the tower does not have sump heaters, the control system may be required to drain the tower and piping when outdoor air approaches freezing, and refill the tower on the next call for cooling.

Air-Cooled Chillers

Air-cooled chillers are controlled similarly to other chillers. If the chiller is to operate during cold weather, it must be equipped with a low-ambient kit. Typically this is a modulating damper or variable-speed fan that limits airflow across the condenser, usually provided as part of the chiller package. In very cold conditions, additional equipment is required. With variable-flow evaporators, careful attention to the manufacturer's recommended minimum flow must be observed. Chilled-water supply temperature can be reset as described above. The chiller may be equipped with a barrel heater, usually controlled by the chiller's packaged controls, to prevent the evaporator from freezing in cold weather.

Water-Side Economizers

Water-side economizers use cold water from the cooling tower to produce chilled water without (or with reduced) mechanical refrigeration. This is accomplished by running the cooling towers to produce water typically at or below 7°C while ambient wet-bulb temperatures are low. The cold water is pumped through a low approach water-to-water heat exchanger (HX), usually a plate-and-frame type, to produce chilled water at or below 10°C. The heat exchanger prevents contamination of the chilled water by debris and chemicals found in tower water. The heat exchangers can be piped in series or in parallel. With parallel operation, the heat exchanger functions like another chiller. In series arrangement, the heat exchanger precools the chilled-water return to the chillers. When there is enough heat exchanger capacity, the chillers may be turned off and a bypass opened to direct flow around the chillers. The series arrangement allows for integrated (simultaneous) economizer and chiller operation, which is required by some energy standards such as ASHRAE *Standard* 90.1. Chilled-water temperature is controlled by varying the tower fan speed. When changing from water-side economizer mode to chiller mode, the condenser water is cold, which requires that chiller head pressure control be addressed. Consult the chiller manufacturer for the requirements of each specific machine. To maintain condenser head pressure, many manufacturers recommend self-contained modulating valves or control valves modulated by the BAS or, preferably, by the chiller controller (many have head pressure control outputs as standard). When modulating the condenser water flow to maintain head pressure, the flow switch may need to be bypassed for a short time to keep the machine operating; consult the manufacturer. When the signal used for modulating the valve is controlled by the BAS, it should be directly from a pressure transmitter; relying on pressures obtained from the chiller controller through a network connection can be unstable or unreliable because data refresh rates may be slow or inconsistent.

Cooling Coil

Chilled-water or brine (glycol) cooling coils are controlled by two- or three-way valves (Figure 14). These valves are similar to those used for heating control, but are usually closed to prevent cooling when the fan is off. The valve typically modulates to maintain discharge temperature or space temperature set point.

Direct-expansion (DX) cooling equipment is usually controlled by an air, space, or coil discharge temperature feedback loop in discrete stages, by starting and stopping compressors and by applying mechanical unloaders, liquid-line solenoid valves, or hot-gas bypass valves. Most DX systems for commercial application have one to six stages.

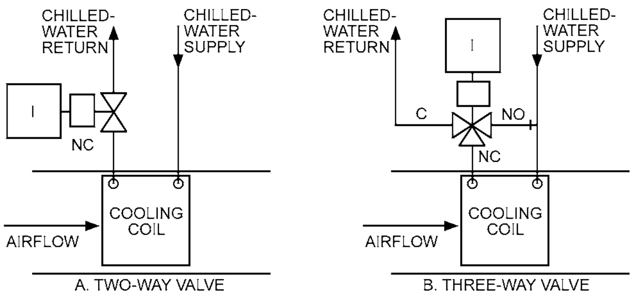

Fig. 14 Control of Chilled-Water Coils

When set up properly, a cycling DX system under a steady load operates like a two-position control loop (see Chapter 7 of the 2017 *ASHRAE Handbook—Fundamentals*). Some stages run steadily, and one stage cycles on and off. The behavior of the closed loop can be described by the cycling rate and corresponding swing in controlled air temperature. Most algorithms for DX control address both temperature control (e.g., set points, feedback gains, staging dead bands) and equipment cycling restriction (e.g., minimum-on timer, minimum-off timer, interstage delay). These two characteristics are inextricably linked by thermal sizing and loading conditions. Either characteristic can be affected by adjusting the control algorithm, but it is not possible to affect both characteristics independently: any reduction in temperature swing is accompanied by an increase in cycling rate. Overtightening temperature control will conflict with cycle controls and be rendered irrelevant.

When set up improperly, a DX system may cycle through multiple stages as the temperature oscillates around the set point, rather than having only one stage cycle on and off. Compared to proper operation, both the cycle rate and temperature swing are excessive. This operation can usually be corrected by adjusting parameters in the feedback algorithm.

Some staging systems are arranged so that it takes a greater temperature error to activate the higher stages. The result is that, at higher loads, the system operates at higher temperatures, which is usually not desired; it is usually intended that the system operate in the same temperature range, regardless of loading on the stages. This can be accomplished in many ways, including a proportional-plus-integral (PI) controller output driving a staging module.

If the DX system serves a single zone, the feedback signal is usually the space temperature, which usually varies by 0.5 to 2.2 K. If the DX equipment serves multiple zones, as in a VAV air handler, the feedback signal is usually the coil discharge temperature. Measured at this point, temperature swings appear much larger, though the effect on zone comfort is the same. When adjusting or specifying a DX system for discharge temperature control, it is important to allow the wider range of temperatures. Also, DX staging capacity on VAV applications should be limited based on air-handling unit (AHU) airflow rate, especially at low-part-load conditions, to prevent the coil from freezing.

Heat pumps are a variation of DX systems. (See Chapter 9 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for a detailed description.) Typically, heat pumps are controlled using manufacturer-supplied package controls. A hard-wired space temperature sensor or thermostat is connected to the unit. The controls regulate the unit's staging and cycling of any control valve(s). A BACnet® interface is available on many heat pump units, and can be wired to a BACnet network for monitoring and supervision. Typical BACnet objects include the following:

Analog Inputs	Analog Outputs	Analog Values
Space temperature	Space temperature set point	Occupied cooling set point
Supply air temperature	ECM fan override	Occupied heating set point
Effective cooling set point	Fan variable-frequency-drive (VFD) speed control	Unoccupied cooling set point
Effective heating set point		Unoccupied heating set point
Multistate Inputs	**Multistate Outputs**	**Multistate Values**
Effective occupancy state	Occupancy command	Cycle fan
Effective mode of operation	Fan command	
Compressor status	Compressor command	
Fan status	Emergency heat command	

Depending on the BACnet device, many more objects may be available. Some objects may be **read-only;** these are generally field input sensors (e.g., temperature) or objects that could cause equipment damage if commanded inappropriately (e.g., commanding compressor directly). **Writable** objects are available to the BAS for commanding (e.g., set points).

4. AIR SYSTEMS

Variable Air Volume (VAV)

Variable-air-volume systems provide thermal control by varying the amount of airflow delivered. A reduction in demand for cool air means the supply fan can operate at a reduced speed, saving energy. Most VAV systems have pressure-independent terminals, which means a separate airflow control loop operates each terminal damper.

Supply Fan Control. The VAV supply fan controller

- Ensures pressure in the duct is enough to serve the terminals
- Prevents excessive pressure from disrupting terminal flow loops
- Reduces the risk of excessive pressure from damaging duct systems
- Allows for reduced energy consumption at the fan
- Keeps the fan in a stable region of the pressure-flow curve

Historically, various mechanisms (e.g., bypass damper, variable inlet vanes) have been used to regulate fan output. These methods vary widely in efficiency and energy consumption. Currently, variable-speed drives (VSDs) and electrocommutated (EC) motors are the most common because their low energy consumption and low first cost makes them cost effective. They are prescriptively required for most VAV systems by energy standards such as ASHRAE *Standard* 90.1.

The most common variable-airflow method is a closed-loop proportional-with-integral (PI) control, using the pressure measured at a selected point in the duct system. Historically, the set point was a constant, selected by the designer and confirmed by the balancer during system commissioning. However, this control strategy is based on the readings of a single sensor that is assumed to represent the pressure available to all VAV boxes. Choosing duct pressure sensor location can be difficult: if it malfunctions or is placed in a nonrepresentative location, operating problems will result; if it is located too close to the fan, the sensor will not sufficiently indicate service of the terminals. This usually leads to excessive energy consumption. Some have reported that placing the sensor at the far end of the duct system couples fan control too closely with the action of a single terminal, making it difficult to stabilize the system. Experience indicates that performance is satisfactory when the sensor is located at 75 to 100% of the distance from the first to the most remote terminal (Figure 15). ASHRAE *Standard* 90.1 prescriptively requires that the location result in a set point no higher than one-third of the total system static pressure drop.

Even with a good sensor location, fixed-pressure set point uses more energy than necessary. There are many operating hours when the fan pushes air through a system full of partly closed dampers. Many energy standards such as ASHRAE *Standard* 90.1 prescriptively requires automatically adjusting duct pressure based on zone demand as system load varies for systems with DDC at the zone level integrated with the air handler control. Airflow to zones is still regulated by flow loops in the terminal controllers and is unaffected, but all else being equal, the system meets the load more efficiently with the terminal dampers closer to open. This reduces energy consumption at the fan. Ideally, pressure is reduced to the point that at least one of the dampers opens all the way. Any further supply fan speed reduction reduces airflow at the terminals.

Many methods have been published to automatically reset duct pressure (Ahmed 2001; EDR 2007; Englander and Norford 1992).

Reported energy savings, monitored over weeks or months, have ranged from 30 to 50% of fan energy used by the same system running with a constant-pressure set point. All of these reset designs use data from terminal controllers to alter fan operation.

Most reset strategies use zone control data to adjust the set point of the duct pressure control loop. This makes the location of the pressure sensor much less important.

Other reset strategies (Hartman 1993) eliminate the pressure control loop, using data from zones to drive the fan directly.

Reset strategies may be categorized according to the type of data collected from the terminal controllers. At least three approaches are in commercial use. The terminal controllers may deliver

- Damper position (or damper position and flow error)
- Flow set point
- Saturation signal (terminal indicates that the pressure is insufficient)

Data available for coordinating a fan control system vary with the model of terminal controller. Most have both a flow set point and a damper position value, though the suitability of the data for coordination varies. Control system designers should ensure that the data available from terminal controllers, the fan control strategy, and network data capacity are compatible.

The signal selected for coordination can determine the data communication load that the fan control strategy places on the network. Flow set points and saturation signals tend to change less often than damper position or flow measurements, so using them may be more practical with lower available bandwidth, especially in systems with many terminals. Saturation signals are binary, so they do not indicate their distance from the critical point. This can affect reset algorithm design.

One approach (using **damper position data**) is based on the idea that the desired mechanical operating point occurs when at least one damper is fully (or almost fully) open, and all terminals deliver the required flow. The fan controller processes damper position data from each terminal and adjusts duct pressure (or fan speed) to drive one damper open. To ensure that the open box is not starved, the reference may be set a little lower (95% open, for example), or the controller may check flow (or flow error) data from the terminal controllers. Floating actuator application methods may result in unreliable damper position values for some terminal controllers. It is important to take this into account when selecting a reset method. Rogue zones can provide false feedback and keep the fan at a higher speed than is necessary, and should be identified and corrected or removed from the control logic. Rogue zones can be caused by improper box sizing, false thermostat readings, or constantly loaded spaces.

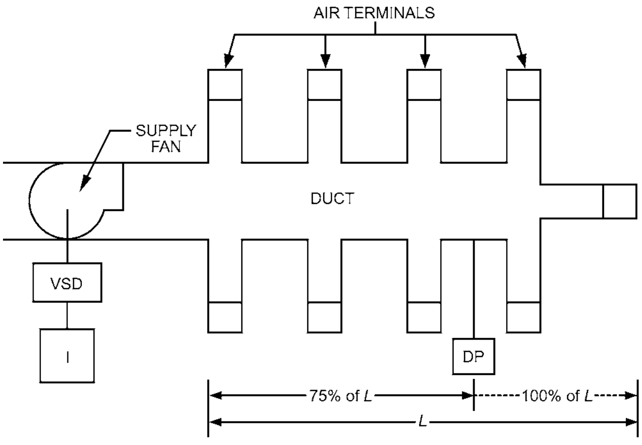

Fig. 15 Duct Static-Pressure Control

Another approach (using **flow set points**) is based on the fact that the required pressure depends on the distribution system (ducts, terminals, diffusers) and required flow. One way is to add the flow set points from each terminal and then use an empirically determined function to set the pressure. A more exact approach puts the individual flow set points into a calibrated model of the duct network, and calculates the pressure needed at fan discharge to drive the required flow to each terminal (Kalore et al. 2003). This online optimization applies the same calculations used to size a fan in real time. The pressure control loop then adjusts the fan speed to maintain the calculated pressure, which results in all terminals being satisfied, with one critical damper fully open (Ahmed 2001, 2002). This method is now in commercial use. In contrast to a reset based on damper position or saturation signals, a reset based on flow set point is open loop; this means that performance depends on careful calibration, but is inherently stable.

A third approach (using a **saturation signal**) distributes more of the logic. Each terminal controller uses flow data, damper position data, timing, or other information to decide whether its local loop is sufficiently supplied by the fan. If not, the saturation signal is activated. If a saturation signal is available, then the fan control algorithm depends less on the details of the terminal control than other methods. These signals are typically mated with a fan algorithm that ramps pressure up or down according to the number of unsatisfied terminals or resets static pressure set point using trim-and-respond logic (Taylor 2007).

To specify a pressure reset system, a designer can select the fan control algorithm, data that integrate terminal controllers, and characteristics of the communication network. Alternatively, the designer can specify the logic in performance terms (i.e., that the intended mechanical operating point is the lowest pressure that satisfies the terminals with at least one damper wide open). A performance-based specification allows proposals from vendors with a wider variety of equipment and algorithms.

Duct Static Pressure Limit Control. In larger fan systems, or where fire or fire/smoke dampers could close off a significant percentage of airflow, static pressure limit controls are recommended. When the high limit set point is reached (or low limit on the suction side of the fans for systems with economizer dampers), the fan is deenergized. Limit controls should be manually reset. On large fans, inertia of the fan wheel could damage the ductwork even after the fan is deenergized. Additional protection for the ductwork (e.g., duct pressure relief doors or mechanical relief dampers) is needed in these situations.

Space Pressure Control. Differential static-pressure control, differential airflow (CFM offset), and directional bleed airflow are methods used to control pressurization of a space relative to adjacent spaces or the outdoors. Typical applications include pressure barriers for any occupied space to prevent infiltration of moist unfiltered and untreated air, or to maintain interior comfort conditions. Applications requiring higher-performance controls include cleanrooms (positive pressure to prevent infiltration; see Chapter 18), laboratories and health care infection control (positive or negative, depending on use; see Chapter 8), and various manufacturing processes, such as spray-painting rooms (see Chapters 31 and 32 for industrial applications). The pressure controller usually modulates fan speed, dampers or airflow valves to maintain the desired pressure relationship or bleed airflow direction as exhaust volumes change. An alternative is to supply sufficient makeup air and to modulate a separate exhaust system to maintain space pressurization flow as auxiliary exhausts in the space are turned on or off.

Health Care Pressurization Codes, Regulations, and Application Design Guides. The Facility Guidelines Institute (FGI 2014) incorporated ASHRAE/ASHE *Standard* 170 into their guidelines.

These guidelines include requirements for differential pressure or differential flow control for rooms such as positive and negative isolation rooms. Refer to the guidelines for details.

Building Pressurization. A slight positive building pressure (1 to 20 Pa) is generally desired to reduce infiltration of unconditioned outdoor air. Pressure results from the development of a pressurization flow between adjacent pressure zones. A zone is positive to an adjacent zone if the pressurization flow across the zone barrier is positive. Generally, outdoor air is required to pressurize the building as a whole.

Building static pressure control is one method for control of the relief or exhaust fan; this requires direct measurement of the space and outdoor static pressures. The inside static pressure measuring location must be selected carefully, away from openings to the outdoors, elevator lobbies, and other locations where it can be affected by wind pressure and drafts. Stack effect also affects the reading for tall buildings in hot or cold weather; multiple pressure zones with independent sensors controls may be required to maintain positive pressure on all floors without overpressurizing some. The outdoor static pressure measuring location must also be selected carefully and oriented to minimize wind effects from all directions. Even with good sensor port locations, pressure readings can fluctuate and should be buffered before using for control. If multiple fan systems serve areas that are open to one another, a single pressure control loop should be used to prevent instability.

The amount of minimum outdoor air for pressurization varies with building permeability and relief or exhaust fan operation. Control of building pressurization can affect the amount of outdoor air entering the building.

Proper return fan control for VAV systems is required for building pressurization. In one approach, outlined in ASHRAE *Guideline* 16, the return fan is controlled to maintain the return air plenum pressure while exhaust (relief) air dampers are controlled to maintain building static pressure (see Figure 16). For relief fan systems, the relief fan speed is generally directly controlled by building pressure.

Direct-measurement pressurization flow compares an interior static pressure location to an outdoor reference to modulate relief fan speed or relief dampers. This control allows for greater operational repeatability, and improved energy savings potential where there are natural relief paths such as operable windows.

Indirect building pressure control uses duct or fan airflow measurements to control a fixed differential air volume by modulating dampers, fan speed, or discharge rates (Figure 17). Because return air is typically the controlled variable and its rate is set to track the normal changes in VAV supply at a fixed rate, this method is referred to as return fan or airflow tracking. The airflow differential set point is often determined empirically during commissioning as that needed to maintain a slight positive pressure with doors and windows closed.

Using fixed-differential air volume to maintain pressurization flow, rather than measured space static pressure, results in very stable control. It avoids the instabilities described previously for direct pressure control caused by fluctuating pressures from gusts of wind, opening doors and windows, and multiple air-handling systems serving interconnected areas that interact. However, the control is indirect, so actual space pressure varies (e.g., with stack effect as outdoor air temperature changes). Also, fan tracking is less reliable than direct-measurement pressurization control because the cumulative error of the two airflow measurements can be large, particularly at low supply/return airflow rates (*Advanced VAV Design Guidelines*).

Airflow quantity is indicated in Figure 18 by Q. Q_P is leakage in or out of the room, driven by the net pressure differential. Note that each surface may have a different ΔP because this value is relative to the pressure in the space on the other side of the wall.

When the control strategy changes from occupied (ventilation air required) to unoccupied warm-up, which does not require ventilation but needs thermal control to change the air-balancing requirements, warm-up is accomplished by setting return airflow equal to or just slightly less than the supply fan airflow, with toilet and other exhaust fans turned off and limiting supply fan volume to return fan capability. If exhaust fans remain running, then the supply fan must deliver sufficient outdoor air to make up the exhaust and still have a slightly pressurized space. During night cooldown, when using large quantities of outdoor air, the return fan operates in the normal mode (Kettler 1995).

Unstable fan operation in VAV systems can usually be avoided by proper fan sizing. However, if airflow reduction is large (typically over 60%), fan sequencing is often required to maintain airflow in the fan's stable range. Zone-based static pressure set point

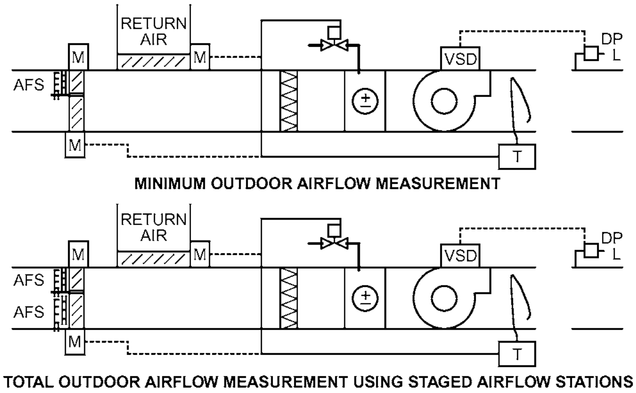

Fig. 21 Outdoor Air Control with Airflow Measuring Stations

reset, described previously, also allows the fan system with variable-speed drives to almost completely avoid the unstable region of its operating curves until fan speed is so low that instabilities are minor. This logic can allow very large VAV fans to serve very small airflows, during off-hours for instance.

Supply air temperature reset can be used to improve energy performance in most multiple-zone systems, including VAV systems, and is prescriptively required by energy standards such as ASHRAE *Standard* 90.1 for systems that have simultaneous heating and cooling at the zone level. In cool weather, supply air temperature can be reset upward based on zone demand, similar to static pressure reset. This reduces reheat energy losses and extends economizer operation, reducing mechanical cooling energy. In warmer weather, when space heat is not needed, supply air temperature should be reduced to reduce fan energy (EDR 2007).

Minimum Outdoor Air Control. Fixed minimum outdoor airflow control provides dilution air for ventilation, pressurization flow (usually exfiltration), and makeup air for exhaust fans. In some circumstances, minimum outdoor air may also provide combustion air for processes converting fuel to heat.

Several variations of minimum outdoor airflow control for VAV systems are possible (ASHRAE 2011; Felker and Felker 2010; Kettler 2000):

- Differential pressure is measured across the outdoor air intake louver or two-position minimum outdoor air damper. The differential pressure set point correlating to the minimum outdoor airflow is determined by measuring intake airflow directly upstream of the outdoor air damper in the field. This set point is maintained by modulating the return damper when not in economizer operation (Figure 19).
- A dedicated outdoor air injection fan with airflow station (Figure 20).
- An airflow station installed in the minimum outdoor air section with a minimum flow rate maintained by modulating the intake and return dampers in sequence (Figure 21). In this case, the intake opening should be sized for velocities high enough to facilitate measurement; some airflow sensors have relatively high minimum velocity requirements.

According to the *Standard 62.1 User's Manual* (ASHRAE 2016), VAV systems require one of the preceding methods for minimum outdoor air control or similar dynamic airflow controls for compliance; a fixed minimum damper position or a fixed-speed outdoor-air fan without control devices will not maintain rates within the required accuracy without overventilating.

ASHRAE research project RP-980 (Krarti et al. 2000) and the *Standard 62.1 User's Manual* suggest that return fan or airflow tracking are unsatisfactory for minimum outdoor ventilation control because even small errors in measurements of total supply airflow and total return flow can cause significant errors in the determination and control of minimum outdoor airflow rates. Although airflow tracking may be an option for building pressurization control, minimum outdoor air must be controlled independently.

Measuring the total outdoor airflow range of a VAV design from a minimum of less than 50% to maximum design capacity requires a measurement tool that can provide the needed reliability across the entire anticipated temperature and velocity range. One way to do this with pitot arrays is to subdivide the intake and use dual airflow stations sized for 1/4 and 3/4, or 1/3 and 2/3, of the maximum opening size. This increases the velocity pressure for the pitot array to ensure accurate measurement at minimum pressure drop (Kettler 2000). Thermal velocity sensors, which have a much lower minimum velocity than pitot devices, may be used without creating damper sections.

Regardless of the type of system, pressurization flow rate and outdoor airflow rate are controlled separately: the two functions are related but must be independently controlled.

The outdoor airflow set point for dilution ventilation should be established using ASHRAE *Standard* 62.1. In addition, the outdoor air set point for pressurization should be established by adding the pressurization flow requirement to the sum of the local exhausts in the zones served by the air-handling system. The greater of the two dictates the outdoor air set point.

Traditional economizer controls call for the outdoor air and recirculation dampers to be modulated inversely to maintain set point: one opens as the other closes. A more energy-efficient approach for VAV systems is to decouple the outdoor air and recirculation

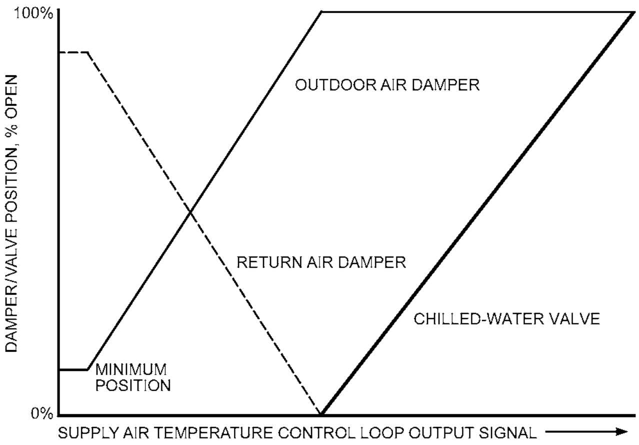

Fig. 22 "Integrated" Economizer Cycle Control

dampers by individually actuating each. The outdoor airflow rate is then controlled by sequencing the dampers (ASHRAE *Guideline* 16). This reduces pressure drop and thus reduces fan energy.

Dynamic Reset of Minimum Outdoor Air Intake Rates. Demand-controlled ventilation (DCV) is a control scheme designed to reduce minimum outdoor air levels when the spaces served have less than design occupancy. The most common scheme is to use CO_2 concentration to reset the occupant component of the minimum outdoor air rate required by ASHRAE *Standard* 62.1. **Ventilation reset control (VRC)** is a related control scheme for resetting outdoor air and minimum supply air rates as system ventilation efficiency changes because of operational changes in the system. Both control schemes are required by ASHRAE *Standard* 90.1 for many applications and are described in detail in the user's manual (ASHRAE 2011) for ASHRAE *Standard* 62.1.

When implementing dynamic ventilation reset schemes that reduce outdoor air intake, ensure that pressurization flow is maintained (i.e., the relationship between outdoor and exhaust air is maintained). When outdoor air dew point approaches or exceeds 16°C, a net positive pressurization flow is required to prevent transport of water and outdoor air contaminants into the building or its envelope (ASHRAE *Standard* 62.1).

Air-Side Economizer Cycle. Economizer-cycle control reduces cooling costs when outdoor air is cool and dry enough to be used as a cooling medium. The economizer is enabled when outdoor air conditions are below the high-limit device setting. When enabled, the economizer return and outdoor air dampers modulate to maintain a supply air temperature in sequence with the mechanical cooling. Typically, the economizer is controlled in sequence with the mechanical cooling, using the same supply air temperature control loop. Figure 22 shows integrated control, in which the economizer and mechanical cooling can be active at the same time. This is prescriptively required in most applications by ASHRAE *Standard* 90.1. When the outdoor air temperature exceeds the economizer high-limit set point, the economizer is disabled and only minimum outdoor air is supplied.

ASHRAE *Guideline* 16 addresses the sizing and selection of dampers for outdoor air economizer systems. Table 1 summarizes the guideline's recommendations as a function of the relief air system. Refer to the guideline for additional details and rationale.

High-limit controls are intended to disable the economizer when supplying outdoor air would use more energy than recirculating air. Common high-limit controls are

- Fixed dry-bulb temperature (compares outdoor air dry bulb to a fixed set point)

Table 1 Economizer Damper Type and Sizing

Relief System	Damper	Blade Type	Face Velocity, m/s
Return Fan	Relief/exhaust	Opposed	5.1 to 7.6
	Outdoor air	Parallel	2.0 to 5.1
	Return air	Parallel	Per Δ*P* across damper ~7.6
Relief Fan or Barometric	Outdoor air	Parallel	2.0 to 5.1
	Return air	Parallel	4.1 to 5.1

- Differential dry-bulb temperature (compares outdoor air dry bulb to return air dry bulb)
- Fixed enthalpy (compares outdoor air enthalpy to a fixed set point)
- Differential enthalpy (compares outdoor air enthalpy to return air enthalpy)
- Electronic enthalpy (compares outdoor air temperature and humidity to a set point that is a curve on the psychrometric chart)
- Combinations of these controls

ASHRAE *Standard* 90.1 includes some limitations on which controllers can be used and controller set points based on climate zone. The most energy-efficient high limit theoretically is a combination of differential enthalpy and differential dry-bulb temperature. However, it effectively requires four sensors (one temperature and one humidity in each of the outdoor air and return airstreams), all of which have inaccuracy and can get out of calibration, in particular the humidity sensors. Sensor error may result in increased energy usage relative to other, less expensive high-limit controls. In practice, the simplest, least expensive, and most reliable high-limit control is a fixed outdoor air dry-bulb temperature sensor set to the set point prescriptively required by ASHRAE *Standard* 90.1.

The relief air system should be enabled during economizer operation because the large quantities of outdoor air should leave the building along a planned path of flow and not an unplanned path, such as entry doors that may be pushed open.

VAV warm-up control during unoccupied periods requires no outdoor air if exhaust fans are off; typically, outdoor and exhaust dampers remain closed. Where a return fan is installed, the supply fan and return airflows are offset to maintain zero differential airflow.

Where outdoor conditions allow, night cooldown control provides 100% outdoor air for cooling during unoccupied periods. The space is cooled to the space set point, typically 5 K above outdoor air temperature. Limit controls prevent operation if outdoor air is above space dry-bulb temperature, if outdoor dew-point temperature is excessive, or if outdoor dry-bulb temperature is too cold (typically 10°C or below). When outdoor air conditions are acceptable and the space requires cooling, the cooldown cycle is the first phase of the optimum start sequence.

During unoccupied mode, with air-handling units off or not providing outdoor air, offgassing from building contents and construction materials can accumulate in the space. A **preoccupancy purge** sequence may be used to dilute the resultant volatile organic compounds (VOCs) before initial or daily scheduled occupancy. Purge damper settings are a fixed set point and should be adjusted equivalent to the building floor area component of the minimum outdoor air damper settings.

Constant-Volume (CV) Systems

In a constant-volume system, supply and return fan airflow rates are manually set to meet the airflow requirements for peak thermal load and ventilation for full occupancy. Once set, the airflow does not change; it is constant except when no airflow is needed and the unit is off. The air-handling unit's economizer outdoor air dampers, heating coil (where applicable), and cooling coil are controlled in sequence to maintain the **supply air temperature (SAT)** at a set point. For a single-zone constant-volume system, the SAT may also be reset based on outdoor air or return air temperature. For a constant-volume system serving multiple zones, the SAT may be reset to satisfy the zone with the maximum load or the cumulative change represented by the return air temperature. For a SAT reset strategy, the minimum cooling SAT set point should be set no lower than the design cooling coil's leaving air temperature, to prevent excessive chilled-water temperature reset requests that can reduce chiller plant efficiency. The maximum cooling SAT set point is typically 15.6°C in humid climates and 18°C in milder climates.

If unoccupied warm-up mode is used, the outdoor damper is closed and the supply air set point is adjusted upward to the desired value.

Control strategies for economizers, demand-controlled ventilation, morning warm-up, and night cooldown are the same as for VAV systems.

Terminal Units

A terminal unit (also called a constant-air volume [CAV] or variable-air-volume [VAV] box) is the zone-level control device for constant- or variable-volume systems. At a minimum, a terminal unit consists of a calibrated air damper, though different types also include components such a heating coil (in reheat boxes), automatic actuator controlling the calibrated air damper (in VAV boxes), and an integral fan in fan-powered terminal units.

A system is considered to be variable volume if primary airflow to the space varies. Total airflow to the space (primary air + plenum air) may be constant for some terminal units, even in a variable-volume system. Space set point is maintained by changing the temperature of the air delivered to the space or, with constant low-temperature supply air, by limiting the amount of the cool air that enters the space, or both. A space temperature of 24°C and 50% rh requires air supplied from the AHU that has typically been cooled to 13°C for moisture removal. Minimum ventilation may require so much cool air that the space is below the desired temperature. Zonal reheat coils at the terminal units heat the supply air at the zone to meet the space temperature set point.

VAV systems typically serve fewer than 15 zones per AHU. A terminal unit typically serves 1 to 8 outlets. The system should serve zones with similar thermal loads (e.g., all internal zones or all zones on the same exterior exposure), so that the unit is not continually switching between heating and cooling. To ensure minimum outdoor air ventilation is maintained, outdoor airflow must be controlled (see the section on Minimum Outdoor Air Control). A simple fixed damper position typically is not adequate.

Individual systems and their respective zones should be grouped together for easy scheduling and system-wide override. The system and zone groups all work in the same operating mode based on their operating schedule, occupancy status, and deviations from set point. See ASHRAE *Guideline* 13 for best practices in locating zone group operating mode programming logic based on network architecture. Depending on region, climate, and application, terminal unit zone groups should consider the following operating modes:

- Occupied
- Warmup
- Cooldown
- Setback
- Freeze protection setback
- Setup

Single-Duct, Constant-Volume. Reheat terminals use a single constant-volume fan system that serves multiple zones (Figure 23). All of the system's supply air is cooled to satisfy the greatest zone cooling load. Air delivered to other zones is then reheated with heating coils (hot-water, steam, or electric) in individual zone ducts. The reheat coil valve (or electric heating element) modulates as required to maintain the space condition. Because these systems consume more energy than VAV systems, they are generally limited by energy standards to applications with fixed ventilation needs, such as hospitals, special processes, or laboratories.

No fan control is required for constant-volume terminal units, because the design, selection, and adjustment of fan components determine the air volume and duct static pressure. The same temperature air is supplied to all zones. However, the controller can vary the supply temperature to respond to demand from the zone with the greatest cooling load, thus conserving energy, and demand-controlled ventilation may be implemented where applicable.

Single-Duct Variable-Volume. A **throttling VAV terminal** has an inlet damper that controls the flow of primary supply air (Figure 24). For spaces with exterior exposures or a high airflow requirement of ventilation air requiring heating, a reheat coil can be installed in the discharge. With pressure-independent controls, the space temperature sensor does not control the inlet damper directly. The space temperature control loop output is used to reset the primary airflow delivered to the space between a maximum and minimum rate. Direct control of airflow makes the VAV box independent of variations in duct static pressure.

The currently recommended control sequence is the dual maximum sequence in Figure 25. As the space goes from design cooling load to design heating load, the airflow set point is first reset from the cooling maximum to the minimum value needed for ventilation. Then the supply air temperature is reset from minimum (e.g., 13°C) to maximum (e.g., 32°C), and the reheat coil is modulated to maintain the supply air temperature at set point. Lastly, the airflow set point is reset from the minimum up to the heating maximum. The minimum flow rated for ventilation may be a constant, but is more likely adjusted by occupancy. The minimum flow rate may be further adjusted according to a measured concentration of some air constituent, typically carbon dioxide.

Previously, it was common to keep the primary airflow rate always high enough to handle the maximum heating load. ASHRAE *Standard* 90.1 and some other energy codes do not allow that practice because it increases simultaneous heating and cooling.

An **induction VAV terminal** controls space temperature by reducing supply airflow to the space and by inducing return air from the plenum into the airstream for the space (Figure 26). Both dampers are controlled simultaneously, so as the primary air opening decreases, the return air opening increases. When space temperature drops below the set point, the supply air damper begins to close and the return air damper begins to open.

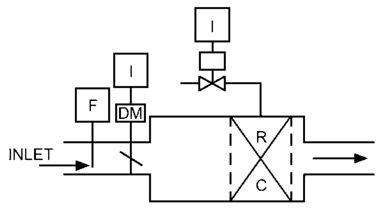

Fig. 24 Throttling VAV Terminal Unit

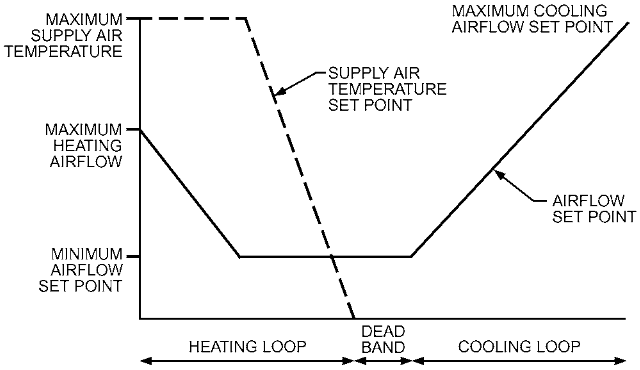

Fig. 25 Throttling VAV Terminal Unit: Dual Maximum Control Sequence

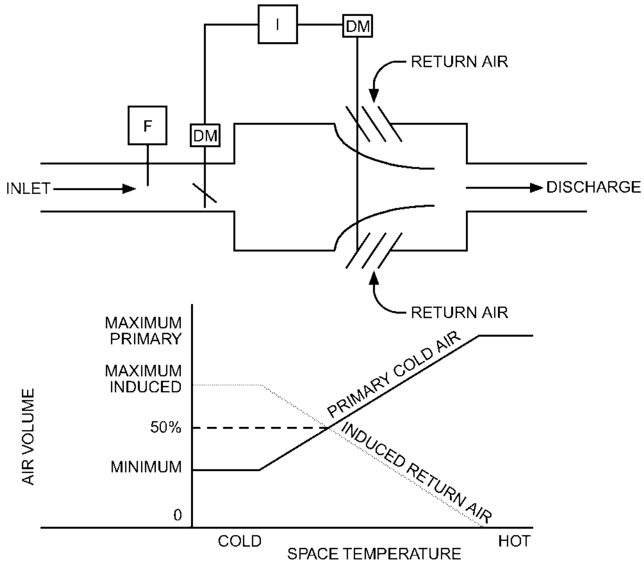

Fig. 26 Induction VAV Terminal Unit

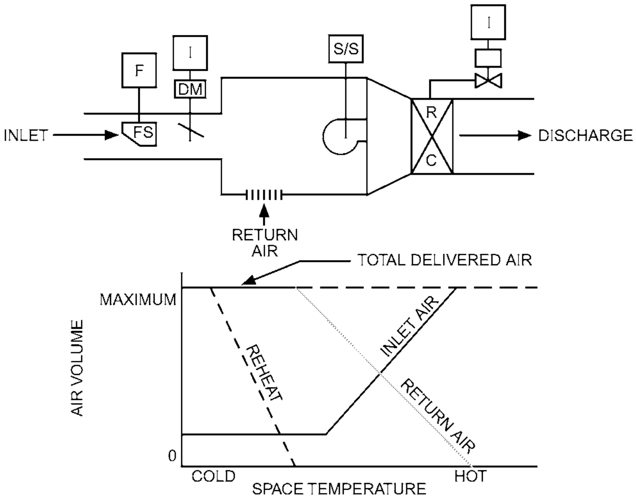

Fig. 27 Series Fan-Powered VAV Terminal Unit

A **series fan-powered terminal unit** has an integral fan in series with the primary supply air damper that supplies to the space (Figure 27). These terminals can be either constant or variable volume. In addition to enhancing air distribution in the space, a reheat coil can be added for space heating and to maintain a minimum temperature in the space when the primary system is off, for strategies such as setback, warm-up, and demand-controlled ventilation. When the space is occupied, the fan runs to provide air to the space. The fan can draw air from the return plenum to compensate for reduced supply air volume. As temperature in the space decreases below the cooling set point, the supply air damper begins to close and the fan draws more air from the return plenum. For zones with a reheat coil, when supply air reaches its minimum volume and the space temperature begins to drop below the heating set point, the valve to the reheat coil begins to open. Depending on the fan and motor, it may be important to start the terminal fan before the central air handler. If primary air is flowing when the terminal fan is off, it can spin the fan backwards. This can damage the motor when the terminal fan starts.

A **parallel fan terminal unit** is similar to the series fan terminal, except that the fan is in parallel with the primary supply air VAV damper (Figure 28). These terminals can be either constant or variable volume. A reheat coil may be placed in the discharge to the space or in the return plenum opening. The fan is intended to operate primarily in heating mode, but may also operate to maintain a minimum airflow to the space, allowing reduced primary airflow rates. Total airflow to the space is the sum of the fan output and supply air quantity. When space temperature drops below the cooling set point, the supply air damper begins to reduce the quantity of supply air entering the terminal. Once the supply damper reaches its minimum position and the space temperature begins to drop below the heating set point, the reheat coil valve starts to open. When the space is unoccupied and requires heating for setback or warm-up, the supply air damper is closed, the fan turns on, and the reheat coil valve modulates to maintain the unoccupied set point.

Variable-volume, dual-duct terminal units (Figure 29) have inlet dampers (with individual damper actuators and airflow controllers) on the cooling and heating supply ducts. The space thermostat resets the airflow controller set points in sequence as the space load changes. The airflow controllers maintain adjustable minimum flows for ventilation. If the heating supply has sufficient ventilation air, there need not be any overlap of damper operations (one snaps closed and the other snaps open at the heat/cool changeover point), resulting in no simultaneous heating and cooling in the terminal

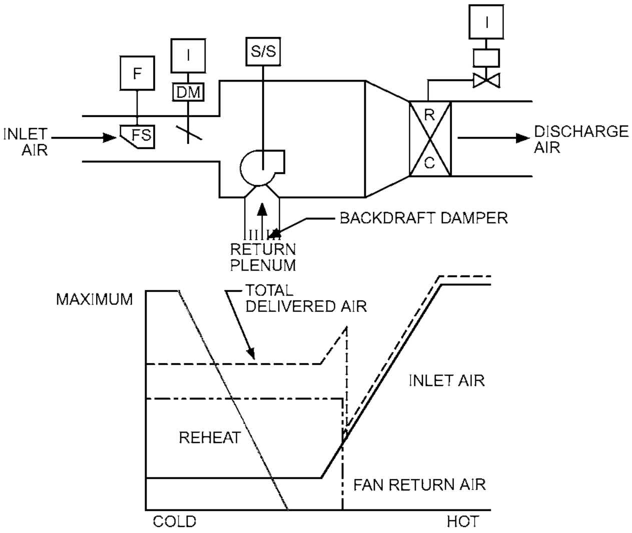

Fig. 28 Parallel Fan Terminal Unit

unit. On systems where the heating supply does not have sufficient ventilation air (e.g., on some dual-fan dual-duct applications), the cooling damper can be controlled to a minimum for ventilation.

There are two main control strategies for dual-duct terminal units. **Snap acting control** is the most efficient control logic and does not require dual-duct boxes with mixing sections that have a high pressure drop. It eliminates the need for mixing plenum because airflows do not mix. However, snap action control logic is not recommended for demand control, because it can cause the zone to oscillate between cooling and heating. It may also cause low supply air temperature on systems with high outdoor airflows and no preheat coils because it cannot mix hot and cold air. **Mixing control logic** is the preferred option for applications with demand-control ventilation or application with high minimum airflow rates.

Chilled-beam terminal units are available as active or passive. Active chilled beams are supplied with constant-volume primary air from a dedicated outdoor air system (DOAS) unit or other air system. This air flows through the chilled beam and induces room air. Passive chilled beams do not receive any system air; see Chapter 20 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Chilled beams can be two pipe or four pipe, and are controlled similarly to other radiant elements. Compared to some other HVAC systems, chilled beams with DOAS can simplify room control sequences because temperature control and ventilation control are separated. This separation helps HVAC designers when planning to meet the individual loads and makes it easy to design control sequences.

Modulating and two-position valves have been applied for temperature control with chilled beams. For temperature control, the system needs at least one flow control valve for each temperature control zone. One control valve may serve multiple chilled beams. Mechanical sizing issues or piping arrangements may favor driving several flow control valves in unison from one temperature controller.

Preventing condensation on cooling surfaces is important in design and operation of chilled beams and radiant cooling devices. This is mainly accomplished by coordinating the primary systems delivering air and chilled water to the room. The general approach is to dry the supply air sufficiently to keep the space dew point a couple of degrees below the chilled-water supply temperature. Depending on loads and sizing, this may be possible without active control. Often, the solution is to sense relative humidity in some or all of the spaces, calculate the dew point, and deliver that information to the primary air and water control systems, where reset strategies prevent condensation.

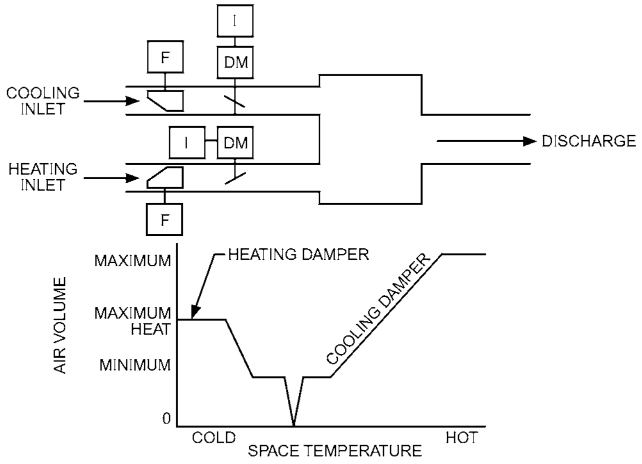

Fig. 29 Variable-Volume Dual-Duct Terminal Unit

As a back-up, condensation detectors at the chilled beams are recommended. When the switch closes, indicating condensing conditions, the system closes the control valve to the cooling coil. This prevents damage by condensation, but also disables cooling in the space. It is a back-up, safety measure; coordinating air and water distribution temperatures is the primary strategy. Sometimes, the energy advantage that leads to a chilled-beam design depends on optimizing features in the primary systems. In the cooling plant, the water-side economizer and other special strategies that deliver relatively warm water to the chilled beams may be critical to efficiency. Overall system efficiency may also depend on reducing use of reheat in the rooms. The supply air temperature reset strategy that minimizes reheat and controls moisture in the space may be sophisticated. Typically, the simple room control strategies must deliver coordinating data into relatively advanced primary plant controls.

Humidity Control

Humidity control relies on the output of a humidity sensor located either in the space or in the return air duct. Most comfort cooling involves some natural but uncontrolled dehumidification. The amount of dehumidification is a function of the effective coil surface temperature and is limited by the coolant's freezing point. If water condensing out of the airstream freezes on the coil surface, airflow is restricted and, in severe cases, may be shut off. The practical limit is about 5°C dew point on the coil surface. As indicated in Figure 30, this results in a relative humidity of no less than 30% at a space temperature of 24°C. When lower humidity is needed for a process application (e.g., dryroom), a desiccant dehumidifier is required.

Although simple cooling by refrigeration typically provides dehumidification as a by-product of the cooling process, without additional equipment, it does not directly control space humidity. **Dehumidification** can be directly controlled in several ways. If relative humidity is the critical measure, adding heat to the space decreases the relative humidity, but usually the object is to remove moisture and lower the dew point. One method is to control the cooling coil based on relative humidity, not space temperature. The supply air temperature leaving the coil is lowered until enough moisture is removed from the supply air to maintain the humidity set point. When a relative humidity limit is required, a space or return air humidistat is provided in addition to the space thermostat. A control function selects the higher of the output signals from the two devices and controls the cooling coil valve to provide either temperature or humidity control. A low-temperature coil used to remove

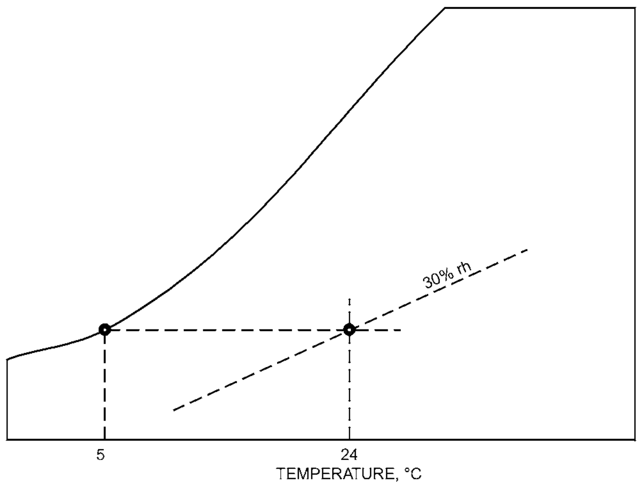

Fig. 30 Psychrometric Chart: Cooling and Dehumidifying, Practical Low Limit

moisture from an airstream may lower a space temperature below the desired set point. The process line in Figure 30 shows a significant loss of sensible temperature before moisture is removed. As space temperature decreases, the relative humidity increases even though the absolute humidity (dew point, grams of moisture, kilograms of water to kilograms of air) decreases.

A reheat coil is required to maintain the space temperature if moisture removal results in too low a supply air temperature. This coil may be located in the AHU, as shown (Figure 31), or a space-temperature-controlled reheat coil may be provided at the room terminal unit.

Sprayed-coil dehumidifiers (Figure 32) have been used for dehumidification. Space relative humidity ranging from 35 to 55% at 24°C can be obtained with this equipment; however, the costs of maintenance, reheat, and removal of solid deposits on the coil make the sprayed-coil dehumidifier less desirable than other methods.

Air washers with a cold-water spray (down to 5°C) do not require the coil for cooling, though mist eliminators add to the equipment in the air handler. The spray cools the air, removes moisture down to the temperature of the spray water, and collects and concentrates particulates in the spray pan. As with the spray coil, this is messy and slower to respond than other methods.

A **desiccant-based dehumidifier** can lower space humidity below that possible with cooling/dehumidifying coils. This device adsorbs moisture using silica gel or a similar material. For continuous operation, heat is added to the adsorbent material out of the dehumidification airstream to evaporate moisture and regenerate the material. This is often in a wheel configuration that rotates the gel from the wet side, where it absorbs moisture, into the heated dryer side, where moisture is driven off and exhausted from the system. The adsorption process adds heat to the dehumidified air. Cooling is required, but at a warmer temperature to limit the need for lower-temperature cooling coils. The psychrometric process is shown in Figure 33, and Figure 34 shows a typical control. There are two control loops to consider: (1) the heating source must be hot enough to regenerate the media for effective moisture removal, and (2) the cooling coil needs only lower the temperature to a point that provides a comfortable space condition. Because the moisture has been removed by adsorption, the conditioned air to the space may be 5 to 7 K warmer than required for an AHU that uses only cooling to control moisture. When the outdoor air is drier, regeneration can use a lower-temperature source, saving heating and subsequent cooling energy.

Humidification can be achieved by adding moisture to supply air, using evaporative pans (usually heated), steam injection, or atomizing spray tubes. A space or return air humidity sensor provides the necessary signal for the controller. A humidity sensor in the duct

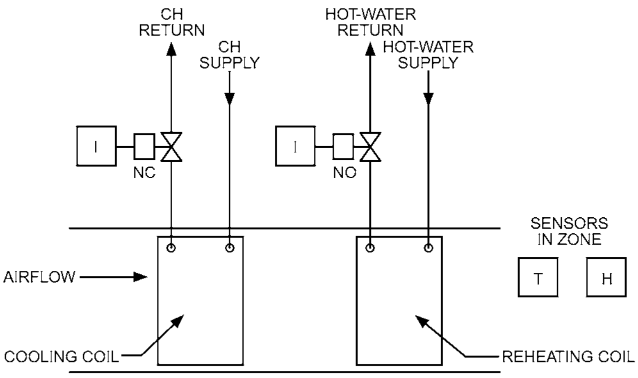

Fig. 31 Cooling and Dehumidifying with Reheat

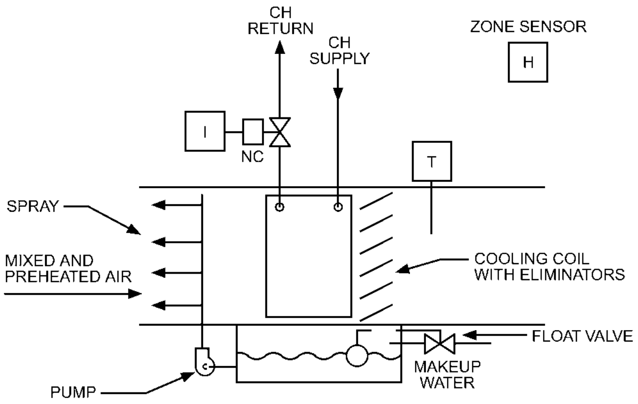

Fig. 32 Sprayed-Coil Dehumidifier

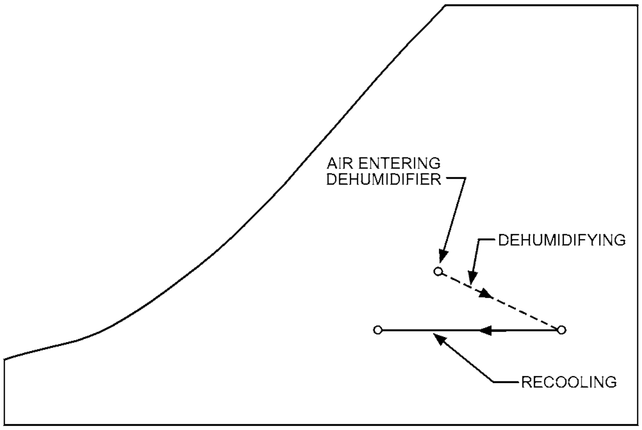

Fig. 33 Psychrometric Chart: Desiccant-Based Dehumidification

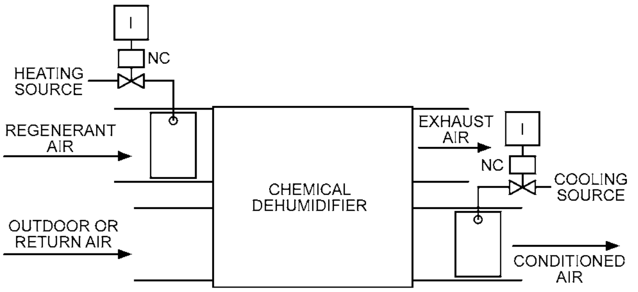

Fig. 34 Desiccant Dehumidifier

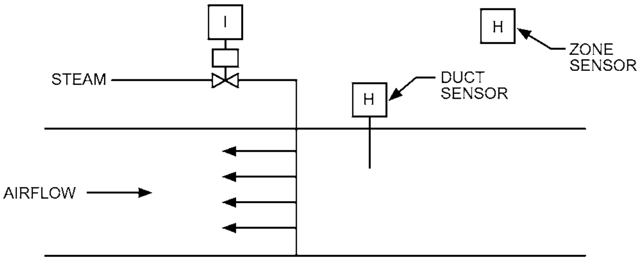

Fig. 35 Steam Injection Humidifier

should be used to minimize moisture carryover or condensation in the duct (Figure 35). With proper use and control, humidifiers can achieve high space humidity, although they more often are used to maintain design minimum humidity during the heating season. Atomized fine droplets make it easier to mix water in to an airstream, but converting a droplet into water vapor requires heat for the change of state. Because evaporative cooling occurs with an atomized method, additional heat must be provided. Steam is already a vapor, so additional heat is not required for the humidification process. It is important to have not only a space or return sensor to call for adding humidity, but also a duct sensor just downstream of the humidifier to limit the moisture concentration being injected to less than 85%, to avoid condensation on the duct walls.

Single-Zone Systems

A single-zone system (Figure 36)) is an air handler serving one area of a building that has similar loads and occupancy throughout the zone. Single-zone systems do not require terminal boxes, because zone temperature can be maintained by modulating fan speed and using the heating and cooling control valves (and optional economizer dampers) to control discharge air temperature, as indicated in Figure 37 The fan is typically variable speed, which is now required for many applications by energy standards such as ASHRAE *Standard* 90.1.

A **unit ventilator (UV)** is designed to heat and ventilate a space by introducing up to 100% outdoor air. Optionally, it can cool and dehumidify with a cooling coil (either chilled-water or direct-expansion). Heating can be by a gas furnace, hot water, steam, or electric resistance. Control of these coils can be by valves or by face-and-bypass dampers.

A typical control sequence for a UV is shown schematically in Figure 38 and logically in Figure 39. During the heating stage, this approach (Figure 38) supplies a set minimum quantity of outdoor air. Outdoor air is gradually increased as required for cooling. During warm-up, the heating valve is open, the outdoor air (OA) damper is closed, and the return air (RA) damper is open. As space temperature rises into the operating range of the space thermostat, ventilation dampers move to their set minimum ventilation positions. The heating valve and ventilation dampers are operated in sequence as required to maintain space temperature. The airstream thermostat can override space thermostat action on the heating valve and ventilation dampers to prevent discharge air from dropping below a minimum temperature. Figure 39 shows the relative positions of the heating valve and ventilation dampers with respect to space temperature.

Makeup air units (Figure 40) are 100% outdoor air units that replace air exfiltrated or exhausted from the building through toilet, laboratory, industrial, and combustion processes. Makeup air is often supplied at or near space conditions, but may also provide space heating and cooling. The makeup air fan is usually turned on, either manually or automatically, whenever exhaust fans are turned on. However, the fan should not start until the outdoor air damper is fully open as proven by an end switch. The two-position outdoor air damper remains closed when the makeup fan is not in operation. The outdoor air limit control opens the preheat coil valve when outdoor air temperature drops to the point where the air requires heating to raise it to the desired supply air temperature. To prevent low-temperature shutdowns on start-up, the heating coil should begin circulation and prove heating is available before the outdoor damper

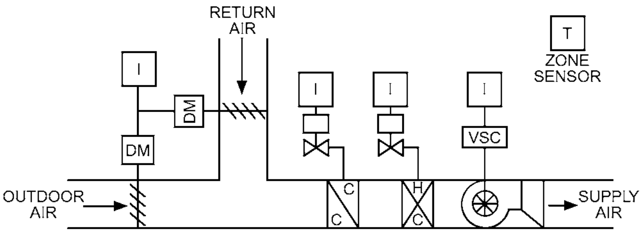

Fig. 36 Single-Zone Fan System

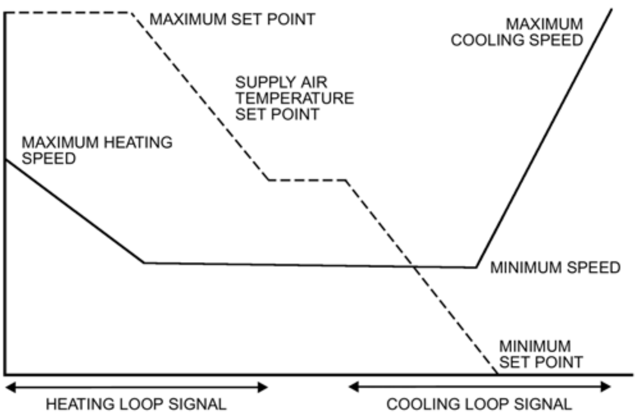

Fig. 37 Single-Zone VAV Control

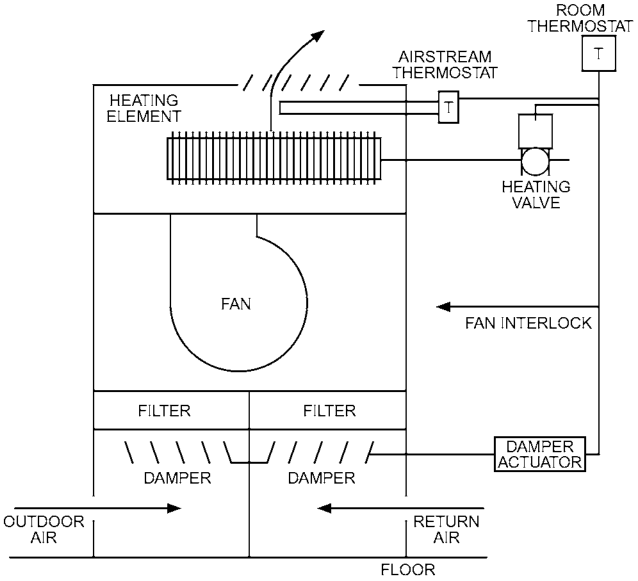

Fig. 38 Unit Ventilator Control Arrangements

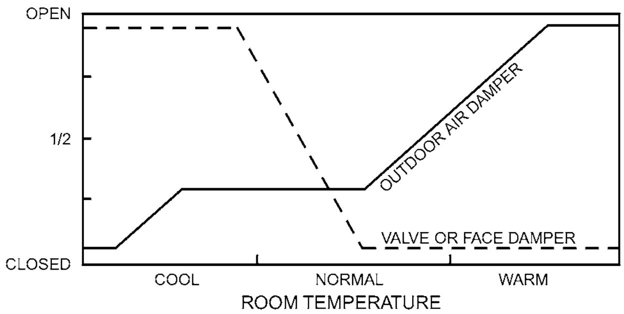

Fig. 39 Valve and Damper Positions with Respect to Room Temperature

opens and the fan starts. A capillary element freezestat located adjacent to the coil shuts the fan down for low-temperature detection if air temperature approaches freezing at any spot along the sensing element.

Fuel-fired makeup air units have staged or modulating fuel-fired direct or indirect furnaces. Units have manufacturer-supplied controls and safeties for flame proving, airflow proving, and discharge air low limit to meet the ANSI *Standard* Z83.4/CSA *Standard* 3.7 combined safety standard. The manufacturer's controls either include temperature controls or provide an interface for the control contractor's temperature controls.

Multiple-Zone, Dual-Duct Systems

A **single-fan, dual-duct system** uses a single fan to supply separate heating and cooling ducts (Figure 41). Dual-duct terminal mixing boxes are used to control the zone temperature. For VAV terminals, static control is similar to that in VAV single-duct systems except that static pressure sensors are needed in each supply duct. A controller allows the sensor detecting the lowest pressure to control the fan output, thus ensuring that there is adequate static pressure to supply the necessary air for all zones.

The hot deck has its own heating coil, and the cold deck has its own cooling coil. Each coil is controlled by its own **discharge air temperature controller**. The hot deck set point may be reset from the zone with the greatest heating demand, and the cold deck

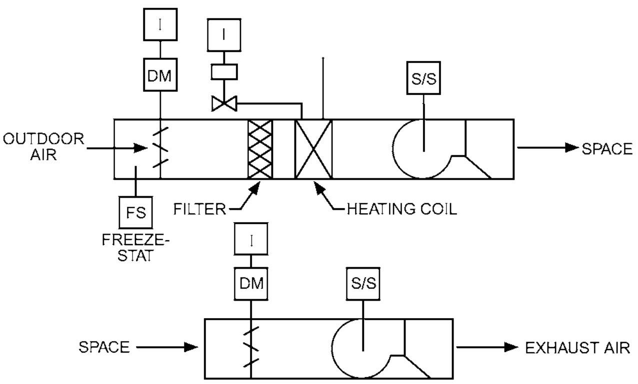

Fig. 40 Makeup Air Unit

set point may be reset from the zone with the greatest cooling demand.

Cooling supply air temperature control is similar to that in single-duct systems, with economizer dampers sequenced with the cooling coil. The economizer causes the supply air temperature entering the hot deck to be as cold as the cold deck, increasing heating energy usage. Because of this inefficiency, single-fan, dual-duct systems with air economizers are not allowed by many energy standards such as ASHRAE *Standard* 90.1.

Dual-fan, dual-duct systems (Figure 41) use separate supply fans for the heating and cooling ducts. This eliminates the economizer inefficiency of single-fan, dual-duct systems. Static-pressure control is similar to that for VAV single-fan, dual-duct, systems, except that each supply fan has its own static pressure sensor and control.

5. SPECIAL APPLICATIONS

Mobile Unit Control

The operating point of any control that relies on pressure to operate a switch or valve varies with atmospheric pressure. Normal variations in atmospheric pressure do not noticeably change the operating point, but a change in altitude affects the control point to an extent governed by the change in absolute pressure. This pressure change is especially important with controls selected for use in land and aerospace vehicles that are subject to wide variations in altitude. The effect can be substantial; for example, barometric pressure decreases by nearly one-third as altitude increases from sea level to 3000 m.

In mobile applications, three detrimental factors are always present in varying degrees: vibration, shock, and acceleration forces. Controls selected for service in mobile units must qualify for the specific conditions expected in the installation. In general, devices containing mercury switches, slow-moving or low-force contacts, or mechanically balanced components are unsuitable for mobile applications; electronic solid-state devices are generally less susceptible to these three factors.

Explosive Atmospheres

Sealed-in-glass contacts are not considered explosionproof; therefore, other means must be provided to eliminate the possibility of a spark in an explosive atmosphere.

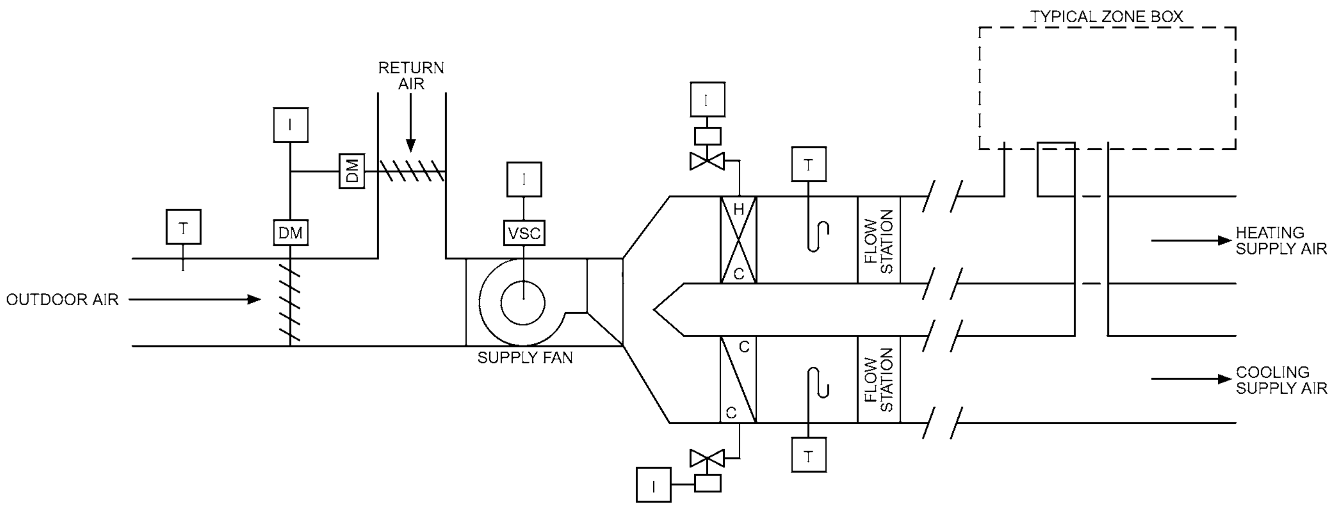

Fig. 41 Single-Fan, Dual-Duct System

When using electric control, the control case and contacts can be surrounded with an explosionproof case, allowing only the capsule and the capillary tubing to extend into the conditioned space. It is often possible to use a long capillary tube and mount the instrument case in a nonexplosive atmosphere. This method can be duplicated with an electronic control by placing an electronic sensor in the conditioned space and feeding its signal to an electronic transducer located in the nonexplosive atmosphere.

Because pneumatic control uses compressed air, it is safe in otherwise hazardous locations. However, many pneumatic controls interface with electrical components. All electrical components require appropriate explosionproof protection.

Sections 500 to 503 of the *National Electrical Code*® (NFPA *Standard* 70) include detailed information on electrical installation protection requirements for various types of hazardous atmospheres.

6. DESIGN CONSIDERATIONS AND PRINCIPLES

In designing and selecting the HVAC system for the entire building, the type, size, use, and operation of the structure must be considered. Subsystems such as fan and water supply are normally controlled by local automatic control or a local loop control, which includes the sensors, controllers, and controlled devices used with a single HVAC system and excludes any supervisory or remote functions such as reset and start/stop. However, local control is frequently extended to central control to diagnose malfunctions that might result in damage from delay, or that might increase labor and energy costs. Special modes of operation may be required to allow for load shedding, purge, warm-up, cooldown, and lockdown. Initiators may be manual or automatic, based on weather, announcements of extraordinary events, high concentrations of expected and therefore measured hazardous gases, or daily schedules reset by outdoor air temperature.

Distributed processing using microprocessors has enabled computer use at many locations other than the central control point. It is more common to use DDC instead of pneumatic or electric thermostats for local loop controllers. The local loop control is integrated with energy management functions performed by upper-level DDC devices to form a complete BAS.

Because HVAC systems are designed to meet maximum design conditions, they nearly always function at partial capacity. The system must be adjusted and operated for many years, so the simplest control that produces the necessary results is usually the best.

Extraordinary Incidents

Building owners and design engineers are sometimes interested in applying the BAS to implement strategies that protect occupants from airborne attack. It is crucial that the engineer does not approach this complex topic as a control system issue. The BAS may include protective features, but only in the context of a comprehensively designed ventilation system. A protective ventilation strategy only makes sense in the context of a thorough risk assessment and an overall security plan. If a protective ventilation strategy is attempted, it is crucial to consider every air movement device and pathway, not just the main fan(s) and damper(s). It is also necessary to consider possible interaction of a protective operation with other emergency control operations, such as the response to a fire/life safety device (e.g., a smoke detector).

ASHRAE (2003), FEMA (2007), and NIOSH (2002), among others, have published references to guide an engineer or building owner in organizing a comprehensive plan. Also see Chapter 59 for more information on this topic.

Mechanical and Electrical Coordination

Even a pneumatic control system includes wiring, conduit, switchgear, and electrical distribution for many electrical devices. The mechanical designer must inform the electrical designer of the total electrical requirements if controls are to be wired by the electrical contractor. Requirements include (1) the devices to be furnished and/or connected, (2) electrical load, (3) location of electrical items, (4) a description of each control function, and (5) whether the control system needs to be on emergency power or UPS.

Coordination is essential. Proper coordination should produce a control diagram that shows the interface with other control elements to form a complete and usable system. As an option, the control engineer may develop a complete performance specification and require the control contractor to install all wiring related to the specified sequence. The control designer must run the final checks of

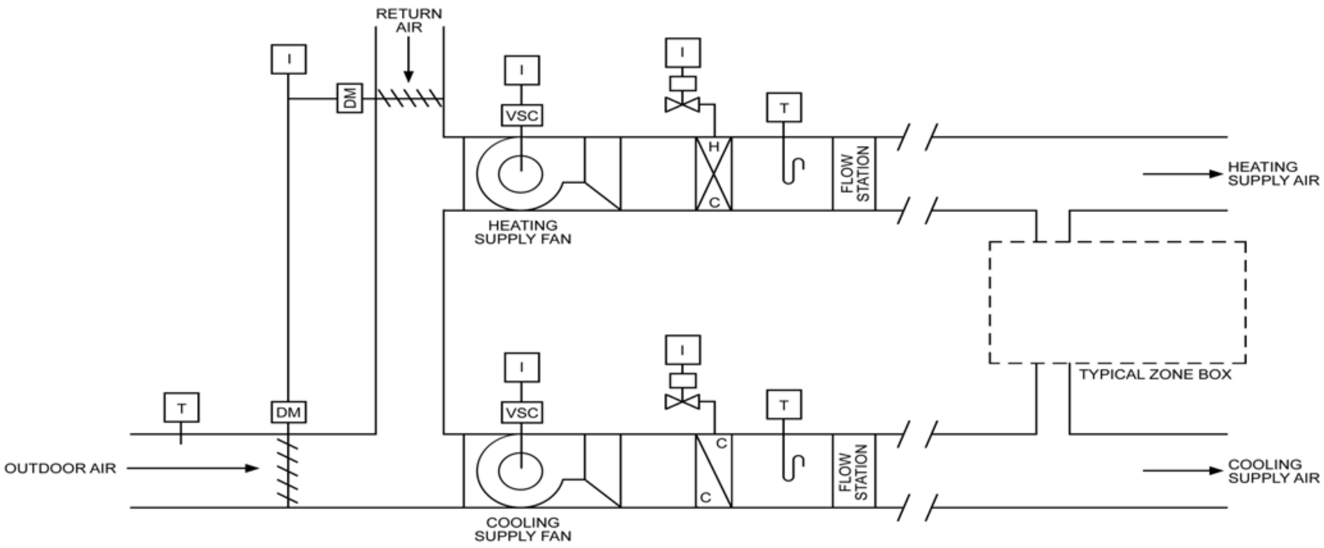

Fig. 42 Dual-Fan, Dual-Duct Systems

drawings and specifications. Both mechanical and electrical specifications must be checked for compatibility and uniformity.

Sequences of Operation

A BAS requires that the engineer define how the system is to be controlled. These sequences are then programmed into the system by the system installer. Writing clear, unambiguous, concise, yet comprehensive sequences of controls is key to the energy and comfort performance of the HVAC system, yet it is very difficult to do well. It requires a clear understanding of how controls work, the limitations of the specific DDC hardware specified and the HVAC system design, and a knack for clear thinking and writing. Techniques for writing successful control sequences are discussed in ASHRAE *Guideline* 13. Sequences for typical HVAC systems can be found in the ASHRAE (2005) CD-ROM, Sequences of Operation for Common HVAC Systems. ASHRAE research project RP-1455 (Hydeman, in progress) investigates sequences of operation for variable-air-volume (VAV) air handlers and terminal units. One goal of the project is to specify control sequences that can be readily implemented by design engineers and controls contractors. Other ASHRAE research projects that may be helpful in developing control sequences include RP-1515, on saving energy by reducing minimum airflow from overhead diffusers (Arens et al. 2014) and RP-1547 (Lau et al. 2013), which addresses demand-controlled ventilation based on CO_2 in multizone systems.

Energy-Efficient Controls

The U.S. Green Building Council's (USGBC) Leadership in Energy Efficient Design (LEED) program for new construction and existing buildings provides guidance on designing and building commercial, institutional, and government buildings to produce quantifiable benefits for occupants, owners, and the environment.

During design and construction, LEED provides many opportunities for using a BAS. LEED awards points, based on design criteria, to determine at which level a building is certified: platinum, gold, silver, or certified. (For specifics, see http://www.usgbc.org.) Many of these points depend on the sophistication, flexibility, and power of the BAS, not only for comfort and energy efficiency, but also for sustainability verification throughout the facility's lifetime.

Applications. It is recommended that the LEED design team choose the controls consultant/contractor and to have them involved with the team early in design, allowing for controls input on the control schemes.

For any facility, the BAS provides thermal comfort and routine programming (e.g., occupied/unoccupied). Under LEED, the controls consultant or contractor uses the BAS for benchmarking and alarming when reference points are exceeded (e.g., monitoring facility electrical use). Once a baseline is established, programs with established alarm limits can alert the owner if the facility exceeds the baseline by 10% or more, so corrections can be made and continued higher utility expenses avoided. Depending on the facility, this may be monitored for hourly, daily, weekly, or monthly comparison.

The BAS can also

- Turn solar panels for optimum sun exposure
- Adjust blinds and awnings
- Keep indoor air quality (IAQ) acceptable by adjusting outdoor air (OA) without overventilating
- Open and close windows for natural ventilation
- Monitor and adjust indoor and outdoor lighting
- Control irrigation based on weather
- Collect weather data
- Track scheduling hours for occupancy
- Monitor equipment run times and set points
- Track electricity use profiles
- Monitor efficiency of large equipment performance (e.g., chillers, variable-frequency-drive [VFD] pumping, boilers)

All of these factors affect building sustainability.

Because the BAS operates in real time, and can compare real-time data to previously defined baselines, it is a valuable tool. Open protocols allow the BAS to monitor, control, and provide critical alarming for non-HVAC equipment (e.g., for power monitoring, chiller performance, VFDs for VAV systems or variable-speed pumping, water efficiency, emergency generators, indoor and outdoor lighting, boilers) for a minimal investment.

The BAS provides an excellent tool for commissioning both HVAC and other equipment, as required by LEED. Its data acquisition abilities allow comparisons of daily performance as building use changes, thereby allowing the commissioning agent to determine whether equipment is operating properly, and allowing the owner to compare real-time data to previously defined benchmarks in **measurement and verification (M&V)**. Typical operation sequences, such as optimizing outdoor air quantities or chiller efficiency, and providing multiple sensing points for thermal comfort, are still used, and are critical for maintaining sustainability.

Perhaps the most important aspect of a successful control system is training the owner. Many owners do not fully realize the capabilities of BAS, many of which are intangible and somewhat obscure, so it is critical that the owner be given proper training in using the controls system. The order in which training takes place is equally important: mechanical equipment training should come first, then operation and maintenance (O&M) and controls layout configurations, use of the controls system to provide thermal comfort and maintain equipment, and, finally, written M&V procedures to maintain sustainability.

If the facility cannot justify a full-time energy manager, then the owner should consider third-party contracting to ensure the facility performs at its designed energy efficiency.

7. CONTROL PRINCIPLES FOR ENERGY CONSERVATION

After a building's general needs have been established and the building and system subdivision has been made, the mechanical system and its control approach can be considered. Designing systems that conserve energy requires knowledge of (1) the building, (2) its operating schedule, (3) the systems to be installed, and (4) ASHRAE *Standard* 90.1. The principles or approaches that conserve energy are as follows:

- *Run equipment only when needed*. Schedule HVAC unit operation for occupied periods. Run heat at night only to maintain internal temperature at around 13 and 16°C to prevent freezing. Start morning warm-up as late as possible to achieve design internal temperature by occupancy time, considering residual space temperature, outdoor temperature, and equipment capacity (optimum start control). Under most conditions, heating and cooling equipment can be shut down some time before the end of occupancy, depending on internal and external load and space temperature (optimum stop control). Calculate shutdown time so that space temperature does not drift out of the selected comfort zone before occupancy ends and ensure that ventilation is provided throughout occupancy.
- *Sequence heating and cooling*. Do not supply heating and cooling simultaneously unless it is required for humidity control. Central fan systems should use cool outdoor air, if available, in sequence between heating and cooling. Zoning and system selection should eliminate, or at least minimize, simultaneous heating and cooling. Also, humidification and dehumidification should not take place concurrently.

- *Provide only the heating or cooling actually needed*. Reset the supply temperature of hot and cold air (or water). In air systems that support variable-speed fans, reset duct static pressure to provide thermal comfort at the lowest possible fan speed and energy consumption.
- *Supply heating and cooling from the most efficient source*. Use free or low-cost energy sources first, then higher-cost sources as necessary.
- *Apply outdoor air control*. When on minimum outdoor air, supply no less than that recommended by ASHRAE *Standard* 62.1 and, on VAV systems, include controls that ensure that outdoor air rates are maintained under all expected supply air operating conditions.

System Selection

The mechanical system significantly affects the control of zones and subsystems. System type and number and location of zones influence the amount of simultaneous heating and cooling that occurs. For perimeter areas, heating and cooling should be controlled in sequence to minimize simultaneous heating and cooling. In general, this sequencing must be accomplished by the control system because only a few mechanical systems (e.g., two-pipe and single-coil) can prevent simultaneous heating and cooling. Systems that require engineered control systems to minimize simultaneous heating and cooling include the following:

- *VAV cooling with zone reheat*. Reduce cooling energy and/or air volume to a minimum before applying reheat.
- *Four-pipe heating and cooling for unitary equipment*. Sequence heating and cooling.
- *Dual-duct systems*. Condition only one duct (either hot or cold) at a time. The other duct should supply a mixture of outdoor and return air.
- *Single-zone heating/cooling*. Sequence heating and cooling.

Some exceptions exist, such as dehumidification with reheat.

Control zones are determined by the location of the thermostat or temperature sensor that sets the requirements for heating and cooling supplied to the space. Typically, control zones are for a room or an open area of a floor.

Energy standards such as ASHRAE *Standard* 90.1 no longer allow constant-volume systems that reheat cold air or that mix heated and cooled air, except in special applications such as hospitals. If used, they should be designed for minimal use of reheat through zoning to match actual dynamic loads and resetting cold and warm air temperatures based on the zone(s) with the greatest demand. Heating and cooling supply zones should be structured to cover areas of similar load. Areas with different exterior exposures should have different supply zones.

Systems that provide changeover switching between heating and cooling prevent simultaneous heating and cooling. Some examples are hot or cold secondary water for fan-coils or single-zone fan systems. They usually require small operational zones, which have low load diversity, to allow changeover from warm to cold water without occupant dissatisfaction.

Systems for building interiors usually require year-round cooling and are somewhat simpler to control than exterior systems. These interior areas normally use all-air systems with a constant supply air temperature, with or without VAV control. Proper control techniques and operational understanding can reduce the energy used to treat these areas. General load characteristics of different parts of a building may lead to selecting different systems for each.

Load Matching

With individual room control, the environment in a space can be controlled more accurately and energy can be conserved if the entire system can be controlled in response to the major factor influencing the load. Thus, water temperature in a water-heating system, steam temperature or pressure in a steam-heating system, or delivered air temperature in a central fan system can be varied as building load varies. Control of the entire system relieves individual space controls of part of their burden and provides more accurate space control. Also, modifying the basic rate of heating or cooling input in accordance with the entire system load reduces losses in the distribution system.

The system must always satisfy the area with the greatest demand. Individual controls handle demand variations in the area the system serves. The more accurate the system zoning, the greater the control, the smaller the distribution losses, and the more effectively space conditions are maintained by individual controls.

Buildings or zones with a modular arrangement can be designed for subdivision to meet occupant needs. Before subdivision, operating inefficiencies can occur if a zone has more than one thermostat. In an area where one thermostat activates heating while another activates cooling, the terminals should be controlled from a single thermostat until the area is properly subdivided.

Size of Controlled Area

No individually controlled area should exceed about 500 m^2 because of the difficulty of obtaining good distribution and of finding a representative location for space control increases with zone area. Each individually controlled area must have similar load characteristics throughout. Equitable distribution, provided through competent engineering design, careful equipment sizing, and proper system balancing, is necessary to maintain uniform conditions throughout a controlled area. The control can measure conditions only at its location; it cannot compensate for nonuniform conditions caused by improper distribution or inadequate design. Areas or rooms having dissimilar load characteristics or different conditions to be maintained should be controlled individually. The smaller the controlled area, the better the control and the performance and flexibility.

Location of Space Sensors

Space sensors and controllers must be located where they accurately sense the variables they control and where the condition is representative of the area (zone) they serve. In large open areas having more than one zone, thermostats should be located in the middle of their zones to prevent them from sensing conditions in surrounding zones. Typically, space temperature controllers or sensors are placed in the following locations.

- **Wall-mounted thermostats** or **sensors** are usually placed on inside walls or columns in the space they serve. Avoid outdoor wall locations. Mount thermostats at generally accessible heights according to the Americans with Disabilities Act (ADA) (USDOJ 1994) (usually 1220 mm) and in locations where they will not be affected by heat from sources such as direct sun rays, wall pipes or ducts, convectors, or direct air currents from diffusers or equipment (e.g., copy machines, coffeemakers, refrigerators). The wall itself should be sealed tightly if it penetrates a pressurized supply air plenum either under the floor or overhead. Air circulation should be ample and unimpeded by furniture or other obstructions, and the thermostat should be protected against mechanical damage. Thermostats in spaces such as corridors, lobbies, or foyers should be used to control those areas only.
- **Return air thermostats** can control floor-mounted unitary conditioners such as induction or fan-coil units and unit ventilators. On induction and fan-coil units, the sensing element is behind the return air grille. On classroom unit ventilators that use up to 100% outdoor air for natural cooling, however, provide a forced-flow sampling chamber for the sensing element, which should be located carefully to avoid radiant effect and to ensure adequate air velocity across the element.

If return air sensing is used with a central fan system, locate the sensing element as near as possible to the space being controlled to eliminate any influence from other spaces and the effect of any heat gain or loss in the duct. Where supply/return light fixtures are used to return air to a ceiling plenum, the return air sensing element can be located in the return air opening. Be sure to offset the set point to compensate for heat from the light fixtures.

- **Diffuser-mounted thermostats** usually have sensing elements mounted on circular or square ceiling supply diffusers and depend on aspiration of room air into the supply airstream. They should be used only on high-aspiration diffusers adjusted for a horizontal air pattern. The diffuser on which the element is mounted should be in the center of the occupied area of the controlled zone.
- **CO_2 sensors** for DCV are usually located in spaces with high occupant densities (e.g., conference rooms, auditoriums, courtrooms). Locating the sensor in return air ducts/plenums that serve multiple spaces measures average concentrations and does not provide information on CO_2 levels in rooms with the highest concentrations. CO_2 sensors should be located in the breathing zone of the occupied space (see ASHRAE [2011] and USGBC [2009]).

Commissioning

Commissioning is the process of ensuring that systems are designed, installed, functionally tested, and capable of being operated and maintained in conformity with the design intent. Commissioning HVAC systems begins with planning and includes design, construction, start-up, acceptance, and training, and can be applied throughout the life of the building.

For HVAC systems, **functional performance testing (FPT)** is an important part of the commissioning process. FPT is the process of determining the ability of HVAC system to deliver heating, ventilating, and air conditioning in accordance with the final design intent. Commissioning is team-oriented and generally involves cooperation of various parties, including the owner, design engineers, and contractors and subcontractors. A commissioning authority (the designated person, company, or agent who implements the overall commissioning process) generally leads the process. Each commissioning process must have a plan that defines the commissioning process and is developed in increasing detail as the project progresses. The most useful tool used to challenge (simulate changes to) systems operation is the control system itself. A BAS provides the added convenience of central execution of test steps, and the ability to record responses. The BAS must be commissioned before it can be used to validate the HVAC systems. Commissioning a BAS is discussed in ASHRAE *Guideline* 11. Commissioning HVAC systems is recommended for construction of new buildings, and should be repeated periodically in existing buildings. See Chapter 43 and ASHRAE *Guidelines* 0 and 11 for more information.

HVAC equipment for a building is one of the major sources of interior noise, and its effect on the acoustical environment is important. Also, noise from equipment located outdoors often propagates to the community. Therefore, mechanical equipment must be selected, and equipment spaces designed, with an emphasis on both the intended uses of the equipment and the goal of providing acceptable sound levels in occupied spaces of the building and in the surrounding community. Operation of HVAC equipment can also induce mechanical vibration that propagates into occupied spaces through structureborne paths such as piping, ductwork, and mounts. Vibration can cause direct discomfort and also create secondary radiation of noise from vibrating walls, floors, piping, etc.

In this chapter, *sound* and *noise* are used interchangeably, although only *unwanted* sound is considered to be noise.

System analysis for noise control uses the source-path-receiver concept. The source of the sound is the noise-generating mechanism. The sound travels from the source via a path, which can be through the air (airborne) or through the structure (structureborne), or a combination of both paths, until it reaches the receiver (building occupant or outdoor neighbor).

Components of the mechanical system (e.g., fans, dampers, diffusers, duct junctions) all may produce sound by the nature of the airflow through and around them. As a result, almost all HVAC components must be considered. Because sound travels effectively in the same or opposite direction of airflow, downstream and upstream paths are often equally important.

This chapter provides basic sound and vibration principles and data needed by HVAC system designers. Many of the equations associated with sound and vibration control for HVAC may be found in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*. Additional technical discussions along with detailed HVAC component and system design examples can be found in the references.

1. DATA RELIABILITY

Data in this chapter come from both consulting experience and research studies. Use caution when applying the data, especially for situations that extrapolate from the framework of the original research. Test data tolerances and cumulative system effects lead to a typical uncertainty of ±2 dB. However, significantly greater variations may occur, especially in low frequency ranges and particularly in the 63 Hz octave band, where experience suggests that even correctly performed estimates may disagree with actual measured levels by 5 dB, so conservative design practices should be followed.

2. ACOUSTICAL DESIGN OF HVAC SYSTEMS

For most HVAC systems, sound sources are associated with the building's mechanical and electrical equipment. As shown in Figure 1, there are many possible paths for airborne and structureborne sound and vibration transmission between a sound source and receiver. Noise control involves (1) selecting a quiet source, (2) optimizing room sound absorption, and (3) designing propagation paths for minimal noise transmission.

Different sources produce sounds that have different frequency distributions, called **spectral characteristics**. For example, as shown in Figure 2, fan noise generally contributes to sound levels in the 16 to 250 Hz octave bands (curve A). (Frequencies that designate the octave bands are often called **octave midband** [or **center**]

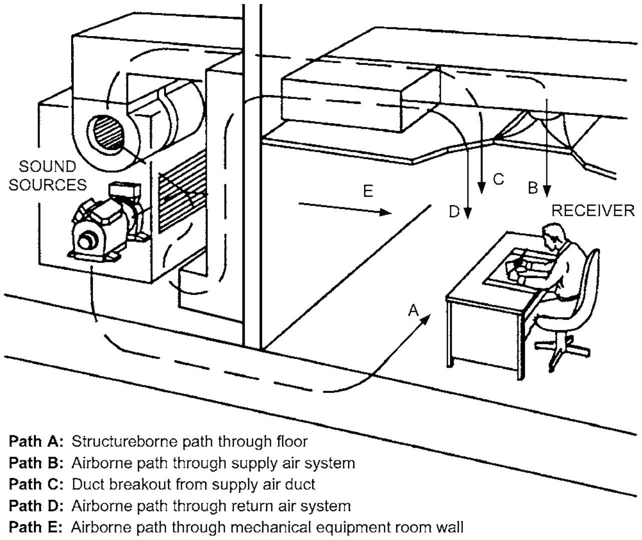

Fig. 1 Typical Paths of Noise and Vibration Propagation in HVAC Systems

The preparation of this chapter is assigned to TC 2.6, Sound and Vibration.

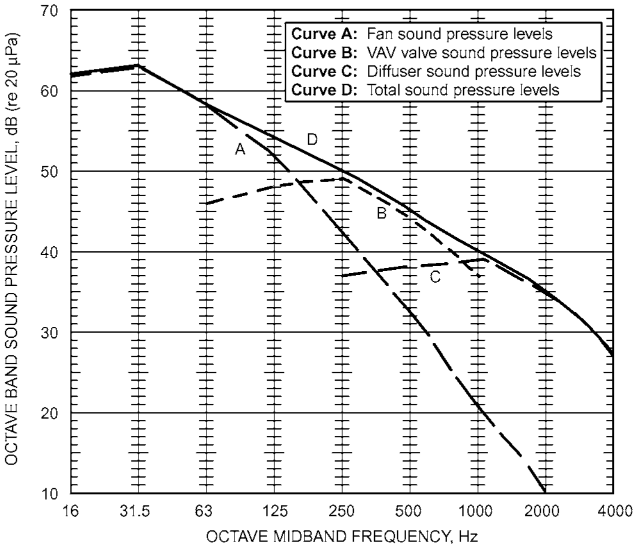

Fig. 2 HVAC Sound Spectrum Components for Occupied Spaces

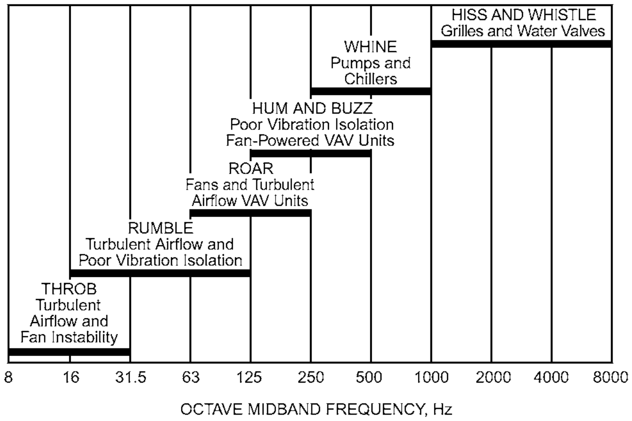

Fig. 3 Frequency Ranges of Likely Sources of Sound-Related Complaints
(Schaffer 2005)

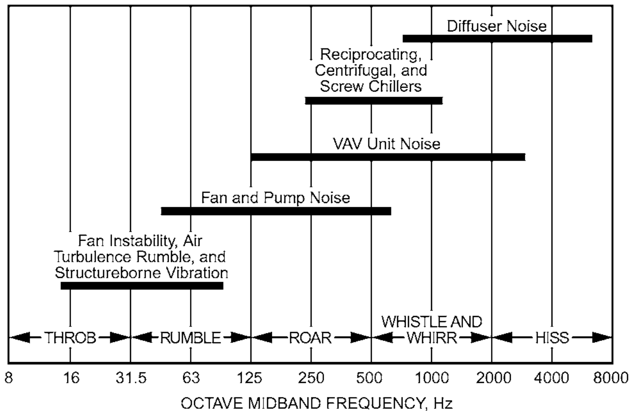

Fig. 4 Frequencies at Which Different Types of Mechanical Equipment Generally Control Sound Spectra
(Schaffer 2005)

frequencies.) Variable-air-volume (VAV) valve noise usually contributes to sound levels in the 63 to 1000 Hz octave bands (curve B). Diffuser noise usually contributes to the overall HVAC noise in the 250 to 8000 Hz octave bands (curve C). The overall sound pressure level associated with all of these sound sources combined is shown as curve D.

Figure 3 (Schaffer 2005) shows the frequency ranges and descriptive terminology of the most likely sources of HVAC sound-related complaints. Figure 4 (Schaffer 2005) shows the frequencies at which different types of mechanical equipment generally control the sound spectra in a room. Occupant complaints may occur, however, despite a well-designed sound spectrum in the room. Criteria specified in this chapter do not necessarily correspond with all individuals' acceptability criteria.

2.1 RECEIVER CONSIDERATIONS

Indoor Sound Criteria

Whether an occupant considers the background noise acceptable generally depends on two factors. First is the **perceived loudness** of the noise relative to that of normal activities; if it is clearly noticeable, it is likely to be distracting and cause complaint. Second is the **sound quality** of the background noise; if the noise is perceived as a rumble, throb, roar, hiss, or tone, this may result in complaints of annoyance and stress. The frequency spectrum is then said to be unbalanced.

The acoustical design must ensure that HVAC noise is of sufficiently low level and unobtrusive quality so as not to interfere with occupancy use requirements. If background noise reduces speech intelligibility, for example, complaints of lost productivity can result. Accordingly, methods of rating HVAC-related noise ideally assess both perceived loudness and sound quality (Wang et al. 2013).

Design Guidelines for HVAC-Related Background Sound in Rooms. Table 1 presents recommended goals for indoor background noise levels in various types of unoccupied rooms served by HVAC systems. Perceived loudness and task interference are factored into the numerical part of the rating. The sound quality design target is assumed to be a neutral-sounding spectrum, although some spectral imbalance is probably tolerable within limits for most users. The criteria used are described in the next section.

An acceptable noise level depends on the specific use of the space, so each number rating typically represents a range of ±5 dB for the design target. For example, private offices and conference rooms are listed as NC/RC 30. This means that unless there are extenuating circumstances, the background noise level should be less than NC/RC 35, but in some locations (e.g., executive offices or specialty conference rooms), a noise criterion of as low as NC/RC 25 might be warranted. On the other hand, there is not necessarily a benefit to achieving the lower number in regular offices, as some background noise maintains a minimum level of acoustic privacy between adjacent offices.

The NC/RC designations relate to reference curves with octave band sound pressure levels that are (1) selected based on appropriate loudness in the speech interference range (500 to 2000 Hz) and (2) show contours for high and low frequencies that are balanced at the same loudness level. Acoustical evaluation based on octave bands and target balanced contours is recommended, because overall dBA ratings do not reflect undesirable contributions of excessive low-frequency noise. The dBA and dBC levels are listed only as approximate references in the case of simplistic measurements, where dBA indicates relative loudness and dBC indicates prevalence of low-frequency noise. Exact specifications should be established by acoustical experts considering occupant sensitivity.

Criteria Descriptions. This section presents ways to rate or measure the sound to determine acceptability. The information should help the design engineer select the most appropriate background

Table 1 Design Guidelines for HVAC-Related Background Sound in Rooms

Room Types		Octave Band Analysis[a]	Approximate Overall Sound Pressure Level[a]	
		NC/RC[b]	dBA[c]	dBC[c]
Rooms with intrusion from outdoor noise sources[d]	Traffic noise	N/A	45	70
	Aircraft flyovers	N/A	45	70
Residences, apartments, condominiums	Living areas	30	35	60
	Bathrooms, kitchens, utility rooms	35	40	60
Hotels/motels	Individual rooms or suites	30	35	60

N/A = Not applicable

[a]Values and ranges are based on judgment and experience, and represent general limits of acceptability for typical building occupancies.

[b]NC: this metric plots octave band sound levels against a family of reference curves, with the number rating equal to the highest tangent line value.

RC: when sound quality in the space is important, the RC metric provides a diagnostic tool to quantify both the speech interference level and spectral imbalance.

[c]dBA and dBC: these are overall sound pressure level measurements with A- and C-weighting, and serve as good references for a fast, single-number measurement. They are also appropriate for specification in cases where no octave band sound data are available for design.

[d]Intrusive noise is addressed here for use in evaluating possible non-HVAC noise that is likely to contribute to background noise levels.

[e]An experienced acoustical consultant should be retained for guidance on acoustically critical spaces (below RC 30) and for all performing arts spaces.

[f]Some educators and others believe that HVAC-related sound criteria for schools, as listed in previous editions of this table, are too high and impede learning for affected groups of all ages. See ANSI/ASA *Standard* S12.60 for classroom acoustics and a justification for lower sound criteria in schools. The HVAC component of total noise meets the background noise requirement of that standard if HVAC-related background sound is approximately NC/RC 25. Within this category, designs for K-8 schools should be quieter than those for high schools and colleges.

[g]RC or NC criteria for these spaces need only be selected for the desired speech and hearing conditions.

noise rating method for a specific project. Current methods described here and in other references include the traditional A-weighted sound pressure level (dBA) and tangent Noise Criteria (NC), the Room Criterion (RC) and more recent RC Mark II, the Balanced Noise Criterion (NCB), and the Room Noise Criteria (RNC). Each method was developed based on data for specific applications; hence, not all are equally suitable for rating HVAC-related noise in the variety of applications encountered. The preferred sound rating methods generally comprise two distinct parts: a family of criterion curves (specifying sound levels by octave bands), and a procedure for rating the calculated or measured sound data relative to the criterion curves with regard to sound quality.

Ideally, HVAC-related background noise should have the following characteristics:

- Balanced contributions from all parts of the sound spectrum with no predominant frequency bands of noise
- No audible tones such as hum or whine
- No fluctuations in level such as throbbing or pulsing

dBA and dBC: A- and C-Weighted Sound Level. The A-weighted sound level (described in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*) has been used for more than 60 years as a single-number measure of the relative loudness of noise, especially for outdoor environmental noise standards. The rating is expressed as a number followed by dBA (e.g., 40 dBA).

A-weighted sound levels can be measured with simple sound level meters. The ratings correlate fairly well with human judgments of relative loudness but take no account of spectral balance or sound quality. Thus, two different spectra can result in the same numeric value, but have quite different subjective qualities.

Along with dBA, there is also a C-weighted sound level, denoted as dBC, which is more sensitive to low-frequency sound contributions to the overall sound level than is dBA. When the quantity dBC – dBA is large (e.g., greater than 25 dB), significant low-frequency sound is present. It is recommended that when specifying background sound levels in dBA, the dBC is also included in the specification and does not exceed the dBA reading by more than 20 dB.

NC: Noise Criteria Method. The NC method for rating noise (described in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*) has been used for more than 50 years. It is a single-number rating that is somewhat sensitive to the relative loudness and speech interference properties of a given noise spectrum. The method consists of a family of criterion curves, shown in Figure 5, extending from 63 to 8000 Hz, and a **tangency rating procedure**. The criterion curves define the limits of octave band spectra that must not be exceeded to meet occupant acceptance in certain spaces. The rating is expressed as NC followed by a number (e.g., NC 40). The octave midband frequency of the point at which the spectrum is tangent to the highest NC curve should also be reported (e.g. NC 40 [125 Hz]). The NC values are formally defined only in 5 dB increments, with intermediate values determined by discretionary interpolation.

Widely used and understood, the NC method is sensitive to level but has the disadvantage that the tangency method used to determine the rating does not require that the noise spectrum precisely follow the balanced shape of the NC curves. Thus, sounds with different frequency content can have the same numeric rating, but rank differently on the basis of sound quality. With the advent of VAV systems, low-frequency content (i.e., below the 63 Hz octave band) is prevalent, and the NC rating method fails to properly address this issue (Ebbing and Blazier 1992). Consequently, if the NC method is

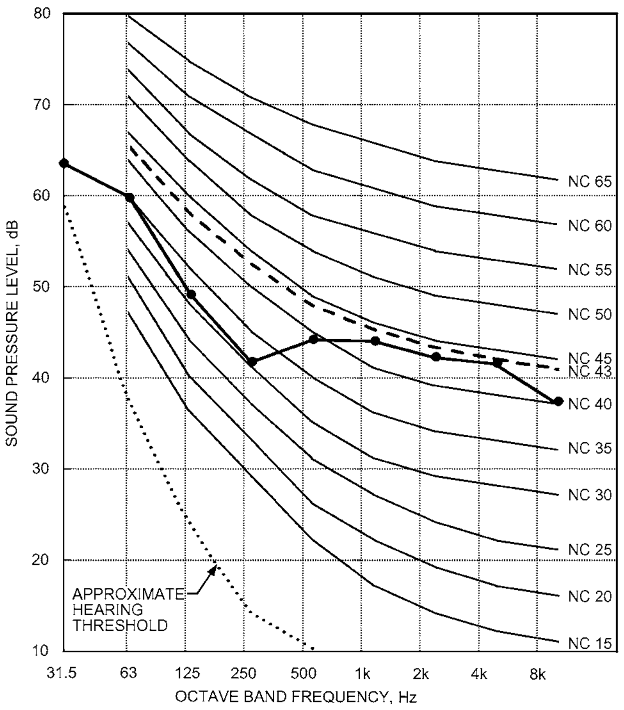

Fig. 5 Noise Criteria Curves

chosen, sound levels at frequencies below 63 Hz must be evaluated by other means.

In HVAC systems that do not produce excessive low-frequency noise and strong discernible pure tones, the NC rating correlates relatively well with occupant satisfaction if sound quality is not a significant concern. NC rating is often used because of its simplicity.

RC/RC Mark II: Room Criteria Method. ASHRAE previously recommended the Room Criterion (RC) curves (beginning in Chapter 43 in the 1995 *ASHRAE Handbook—HVAC Systems and Equipment*; Blazier 1981a, 1981b) as an enhanced method for rating HVAC system related noise. The revised RC Mark II method is now preferred.

The RC method is a family of criterion curves and a rating procedure. The shape of these curves represents a well-balanced, bland-sounding spectrum, including two additional octave bands (16 and 31.5 Hz) to deal with excessive low-frequency noise. This rating procedure assesses background noise in spaces on the basis of its effect on speech, and on subjective sound quality. The rating value is expressed as RC followed by a number that represents the level of noise in the speech interference region of the spectrum, and a letter to indicate the quality (e.g., RC 35[N], where N denotes the desirable neutral rating). The RC method includes evaluation of the potential for noise-induced vibration from excessive airborne sound levels at and below 63 Hz.

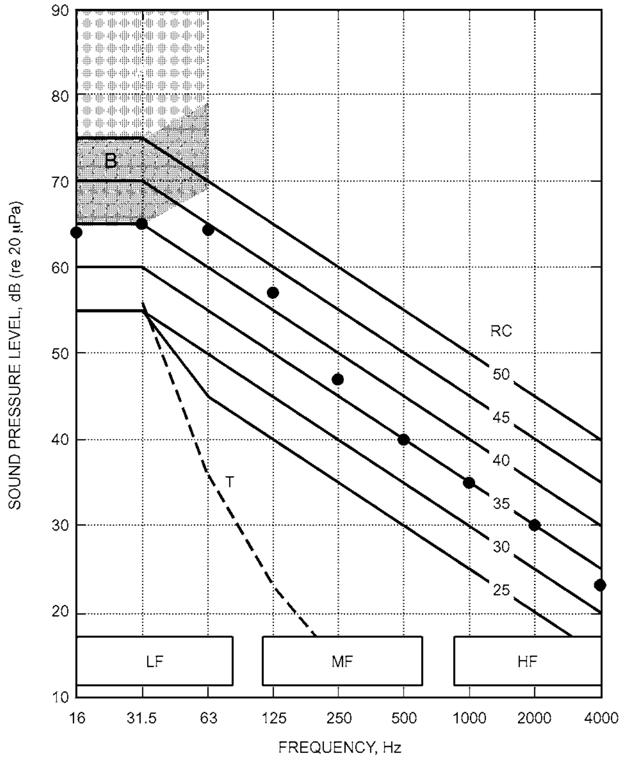
Based on experience and ASHRAE-sponsored research (Broner 1994), the RC method was revised to the RC Mark II method (Blazier 1997). Like its predecessor, the RC Mark II method is intended for use as a diagnostic tool for analyzing noise problems in the field. The RC Mark II method is complicated, but computerized spreadsheets and HVAC system analysis programs are available to perform the calculations and graphical analysis.

The RC Mark II method has three parts: (1) a family of criterion curves (Figure 6), (2) a procedure for determining the RC numerical rating and the noise spectral balance (quality), and (3) a procedure for estimating occupant satisfaction when the spectrum does not have the shape of an RC curve (quality assessment index) (Blazier 1995). The rating is expressed as RC followed by a number and a letter (e.g., RC 35[N]). The number is the arithmetic average rounded to the nearest integer of sound pressure levels in the 500, 1000, and 2000 Hz octave bands (the main speech frequency region) and is known as the **preferred speech interference level (PSIL)**. The letter is a qualitative descriptor that identifies the sound's perceived character: (N) for neutral, (LF) for low-frequency rumble, (MF) for midfrequency roar, and (HF) for high-frequency hiss. There are also two subcategories of the low-frequency descriptor: (LF_B), denoting a moderate but perceptible degree of sound-induced ceiling/wall vibration, and (LF_A), denoting a noticeable degree of sound-induced vibration.

Each reference curve in Figure 6 identifies the shape of a neutral, bland-sounding spectrum, indexed to a curve number corresponding to the sound level in the 1000 Hz octave band. The shape of these curves is based on Blazier (1981a, 1981b), modified at 16 Hz following recommendations of the research in Broner (1994). Regions A and B denote levels at which sound can induce vibration in light wall and ceiling construction, which can potentially cause rattles in light fixtures, furniture, etc. Curve T is the octave band threshold of hearing as defined by ANSI *Standard* S12.2.

Procedure for Determining the RC Mark II Rating for a System.

Step 1. Obtain the arithmetic average of the sound levels in the principal speech frequency range represented by the levels in the 500, 1000, and 2000 Hz octave bands (PSIL). (This is not to be confused with the ANSI-defined "speech-interference level" [SIL], a four-band average obtained by including the 4000 Hz octave band as used with the NCB method.) The RC reference curve is chosen to



Note:
- Noise levels for lightweight wall and ceiling constructions:
  - In shaded region B are likely to generate vibration that may be perceptible. There is a slight possibility of rattles in light fixtures, doors, windows, etc.
  - In shaded region A have a high probability of generating easily perceptible noise-induced vibration. Audible rattling in light fixtures, doors, windows, etc. may be anticipated.
- Regions LF, MF, and HF are explained in the text.
- Solid dots are sound pressure levels for the example discussed in the text.

Fig. 6 Room Criterion Curves, Mark II

be that which has the same value at 1000 Hz as the calculated average value.

Step 2. Calculate the **quality assessment index (QAI)** (Blazier 1995), which measures the deviation of the spectrum under evaluation from the shape of the RC reference curve. Calculate the *energy-averaged* spectral deviations from the RC reference curve in each of three frequency groups: low (LF; 16 to 63 Hz), medium (MF; 125 to 500 Hz), and high (HF; 1000 to 4000 Hz). (A simple arithmetic average of these deviations is often adequate for most engineering purposes.) Equation (1) gives the procedure for the LF region; repeat for the MF and HF regions by substituting the corresponding values at each frequency.

$$LF = 10 \log[(10^{0.1\Delta L_{16}} + 10^{0.1\Delta L_{31.5}} + 10^{0.1\Delta L_{63}})/3] \quad (1)$$

The ΔL terms are the differences between the spectrum being evaluated and the RC reference curve in each frequency band. In this way, three specific spectral deviation factors, expressed in dB with either positive or negative values, are associated with the spectrum being rated. QAI is the *range* in dB between the highest and lowest values of the spectral deviation factors.

If QAI ≤ 5 dB, the spectrum is assigned a *neutral* (N) rating. If QAI exceeds 5 dB, the sound quality descriptor of the RC rating is the letter designation of the frequency region of the deviation factor having the highest positive value.

Example 1. The spectrum plotted in Figure 6 indicated by large dots is processed in Table 2. The arithmetic average of the sound levels in the 500, 1000, and 2000 Hz octave bands is 35 dB, so the RC 35 curve is selected as the reference for spectrum quality evaluation.

The spectral deviation factors in the LF, MF, and HF regions are 6.6, 4.0, and –0.6 respectively, giving a QAI of 7.2. The maximum positive deviation factor occurs in the LF region and QAI exceeds 5; therefore, the rating of the spectrum is RC 35(LF). An average room occupant should perceive this spectrum as rumbly in character.

Table 2 Example 1 Calculation of RC Mark II Rating

	Frequency, Hz								
	16	**31**	**63**	**125**	**250**	**500**	**1000**	**2000**	**4000**
Spectrum levels	64	65	64	57	47	40	35	30	23
Average of 500 to 2000 Hz levels							**35**		
RC contour	60	60	55	50	45	40	35	30	25
Levels: RC contour	4	5	9	7	2	0	0	0	–2
		LF			MF			HF	
Spectral deviations		6.6			4.0			–0.6	
QAI					7.2				
RC Mark II rating					**RC 35(LF)**				

Estimating Occupant Satisfaction Using QAI.

The QAI estimates the probable reaction of an occupant when system design does not produce optimum sound quality. The basis for estimating occupant satisfaction is that changes in sound level of less than 5 dB do not cause subjects to change their ranking of sounds of similar spectral content. However, level changes greater than 5 dB do significantly affect subjective judgments. A QAI of 5 dB or less corresponds to a generally acceptable condition, provided that the perceived level of the sound is in a range consistent with the given type of space occupancy as recommended in Table 2. (An exception to this rule is when sound pressure levels in the 16 or 31 Hz octave bands exceed 65 dB. In such cases, there is potential for acoustically induced vibration in typical low-mass office construction. Levels above 75 dB in these bands indicate a significant problem with induced vibration.)

A QAI that exceeds 5 dB but is less than or equal to 10 dB represents a marginal situation, in which acceptance by an occupant is questionable. However, a QAI greater than 10 dB will likely be objectionable to the average occupant. Table 3 lists sound quality descriptors and QAI values and relates them to probable occupant reaction to the noise.

The numerical part of the RC rating may sometimes be less than the specified maximum for the space use, but with a sound quality descriptor other than the desirable (N). For example, a maximum of RC 40(N) is specified, but the actual noise environment turns out to be RC 35(MF). There is insufficient knowledge in this area to decide which spectrum is preferable.

Even at moderate levels, if the dominant portion of the background noise occurs at a very low frequency, some people can experience a sense of oppressiveness or depression in the environment (Persson-Wayne et al. 1997). Such a complaint may result after exposure to that environment for several hours, and thus may not be noticeable during a short exposure period.

NCB: Balanced Noise Criteria Method. The NCB method (ANSI *Standard* S12.2; Beranek 1989) is used to specify or evaluate room noise, including that from occupant activities. The NCB criterion curves (Figure 7) are intended as an improvement over the NC curves by including the two low-frequency octave bands (16 and 31.5 Hz), and by lowering permissible noise levels at high frequencies (4000 and 8000 Hz). Rating is based on the speech interference level (SIL = the average of the four sound pressure levels at octave midband frequencies of 500, 1000, 2000, and 4000 Hz) with additional tests for rumble and hiss compliance. The rating is expressed as NCB followed by a number (e.g., NCB 40).

Table 3 Definition of Sound-Quality Descriptor and Quality Assessment Index (QAI), to Aid in Interpreting RC Mark II Ratings of HVAC-Related Sound

Sound-Quality Descriptor	Description of Subjective Perception	Magnitude of QAI	Probable Occupant Evaluation, Assuming Level of Specified Criterion is Not Exceeded
(N) Neutral (Bland)	Balanced sound spectrum, no single frequency range dominant	QAI ≤ 5 dB, L_{16}, L_{31} ≤ 65 QAI ≤ 5 dB, L_{16}, L_{31} > 65	Acceptable Marginal
(LF) Rumble	Low-frequency range dominant (16 to 63 Hz)	5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Objectionable
(LFV_B) Rumble, with moderately perceptible room surface vibration	Low-frequency range dominant (16 to 63 Hz)	QAI ≤ 5 dB, 65 < L_{16}, L_{31} < 75 5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Marginal Objectionable
(LFV_A) Rumble, with clearly perceptible room surface vibration	Low-frequency range dominant (16 to 63 Hz)	QAI ≤ 5 dB, L_{16}, L_{31} > 75 5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Marginal Objectionable
(MF) Roar	Mid-frequency range dominant (125 to 500 Hz)	5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Objectionable
(HF) Hiss	High-frequency range dominant (1000 to 4000 Hz)	5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Objectionable

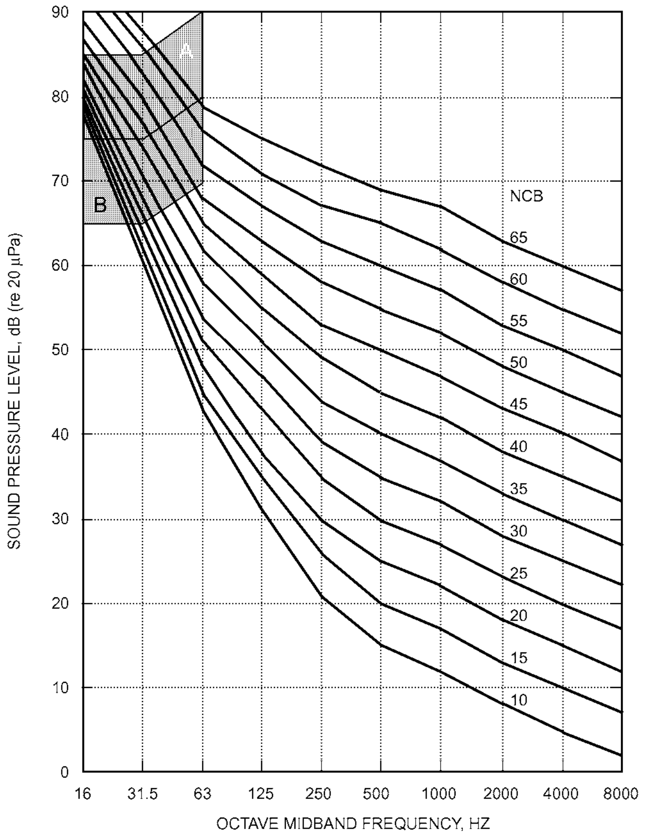


Fig. 7 NCB Noise Criterion Curves

The NCB method is better than the NC method in determining whether a noise spectrum has an unbalanced shape sufficient to demand corrective action, and it addresses the issue of low-frequency noise. Rating is, however, more complicated than the familiar NC tangency method. The NCB method can still be used as a tangency method; if so used, the point of tangency, which sets the rating, must be cited.

RNC: Room Noise Criteria Method. This rating method has been recently introduced and is described in detail in the American National Standards Institute (ANSI) *Standard* S12.2-2008. It is mentioned here for reference only and, at present, ASHRAE has no formal position on the use of this method.

Table 4 summarizes the essential differences, advantages, and disadvantages of rating methods used to characterize HVAC-related background noise. Unfortunately, at this time there is no acceptable and simple process to characterize the effects of audible tones and level fluctuations, so none of these rating methods address these issues.

Noise Criteria for Plumbing Systems. Acceptable noise levels from plumbing fixtures and piping have not been widely identified in the literature, except in ANSI/ASA *Standard* S12.60. Continuous noise from plumbing fixtures and piping systems with circulating fluids should meet the same noise criteria as HVAC systems. However, many sounds from plumbing fixtures and piping are of short duration or are transient, and typically have a somewhat higher threshold of acceptance. Examples of these sources include water flow noise associated with typical restroom fixtures; noise from waste lines connected to restroom, kitchen, and/or laundry drains; and noise from jetted bathtubs.

Table 5 presents suggested maximum A-weighted sound pressure levels for various transient plumbing noise sources in buildings with multiple occupancies. These criteria are minimum standards and are intended to apply to plumbing systems serving adjacent and nearby units in multifamily housing projects (apartments and condominiums), hospitals, educational facilities, and office buildings. Plumbing noise levels in luxury condominiums or private homes should be 5 to 10 dB lower than levels shown in Table 5.

Achieving the recommended plumbing noise criteria in the finished space usually requires special attention to pipe installation details, selection of suitable piping materials, design flow velocities, and selection of appropriate fixtures.

Determining Compliance. When taking field measurements to determine whether a space complies with the guidelines presented in Table 1, follow ANSI/ASA *Standard* S12.72 and note these precautions:

- Measure the noise with an integrating sound level meter with a real-time frequency analyzer meeting type 1 or 2 specifications, as defined in ANSI *Standards* S1.4 and S1.11. The meter should have been calibrated by an accredited calibration laboratory, with some assurance that the calibration accuracy has been maintained.
- Set the meter to display and save the equivalent energy sound pressure level L_{eq} with the desired frequency filtering (e.g., octave bands, A-weighted, etc.). Each measurement should be a minimum of 15 s long.

Table 4 Comparison of Sound Rating Methods

Method	Overview	Considers Speech Interference Effects	Evaluates Sound Quality	Components Presently Rated by Each Method
dBA	No quality assessment Frequently used for outdoor noise ordinances	Yes	No	Cooling towers Water chillers Condensing units
NC	Can rate components Limited quality assessment Does not evaluate low-frequency rumble	Yes	Somewhat	Air terminals Diffusers
RC Mark II	Used to evaluate systems Should not be used to evaluate components Evaluates sound quality Provides improved diagnostics capability	Yes	Yes	Not used for component rating
NCB	Can rate components Some quality assessment	Yes	Somewhat	See NC
RNC	Some quality assessment Attempts to quantify fluctuations	Yes	Somewhat	Not used for component rating

Table 5 Plumbing Noise Levels

Receiving (listening) room	L_{max} (slow response)
Residential bedroom/living room/dining room	35
Hospital patient room/classroom	40
Private office/conference room	40
Residential bathroom/kitchen	45
Open office/lobby/corridor	50

- Place the measurement microphone in potential listening locations at least 1 m from room boundaries and noise sources and at least 0.5 m from furniture. More than one location may be measured, and the microphone may be moved during measurement; movement should not exceed 0.15 m/s.
- Note the operational conditions of the HVAC system at the time of the test. Turn off all non-HVAC system noises during the test. If possible, measure in a normally furnished, unoccupied room.
- The test may be repeated with the entire HVAC system turned off, to determine whether the room's ambient noise level from non-HVAC sources is contributing to the results.
- Record the sound level meter make, model, and serial number; measured sound pressure levels for each microphone location; HVAC system's operating conditions; and microphone location(s).

When these levels are used as a basis for compliance verification, the following additional information must be provided:

- What sound metrics are to be measured (specify L_{eq} or L_{max} levels, etc., in each octave frequency band)
- Where and how the sound levels are to be measured (specify the space average over a defined area or specific points for a specified minimum time duration, etc.)
- What type(s) of instruments are to be used to make the sound measurements (specify ANSI or IEC Type 1 or Type 2 sound level meters with octave band filters, etc.)
- How sound measurements instruments are to be calibrated or checked (specify that instruments are to be checked with an acoustical calibrator both before and after taking sound level measurements, etc.)
- How sound level measurements are to be adjusted for the presence of other sound sources (specify that background sound level measurements be performed without other sound sources under consideration operating; if background sound levels are within 10 dB of operational sound levels, then corrections should be performed; etc.)
- How results of sound measurements are to be interpreted (specify whether octave band sound levels, NC, RC, dBA, dBC or other values are to be reported)

Unless these six points are clearly stipulated, the specified sound criteria may be unenforceable.

When applying the levels specified in Table 1 as a basis for design, sound from non-HVAC sources, such as traffic and office equipment, may establish the lower limit for sound levels in a space.

Outdoor Sound Criteria

Acceptable outdoor sound levels are generally specified by local noise ordinances or other government codes, which almost always use the A-weighted noise level (dBA) as their metric. The usual metric is either L_{max} (maximum noise level over a period) or L_{eq} (average noise level over a period). The time constant (FAST or SLOW) used for L_{max} or L_p depends on the code.

Some communities have no ordinance and depend on state regulations that often use the day/night noise level descriptor L_{DN}, which is a combination of the daytime (7:00 AM to 10:00 PM) and nighttime (10:00 PM to 7:00 AM) average noise levels (L_{eq}) with a 10 dB penalty for nighttime. Other descriptors also exist; specific requirements should be identified at the outset of each project. In some cases, regulatory agencies may also impose project-specific noise conditions on the basis of community reaction and for maintaining an appropriate acoustic environment at the project vicinity.

Measurement or estimation of community noise is based on a location, often at the receiver's property line, from a height of approximately 1.2 m that represents ear height for a typical person seated at ground level to any height to address upper-floor elevations, but can be anywhere within the property line, and often near the facade of the closest dwelling unit. Alternatively, the measurement may be made at the property line of the noise source.

In the absence of a local noise ordinance, county or state laws or codes or those of a similar community should be used. Even if activity noise levels do not exceed those specified by an ordinance, community acceptance is not ensured. Very low ambient levels or a noise source with an often-repeated, time-varying characteristic or strong tonal content may increase the likelihood of complaints. Without local ordinances, noise levels between 45 and 55 dBA may be considered in residential zones and 55 to 65 dBA in commercial zones. These are for outdoor use areas and, with standard building constructions, they also typically result in acceptable interior noise levels. Often, daytime noise levels (the period of daytime to be defined) are 10 dB higher than nighttime levels.

Although most ordinances are given as A-weighted pressure level, attenuation by distance, barriers, buildings, and atmosphere are all frequency dependent. Thus, A-weighted levels do not give an accurate estimation of noise levels at distances from the source. If A-weighted sound levels of sources must be determined by means other than measurement, then octave band or one-third octave band measurements of source sound pressure level at a distance, or (preferably) sound power level, must be obtained before calculating the attenuation.

2.2 BASIC ACOUSTICAL DESIGN TECHNIQUES

To minimize sound transmitted from system components to occupied spaces, select fans and other related mechanical equipment and design air distribution systems considering the following:

- Design the air distribution system to minimize flow resistance and turbulence. High flow resistance increases required fan pressure, which results in higher noise being generated by the fan, especially at low frequencies. Turbulence also increases flow noise generated by duct fittings and dampers, especially at low frequencies.
- Select a fan to operate as near as possible to its rated peak efficiency when handling the required airflow and static pressure. Also, select a fan that generates the lowest possible noise at required design conditions. Using an oversized or undersized fan that does not operate at or near rated peak efficiency can substantially increase noise levels.
- Design duct connections at both fan inlet and outlet for uniform and straight airflow. Both turbulence (at fan inlet and outlet) and flow separation at the fan blades can significantly increase fan-generated noise. Turning vanes near fan outlets can also increase turbulence and noise, especially if airflow is not sufficiently uniform.
- Select duct silencers that do not significantly increase the required fan total static pressure. Silencers with static pressure losses of 90 Pa or less can minimize regenerated noise from silencer airflow.
- Place fan-powered mixing boxes associated with variable-volume air distribution systems away from noise-sensitive areas.
- Minimize flow-generated noise by elbows or duct branch takeoffs whenever possible by locating them at least four to five duct diameters from each other. For high-velocity systems, it may be necessary to increase this distance to up to 10 duct diameters in critical noise areas. Using flow straighteners or honeycomb grids, often called “egg crates,” in the necks of short-length takeoffs that lead directly to grilles, registers, and diffusers is preferred to using volume extractors that protrude into the main duct airflow.
- Keep airflow velocity in ducts serving sound-sensitive spaces as low as possible by increasing the duct size to minimize turbulence and flow-generated noise (see Tables 8 and 9, in the section on Aerodynamically Generated Sound in Ducts).
- Duct transitions should not exceed an included expansion angle of 15°, or the resulting flow separation may produce rumble noise.
- Use turning vanes in large 90° rectangular elbows and branch takeoffs. This provides a smoother directional transition, thus reducing turbulence.
- Place grilles, diffusers, and registers into occupied spaces as far as possible from elbows and branch takeoffs.
- Minimize use of volume dampers near grilles, diffusers, and registers in acoustically critical situations.
- Vibration-isolate all reciprocating and rotating equipment connected to structure. Also, it is usually necessary to vibration-isolate mechanical equipment in the basement of a building as well as piping supported from the ceiling slab of a basement, directly below tenant space. It may be necessary to use flexible piping connectors and flexible electrical conduit between rotating or reciprocating equipment and pipes and ducts that are connected to the equipment.
- Vibration-isolate ducts and pipes, using spring and/or neoprene hangers for at least the first 15 m from vibration-isolated equipment.
- Use barriers near outdoor equipment when noise associated with the equipment will disturb adjacent properties. In normal practice, barriers typically produce no more than 15 dB of sound attenuation in the midfrequency range. To be effective, the noise barrier must at least block the direct “line of sight” between the source and receiver.

Table 6 lists several common sound sources associated with mechanical equipment noise. Anticipated sound transmission paths and recommended noise reduction methods are also listed. Airborne and/or structureborne sound can follow any or all of the transmission paths associated with a specified sound source. Schaffer (2005) has more detailed information in this area.

2.3 SOURCE SOUND LEVELS

Accurate acoustical analysis of HVAC systems depends in part on reliable equipment sound data. These data are often available from equipment manufacturers in the form of sound pressure levels at a specified distance from the equipment or, preferably, equipment sound power levels. Standards used to determine equipment and component sound data are listed at the end of this chapter.

When reviewing manufacturers’ sound data, obtain certification that the data have been obtained according to one or more of the relevant industry standards. If they have not, the equipment should be rejected in favor of equipment for which data have been obtained according to relevant industry standards. See Ebbing and Blazier (1998) for further information.

Fans

Prediction of Fan Sound Power. The sound power generated by a fan performing at a given duty is best obtained from manufacturers’ test data taken under approved test conditions (AMCA *Standard* 300 or ASHRAE *Standard* 68/AMCA *Standard* 330). Applications of air-handling products range from stand-alone fans to systems with various modules and attachments. These appurtenances and modules can have a significant effect on air-handler sound power levels. In addition, fans of similar aerodynamic performance can have significant acoustical differences.

Predicting air-handling unit sound power from fan sound levels is difficult. Fan sound determined by tests may be quite different once the fan is installed in an air handler, which in effect creates a new acoustical environment. Proper testing to determine resulting sound power levels once a fan is installed is essential. Fan manufacturers are in the best position to supply information on their products, and should be consulted for data when evaluating the acoustic performance of fans for an air handler application. Similarly, air handler manufacturers are in the best position to supply acoustic information on air handlers.

Air handler manufacturers typically provide discharge, inlet, and casing-radiated sound power levels for their units based on one of two methods. A common method is the **fan-plus-algorithm** method: the fan is tested as a stand-alone item, typically using AMCA *Standard* 300, and an algorithm is used to predict the effect of the rest of the air-handling unit on the sound as it travels from the fan to the discharge and intake openings or is radiated through a casing with known transmission loss values. Another method is described in **AHRI *Standard* 260**, in which the entire unit is tested as an assembly, including fans, filters, coils, plenums, casing, etc., and the sound power level at the inlet and discharge openings, as well as the radiated sound power, is measured in a qualified reverberant room. Whenever possible, data obtained by the AHRI *Standard* 260 method should be used because it eliminates much of the uncertainty present in the fan-plus-algorithm method. For a detailed description of fan operations, see Chapter 21 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Different fan types have different noise characteristics and within a fan type, several factors influence noise.

Table 6 Sound Sources, Transmission Paths, and Recommended Noise Reduction Methods

Sound Source	Path No.
Circulating fans; grilles; registers; diffusers; unitary equipment in room	1
Induction coil and fan-powered VAV mixing units	1, 2
Unitary equipment located outside of room served; remotely located air-handling equipment, such as fans, blowers, dampers, duct fittings, and air washers	2, 3
Compressors, pumps, and other reciprocating and rotating equipment (excluding air-handling equipment)	4, 5, 6
Cooling towers; air-cooled condensers	4, 5, 6, 7
Exhaust fans; window air conditioners	7, 8
Sound transmission between rooms	9, 10

No.	Transmission Paths	Noise Reduction Methods
1	Direct sound radiated from sound source to ear Reflected sound from walls, ceiling, and floor	Direct sound can be controlled only by selecting quiet equipment. Reflected sound is controlled by adding sound absorption to room and to equipment location.
2	Air- and structureborne sound radiated from casings and through walls of ducts and plenums is transmitted through walls and ceiling into room	Design duct and fittings for low turbulence; locate high-velocity ducts in noncritical areas; isolate ducts and sound plenums from structure with neoprene or spring hangers.
3	Airborne sound radiated through supply and return air ducts to diffusers in room and then to listener by Path 1	Select fans for minimum sound power; use ducts lined with sound-absorbing material; use duct silencers or sound plenums in supply and return air ducts.
4	Noise transmitted through equipment room walls and floors to adjacent rooms	Locate equipment rooms away from critical areas; use masonry blocks or concrete for mechanical equipment room walls; use floating floors in mechanical rooms.
5	Vibration transmitted via building structure to adjacent walls and ceilings, from which it radiates as noise into room by Path 1	Mount all machines on properly designed vibration isolators; design mechanical equipment room for dynamic loads; balance rotating and reciprocating equipment.
6	Vibration transmission along pipes and duct walls	Isolate pipe and ducts from structure with neoprene or spring hangers; install flexible connectors between pipes, ducts, and vibrating machines.
7	Noise radiated to outdoors enters room windows	Locate equipment away from critical areas; use barriers and covers to interrupt noise paths; select quiet equipment.
8	Indoor noise follows Path 1	Select quiet equipment.
9	Noise transmitted to an air diffuser in a room, into a duct, and out through an air diffuser in another room	Design and install duct attenuation to match transmission loss of wall between rooms; use crosstalk silencers in ductwork.
10	Sound transmission through, over, and around room partition	Extend partition to ceiling slab and tightly seal all around; seal all pipe, conduit, duct, and other partition penetrations.

Point of Fan Operation. The point of fan operation has a major effect on acoustical output. Fan selection at the calculated point of maximum efficiency is common practice to ensure minimum power consumption. In general, for a given design, fan sound is at a minimum near the point of maximum efficiency. Noise increases as the operating point shifts to the right, as shown in Figure 8 (higher airflow and lower static pressure). Low-frequency noise can increase substantially at operating points to the left of maximum efficiency (lower airflow and higher static pressure). These operating points should be avoided.

Blade-Pass Frequency. The blade-pass frequency is represented by the number of times per second a fans impeller passes a stationary item: f_{bp} = (rpm × number of impeller blades)/60. All fans generate a tone at this frequency and its multiples (harmonics). Whether this tone is objectionable or barely noticeable depends on the type and design of the fan and the point of operation.

Housed Centrifugal Fans. Forward-curved (FC) fans are commonly used in a wide range of standard air-handler products. The blade-pass of FC fans is typically less prominent and is at a higher frequency than other fans. The most distinguishing acoustical concern of FC fans is the prevalent occurrence of low-frequency rumble from airflow turbulence generated at blade tips, which can be exacerbated by nonideal discharge duct conditions (less than five diameters of straight duct). FC fans are commonly thought to have 16, 31.5, and 63 Hz (full octave band) rumble, particularly when operating to the left of the maximum efficiency point.

Backward-inclined (BI) fans and airfoil (AF) fans are generally louder at the blade-pass frequency than a given FC fan selected for the same duty, but are much more energy efficient at higher pressures and airflow. The blade-pass tone generally increases in prominence with increasing fan speed and is typically in a frequency range that is

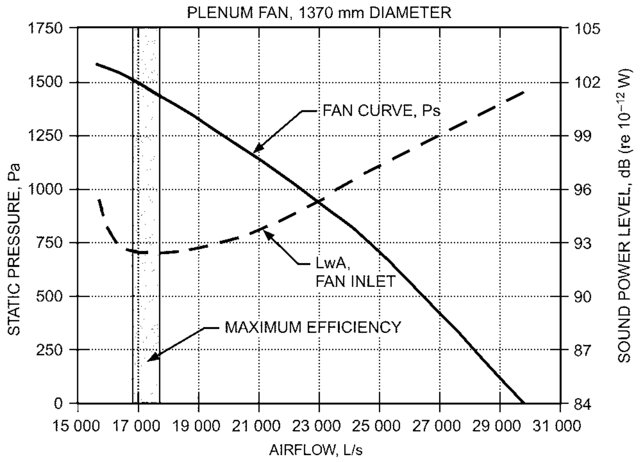

Fig. 8 Test Data for Plenum Fan, Comparing Operating Point (Static Pressure and Airflow), A-Weighted Sound Power Level

difficult to attenuate. Below the blade-pass frequency, these fans generally have lower sound amplitude than FC fans and are often quieter at high frequencies.

Care should be taken with all types of housed fans to allow adequate clearance around the inlets. Also, note that belt guards and inlet screens may decrease airflow and increase sound generation.

Plenum Fans. A plenum fan has no housing around the fan impeller and discharges directly into the chamber, pressurizing the plenum, and forcing air through the attached ductwork. Air flows into the fan impeller through an inlet bell located in the chamber wall. These fans can substantially lower discharge sound power levels if the fan plenum is appropriately sized and acoustically treated with sound-absorptive material.

The plenum discharge should be located away from the fan's air blast, because blowing directly into the duct can aggravate the blade-pass sound. Avoid obstructing the inlet or crowding the coils or filters.

Vaneaxial Fans. Generally thought to have the lowest amplitudes of low-frequency sound of any of the fan types, axial fans are often used in applications where the higher-frequency noise can be managed with attenuation devices. In the useful operating range, noise from axial fans is a strong function of the inlet airflow symmetry and blade tip speed.

Propeller Fans. Sound from propeller fans generally has a low-frequency-dominated spectrum shape; the blade-pass frequency is typically prominent and occurs in the low-frequency bands because of the small number of blades. Propeller fan blade-pass frequency noise is very sensitive to inlet obstructions. For some propeller fan designs, the shape of the fan venturi (inlet) is also a very important parameter that affects sound levels. In some applications, noise of a propeller fan is described as sounding like a helicopter. Propeller fans are most commonly used on condensers and for power exhausts.

Minimizing Fan Noise. To minimize the required air distribution system sound attenuation, proper fan selection and installation are vital. The following factors should be considered:

- Design the air distribution system for minimum airflow resistance. High system resistance requires fans to operate at a higher wattage, which generates higher sound power levels.
- Carefully analyze system pressure losses. Higher-than-expected system resistance may result in higher sound power levels than originally estimated.
- Examine the sound power levels of different fan types and designs. Select a fan (or fans) that generates the lowest sound power levels while meeting other fan selection requirements.
- Many fans generate tones at the blade-pass frequency and its harmonics that may require additional acoustical treatment of the system. Amplitude of these tones can be affected by resonance in the duct system, fan design, and inlet flow distortions caused by poor inlet duct design, or by operation of an inlet volume control damper. When possible, use variable-speed volume control instead of volume control dampers.
- Design duct connections at both fan inlet and outlet for uniform and straight airflow. Avoid unstable, turbulent, and swirling inlet airflow. Deviation from acceptable practice can severely degrade both aerodynamic and acoustic performance of any fan and invalidate manufacturers' ratings or other performance predictions.

Variable-Air-Volume (VAV) Systems

General Design Considerations. As in other aspects of HVAC system design, ducts for VAV systems should be designed for the lowest practical static pressure loss, especially ductwork closest to the fan or air-handling unit (AHU). High airflow velocities and convoluted duct routing with closely spaced fittings can cause turbulent airflow that results in excessive pressure drop and fan instabilities that can cause excessive noise, fan stall, or both.

Many VAV noise complaints have been traced to control problems. Although most problems are associated with improper installation, many are caused by poor design. The designer should specify high-quality fans or air handlers within their optimum ranges, not at the edge of their operation ranges where low system tolerances can lead to inaccurate fan flow capacity control. Also, in-duct static pressure sensors should be placed in duct sections having the lowest possible air turbulence (i.e., at least three equivalent duct diameters from any elbow, takeoff, transition, offset, or damper).

Balancing. VAV noise problems have also been traced to improper air balancing. For example, air balance contractors commonly balance an air distribution system by setting all damper positions without considering the possibility of reducing fan speed. The result is a duct system in which no damper is completely open and the fan delivers air at a higher static pressure than would otherwise be necessary. If the duct system is balanced with at least one balancing damper wide open, fan speed and corresponding fan noise could be reduced. Lower sound levels occur if most balancing dampers are wide open or eliminated. The specified goal should be to balance the system at the lowest static pressure required to operate the box located at the farthest point in the system.

Fan Selection. For constant-volume systems, fans should be selected to operate at maximum efficiency at design airflow. However, VAV systems must be selected to operate with efficiency and stability throughout the operating range. For example, a fan selected for peak efficiency at full output may aerodynamically stall at an operating point of 50% of full output, resulting in significantly increased low-frequency noise and unstable airflow. A stalling fan can indicate operation in the **surge region**, an area of operational instability where airflow reverses direction at the fan blade because of insufficient air entering the fan wheel. Similarly, a fan selected to operate most efficiently at the 50% output point may be very inefficient at full output, resulting in substantially increased fan noise at all frequencies. In general, a fan for a VAV system should be selected for peak efficiency at an operating point between 70 and 80% of the maximum required system capacity, which is where the fan will operate most of the time. This usually means selecting a fan that is one size smaller than that required for peak efficiency at 100% of maximum required system capacity (Figure 9). When the smaller fan operates at higher capacities, it produces up to 5 dB more noise. This occasional increase in sound level is usually more tolerable than stall-related sound problems that can occur with a larger fan operating at less than 100% design capacity most of the time.

Air Modulation Devices. The control method selected to vary the air capacity of a VAV system is important. Variable-capacity control methods can be divided into three general categories: (1) variable inlet vanes (sometimes called inlet guide vanes) or discharge dampers that yield a new fan system curve at each vane or damper setting, (2) variable-pitch fan blades (usually used on axial fans) that adjust the blade angle for optimum efficiency at varying capacity requirements, and (3) variable-speed motor drives in which motor speed is varied by modulation of the power line frequency or by mechanical

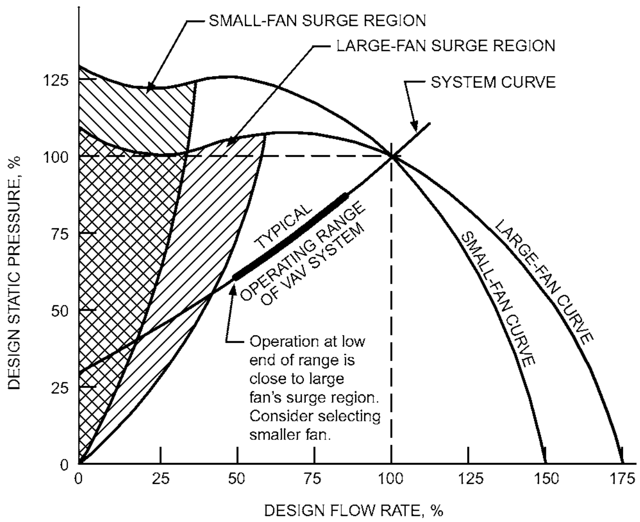

Fig. 9 Basis for Fan Selection in VAV Systems

means such as gears or continuous belt adjustment. Inlet vane and discharge damper volume controls can add noise to a fan system at reduced capacities, whereas variable-speed motor drives and variable-pitch fan blade systems are quieter at reduced air output than at full air output.

Variable-Inlet Vanes and Discharge Dampers. Variable-inlet vanes vary airflow capacity by changing inlet airflow to a fan wheel. This type of air modulation varies the total air volume and pressure at the fan, but fan speed remains constant. Although fan pressure and air volume reductions at the fan reduce duct system noise by reducing air velocities and pressures in the duct work, there is an associated increase in fan noise caused by airflow turbulence and flow distortions at the inlet vanes. Fan manufacturers' test data show that, on airfoil centrifugal fans, as vanes mounted inside the fan inlet (nested inlet vanes) close, the sound level at the blade-pass frequency of the fan increases by 2 to 8 dB, depending on the percent of total air volume restricted. For externally mounted inlet vanes, the increase is on the order of 2 to 3 dB. The increase for forward-curved fan wheels with inlet vanes is about 1 to 2 dB less than that for airfoil fan wheels. In-line axial fans with inlet vanes generate increased noise levels of 2 to 8 dB in the low-frequency octave bands for a 25 to 50% closed vane position.

Discharge dampers, typically located immediately downstream of the supply air fan, reduce airflow and increase pressure drop across the fan while fan speed remains constant. Because of air turbulence and flow distortions created by the high pressure drop across discharge dampers, there is a high probability of duct rumble near the damper location. If the dampers are throttled to a very low flow, a stall condition can occur at the fan, resulting in an increase in low-frequency noise.

Variable-Pitch Fans for Capacity Control. Variable-pitch fan blade controls vary the fan blade angle to reduce airflow. This type of system is predominantly used in axial fans. As air volume and pressure are reduced at the fan, there is a corresponding noise reduction. In the 125 to 4000 Hz octave bands, this reduction usually varies between 2 to 5 dB for a 20% reduction in air volume, and between 8 to 12 dB for a 60% reduction in air volume.

Variable-Speed-Motor-Controlled Fan. Three types of electronic variable-speed control units are used with fans: (1) current source inverter, (2) voltage source inverter, and (3) pulse-width modulation (PWM). The current source inverter and third-generation PWM control units are usually the quietest of the three controls. In all three types, matching motors to control units and the quality of the motor windings determine the motor's noise output. The motor typically emits a pure tone with an amplitude that depends on the smoothness of the waveform from the line current. The frequency of the motor tone depends on the motor type, windings, and speed, but is typically at the drive's switching frequency. Some drives allow adjustment to a higher frequency that does not carry as well, but at a cost of lower drive efficiency. Both inverter control units and motors should be enclosed in areas, such as mechanical rooms or electrical rooms, where the noise effect on surrounding rooms is minimal. The primary acoustic advantage of variable-speed fans is reduction of fan speed, which translates into reduced noise; dB reduction is approximately equal to 50 × log (higher speed/lower speed). Because this speed reduction generally follows the fan system curve, a fan selected at optimum efficiency initially (lowest noise) does not lose efficiency as the speed is reduced. When using variable-speed controllers,

- Select fan vibration isolators on the basis of the lowest practical speed of the fan. For example, the lowest rotational speed might be 600 rpm for a 1000 rpm fan in a commercial system.
- Select a controller with a feature typically called **critical frequency jump band**. This feature allows a user to program the controller to avoid certain fan or motor rpm settings that might excite vibration isolation system or building structure resonance frequencies, or correspond to speeds of other fans in the same system.
- Check the intersection of the fan's curve at various speeds against the duct system curve. When selecting a fan controlled by a variable-speed motor controller, keep in mind that the system curve does not go to zero static pressure at no flow. The system curve is asymptotic at the static pressure control set point, typically 250 to 370 Pa. An improperly selected fan may be forced to operate in its stall range at slower fan speeds.

Terminal Units. Fans and pressure-reducing valves in VAV units should have manufacturer-published sound data indicating sound power levels that (1) are discharged from the low-pressure end of the unit and (2) radiate from the exterior shell of the unit. These sound power levels vary as a function of valve position and fan point of operation. Sound data for VAV units should be obtained according to the procedures specified by the latest AHRI *Standard* 880. In critical situations, a mock-up test should be conducted of a production terminal box under project conditions and space finishes. The test is required because minor changes in box motor, fan, or valve components can affect the noise generated by such equipment.

If the VAV unit is located in noncritical areas (e.g., above a storeroom or corridor), sound radiated from the shell of the unit may be of no concern. If, however, the unit is located above a critical space and separated from the space by a ceiling with little or no sound transmission loss at low frequencies, sound radiated from the shell into the space below may exceed the desired noise criterion. In this case, it may be necessary to relocate the unit to a noncritical area or to enclose it with a high-transmission-loss construction. Room sound levels can be estimated using attenuation factors detailed in AHRI *Standard* 885. In general, fan-powered VAV units should not be placed above or near any room with a required sound criterion rating of less than RC 40(N) (Schaffer 2005). For further information, see the section on Indoor Sound Criteria.

Full shutoff of VAV units can produce excessive duct system pressure at low flow, sometimes causing a fan to go into stall, resulting in accompanying roar, rumble, and surge. Systems providing more than 30% of their air to VAV devices should be provided with a means of static pressure control. Variable-frequency drives are preferred, but in the case of constant-volume air handlers, some means of bypass pressure control should be used to relieve system pressure as VAV devices close down (Schaffer 2005).

Rooftop-Mounted Air Handlers

Rooftop air handlers can have unique noise control requirements because these units are often integrated into a low-mass roof construction. Large roof openings are often required for supply and return air duct connections. These ducts run directly from noise-generating rooftop air handlers to the building interior. Generally, there is insufficient space or distance between roof-mounted equipment and the closest occupied spaces below the roof to apply standard sound control treatments. Rooftop units should be located above spaces that are not acoustically sensitive and should be placed as far as possible from the nearest occupied space. This measure can reduce the amount of sound control treatment necessary to achieve an acoustically acceptable installation.

The common sound transmission paths associated with rooftop air handlers (Figure 10) are

- Flanking-path-borne sound from condenser fans, or compressors breaking in through low-mass roofs or through windows
- Airborne through bottom of rooftop unit to spaces below
- Structureborne from vibrating equipment in rooftop unit to building structure
- Ductborne through supply air duct from air handler

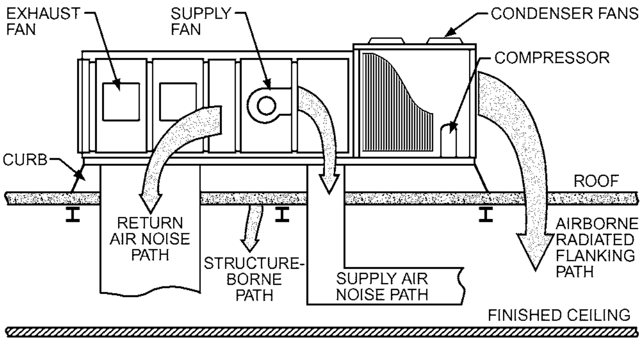

Fig. 10 Sound Paths for Typical Rooftop Installations

- Ductborne through return air duct to air handler
- Duct breakout noise (see the section on Sound Radiation Through Duct Walls)

Flanking-path noise can enter through low-mass roof structures, adjacent walls, and windows. Avoid placing rooftop units on light structure over sensitive spaces or close to higher sidewalls with windows or other lightly constructed building elements. If it is necessary to place the rooftop unit over sensitive spaces or lightly constructed walls, then lagging with additional layers of gypsum board or other similar material may be required in these areas.

Using proper vibration isolation can minimize structureborne sound and vibration from vibrating equipment in a rooftop unit. Special curb mounting bases are available to support and provide vibration isolation for rooftop units. For roofs constructed with open web joists, thin long-span slabs, wooden construction, and any unusually light construction, evaluate all equipment with a mass of more than 130 kg to determine the additional deflection of the structure at mounting points caused by the equipment. Isolator deflection should be a minimum of 10 times the additional static deflection. If the required spring isolator deflection exceeds commercially available products, stiffen the supporting structure or change the equipment location.

Airborne paths are associated with casing-radiated sound that passes through the air handler enclosure and roof structure to the spaces below. Airborne sound can result from air handler noise or from other equipment components in the rooftop unit. Rooftop units should not be placed on open curbs or over a large opening in the roof structure through which both supply and return air ducts pass. Roof penetrations should be limited to two openings sized to accommodate only the supply and return air ducts. These openings should be properly sealed after installation of the ducts. If a large single opening exists under the rooftop unit, it should be structurally, acoustically, and flexibly sealed with one or more layers of gypsum board or other similar material around the supply and return air ducts. Airborne sound transmission to spaces below a rooftop unit can be greatly reduced by placing the rooftop unit on a structural support extending above the roof structure, and running supply and return air ducts horizontally along the roof for several duct diameters before the ducts turn to penetrate the roof. The roof deck/ceiling system below the unit can be constructed to adequately attenuate sound radiated from the bottom of the unit.

Ductborne transmission of sound through the supply air duct consists of two components: sound transmitted from the air handler through the supply air duct system to occupied areas, and sound transmitted via duct breakout through a section or sections of the supply air duct close to the air handler to occupied areas. Sound transmission below 250 Hz through duct breakout is often a major acoustical limitation for many rooftop installations. Excessive low-frequency noise associated with fan noise and air turbulence in the region of the discharge section of the fan (or air handler) and the first duct elbow results in duct rumble, which is difficult to attenuate. This problem is often worsened by the presence of a high-aspect-ratio duct at the discharge section of the fan (or air handler). Rectangular ducts with duct lagging are often ineffective in reducing duct breakout noise. Using either a single- or dual-wall round duct with a radiused elbow coming off the discharge section of the fan can reduce duct breakout. If space does not allow for the use of a single duct, the duct can be split into several parallel round ducts. Another effective method is using an acoustic plenum chamber constructed of a minimum 50 mm thick, dual-wall plenum panel, lined with fiberglass and with a perforated inner liner, at the discharge section of the fan. Either round or rectangular ducts can be taken off the plenum as necessary for the rest of the supply air distribution system. Table 7 shows 12 possible rooftop discharge duct configurations with their associated low-frequency noise reduction potential (Beatty 1987; Harold 1986, 1991).

Ductborne transmission of sound through the return air duct of a rooftop unit is often a problem because there is generally only one short return air duct section between the plenum space above a ceiling and the return air section of the air handler. This does not allow for adequate sound attenuation between the fan inlet and spaces below the air handler. Sound attenuation through the return air duct system can be improved by adding at least one (more if possible) branch division where the return air duct is split into two sections that extend several duct diameters before they terminate into the plenum space above the ceiling. The inside surfaces of all return air ducts should be lined with a minimum of 25 mm thick duct liner. If conditions permit, duct silencers in duct branches or an acoustic plenum chamber at the air-handler inlet section give better sound conditions.

Aerodynamically Generated Sound in Ducts

Aerodynamic sound is generated when airflow turbulence occurs at duct elements such as duct fittings, dampers, air modulation units, sound attenuators, and room air devices. For details on air modulation units and sound attenuators, see the sections on Variable-Air-Volume (VAV) Systems and Duct Silencers.

Although fans are a major source of sound in HVAC systems, aerodynamically generated sound can often exceed fan sound because of close proximity to the receiver. When making octave-band fan sound calculations using a source-path-receiver analysis, aerodynamically generated sound must be added in the path sound calculations at the location of the element.

Duct Velocities. The extent of aerodynamic sound is related to the airflow turbulence and velocity through the duct element. The sound amplitude of aerodynamically generated sound in ducts is proportional to the fifth, sixth, and seventh power of the duct airflow velocity in the vicinity of a duct element (Bullock 1970; Ingard et al. 1968). Therefore, reducing duct airflow velocity significantly reduces flow-generated noise. Tables 8 (Schaffer 2005) and 9 (Egan 1988) give guidelines for recommended airflow velocities in duct sections and duct outlets to avoid problems associated with aerodynamically generated sound in ducts.

Fixed Duct Fittings. Fixed duct fittings include elbows, tees, transitions, fixed dampers, and branch takeoffs. In all cases, less generated air turbulence and lower airflow velocities result in less aerodynamic sound. Figures 11 and 12 show typical frequency spectra for specific sizes of elbows and transitions. Data in these figures are based on empirical data obtained from ASHRAE RP-37 (Ingard et al. 1968). Normalized data from ASHRAE RP-37 and others, which can apply to all types of duct fittings and dampers, have been published (Bullock 1970) and presented in ASHRAE RP-265 (Ver 1983a). When multiple duct fittings are installed adjacent to each other, aerodynamic sound can increase significantly because of the added air turbulence and increased velocity pressures. Note that the magnitude of the field-measured static pressure

Table 7 Duct Breakout Insertion Loss—Potential Low-Frequency Improvement over Bare Duct and Elbow

Discharge Duct Configuration, 3660 mm of Horizontal Supply Duct	Duct Breakout Insertion Loss at Low Frequencies, dB 63 Hz	125 Hz	250 Hz	Side View	End View
Rectangular duct: no turning vanes (reference)	0	0	0

Round drop: radiused elbow (2.0 mm thick), single 940 mm diameter supply duct	15	17	10		

drop across fixed duct fittings does not relate to the aerodynamic generated sound. However, total pressure drop across a duct fitting, which includes the velocity pressure change resulting from air turbulence, does affect aerodynamically generated sound.

Operable Volume Dampers. Operable damper aerodynamic sound is created because the damper is an obstacle in the airstream, and air turbulence increases as the damper closes. Because total pressure drop across the damper also increases with closure, the aerodynamic sound is related to the total pressure drop. Both single-blade and multiblade dampers, used to balance and control the airflow in a duct system and at room air devices, have similar frequency spectra. Figure 13 shows the frequency spectrum for a 45° damper in a 600 by 600 mm duct (Ingard et al. 1968).

Depending on its location relative to a room air device, a damper can generate sound that is transmitted down the duct to the room air device, or radiate sound through the ceiling space into the occupied space below. When an operable control damper is installed close to an air device to achieve system balance, the acoustic performance of the air outlet must be based not only on the air volume handled, but also on the magnitude of the air turbulence generated at the damper. The sound level produced by closing the damper is accounted for by adding a correction to the air device sound rating. As the damper is modulated for air balance, this quantity is proportional to the pressure ratio (PR), that is, the throttled total pressure drop across the damper divided by the minimum total pressure drop across the damper. Table 10 provides decibel corrections to determine the effect of damper location on linear diffuser sound ratings.

Volume dampers in sound-critical spaces should always be a minimum of 5 to 10 duct diameters from the air device, with an acoustically lined duct between the damper and air device. Acoustically lined plenums may also be used between the damper and room air device to reduce damper sound. Linear air devices with a round duct connected to an insulated plenum have been successfully used for damper sound control. However, acoustical lining in this type of plenum does not minimize the sound generated by air flowing through a short section of the linear air device. If multiple inlets/outlets are used to spread airflow uniformly over the lined plenum and air device, then the linear slot generates less sound.

Note: Comparison of octave band sound power levels produced by airflow through 200 × 200 mm rectangular elbow with and without 7 circular arc turning vanes.

Fig. 12 Velocity-Generated Sound of Elbows

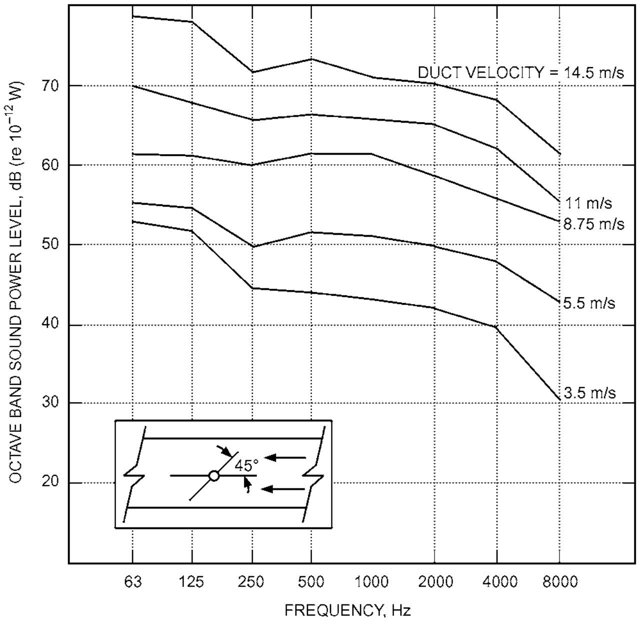

Fig. 13 Velocity-Generated Sound of 600 by 600 mm Volume Damper
(Ingard et al. 1968)

Table 8 Maximum Recommended Duct Airflow Velocities to Achieve Specified Acoustic Design Criteria

Main Duct Location	Design RC(N)	Maximum Airflow Velocity, m/s Rectangular Duct	Maximum Airflow Velocity, m/s Circular Duct
In shaft or above drywall ceiling	45	17.8	25.4
	35	12.7	17.8
	25	8.6	12.7
Above suspended acoustic ceiling	45	12.7	22.9
	35	8.9	15.2
	25	6.1	10.2
Duct located within occupied space	45	10.2	19.8
	35	7.4	13.2
	25	4.8	8.6

Notes:
1. Branch ducts should have airflow velocities of about 80% of values listed.
2. Velocities in final runouts to outlets should be 50% of values or less.
3. Elbows and other fittings can increase airflow noise substantially, depending on type. Thus, duct airflow velocities should be reduced accordingly.

Proper air balancing of a fan/duct system directly affects aerodynamically generated sound even in a correctly designed and installed duct system. Primary volume dampers in the longest duct from a fan should always be nearly wide open. If the primary damper in the longest duct run is more than 20% closed, the duct system has not been properly air balanced, and the fan may operate at a higher speed than required for the duct system. The result is an increase in air velocities and turbulence throughout the entire duct system, with excessive aerodynamic sound generated at all duct elements.

Room Air Devices (Grilles, Registers, Diffusers). Manufacturers' test data should be obtained in accordance with ASHRAE *Standard* 70 for room air devices such as grilles, registers, diffusers, air-handling light fixtures, and air-handling suspension bars. Devices should be selected to meet the noise criterion required or specified for the room. However, the manufacturer's sound power rating

Table 9 Maximum Recommended Air Velocities at Neck of Supply Diffusers or Return Registers to Achieve Specified Acoustical Design Criteria

Type of Opening	Design RC(N)	"Free" Opening Airflow Velocity, m/s
Supply air outlet	45	3.2
	40	2.8
	35	2.5
	30	2.2
	25	1.8
Return air opening	45	3.8
	40	3.4
	35	3.0
	30	2.5
	25	2.2

Note: Table intended for use when no sound data are available for selected grilles or diffusers, or no diffuser or grille is used. The number of diffusers or grilles increases sound levels, depending on proximity to receiver. Allowable outlet or opening airflow velocities should be reduced accordingly in these cases.

Table 10 Decibels to Be Added to Diffuser Sound Rating to Allow for Throttling of Volume Damper

	Damper Pressure Ratio					
	1.5	2	2.5	3	4	6
Location of Volume Damper	dB to Be Added to Diffuser Sound Rating					
In neck of linear diffuser	5	9	12	15	18	24
In inlet of plenum of linear diffusers	2	3	4	5	6	9
In supply duct at least 1.5 m from inlet plenum of linear diffuser	0	0	0	2	3	5

is obtained with a uniform velocity distribution throughout the air device neck or grille collar; this is often not met in practice when a duct turn, sharp transition, or balancing damper immediately precedes the entrance to the diffuser. In these cases, airflow is turbulent and noise generated by the device can be substantially higher than the manufacturer's published data (by as much as 12 dB). In some cases, placing an equalizer grid in the neck of the air device can greatly reduce this turbulence by helping to provide a uniform velocity gradient in the neck of the device, so the sound power generated in the field is closer to that listed in the manufacturer's catalog.

At present, air devices are rated by manufacturers in terms of noise criterion (NC) levels, which usually includes a receiver room effect sound correction of 10 dB. The NC ratings may be useful for comparison between different air devices, but are not helpful for source-path-receiver calculations in terms of octave bands. For a complete analysis, the designer should request the component sound power level data in octave bands from the manufacturer. Whether using NC levels or sound power levels, the designer should also correct manufacturer's data for actual room effect, location of air devices, and number of air devices used in a specific design. The acoustical room effect is the reduction in sound level caused by distance from the sound source (e.g., air outlet); the room volume and amount of acoustical absorption present also affect the value. For example, in a small room with an actual calculated room effect of 6 dB, and given a manufacturer's room effect correction of 10 dB, the discrepancy (in this case, 4 dB) must be added to the manufacturer's data. When an air device is located at the intersection of the ceiling and vertical wall, 6 dB should be added, and in the corner of a room, 9 dB should be added to manufacturer's data. When multiple room air devices are located in a small room or grouped together in a large room, the sound of air devices is additive by up to 10 × log(number of air devices). For more information, see the section on Receiver Room Sound Correction.

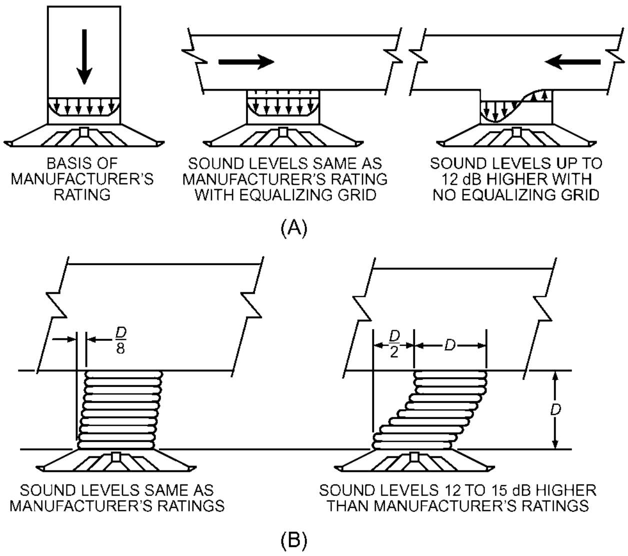

Fig. 14 (A) Proper and Improper Airflow Condition to an Outlet; (B) Effect of Proper and Improper Alignment of Flexible Duct Connector

A flexible duct connection between a branch air duct and an air device provides a convenient means to align the air device with the ceiling grid. The resulting misalignment in this connection, as shown in Figure 14, can cause as much as 12 to 15 dB higher sound levels in the air device's aerodynamically generated sound.

Avoiding Aerodynamically Generated Noise. Aerodynamic noise in duct systems can be avoided by

- Sizing ductwork and duct elements for low air velocities
- Avoiding abrupt changes in duct cross-sectional area or direction
- Providing smooth airflow at all duct elements, including branches, elbows, tees, transitions, and room air devices
- Providing straight ductwork (preferably 5 to 10 duct diameters) between duct elements
- Air-balancing duct system for lowest reasonable fan speed with dampers generally open
- Locating volume control dampers a minimum of 3 (preferably 5 to 10) duct diameters away from room air devices (Schaffer 2005)

Water and Air-Cooled Chillers and Air-Cooled Condensers

Chillers and air-cooled condensers have components such as compressors, motors, gears, and fans that can produce significant amounts of both broadband and tonal noise. The broadband noise is typically caused by flows of refrigerant, water, and air, whereas the tonal noise is caused by rotation of compressors, motors, gears, and fans (in fan-cooled equipment). Chiller and condenser noise is significant in the octave bands from 63 to 4000 Hz and depends primarily on the type of compressor used.

Noise from Compressors and Chillers. All compressors produce tonal noise to varying degrees. Acoustical differences among compressors relate in large part to their tonal content:

- **Centrifugal compressor** tonal noise comes from rotation of the impeller, refrigerant flow, and gears (if present). Impeller blade-related tonal content is typically not very strong; sound radiates mainly from the compressor and condenser shell. Centrifugal chiller noise can increase at low capacity (10 to 25%) because changing the inlet guide vane to lower the pressure also increases turbulence. The noise gets worse as flow approaches rotating stall. If capacity is reduced using motor speed control, the resulting compressor sound levels generally decrease with decreasing capacity.

- **Reciprocating compressor** noise has a low-frequency drumming quality, caused by the oscillatory motion of pistons. The tonal content is high, and the sound level decreases very little with decreasing capacity.
- **Scroll compressors** tend to produce relatively weak tones.
- **Screw compressors** (sometimes called helical rotor or rotary compressors) generate very strong tones in the 250 to 2000 Hz octave bands. Rotor-induced tones can be amplified by resonances in the oil separation component or refrigerant lines, and by sound radiation from the condenser shells. Screw compressors have been a source of chiller noise complaints in many installations where their tonal characteristics have not been properly accounted for in the building design process.
- **Absorption chillers** produce relatively little noise themselves, but the flow of steam in associated pumps and valves causes significant high-frequency noise. Noise levels may increase with decreasing capacity as valves close, and combustion air blowers on direct gas-fired units can be noisy.

The noise levels of indoor chillers are used primarily for determining compliance with occupational noise exposure in the workplace (in accordance with U.S. Occupational Safety and Health Administration [OSHA] regulations), and secondarily for determining equipment room transmission loss requirements to ensure that the desired sound levels in adjacent or remote spaces are achieved. The noise levels of outdoor chillers and condensing units are primarily used to determine compliance with local noise ordinances at property lines and to predict sound levels inside adjacent or nearby buildings and residences.

Indoor Water-Cooled Chillers. The dominant noise sources in water-cooled chillers are the compressor (most often centrifugal or screw) and condenser. As physical sizes of chillers increase, their radiated sound power levels also increase.

Factory-provided sound data for indoor chillers are typically obtained following AHRI *Standard* 575, which requires measuring the A-weighted and octave band sound pressure level (L_p) values at many locations 1 m from the chiller and 1.5 m above the floor. AHRI *Standard* 575 sound pressure levels are generally available at operating points of 25, 50, and 100% of a chiller's nominal full capacity. The average A-weighted sound pressure levels can be used directly along with exposure times to determine OSHA compliance (OSHA 2011) in the machinery room. An example of the ranges of AHRI *Standard* 575 values for atypical centrifugal and screw chiller are shown in Figures 15 and 16, respectively. The sound levels depend on manufacturer design, type and size of compressor, and operating conditions.

AHRI *Standard* 575 measurements for factory-provided ratings are often made in very large rooms with an anechoic or minimally reverberant environment rather than that typically found in mechanical equipment rooms. For that reason, assessment of sound pressure levels in situ should typically be adjusted for each chiller installation to account for the mechanical room's size and surface treatment. For a given chiller at a given operating point, a small equipment room (or one with mostly hard surface finishes) has higher L_p values than one that is large or has sound-absorbing treatments on its ceiling and walls. Figure 17 shows maximum typical adjustment factors that should be added to factory-provided AHRI *Standard* 575 values to estimate the L_p values in specific installations caused by reverberant (reflective) sound effects. The adjustment for each octave band requires knowing the size of an imaginary box that is circumscribed 1 m away from the top and sides of the chiller (the AHRI *Standard* 575 measurement surface), the dimensions of the equipment room, and the average sound absorption coefficient of the room surfaces. The adjustment in each octave band depends on the ratio of the areas of the equipment room and the imaginary box as well as the average sound absorption of the room finishes. Each curve in Figure 17 is for a different value of the average sound absorption, with the higher curves being for lower values.

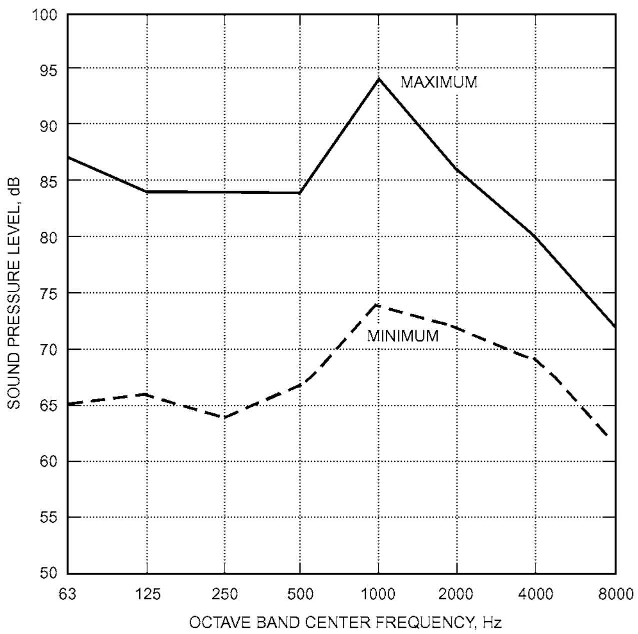

Fig. 15 Typical Minimum and Maximum AHRI *Standard* 575 L_p Values for Centrifugal Chillers (450 to 4500 kW)

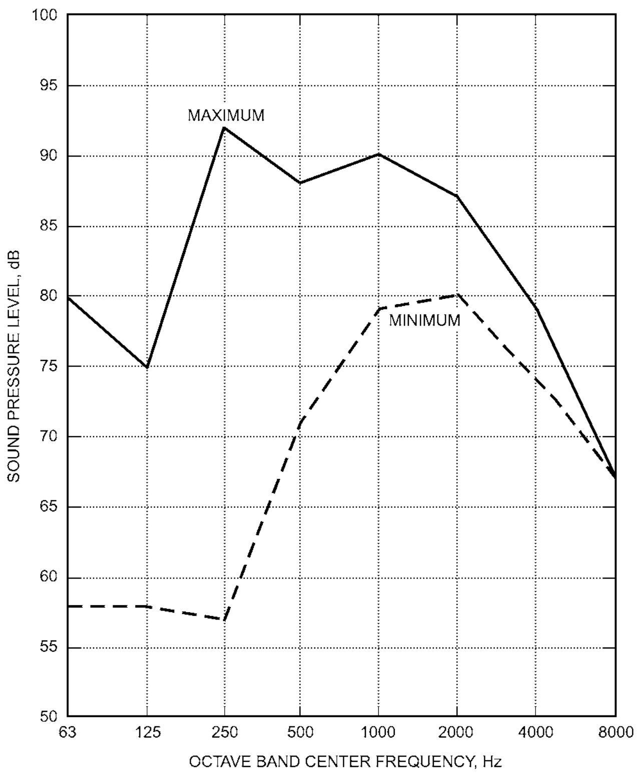

Fig. 16 Typical Minimum and Maximum AHRI *Standard* 575 L_p Values for Screw Chillers (450 to 1400 kW)

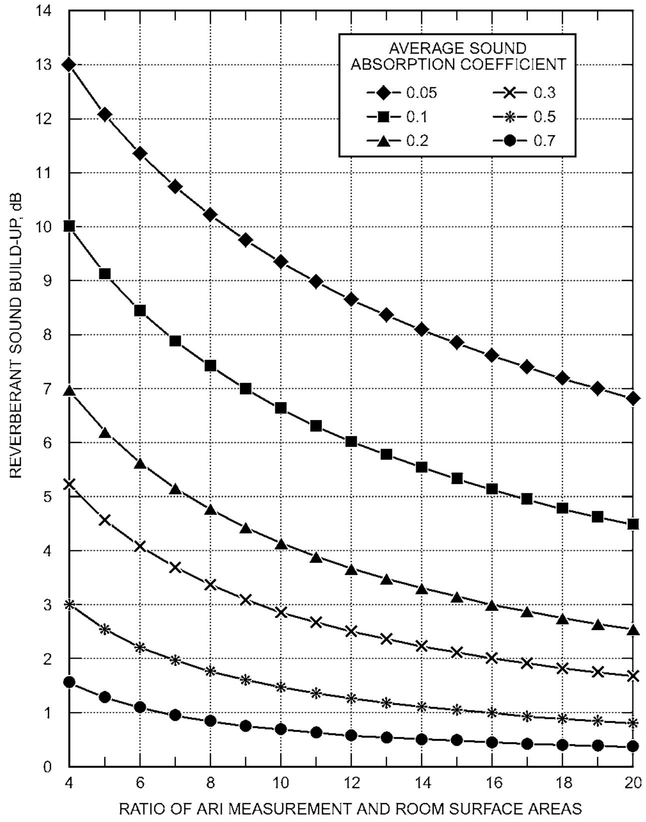

Fig. 17 Estimated Sound Level Build-Up in Mechanical Room for AHRI *Standard* 575 Chiller Sound Levels

Example 2. Estimate the reverberant L_p values in a 13.7 by 12.2 by 6.1 m tall mechanical equipment room (MER) that houses a 1260 kW centrifugal chiller. The room has a concrete floor and gypsum board walls and ceiling; all surfaces have an average absorption coefficient of 0.1. The chiller dimensions are 1500 mm wide, 2000 mm tall, and 3000 mm long.

Solution:

The AHRI *Standard* 575 measurement surface area S_M is determined by adding 1 m to the chiller height and 2 m to both its length and width. The floor area is not included in this calculation. The result is a box 3500 mm wide, 5000 mm long, and 3000 mm tall. The surface area of this box is approximately 68.5 m^2. The surface area of the equipment room (floor included) S_R is 650 m^2. Therefore, the ratio of the areas S_R/S_M is 650/68.5 = 9.5. Because the average absorption coefficient value for room is 0.1 for all octave bands, see Figure 17 for the adjustment factor and Table 11 for calculations.

The approximate reverberant L_p values in the last line of Example 2 can be used with sound transmission loss data of the construction to estimate transmitted L_p values in rooms adjacent to a chiller room.

An alternative approach to this method for estimating L_p in adjacent rooms is to use an estimate of the sound power levels of the chiller from the factory-provided AHRI *Standard* 575 values (Stabley 2006) in conjunction with sound transmission loss data. A conversion factor (CF) is determined and used to convert the AHRI *Standard* 575 sound pressure values to sound power L_w values. The conversion factor is calculated using

$$CF = 10 \log(S/S_o) \qquad (2)$$

where

S = area of measurement parallelepiped (excluding the top) used in AHRI *Standard* 575
= $2(L \times H) + 2(W \times H)$

Table 11 Calculations for Reverberation Build-Up

	Octave Midband Frequency, Hz							
	63	125	250	500	1000	2000	4000	8000
AHRI *Standard* 575 L_p values	73	74	73	72	74	72	69	63
Adjustment from Figure 17	7	7	7	7	7	7	7	7
Approximate revised L_p in MER	80	81	80	79	81	79	76	70

L, W, and H = length, width, and height of measurement parallelepiped, m
S_o = 1 m^2

and

$$L_w = L_p + CF \qquad (3)$$

where

L_w = sound power level (A-weighted or octave band)
L_p = sound pressure levels per AHRI *Standard* 575

This approach assumes that the factory-provided data were obtained in a free-field environment.

Indoor chillers are often offered with various types of factory noise-reduction options. These options can include variable-speed drives, or variable-geometry diffusers on centrifugal compressors, to reduce the strength of the noise sources inside the machine. They may also include various external noise-attenuation devices ranging from compressor, refrigerant line, and heat exchanger blankets (typically providing overall noise reduction of 2 to 6 dBA), to complete enclosures with sound-absorbing inner surfaces (which may reduce the overall noise by as much as 18 dBA). The amount of compressor noise reduction achieved by external attenuation approaches is usually limited by structureborne transmission of compressor vibration into the equipment frame and heat exchanger shells, which act as sounding boards. Attenuation options for chiller noise control vary widely, depending on the application and the type of compressor used. Typically, they either reduce the sound radiating from the source (using acoustic enclosures or blankets) or reduce the internal sound-generating mechanisms of the source (using variable-speed drives on compressors and variable-geometry diffusers for centrifugal compressors). The effectiveness of each approach is affected by variables such as the type of compressor and its behavior with load, heat exchanger design, and type of prime mover used.

Field-installed noise-control options include full-sized sheet metal housings with specially treated openings for piping, electrical conduit, and ventilation. This option may require upgraded building construction. For more information, refer to the section on Mechanical Equipment Room Sound Isolation.

Outdoor Air-Cooled Chillers and Condensers. Outdoor units often use either reciprocating, scroll, or screw compressors. They are also used as the chiller portion of rooftop packaged units. The dominant noise sources in outdoor air-cooled chillers are the compressors and the condenser fans, which are typically low-cost, high-speed propeller fans. For air-cooled condensing units, propeller fans are the only significant noise source.

Factory sound data for outdoor equipment are obtained in accordance with AHRI *Standard* 370, which requires determination of the equipment's octave band sound power levels (L_w), A-weighted overall sound power level (L_{wa}), and tone-adjusted A-weighted overall sound power level (L_{wat}). Because AHRI *Standard* 370 is a sound power measurement technique, it provides certifiable sound data that can be compared across chiller manufacturers with greater certainty than is possible using the sound-pressure-based AHRI *Standard* 575. An example of the range of AHRI *Standard* 370 L_w values for outdoor chillers in the 70 to 1300 kW range is given in Figure 18.

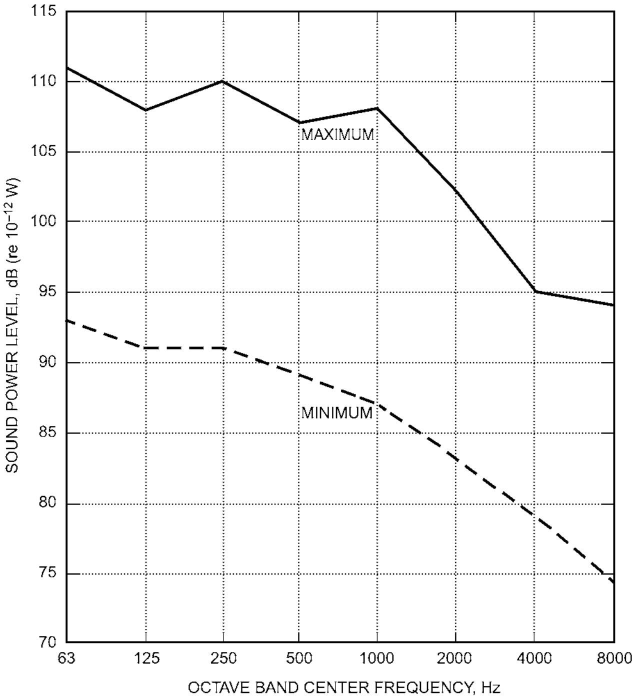

Fig. 18 Typical AHRI 370 L_w Values for Outdoor Chillers (70 to 1300 kW)

Factory-supplied noise reduction options for outdoor equipment include compressor enclosures, component sound blankets, oversized condenser fans, and variable-speed condenser fans. Because air-cooled equipment needs a free flow of cooling air, full enclosures are not feasible. However, strategically placed barriers can help reduce noise propagation on a selective basis. For more information, see the section on Sound Control for Outdoor Equipment.

Emergency Generators

Emergency or standby generators create very high sound levels and require special consideration, especially if used inside an occupied building. The primary noise sources include the engine casing, radiator, and engine exhaust, and must be considered separately if the generator is installed indoors. Sound power levels for these units depend on the power rating, fuel type, engine speed, exhaust muffler design, and radiator system. Overall sound power levels can be as high as 130 dBA (re 10^{-12} W) for larger (1.5 to 2.0 MW) diesel-powered units with standard mufflers. Noise levels inside generator rooms almost always exceed 100 dBA if the power rating of the unit is greater than 50 kW.

Noise from the generator casing is broadband with a relatively uniform spectrum. Octave band noise data are usually available from the generator manufacturer. Casing noise does not vary much with load. Conversely, exhaust noise typically contains strong tones at the engine shaft's running frequency and at the engine firing rate. Standard engine exhaust mufflers reduce exhaust noise by 20 to 25 dBA (compared to unsilenced exhaust), but even with this noise reduction, strong tones still radiate from the exhaust outlet in most cases. High-performance (critical- and supercritical-grade) mufflers are available but are larger and more expensive than standard units. Exhaust pipes should be routed away from noise-sensitive areas, and the exhaust outlet should be located and oriented to ensure that community noise levels are not excessive. In occupied buildings, the entire exhaust pipe should be suspended from the structure above with spring hangers.

Engine casing noise is best controlled by enclosing the generator in a sound-rated enclosure. The biggest problem with generator room design is finding adequate space for ventilation air. Generators require a substantial volume of air for engine cooling, and controlling engine noise transmission using air intake and exhaust paths can be difficult. In most cases, air intake and exhaust openings require sound attenuators. Because engine radiators usually use propeller fans to move air across the radiator core, the ventilation system cannot always handle the added pressure drop created by sound attenuators. In some cases, auxiliary fans are needed to draw fresh air into the generator room through the intake silencers. Sound attenuators at the discharge opening should be located between the radiator and exhaust louver. A smooth, slowly expanding transition duct is required between the radiator and the discharge louver. Nonsymmetrical transitions and transitions with expansion angles greater than 15° usually result in nonuniform airflow through the sound attenuators, causing a higher-than-expected pressure drop and reduced airflow. Unless careful space planning is done early in the design phase, there is often not enough space in the generator room to fit the sound attenuators with a proper transition fitting.

Emergency generator radiator fans usually make as much or more noise than the engine casing. In noise-sensitive installations, consider using a remote radiator. Most manufacturers offer remote radiators as an option, available in a wide variety of designs and noise levels. Lower sound levels with remote radiators are usually achieved by using larger fans running at lower speeds. Using a remote radiator can often save substantial expense in noise-sensitive applications because airflow requirements in the generator room are dramatically reduced.

2.4 PATH NOISE ESTIMATION AND CONTROL

Duct Element Sound Attenuation

A major transmission path of noise from mechanical equipment is through air distribution ductwork. Duct elements and concepts covered in this section include plenums, unlined rectangular ducts, acoustically lined rectangular ducts, unlined round ducts, acoustically lined round ducts, elbows, acoustically lined round radiused elbows, duct silencers, duct branch power division, duct end reflection loss, and terminal volume regulation units. Simplified tabular procedures for obtaining the sound attenuation associated with these elements are presented.

Plenums. Plenums are often placed between a fan and main air distribution ducts to smooth turbulent airflow. They are typically lined with acoustically absorbent material to reduce fan and other mechanical noise. Plenums are usually large rectangular enclosures with an inlet and one or more outlets.

Based on experience, ASHRAE-sponsored research (Mouratidis and Becker 2004), and earlier work (Wells 1958), transmission loss associated with a plenum can be expressed using the following considerations:

- Frequency range (based on the cutoff frequency described in the following paragraphs), which is defined as the upper limit for plane wave sound propagation
- In-line inlet and outlet openings
- End-in/end-out versus end-in/side-out orientation (i.e., in-line versus elbow configuration)

At frequencies above the **cutoff frequency**, as defined by the plenum's inlet duct dimensions, the wavelength of sound is small compared to the characteristic dimensions of the plenum. Plane wave propagation in a duct exists at frequencies below the cutoff, creating a need to consider two frequency ranges, where

$$f_c = \frac{c}{2a} \qquad \text{or} \qquad f_c = 0.586\frac{c}{d} \tag{4}$$

where

f_c = cutoff frequency, Hz
c = speed of sound in air, m/s
a = larger cross-sectional dimension of rectangular duct, m
d = diameter of round duct, m

The **cutoff frequency f_c** is the frequency above which plane waves no longer propagate in a duct. At these higher frequencies, waves that propagate in the duct create **cross** or **spinning modes**. The **transmission loss (TL)** in this higher frequency range may be predicted using the following relationship:

$$\mathrm{TL} = b\left[\frac{S_{out}Q}{4\pi r^2} + \frac{S_{out}(1-\alpha_a)}{S\alpha_a}\right]^n + \mathrm{OAE} \quad (5)$$

where

TL = transmission loss, dB
b = 3.505
n = –0.359
S_{out} = area of plenum outlet, m²
S = total inside surface area of plenum minus inlet and outlet areas, m²
r = distance between centers of inlet and outlet of plenum, m
Q = directivity factor; taken as 2 for opening near center of wall, or 4 for opening near corner of plenum
α_a = average absorption coefficient of plenum lining (see Equation [8])
OAE = offset angle effect; additional attenuation found in Tables 14 and 15, which tabulate frequency-dependent sound transmission properties that are manifested when inlet and outlet of plenum are not in a direct line; 90° angle is referred to as elbow effect

The average absorption coefficient α_a of plenum lining is given by

$$\alpha_a = \frac{S_1\alpha_1 + S_2\alpha_2}{S_1 + S_2} \quad (6)$$

where

α_1 = sound absorption coefficient of any bare or unlined inside surfaces of plenum
S_1 = surface area of any bare or unlined inside surfaces of plenum, m²
α_2 = sound absorption coefficient of acoustically lined inside surfaces of plenum
S_2 = surface area of acoustically lined inside surfaces of plenum, m²

In many situations, inner surfaces of a plenum chamber are lined with a sound-absorbing material. For these situations, $\alpha_a = \alpha_2$. Table 12 gives sound absorption coefficients for selected common plenum materials.

Note: transmission loss (TL) of a plenum is the difference between the duct sound power level at the outlet and inlet of the plenum, unlike **insertion loss (IL)** ratings for silencers, which represent the difference (at a downstream measurement location) between the duct sound pressure levels with the silencer and with no silencer (replaced with an empty duct). For purposes here, both TL and IL are interpreted as attenuation, or the net reduction in propagating duct sound power.

For frequencies that correspond to plane wave propagation in the duct (below the cutoff frequency), the following relationship applies, with a lower frequency limit of 50 Hz:

$$\mathrm{TL} = 10.76A_fS + W_e + \mathrm{OAE} \quad (7)$$

where

A_f = surface area coefficient, dB/m² (see Table 13 for small and large plenum size ranges)
W_e = wall effect, dB (see Table 13 for common HVAC plenum wall types)
OAE = offset angle effect

Table 12 Sound Absorption Coefficients α of Selected Plenum Materials

	Octave Midband Frequency, Hz						
	63	**125**	**250**	**500**	**1000**	**2000**	**4000**
Non-sound-absorbing material

100 mm, 48 kg/m³	0.50	0.84	1.00	1.00	1.00	1.00	0.97

Note: 63 Hz values estimated from higher-frequency values.

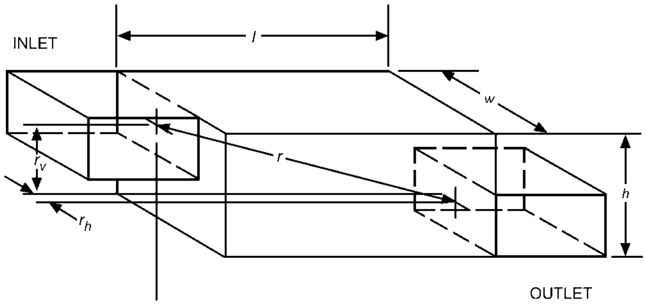

Fig. 19 Schematic of End-In/End-Out Plenum

The maximum TL predicted by Equation (7) should be limited to 20 dB.

For an end-in/end-out plenum configuration, where the openings are not in-line, the offset angle θ must be considered in the TL calculation. The value of θ is obtained from the following relationship:

$$\cos\theta = \frac{l}{r} = \frac{l}{\sqrt{l^2 + r_v^2 + r_h^2}} \quad (8)$$

where (refer to Figure 19)

θ = offset angle representing r to long axis l of duct
l = length of plenum, m
r_v = vertical offset between axes of plenum inlet and outlet, m
r_h = horizontal offset between axes of plenum inlet and outlet, m

For a given offset angle, apply the applicable effects on TL (decibel addition or subtraction) for angles up to 45° (Table 14).

For an end-in/side-out plenum configuration, where openings are perpendicular to each other, the **elbow effect** must be considered in the TL calculation. For any plenum configuration involving an elbow condition, apply the applicable effects on TL (decibel addition or subtraction) for the two frequency ranges, both above and below the cutoff (Table 15).

For plenum applications within a practical size envelope of 0.5 to 30 m³ volume or 5 to 60 m² surface area, using duct sizes in the range $300 < d < 1200$ mm, this model may be applied with an anticipated standard deviation of ±3.5 to 5.0 dB for $50\ \mathrm{Hz} < f \le f_c$ and ±1.5 to 3.0 for $f_c < f \le 5000$ Hz. Use caution when applying these prediction methods for plenum configurations where either the width or height dimension is $<1.5d$. In this case, the plenum may not perform as an expansion chamber, thus changing its broadband TL characteristics significantly.

Example 3. A small plenum with acoustically lined surfaces is 1.8 m high, 1.2 m wide, and 1.8 m long. The inlet and outlet are each 0.9 m wide by 0.6 m high. The horizontal offset between centers of the plenum inlet and outlet is 0.3 m. The vertical offset is 1.2 m. The inside of the plenum is completely lined with 25 mm thick fiberglass insulation board, with sound absorption values as shown in Table 8. Determine the transmission loss TL associated with this plenum.

Solution:

The areas of the inlet section, outlet section, and overall surfaces are

$$S_{in} = 0.9 \times 0.6 = 0.54 \text{ m}^2$$

$$S_{out} = 0.9 \times 0.6 = 0.54 \text{ m}^2$$

$$\begin{aligned} S &= \text{Total surface area (all walls with lining)} \\ &= 2(1.2 \times 1.8) + 2(1.2 \times 1.8) + 2(1.8 \times 1.8) - 0.54 - 0.54 \\ &= 14.04 \text{ m}^2 \end{aligned}$$

with l = 1.8 m, r_v = 1.2 m, and r_h = 0.3 m,

$$r = (1.8^2 + 1.2^2 + 0.3^2)^{1/2} = 2.184 \text{ m}$$

$$\theta = \cos^{-1}(1.8/2.184) = 35°$$

The cutoff frequency f_c is

$$f_c = 343/(2 \times 0.9) = 190 \text{ Hz}$$

where 343 m/s is the approximate speed of sound in standard air.

Frequency Range #1 (1/3-octave TL in 50 Hz $\le f \le f_c$ range)

$$TL = 10.76 \times A_f \times S + W_e + OAE \quad (9)$$

(Consult Table 13 for A_f and W_e and Table 14 for offset angle effect.)

Frequency Range #2 (1/3-octave TL in $f_c < f \leq 5000$ Hz range)

$$TL = b\left[\frac{S_{out}Q}{4\pi r^2} + \frac{S_{out}(1-\alpha_a)}{S\alpha_a}\right]^n + OAE \quad (10)$$

where

b = 3.505
n = –0.359
Q = 4 (directivity factor for inlet opening close to adjacent wall or bihedral corner of plenum)
α_a = 1/3-octave average absorption values for 25 mm fiberglass lining (see Table 12)
OAE = see Table 14

Note: for angles between tabulated values in Table 14, use linear interpolation.

The results are tabulated as follows:

OAE = offset angle effect
[a]Column 1 × S + column 2 + column 3
[b]Includes OAE value from column 3 per calculation from Equation (10).
[c]From column 4 or 5, depending on appropriate frequency range.

Unlined Rectangular Sheet Metal Ducts. Straight, unlined rectangular sheet metal ducts provide a fairly significant amount of low-frequency sound attenuation. Table 16 shows the results of selected unlined rectangular sheet metal ducts (Cummings 1983; Reynolds and Bledsoe 1989a; Ver 1978; Woods Fan Division 1973). Attenuation values in Table 16 apply only to rectangular sheet metal ducts with the lightest gages allowed by Sheet Metal and Air Conditioning Contractors' National Association, Inc. (SMACNA) HVAC duct construction standards. Attenuation for lengths greater than 3 m is not well documented.

Sound energy attenuated at low frequencies in rectangular ducts may manifest itself as breakout noise along the duct. Low-frequency breakout noise should therefore be checked. For additional information on breakout noise, see the section on Sound Radiation Through Duct Walls.

Acoustically Lined Rectangular Sheet Metal Ducts. Internal duct lining for rectangular sheet metal ducts can be used to provide both thermal insulation and sound attenuation. The thickness of duct linings for thermal insulation usually varies from 15 to 50 mm; the density of the internal lining usually varies between 24 and 48 kg/m³, but may be as low as 12 kg/m³. For duct lining to attenuate sound effectively, it should have a minimum thickness of 25 mm. At low frequencies, thicker lining performs slightly better than thinner lining. Tables 17 and 18 give attenuation values of selected rectangular sheet metal ducts for 25 and 50 mm thick glass fiber duct lining, respectively (Herrin et al. 2017; Kuntz 1986; Kuntz and Hoover 1987; Machen and Haines 1983; Reynolds and Albright 2018; Reynolds and Bledsoe 1989a). Note that attenuation values for ducts with a cross-sectional area less than 0.09 m² or greater than 1.49 m² in these tables are taken from previous editions of the *ASHRAE Handbook* and based on laboratory tests using 3 m lengths of lined duct. Insertion loss values for all other duct sizes in these tables were obtained in ASHRAE research project RP-1408 (Reynolds and Albright 2018). This research project included lengths of uninterrupted straight ducts from 0.9 to 12 m with varying sizes and lengths of round and rectangular ducts with fiberglass duct liner. The liner used in this testing was 24 kg/m³ for the rectangular ducts.

Table 16 Sound Attenuation in Unlined Rectangular Sheet Metal Ducts

Duct Size, mm	P/A, 1/mm	Attenuation, dB/m Octave Midband Frequency, Hz: 63	125	250	>250
150 × 150	0.026	0.98	0.66	0.33	0.33

305 × 610	0.010	1.31	0.66	0.33	0.16
610 × 610	0.007	0.82	0.66	0.33	0.10
1220 × 1220	0.003	0.49	0.33	0.23	0.07
1830 × 1830	0.002	0.33	0.33	0.16	0.07

Though previous editions of this table indicated values of dB/m, research projects have shown that attenuation does not vary exactly linearly with length. Therefore, these updated tables show attenuation for lengths as actually tested. For interpolation to various duct lengths and cross sections, using the duct liner attenuation spreadsheet (available as an extra feature for the ASHRAE Handbook Online version of this chapter) is recommended. Note that the total attenuated noise will never be below the flow-generated noise level in the duct, and, because of typical flows and flanking noise in practice, attenuation values are capped at 50 dB.

Insertion loss values in Tables 17 and 18 represent the difference in the space-average sound pressure level measured in a reverberation room with sound propagating through a straight section of unlined rectangular duct minus the corresponding sound pressure level measured when the unlined section of rectangular duct is replaced with a similar section of acoustically lined rectangular duct. The net result is the attenuation resulting from adding duct liner to a sheet metal duct.

Insertion loss values discussed in this section apply only to straight rectangular sheet metal ducts made with the lightest gages allowed by the SMACNA HVAC duct construction standards. Insertion loss values for heavier gage ductwork are expected to be slightly less than the tabulated values. Insertion loss values in octave and 1/3-octave bands are available in the online version of the Handbook. Also available in the online version is a calculator which provides octave band and 1/3-octave band insertion loss values for any duct cross section larger than 305 × 305 mm and smaller than 1220 × 1220 mm in lengths ranging from 0.9 to 12 m.

Insertion loss and attenuation values discussed in this section apply only to rectangular sheet metal ducts made with the lightest gages allowed by SMACNA HVAC duct construction standards. Attenuation for lengths greater than 3 m is not well documented.

Unlined Round Sheet Metal Ducts. As with unlined rectangular ducts, unlined round ducts provide some natural sound attenuation

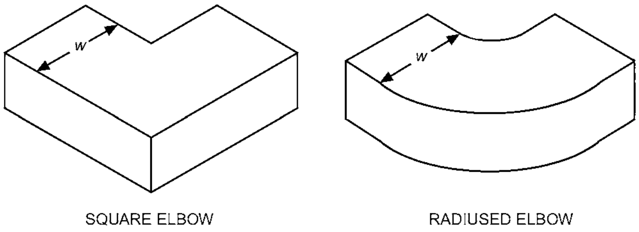

Fig. 20 Rectangular Duct Elbows

that should be taken into account when designing a duct system. Compared to rectangular ducts, round ducts are much more rigid and thus breakout, especially at low frequencies, is significantly less than that from other shapes. Though this reduces attenuation values for low-frequency sound propagating down the duct, it better protects the surrounding space from breakout noise. Table 19 lists sound attenuation values for unlined round ducts (Kuntz and Hoover 1987; Woods Fan Division 1973).

Acoustically Lined Round Sheet Metal Ducts. ASHRAE research project RP-1408 (Reynolds and Albright 2018) measured the insertion loss of round sheet metal ducts with 25 and 50 mm thick glass fiber duct liner and diameters of 305 to 1220 mm. Tables 20 and 21 present the measured insertion loss of acoustically lined round sheet metal ducts as a function of frequency and length of duct lining for a variety of common duct sizes. Insertion loss values for diameters smaller than 305 mm and larger than 1220 mm were taken from previous editions of the *ASHRAE Handbook*. The liner was 64 kg/m^3.

Though previous editions of this table indicated values of dB/m, research projects have shown that attenuation does not vary exactly linearly with length. Therefore, these updated tables show attenuation for lengths as actually tested. For interpolation to various duct lengths and cross sections, using the duct liner attenuation spreadsheet (available as an extra feature for the ASHRAE Handbook Online version of this chapter) is recommended. Note that the total attenuated noise will never be below the flow-generated noise level in the duct, and, because of typical flows and flanking noise in practice, attenuation values are capped at 50 dB.

Rectangular Sheet Metal Duct Elbows. Table 22 displays insertion loss values for unlined and lined square elbows without turning vanes (Beranek 1960). For lined square elbows, duct lining must extend at least two duct widths *w* beyond the elbow. Table 22 applies only where the duct is lined before and after the elbow. Table 23 gives insertion loss values for unlined radiused elbows. Table 24 gives insertion loss values for unlined and lined square elbows with turning vanes. The quantity *fw* in Tables 22 to 24 is the midfrequency of the octave band times the width of the elbow (Figure 20) (Beranek 1960; Ver 1983b).

Nonmetallic Insulated Flexible Ducts. Nonmetallic insulated flexible ducts can significantly reduce airborne noise. Insertion loss values for specified duct diameters and lengths are given in Table 25 and in Appendix D of ARI *Standard* 885. Recommended duct lengths are normally 0.9 to 1.8 m. Take care to keep flexible ducts straight; bends should have as long a radius as possible. Although an

abrupt bend may provide some additional insertion loss, the noise associated with airflow in the bend may be unacceptably high. Because of potentially high breakout sound levels associated with flexible ducts, take care when using flexible ducts above sound-sensitive spaces.

Duct Branch Sound Power Division. When sound traveling in a duct encounters a junction, the sound power contained in the incident sound waves in the main feeder duct is distributed between the branches associated with the junction (Ver 1982, 1983b). This division of sound power is called branch sound power division. The corresponding attenuation of sound power transmitted down each branch of the junction is comprised of two components. The first is

associated with reflection of the incident sound wave if the sum of the cross-sectional areas of individual branches ΣS_{Bi} differs from the cross-sectional area of the main feeder duct. The second and more dominant component is associated with energy division according to the ratio of the cross-sectional area of an individual branch S_{Bi} divided by ΣS_{Bi}. Values for the attenuation of sound power ΔL_{Bi} are given in Table 26.

Duct Silencers. Silencers, sometimes called sound attenuators, sound traps, or mufflers, are designed to reduce the noise transmitted from a source to a receiver. For HVAC applications, the most common silencers are duct silencers, installed on the intake and/or discharge side of a fan or air handler. Also, they may be used on the receiver side of other noise generators such as terminal boxes, valves, dampers, etc.

Duct silencers are available in varying shapes and sizes to fit project ductwork. Generally, a duct silencer's outer appearance is similar to a piece of ductwork. It consists of a sheet metal casing with length commonly ranging from 0.9 to 3 m. Common shapes include rectangular, round, elbow, tee, and transitional. Figure 21 shows some duct silencer configurations.

All silencers can be rated for (1) insertion loss, (2) dynamic insertion loss, (3) pressure drop, and (4) self-generated noise in accordance with ASTM *Standard* E477 test standards. As such, the performance is under rather ideal conditions as seen in Figure 22.

Insertion loss is the reduction in the sound power level at the receiver after the silencer is installed ("inserted") in the system. Insertion loss is measured as a function of frequency and commonly published in full octave bands ranging from 63 to 8000 Hz.

Dynamic insertion loss is insertion loss with given airflow direction and velocity. A silencer's insertion loss varies depending on whether sound is traveling in the same or opposite direction as airflow. Silencer performance changes with absolute duct velocity. However, airflow velocity generally does not significantly affect

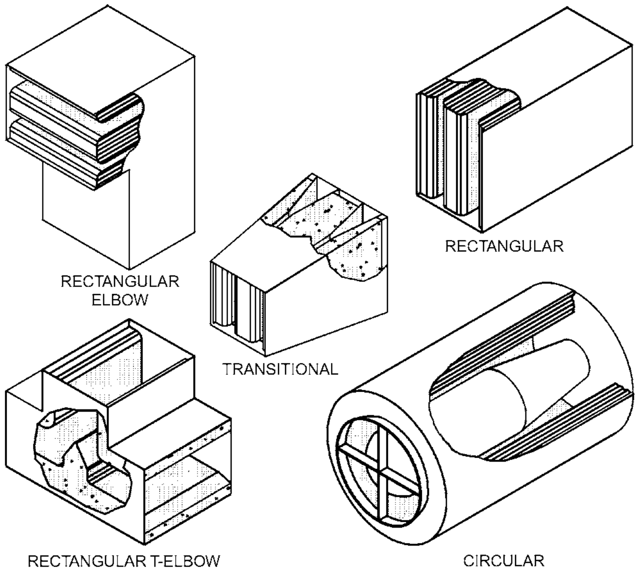

Fig. 21 Duct Silencer Configurations

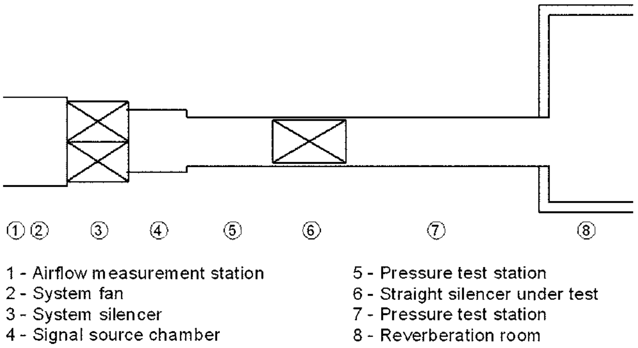

Fig. 22 Typical Facility for Rating Straight Duct Silencers With or Without Airflow

silencers giving a pressure drop of 90 Pa or less, including system effects.

Pressure drop is measured across the silencer at a given velocity. Good flow conditions are required for accurate measurements at both the inlet and discharge of the silencer. The measuring points are usually 2.5 to 5 duct diameters upstream and downstream of the silencer to avoid turbulent flow areas near the silencer and to allow for any static pressure regain. For nonideal installations, with duct elbows or transitions closer than 2.5 to 5 duct diameters, the total system effect will be larger than the laboratory test data.

Airflow-generated self noise is the sound power generated on the receiving side by the silencer when quiet air flows through it. This represents the **noise floor**, or the lowest level achievable regardless of high insertion loss values. A silencer's self-generated noise is a function of frequency and internal geometry, and is referenced to specific velocities and airflow direction (forward or reverse). The airflow-generated sound power of the silencer is logarithmically proportional to silencer cross-sectional area. Self noise generally does not vary with silencer length.

There are three types of HVAC duct silencers: dissipative (with acoustic media), fiber-free reactive (no media), and active.

Dissipative Silencers. Dissipative silencers use sound-absorptive media such as fiberglass as the primary means of attenuating sound; mineral wool can be used in high-temperature applications but may

contain too much contamination (“shot”) for commercial HVAC applications. Usually, the absorptive medium is covered by perforated metal to protect it from erosion by airflow. If internal silencer velocities are high (faster than 23 m/s), media erosion may be further reduced by a layer of material such as fiberglass cloth or polymer film liner placed between the absorptive media and the perforated metal. Dissipative silencers may be supplied as hospital-grade or as film-lined silencers that include special polymer film linings to prevent contamination of the airstream by acoustical media fibers and prevent particles from the airstream from getting into the media. These silencers are commonly used in hospitals, pharmaceutical facilities, cleanrooms, and other places where indoor air quality is of paramount concern. Consult manufacturers for construction and testing performance details.

Dissipative silencer performance is primarily a function of silencer length; airflow constriction; number, thickness, and shape of splitters or centerbodies; and type and density of absorptive media. The absorptive media allows dissipative silencers to provide significant insertion loss performance over a wide frequency range.

Insertion loss performance does not necessarily increase linearly with silencer length; for a given length, silencer designs can produce varying insertion loss and pressure drop data. Even at the same pressure drop and length, silencers can be configured to provide varying insertion loss performance across the frequency spectrum.

Reactive Silencers. Reactive silencers are constructed only of metal, both solid and perforated, with chambers of specially designed shapes and sizes behind the perforated metal that are tuned as resonators to react with and reduce sound power at certain frequencies. The outward appearance of reactive silencers is similar to that of their dissipative counterparts. However, because of tuning, insertion loss over a wide frequency range is more difficult to achieve. Longer lengths may be required to achieve similar insertion loss performance as dissipative silencers. Airflow generally increases the insertion loss of reactive silencers.

Figure 23 compares insertion loss of dissipative silencers, with and without protective film materials, against that of a reactive silencer for the same pressure drop.

Active Silencers. Active duct silencers, sometimes called noise canceling systems, produce inverse sound waves that cancel noise

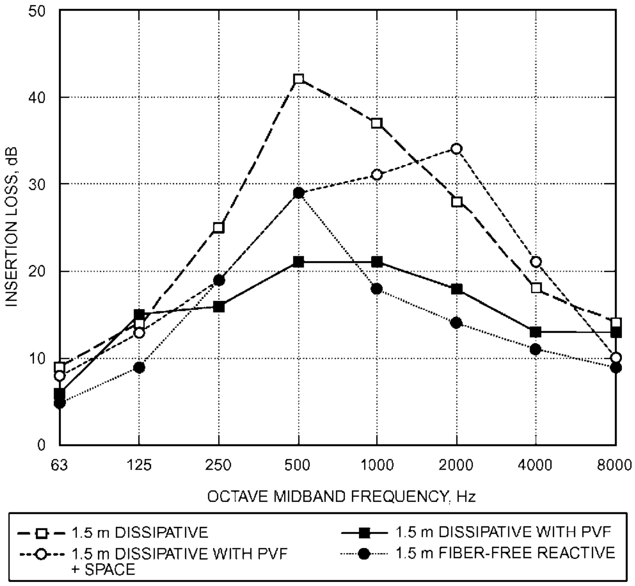

Fig. 23 Comparison of 1.5 m Long Dissipative and Fiber-Free Reactive Silencer Performance

primarily at low frequencies. An input microphone measures noise in the duct and converts it to electrical signals, which are processed digitally to generate opposite, mirror-image sound signals of equal amplitude. A secondary noise source destructively interferes with the primary noise and cancels a significant portion of it. An error microphone measures residual sound beyond the silencer and provides feedback to adjust the computer model for improved performance.

Because components are mounted outside the airflow, there is no pressure loss or airflow-generated noise. Performance is limited, however, if excessive turbulence is detected by the microphones. Manufacturers recommend using active silencers where duct velocities are less than 7.6 m/s and where duct configurations are conducive to smooth, evenly distributed airflow.

Active silencers have significant low-frequency insertion loss, and are self-regulating because, if fan noise levels increase, an active silencer can increase performance to compensate for the increased source noise. Mid- and high-frequency insertion loss is minimal, however, so if required, combinations of active (for low-frequency components) and passive (for mid- and high-frequency components) can be used to achieve insertion loss over a wide frequency range.

Test Standard. Data for dissipative and reactive silencers should be obtained from tests consistent with the procedures outlined in ASTM *Standard* E477. (This standard has not been verified for determining performance of active silencers.) Because insertion loss measurements use a substitution technique, reasonably precise insertion loss values can be achieved (±3 dB down to 125 Hz, and ±5 dB at lower frequencies). Airflow-generated noise values can be obtained with similar accuracy. Round-robin tests performed at several manufacturers’ and independent testing laboratories showed that airflow-generated sound power data have an expected standard deviation of ±3 to 6 dB over the octave band frequency range of 125 to 8000 Hz. (For normal distribution, uncertainty with a 95% confidence interval is about two standard deviations.)

Silencer Selection Issues. When selecting a duct silencer, consider the following:

- Insertion loss required to achieve required room sound criteria
- Allowable pressure drop (if no specific requirement, then keep under 90 Pa, including system effects; when system effects are unknown, keep under 50 Pa, excluding system effects) at system duct velocity
- Silencer location and available space
- Amount of airflow-generated noise that can be tolerated
- Indoor air quality concerns
- Duct configuration

Insertion Loss Issues

To determine the insertion loss required, analyze the duct system, summing noise-generating mechanisms and subtracting attenuation elements (not including the silencer). The silencer’s required insertion loss is the amount by which the estimated resultant sound pressure level in the space exceeds the room criteria for the space. The user should consider both the sound path through the ductwork and outlets as well as potential locations where sound may break out of the ductwork.

Allowable Pressure Drop Issues

Care should be taken in applying test data to actual project installations. Adverse aerodynamic system effects can significantly affect silencer performance. That is, if the silencer is located where less-than-ideal conditions exists on the inlet and/or the discharge of the silencer (3 to 5 duct diameters of straight duct), then the silencer’s effective **pressure drop (PD)** is increased (total silencer PD = silencer PD per ASTM *Standard* E477 + system effect losses). In some situations, the added system effect losses can be greater than the silencer’s pressure drop. Some manufacturers give guidelines

Table 27 Approximate Silencer System Effect Factors

Silencer Condition	Pressure Drop Factor*
Inlet (within 3 to 4 duct diameters)	
Straight unobstructed duct	1.0
Free air/plenum with smooth inlet	1.05
Radiused elbow, with turning vanes	1.05
no turning vanes	1.1
Miter elbow	1.3
Free air/plenum with sharp inlet	1.1 to 1.30
Fan	1.1 to 1.3
Outlet (within 3 to 4 duct diameters)	
Straight unobstructed duct	1.0
Duct doubles area abruptly	1.4
Radiused elbow, with turning vanes	1.5
no turning vanes	1.9
Miter elbow	2.0
Abrupt expansion/plenum	2.0
Fan	1.2 to 1.4

*Silencer pressure drop (including system effects) = silencer pressure drop per test code × pressure drop factor (inlet) × pressure drop factor (outlet).

for estimated pressure loss increases from varying silencer inlet and discharge configurations (Table 27); these should be considered as general guidelines. Substantial variations can occur depending on the type of silencer, its internal geometry, size of silencer, size of duct, airflow turbulence, etc. For example, an elbow fitting located immediately after a silencer prevents regain of the silencer's leaving velocity pressure. In addition, local velocities in the elbow fitting are greater than the average duct velocity that produces higher overall static pressure losses.

Silencer Location Issues

Silencers should generally be located as close to the noise source as possible but far enough away to allow a uniform flow profile to develop. This helps contain noise at the source and limits potential points where unsilenced noise may break out. However, because turbulent airflow usually exists close to noise sources such as fans, valves, dampers, etc., the user should carefully evaluate aerodynamic system effects.

A straight silencer has a lower first cost than a transitional or elbow silencer. If space limitations prohibit effective use of a straight silencer, or if pressure drop (including system effects) is greater than the loss allowed, use of elbow or transitional silencers should be evaluated. Special fan inlet and discharge silencers, including cone and inlet box silencers, minimize aerodynamic system effects, and contain noise at the source.

Airflow-Generated Noise Issues

In most installations, airflow-generated noise is much less than, and does not contribute to, the reduced noise level on the receiver side of the silencer. This is especially true if the silencer is properly located close to the source. In general, airflow-generated noise should be evaluated if pressure drops exceed 90 Pa (including system effects), the noise criterion is below NC/RC 35, or if the silencer is located very close to or in the occupied space.

To evaluate airflow-generated noise, sum the noise-generating mechanisms (from noise source to silencer) and subtract the attenuation elements (including silencer) in the order they occur to determine the resultant sound power level on the quiet side of the silencer. This resultant level must be summed logarithmically with the silencer's generated noise (referenced to actual duct velocities, inlet and discharge configurations, and cross-sectional area). If the generated noise is more than 10 dB below the residual sound, then the silencer's generated noise will have no effect on system noise levels.

Table 28 Duct End Reflection Loss (ERL): Duct Terminated Flush with Wall

Duct Diameter, mm	End Reflection Loss, dB Octave Midband Frequency, Hz				
	63	125	250	500	1000
150	18	12	7	3	1
200	15	10	5	2	1
250	14	8	4	1	0
300	12	7	3	1	0
400	10	5	2	1	0
510	8	4	1	0	0
610	7	3	1	0	0
710	6	2	1	0	0
810	5	2	1	0	0
910	4	2	0	0	0
1220	3	1	0	0	0
1830	1	0	0	0	0

Duct End Reflection Loss. When low-frequency sound waves encounter the end of a duct that is terminated into a large room, some of the incident sound energy is reflected back into the duct. Duct **end reflection loss (ERL)** values for a duct terminated flush with a wall are shown in Table 28.

To use Table 28 for a rectangular duct, calculate the effective duct diameter D by

$$D = \sqrt{4A/\pi} \tag{11}$$

where A is the cross-sectional area of the rectangular duct (m^2). For the frequency range and duct sizes of interest to HVAC designers, the duct ERL may be accurately computed using a simplified equation (Cunefare and Michaud 2008) of the form

$$\text{ERL} = 10 \log 10\left[1 + \left(\frac{a_1 c_o}{\pi f D}\right)^{a_2}\right] \tag{12}$$

where

c_o = speed of sound (dimensionally consistent with D), m/s
f = frequency, Hz
a_1 and a_2 = dimensionless constants determined as follows:

Termination	a_1	a_2
Flush	0.7	2
Free space	1	2

ERL varies slightly with the frequency spectrum and measurement bandwidth. The constants apply to a pink spectrum in octave bands, which is representative of HVAC noise. ERLs greater than 20 dB are difficult to confirm in practice. Many test standards, such as AHRI *Standard* 260 for ducted equipment, limit ERL to 14 dB when reporting equipment sound power levels.

There are many limitations associated with the use of the ERL equation. Free-space conditions may not exist, except for duct terminations of 5D or more from a reflecting plane such as a wall or the floor. Such conditions may exist in test laboratories, but are not typical of HVAC duct applications.

Research (Cunefare and Michaud 2008) has changed our understanding of ERL for ducts terminated with commercial devices. Ducts that terminate with blade-type diffusers and grilles should be treated as having ERL for a flush termination. This includes terminal devices mounted in suspended acoustical ceiling systems. Slot diffusers characterized by high aspect ratios and mounted in a rigid baffle have frequency-independent ERL that may be determined by the analytical expression for the area ratio of the diffuser to duct cross-sectional area. Finally, using flexible duct upstream of diffusers, grilles and other terminal devices reduces ERL to near zero above 63 Hz for all terminal devices. This research suggests that a significant amount of the low-frequency sound that would normally be reflected back into the duct from an open termination is either transmitted through the flexible duct or radiated by the termination. There is however a frequency-independent ERL associated with the area change in the transition to the flexible duct.

Finally, ERL values are based on analytical assumptions and empirical data for long and straight duct sections. Many air distribution systems do not have long straight sections (greater than 3*D*) before they terminate into a room. Many duct sections between a main feed branch and a diffuser may be curved or short. The effects of these configurations on duct end reflection loss are not known. Table 28 can be used with reasonable accuracy for many diffuser configurations. However, use caution when a diffuser configuration differs from the conditions used to derive these ERL values.

Sound Radiation Through Duct Walls

Duct Rumble. Duct rumble is low-frequency sound generated by vibration of a flat duct surface. The vibration is caused when an HVAC fan and its connected ductwork act as a semiclosed, compressible-fluid pumping system; both acoustic and aerodynamic air pressure fluctuations at the fan are transmitted to other locations in the duct system. Rumbling occurs at the duct's resonance frequencies (Ebbing et al. 1978), and duct rumble levels of 65 to 95 dB in the 16 to 100 Hz frequency range have been measured in occupied spaces. With belt-driven fans, the rumble sound level fluctuates above and below the mean dB level by 5 to 25 dB at a rate of 2 to 10 "beats" per second (Blazier 1993). The most common beat frequency occurs at the difference between the fan rpm and twice the belt frequency (belt rpm = fan sheave diameter × sheave rpm × π/belt length). As shown in Figure 24, duct rumble is dependent on the level of duct vibration. The very low resonant frequencies at which duct rumble occurs means that the sound wavelengths are very long (3 to 20 m), and the rumble can exert sound energy over long distances. Low-mass architectural structures such as metal frame and drywall systems near a source of duct rumble can easily vibrate and rattle in sympathy to the rumble.

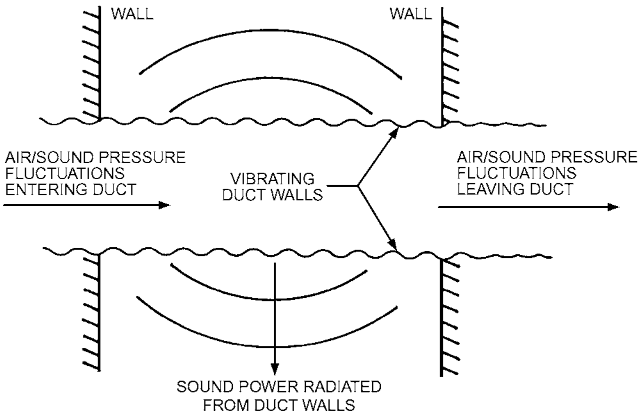

Fig. 24 Transmission of Rumble Noise Through Duct Walls

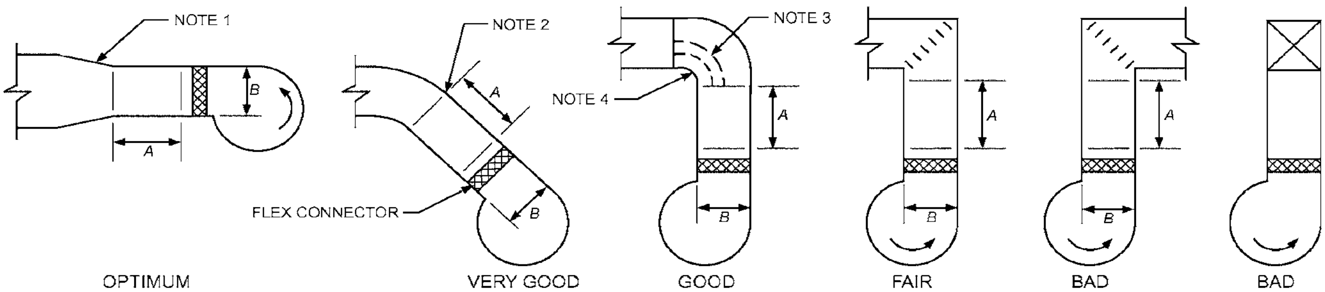
Case histories indicate that duct vibration is much more prevalent when there is a dramatic change in airflow direction near the fan, and at large, flat, unreinforced duct surfaces (usually greater than 1200 mm in any dimension) near the fan. Problems can occur with dimensions as small as 460 mm if high noise levels are present. Figure 25 shows duct configurations near a centrifugal fan. Good to optimum designs of fan discharge transitions minimize potential for duct rumble; however, this may not completely eliminate the potential for duct rumble, which also depends heavily on flow turbulence at the fan wheel, duct stiffness, air velocity in the duct, and duct resonant characteristics.

Duct liner, sound attenuators, and duct lagging with mass-loaded vinyl over fiberglass do not reduce duct rumble. One approach to eliminate or reduce rumble is to alter the fan or motor speed, which changes the frequency of air pressure fluctuations so that they differ from duct wall resonance frequencies. Another method is to apply rigid materials, such as duct reinforcements and drywall, directly to the duct wall to change the wall resonance frequencies (Figure 26). Noise reductions of 5 to 11 dB in the 31.5 and 63 Hz octave frequency bands are possible using this treatment.

Mass-loaded materials applied in combination with absorptive materials do not alleviate duct rumble noise unless both materials are completely decoupled from the duct by a large air separation (preferably greater than 150 mm). The mass-loaded material should have a surface density greater than 20 kg/m^2. An example of this type of construction, using two layers of drywall, is shown in Figure 27. Because the treatment is decoupled from the duct wall, it provides the greatest noise reduction. Mass-loaded/absorptive material directly attached to a round duct can be an effective noise control treatment for high-frequency noise above the duct rumble frequency range of 16 to 100 Hz. In addition, the stiffness of round ductwork prevents flexure of the duct wall. Where space allows, round ductwork is an effective method to prevent duct rumble (Harold 1986). However, unless round ducts are used throughout the primary duct system, duct rumble can be still generated at a remote point where round duct is converted to rectangular or flat oval.



Notes:
1. Slopes of 1 in 7 preferred. Slopes of 1 in 4 permitted below 10 m/s.
2. Dimension *A* should be at least 1.5 times *B*, where *B* is largest discharge duct dimension.
3. Rugged turning vanes should extend full radius of elbow.
4. Minimum 150 mm radius required.

Fig. 25 Various Outlet Configurations for Centrifugal Fans and Their Possible Rumble Conditions

Round ducts can have a resonant ring resonance frequency, which depends on duct material and diameter. The ring frequency is a resonance frequency that occurs where the circumference of the duct is equal to the wavelength of the bending waves in the duct wall. On rare occasions, loud in-duct noise, such as blade-pass frequency noise from a centrifugal or axial fan, can excite this resonance. In all cases, this resonance causes an increase in radiated noise in the frequency region close to the ring frequency.

Sound Breakout and Break-In from Ducts. Breakout is sound associated with fan or airflow noise inside a duct that radiates through duct walls into the surrounding area (Figure 28). Breakout can be a problem if it is not adequately attenuated before the duct runs over an occupied space (Cummings 1983; Lilly 1987). Sound that is transmitted into a duct from the surrounding area is called **break-in** (Figure 29). The main factors affecting breakout and break-in sound transmission are the transmission loss of the duct, total exposed surface area of the duct, and presence of any acoustical duct liner.

Transmission loss (TL) is the ratio of sound power incident on a partition to the sound power transmitted through a partition. This ratio varies with acoustic frequency as well as duct shape, size, and wall thickness. Higher values of transmission loss result in less noise passing through the duct wall.

Breakout sound transmission from ducts is the sound transmitted through a duct wall and then radiated from the exterior surface of the duct wall. Its sound power level is given by

$$L_{w(out)} = L_{w(in)} + 10\log\left(\frac{S}{A}\right) - TL_{out} \qquad (13)$$

where

$L_{w(out)}$ = sound power level of sound radiated from outer surface of duct walls, dB
$L_{w(in)}$ = sound power level of sound inside duct, dB
S = surface area of outer sound-radiating surface of duct, m^2
A = cross-section area of inside of duct, m^2
TL_{out} = normalized duct breakout transmission loss (independent of S and A), dB

Equation (13) is a simplified expression that assumes that the sound power level inside the duct does not decrease with distance over the length of the duct. In fact, for very long ducts (when $S >> A$), the radiated sound power level $L_{w(out)}$ could become greater than the sound power level inside the duct, which would violate the conservation of energy principle. A more accurate expression for breakout is presented in Equation (20).

Values of TL_{out} for rectangular ducts are given in Table 29, for round ducts in Table 30, and for flat oval ducts in Table 31 (Cummings 1983, 1985; Lilly 1987).

Equations for S and A for rectangular ducts are

$$S = 2L(a + b) \qquad (14)$$

$$A = ab \qquad (15)$$

where

a = larger duct cross-section dimension, m
b = smaller duct cross-section dimension, m
L = length of duct sound-radiating surface, m

Equations for S and A for round ducts are

$$S = L\pi d \qquad (16)$$

$$A = \pi\frac{d^2}{4} \qquad (17)$$

where

d = duct diameter, m

2440 × 1220	18	28	31	—	—	—	—	—

Note: Data are for duct lengths of 6.1 m, but values may be used for cross section shown regardless of length.

L = length of duct sound-radiating surface, m

For flat oval ducts,

$$S = L[2(a - b) + \pi b] \tag{18}$$

$$A = b(a - b) + \frac{\pi b^2}{4} \tag{19}$$

where

a = length of major axis, m
b = length of minor axis, m
L = length of duct sound-radiating surface, m

Equation (13) assumes no decrease in the internal sound power level with distance along the length of the duct. Thus, it is valid only for relatively short lengths of unlined duct. For long ducts or ducts that have internal acoustic lining, one approach is to divide the duct into sections, each of which is short enough to be modeled as a section of duct with constant internal sound power level over the length of each section. The recommended maximum length of each section is the length that would result in a 1 dB reduction in the internal sound power level at the frequency of interest. Alternatively, the total sound power radiated from any duct of any length (including an internally lined duct) can be calculated in a single step with a modified version of Equation (13) (Lilly 1987):

$$L_{w(out)} = L_{w(in)} + 10\log\left(\frac{S^*}{A}\right) - TL_{out} \tag{20}$$

where S^* is the effective surface area of the duct. $S^* = PL^*$, where P = duct perimeter, and L^* = effective length. The effective length L^* is calculated as

$$L^* = \frac{\gamma^L - 1}{\ln\gamma} \tag{21}$$

where

$$\gamma = 10^{(-\alpha/10)} \tag{22}$$

where α = duct attenuation rate, dB/m (see Tables 16 to 21). For lined rectangular ducts, Tables 17 and 18 do not have data at 63 Hz. For rough approximations, use Table 16 values.

In most rooms where the listener is close to the duct, an estimate of the breakout sound pressure level can be obtained from

$$L_p = L_{w(out)} - 10\log(\pi r L) \tag{23}$$

where

L_p = sound pressure level at a specified point in the space, dB
$L_{w(out)}$ = sound power level of sound radiated from outer surface of duct walls, given by Equation (13) or Equation (20), dB
r = distance between duct and position for which L_p is calculated, m
L = length of the duct sound-radiating surface, m

Note that Equation (23) gives sound pressure from a duct that is in a wide-open ceiling plenum space. If the duct is in a tight space between floor slab and ceiling, it may be up to 6 dB louder.

Example 4. A 610 mm by 610 mm by 7.5 m long rectangular supply duct is constructed of 0.75 mm sheet metal. Given the following sound power levels in the duct, what are the breakout sound pressure levels 1.5 m from the surface of the duct?

Solution: Using Equations (13) and (23),

Using round duct eliminates the low-frequency rumble present with rectangular ducts but introduces some mid- and high-frequency noise that can be reduced by adding duct liner as shown.

When sound is not transmitted through the wall of a round duct, it propagates down the duct and may become a problem at another point in the duct system. Round flexible and rigid fiberglass ducts do not have high transmission loss properties because they lack the mass or stiffness associated with round sheet metal ducts.

Whenever duct sound breakout is a concern, fiberglass or flexible round duct should not be used; these ducts have little or no transmission loss, and are essentially transparent to sound.

Table 32 Experimentally Measured TL_{in} Versus Frequency for Circular Ducts

Diameter, mm	Length, m	Gage	TL_{in}, dB Octave Midband Frequency, Hz 63	125	250	500	1000	2000	4000

Note: Data are for duct lengths of 6.1 m.

Break-in sound transmission into ducts is sound transmitted into a duct through the duct walls from the space outside the duct. Its sound power level is given by

$$L_{w(in)} = L_{w(out)} - TL_{in} - 3 \qquad (24)$$

where

$L_{w(in)}$ = sound power level of sound transmitted into duct and then transmitted upstream or downstream of point of entry, dB

$L_{w(out)}$ = sound power level of sound incident on outside of duct walls, dB

TL_{in} = duct break-in transmission loss, dB

Values for TL_{in} for rectangular ducts are given in Table 32, for round ducts in Table 33, and for flat oval ducts in Table 34 (Cummings 1983, 1985).

Table 34 TL_{in} Versus Frequency for Flat Oval Ducts

2.5 RECEIVER ROOM SOUND CORRECTION

The sound pressure level at a given location in a room caused by a particular sound source is a function of the sound power level and sound radiation characteristics of the sound source, acoustic properties of the room (surface treatments, furnishings, etc.), room volume, and distance between the sound source and point of observation. Two types of sound sources are typically encountered in HVAC system applications: **point** and **line**. Typical point sources are grilles, registers, and diffusers; air-valve and fan-powered air terminal units and fan-coil units located in ceiling plenums; and return air openings. Line sources are usually associated with sound breakout from air ducts and long slot diffusers.

For a point source in an enclosed space, classical diffuse-field theory predicts that as the distance between the source and point of observation is increased, the sound pressure level initially decreases at the rate of 6 dB per doubling of distance. At some point, the reverberant sound field begins to dominate and the sound pressure level remains at a constant level.

For point sound sources in **reflective unfurnished rooms**, the classic diffuse equation for converting sound power to pressure could be used:

$$L_p = L_W + 10\ \log(Q/4\pi r^2 + 4/R) \qquad (25)$$

where

L_p = sound pressure level, dB (re 20 µPa)
L_W = sound power level, dB (re 10^{-12} W)
Q = directivity of sound source, dimensionless; see Figure 30
r = distance from source, m
R = room constant = $[S\alpha/(1-\alpha)]$ = sum of all surface areas and their corresponding absorption coefficients, m²

A further discussion of assumptions used in converting power to pressure is available in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*.

However, investigators have found that diffuse-field theory does not apply in rooms with furniture or other sound-scattering objects (Schultz 1985; Thompson 1981). Instead, sound pressure levels decrease at the rate of around 3 dB per doubling of distance between sound source and point of observation. Generally, a true reverberant sound field does not exist in small rooms (room volumes less than 425 m³). In larger rooms reverberant fields usually exist, but typically at distances from the sound sources that are significantly greater than those predicted by diffuse-field theory.

Most **normally furnished rooms** of regular proportions have acoustic characteristics that range from *average* to *medium dead*. These usually include carpeted rooms with sound-absorptive ceilings. If such a room has a volume less than 425 m³ and the sound source is a single point source, sound pressure levels associated with the sound source can be obtained from (Schultz 1985).

$$L_p = L_w - 10\ \log r - 5\ \log V - 3\ \log f + 12 \qquad (26)$$

or

$$L_p = L_w + A - B \qquad (27)$$

where

L_p = sound pressure level at specified distance from sound source, dB (re 20 µPa)
L_w = sound power level of sound source, dB (re 10^{-12} W)
r = distance from source to receiver, m
V = volume of room, m³
f = frequency

Values for A and B are given in Tables 35 and 36.

In an alternative calculation for a normally furnished room with volume greater than 425 m³ and a single-point sound source, sound pressure levels associated with the sound source can be obtained from

$$L_p = L_w - C - 5 \qquad (28)$$

Values for C are given in Table 37. Equation (28) can be used for room volumes of up to 4250 m³, with accuracy typically within 2 to 5 dB.

Distributed Array of Ceiling Sound Sources

In many office buildings, air supply outlets are located flush with the ceiling of the conditioned space and constitute an array of distributed ceiling sound sources. The geometric pattern depends on the floor area served by each outlet, ceiling height, and thermal load distribution. In interior zones of a building where thermal load requirements are essentially uniform, air delivery per outlet is usually the same throughout the space; thus, these outlets emit nominally equal sound power levels. One way to calculate sound pressure levels in a room with a distributed array is to use Equation (26), (27), or (28) to calculate the sound pressure levels for each individual air outlet at specified locations in the room and then logarithmically add the sound pressure levels for each diffuser at each observation point. This procedure can be very tedious for a room with a large number of ceiling air outlets.

For a distributed array of ceiling sound sources (air outlets) of nominally equal sound power, room sound pressure levels tend to be

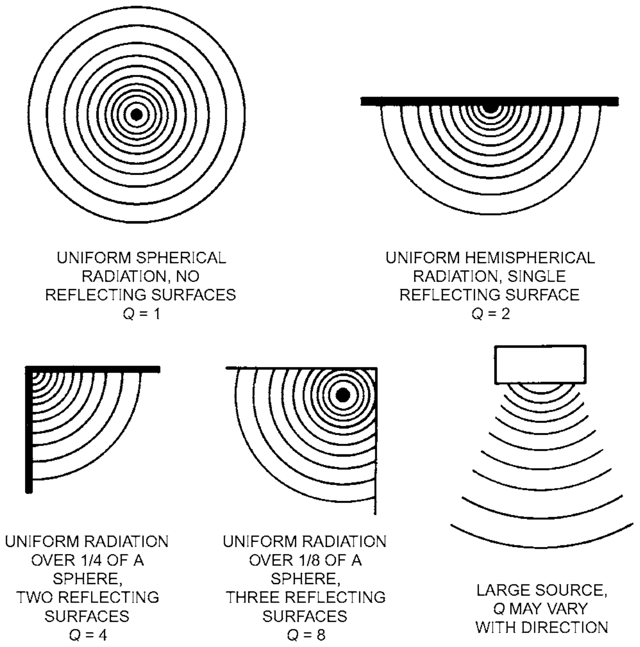

Fig. 30 Directivity Factors for Various Radiation Patterns

Table 35 Values for A in Equation (26)

283	0	–1	–2	–3	–4	–5	–6
425	–1	–2	–3	–4	–5	–6	–7

Table 36 Values for B in Equation (26)

Distance from Sound Source, m	Value for B, dB
0.9	5
1.2	6
1.5	7
1.8	8
2.4	9
3.0	10
4.0	11
4.9	12
6.1	13

uniform in a plane parallel to the ceiling. Although sound pressure levels decrease with distance from the ceiling along a vertical axis, they are nominally constant along any selected horizontal plane. Equation (29) simplifies calculation for a distributed ceiling array. For this case, use a reference plane 1.5 m above the floor.

Thus, $L_{p(1.5)}$ is obtained from

$$L_{p(1.5)} = L_{W(s)} - D \tag{29}$$

where

$L_{p(1.5)}$ = sound pressure level at distance of 1.5 m above floor, dB (re 20 μPa)
$L_{W(s)}$ = sound power level of single diffuser in array, dB (re 10^{-12} W)

Values of D are given in Table 38.

Nonstandard Rooms

The previous equations assume that the acoustical characteristics of a room range from average to medium dead, which is generally true of most rooms. However, some rooms may be acoustically *medium live* to *live* (i.e., they have little sound absorption). These rooms may be sports or athletic areas, concert halls, or other rooms designed to be live, or they may be rooms that are improperly designed from an acoustic standpoint. The previous equations should not be used for acoustically live rooms because they can overestimate the decrease in sound pressure levels associated with room sound correction by as much as 10 to 15 dB. When these or other types of nonstandard rooms are encountered, it is best to use the services of an acoustical engineer.

Line Sound Sources

Sound from breakout from air ducts or long slot diffusers may be modeled as line sources. To convert sound power levels to the corresponding sound pressure levels in a room for such cases, the following equation may be used:

$$L_p = L_W + 10\log(Q/\pi r L + 4/R) \tag{30}$$

where

L_p = sound pressure level, dB (re 20 μPa)
L_W = sound power level, dB (re 10^{-12} W)

Table 37 Values for C in Equation (28)

Distance from Sound Source, m	Value for C, dB Octave Midband Frequency, Hz 63	125	250	500	1000	2000	4000

9.8	15	17	17	18	20	23	30

Table 38 Values for D in Equation (29)

Floor Area per Diffuser, m^2	Value for D, dB Octave Midband Frequency, Hz 63	125	250	500	1000	2000	4000
Ceiling height 2.4 to 2.7 m							
9.3 to 14	2	3	4	5	6	7	8
18.5 to 23	3	4	5	6	7	8	9
Ceiling height 3.0 to 3.7 m							
14 to 18.5	4	5	6	7	8	9	10
23 to 28	5	6	7	8	9	10	11
Ceiling height 4.3 to 4.9 m							
23 to 28	7	8	9	10	11	12	13
32.5 to 37	8	9	10	11	12	13	14

Q = 1 if line source is away from reflecting surfaces; 2 if line source is near a flat reflective surface.
r = distance from source, m
L = length of line source, m
R = room constant = $[S\alpha/(1-\alpha)]$ = sum of all surface areas and their corresponding absorption coefficients, m^2

This is the classic diffuse room equation for a line source, and may not produce accurate results for standard nondiffuse rooms. Unfortunately, no information is available at this time on how to correct more accurately for the effect of the receiver room on line sources.

Room Noise Measurement

Measuring HVAC system noise in a room is complicated by several factors, including the spatial and temporal variability of the noise, variable HVAC system operating conditions, modal characteristics of the room, and intrusion of noise from exterior sources. How noise measurements should be taken depends to some extent on the purpose of the measurement. Is the purpose of the measurement to verify that the noise level in the room meets a specific criteria, or is it meant to troubleshoot an alleged problem? The specific measurement requirements vary depending on the intent.

For commissioning purposes, there are two levels of assessment: (1) a survey method may be used to make a quick assessment of a space and (2) an engineering method for a more detailed and accurate assessment. The **survey approach** is typically used to assess whether there may be a noise problem in the room. This method requires a Type 1 integrating sound level meter equipped with octave band filters if octave band levels are specified by the applicable noise criterion. Measurements can be taken at a single point or at several points, but all measurement points must be at a likely location for the listener's ears. No measurement locations may be less than 1 m from a room boundary or less than 0.5 m from any object in the room. The measurement microphone must be fixed (or slowly moving) for each measurement, and the minimum duration of each measurement is 15 s. It is recognized that HVAC noise is a time-varying signal, so the energy average sound pressure level L_{eq} must be compared against the noise criterion, not the maximum sound level recorded during the measurement.

If the survey method detects a potential noise problem or if a complaint has been registered by an occupant of the space, the **engineering method** may be implemented if compliance with a noise level specification is required. This method uses the same instrumentation but requires a minimum of four separate measurement locations, uniformly distributed throughout the room. For larger rooms (greater than 20 m^2), additional measurement points must be added, proportional to the floor area of the room. Unless specified otherwise, the energy average L_{eq} of all measurement locations in the room is compared against the noise criterion.

If the purpose of the noise measurement is troubleshooting a known problem, more sophisticated instrumentation (e.g., narrow band analyzers, vibration sensors, intensity probes) may be required. Troubleshooting work should be provided by a competent acoustical consultant with specific experience in this field of work. Contact the Institute of Noise Control Engineering (www.inceusa.org) or the National Council of Acoustical Consultants (www.ncac.com) for a list of experts.

In any case, it is important for the operating conditions of the HVAC system to be known at the time of the measurements. If the system contains compressors that cycle on and off during normal operation, the measurements must be taken while the compressors are running. For variable-volume systems, the measurements should be taken at design (maximum) volume. If the condition rarely operates under design flow conditions, measurements must also be taken at a more typical operating condition.

It is also important to make sure that noise from extraneous (non-HVAC) sources does not contaminate the measurements. Room noise measurements may be corrected for these sounds by taking one set of measurements with the HVAC system operating under test conditions and additional measurements with the HVAC system shut down entirely. This correction can only be applied if the ambient noise is shown to be relatively constant with time. If the energy average of two independent ambient noise level measurements (one obtained before and the other obtained after the HVAC system noise measurement) is more than 6 dB below the HVAC noise level in any octave band, then the ambient adjusted HVAC noise level in that octave band may be computed using the following equation:

$$L_{p\ ambient\ adjusted} = 10\ \log\left[10^{(L_{p\ HVAC}/10)} - 10^{(L_{p\ ambient}/10)}\right]$$

where

$L_{p\ HVAC}$ = sound pressure level with HVAC system operating
$L_{p\ ambient}$ = energy average ambient sound pressure level with HVAC system off

The ambient noise correction cannot be allowed if the difference between the two ambient noise levels in any frequency band is more than 3 dB. If this occurs, the ambient noise is not constant with time and the entire set of measurements should be repeated. Remember that that the ambient noise correction is not required if the ambient is at least 10 dB quieter than with the HVAC on.

For more information, see the section on Troubleshooting.

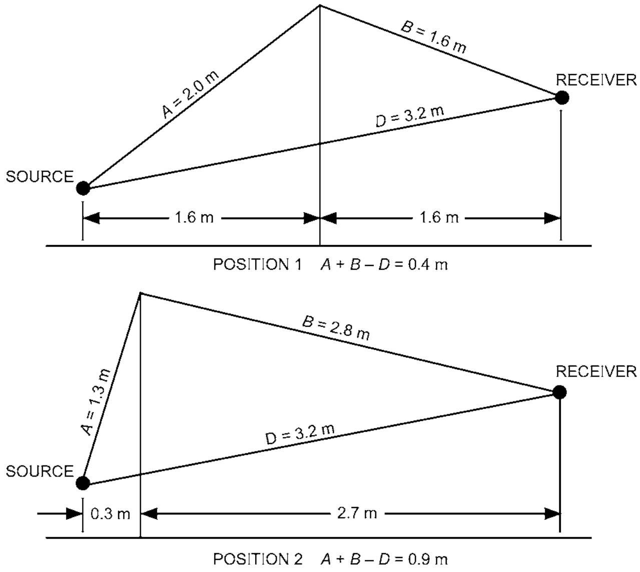

Fig. 31 Noise Barrier

2.6 SOUND CONTROL FOR OUTDOOR EQUIPMENT

Outdoor mechanical equipment should be carefully selected, installed, and maintained to minimize sound radiated by the equipment, and to comply with local noise codes. Equipment with strong tonal components is more likely to provoke complaints than equipment with a broadband noise spectrum.

Sound Propagation Outdoors

If the equipment sound power level spectrum and ambient sound pressure level spectrum are known, the contribution of the equipment to the sound level at any location can be estimated by analyzing the sound transmission paths involved. When there are no intervening barriers and no attenuation because of berms, ground absorption, or atmospheric effects, the principal factor in sound pressure level reduction is distance. The following equation may be used to estimate the sound pressure level of equipment at a distance from it and at any frequency when the sound power level is known:

$$L_p = L_w + 10\ \log Q - 20 \log d - 11 \qquad (31)$$

where

d = distance from acoustic center of source to distant point, m
L_p = sound pressure level at distance d from sound source, dB
L_w = sound power level of sound source, dB
Q = directivity factor associated with way sound radiates from sound source (see Figure 30)

Equation (31) does not apply where d is less than twice the maximum dimension of the sound source. L_p may be low by up to 5 dB where d is between two and five times the maximum sound source dimension. Also, if the distance is greater than about 150 m, wind, thermal gradients, and atmospheric sound absorption need to be considered.

For complex cases, refer to texts on acoustics (e.g., Beranek 1971) and international standards such as ISO *Standard* 9613-2.

Sound Barriers

A sound barrier is a solid structure that intercepts the direct sound path from a sound source to a receiver. It reduces the sound pressure level within its shadow zone. Figure 31 shows the geomet-

15.2	18	20	23	24	24	24	24	24

rical aspects of an outdoor barrier where no extraneous surfaces reflect sound into the protected area. Here the barrier is treated as an intentionally constructed noise control structure. If a sound barrier is placed between a sound source and receiver location, the sound pressure level L_p in Equation (26) is reduced by the **insertion loss (IL)** associated with the barrier.

Table 39 gives the insertion loss of an outdoor ideal solid barrier when no surfaces reflect sound into the shadow zone, and the sound transmission loss of the barrier wall or structure is at least 10 dB greater at all frequencies than the insertion loss expected of the barrier. The path-length difference referred to in Table 39 is given by

$$\text{Path-length difference} = A + B - D \qquad (32)$$

where A, B, and D are as specified in Figure 31.

The limiting value of about 24 dB is caused by sound scattering and refracting into the shadow zone formed by the barrier. Practical factors such as size and space restrictions often limit sound barrier performance to 10 to 15 dBA. For large distances outdoors, this scattering and bending of sound waves into the shadow zone reduces barrier effectiveness. At large distances, atmospheric conditions can significantly affect sound path losses by amounts even greater than those provided by the barrier, with typical differences of 10 dBA. For a conservative estimate, the height of the sound source location should be taken as the topmost part of the sound source, and the height of the receiver should be taken as the topmost location of a sound receiver, such as the top of the second-floor windows in a two-floor house or at a height of 1.5 m for a standing person.

Reflecting Surfaces. No other surfaces should be located where they can reflect sound around the ends or over the top of the barrier into the barrier shadow zone. Figure 32 shows examples of reflecting surfaces that can reduce the effectiveness of a barrier wall.

Width of Barrier. Each end of the barrier should extend horizontally beyond the line of sight from the outer edge of the source to the outer edge of the receiver position by a distance of at least three times the path-length difference. Near the ends of the barrier, the effectiveness of the noise isolation is reduced because some sound is diffracted over the top and around the ends. Also, some sound is reflected or scattered from various nonflat surfaces along the ground near the ends of the barrier. In critical situations, the barrier should completely enclose the sound source to eliminate or reduce the effects of reflecting surfaces.

Reflection from a Barrier. A large, flat reflecting surface, such as a barrier wall, may reflect more sound toward the source than there would have been with no wall present. If the wall produces no special focusing effect, reflections from the wall will produce levels on the side of the barrier facing the source that are 2 to 3 dB higher. Using acoustical absorption on the barrier surface (source side) reduces this increase.

2.7 FUME HOOD DUCT DESIGN

Fume hood exhaust systems are often the major sound source in a laboratory. The exhaust system may consist of individual exhaust fans ducted to separate fume hoods, or a central exhaust fan connected through a collection duct system (commonly known as a manifold) to a large number of hoods, as shown in Figure 33. In either case, a redundancy system consisting of two fans might be used. In addition to fan noise, other sound sources are the air terminal unit serving the hood and aerodynamically generated noise from airflow in the ducts and control valves. Sound pressure levels produced in the laboratory space should be estimated using procedures described in this section and manufacturer-supplied noise emission data. Recommended noise level design criteria for laboratory spaces using fume hoods are given in Table 1.

To minimize static pressure loss and fan power consumption in a duct system, fume hood ducts should be sized to allow rated airflow at no greater than 10 m/s or at a velocity consistent with regulatory requirements. Duct velocities over 10 m/s should be avoided for acoustical reasons and to conserve energy. Above this speed, the

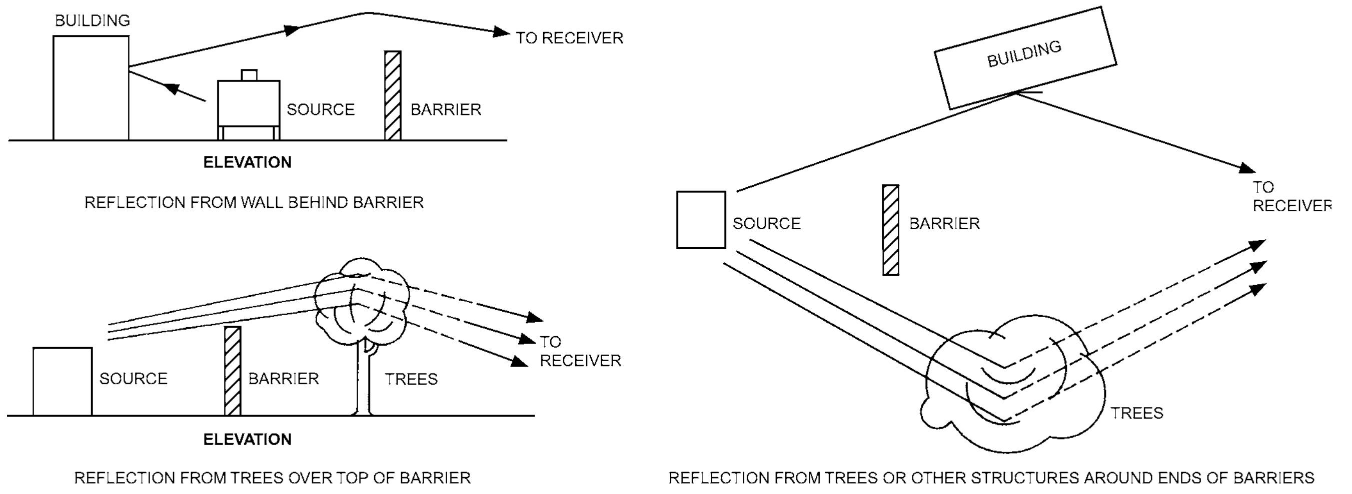

Fig. 32 Reflecting Surfaces That Can Diminish Barrier Effectiveness

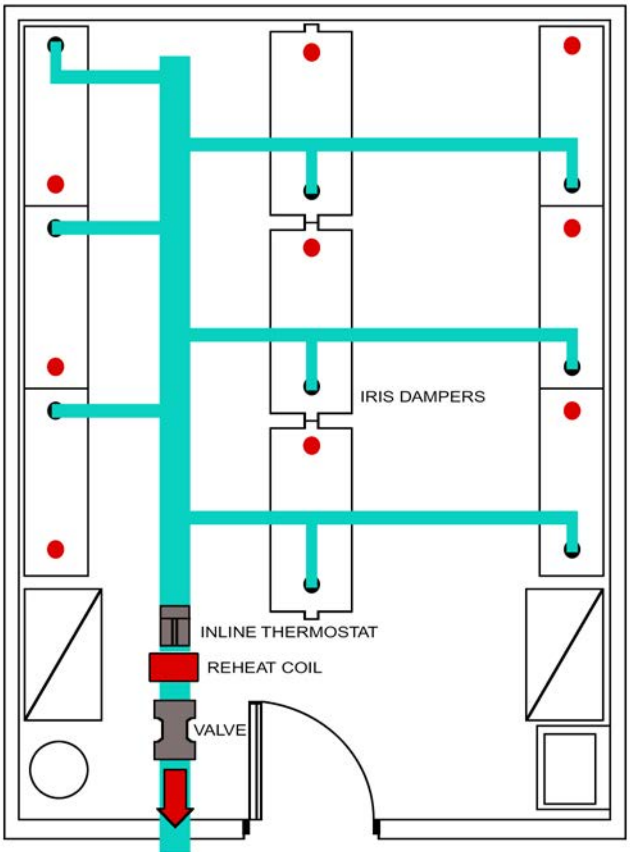

Fig. 33 Typical Manifold Lab Exhaust Layout

design criteria given in Table 1 are unlikely to be met, even with a silenced fan(s).

Noise control measures for fume hood systems include the following:

Fan(s)

- Where conditions allow, use backward-inclined, airfoil, or forward-curved centrifugal fans instead of radial-blade fans, and use caution if applying axial-blade fans.
- Select fan(s) to operate at a low tip speed and maximum efficiency.
- Try to run redundant fans at reduced capacity instead of operating one fan at full capacity.

Manifold

- Design the manifold upstream of the exhaust fan(s) to double as an acoustic plenum as shown in Figure 34 with sound-absorbent sidewall panels, which can be constructed with nonporous lining or packless cavities with perforated inner wall. Fan low-frequency noise can be reduced when the manifold is parallel-piped, with large surface area compared to the cross-sectional area of the fume hood ducts connecting to it.

Duct silencers

- Use prefabricated duct silencers or sections of lined ducts where conditions allow. In addition to galvanized steel, silencers can be fabricated with stainless steel, aluminum, or plastic.
- Silencers should be packless design, or have nonporous fill.

Exhaust silencers

- Where outdoor noise is an issue, round silencers may be required between the fan and the discharge cone. These should be packless or nonporous-fill design.

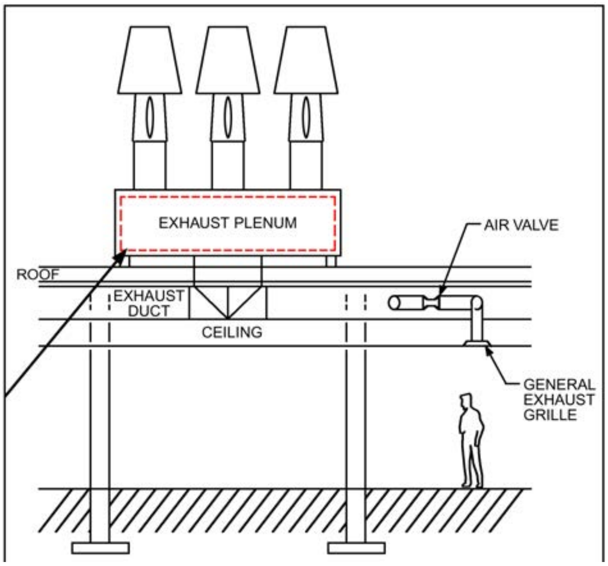

Fig. 34 Inlet Plenum for Multiple Exhaust Fans

Duct design

- Design duct elements such as elbows and junctions with low friction to minimize duct pressure loss and aerodynamically generated noise. Use round ducts, because rectangular ducts can have a noise breakout issue.

Laboratory flow control valves and air terminal units

- Allow 600 to 900 mm minimum of straight duct upstream and downstream from the terminal unit to reduce aerodynamically generated noise at the unit.
- Additional straight length may be required on the room side of valves to accommodate high-performance silencers.
- Noise generation in flow control valves increases exponentially with pressure loss, so system supply or exhaust pressure should be set at the level necessary to achieve design flow rate with minimal safety factor.

Fume hood location

- Where possible, locate fume hoods in private alcoves to reduce lab occupant's noise exposure.

All potential noise control measures should be carefully evaluated for compliance with applicable codes, safety requirements, and corrosion resistance requirements of the specific fume hood system. In addition, vibration isolation for fume hood exhaust fans is generally required. For some laboratory facilities, particularly those with highly vibration-sensitive instruments such as electron microscopes, vibration control can be critical, and a vibration specialist should be consulted.

2.8 MECHANICAL EQUIPMENT ROOM SOUND ISOLATION

Location

Locating HVAC equipment in a common room allows the designer to control noise affecting nearby spaces. Often, these spaces have background noise level criteria that dictate the type of construction and treatment necessary to achieve sufficient reduction in equipment noise transmitted to other spaces.

The most effective noise control measure for indoor mechanical equipment rooms is to locate them as far away as possible from noise-sensitive areas. In some cases, this requires a separate structure, such as a central chiller plant, to house equipment. Subterranean basement locations are typically best for noisy equipment because the basement usually affects the fewest adjacent locations. Penthouse equipment rooms are common but can create significant challenges for noise and vibration isolation. Rooms containing air-handling units should provide sufficient room for the equipment and associated ductwork to allow smooth transitions and full-radius curved elbows. A building corner location can work well by reducing the number of adjacent interior spaces and the amount of associated outdoor-air ductwork. Using adjacent spaces such as corridors, closets, and storage rooms as buffer zones can provide effective noise control. A common mistake in locating mechanical equipment rooms is to position the room in the core of the building between a stairway, an elevator shaft, and a telecommunications closet, leaving only one wall where supply and return air ductwork can enter and leave the room. This leads to high-velocity air in the ductwork and high static pressures for fans to overcome, leading to higher noise levels.

Once the mechanical equipment room location has been established, the amount of noise created in the room should be assessed and appropriate constructions selected for walls, ceilings, and floors. Concrete masonry units of various available thickness and densities are often used for their durability and effectiveness in reducing low-frequency noise levels. Typically, heavier and thicker materials contain more sound within the space. Special masonry units that provide a limited amount of acoustical absorption using slotted openings and resonator cavities can also be used. The sound isolation of a masonry wall can be significantly improved by using furred-out gypsum wallboard and insulation in cavities. Chillers and other equipment with very high noise levels are best situated in rooms with concrete masonry unit walls.

Wall Design

Often, because of structural issues and mass limitations, mechanical equipment room walls are built from gypsum wallboard on metal or wood studs. To adequately attenuate low-frequency noise, sufficient mass and thickness must be provided in the wall partition construction. This typically entails using multiple layers of gypsum wallboard on both sides of the wall with batt insulation in the cavities. Where greater levels of noise reduction are required, walls are built on double, staggered-stud construction using two separate rows of studs on separate tracks with multiple layers of gypsum wallboard and batt insulation in the cavities (see Table 40).

Doors

Doors into mechanical equipment rooms are frequently the weak link in the enclosure. Where noise control is important, the doors should be as heavy as possible, gasketed around the perimeter, have no grilles or other openings, and be self-closing. If they lead to sensitive spaces, two doors separated by a 1 to 3 m corridor may be necessary.

Penetrations

For all types of walls, service penetrations should be fully caulked and sealed. Pipes, ducts, and conduits that penetrate walls, ceilings, or floors of mechanical rooms should be acoustically treated. Typically, a 13 mm gap around the penetrating element is filled with an appropriate material such as mineral fiber insulation. The penetration is then sealed airtight with resilient caulk (Figure 35).

Ducts passing through the mechanical equipment room enclosure pose an additional problem. Sound can be transmitted to either side of the wall through duct walls. Airborne sound in the mechanical room can be transmitted into the duct (break-in) and enter an adjacent space by reradiating (breakout) from duct walls, even if the duct contains no grilles, registers, diffusers, or other openings.

Sound levels in ducts close to fans are usually high. Sound can come not only from the fan but also from pulsating duct walls, excessive air turbulence, and air buffeting caused by tight or restricted fan airflow entrance or exit configurations. Duct layout for good aerodynamics and airflow conditions should minimize low-frequency sound generation, which, once generated, is difficult or impossible to remove, especially near noise-sensitive areas. Avoid elements conducive to increased breakout noise transmission and/or with a tendency to vibrate at low frequencies because of nonlaminar airflow. Round ductwork is most resistant to these problems, followed by square and rectangular ducts with aspect ratios less than 2:1. Heavier-than-normal gage metal ductwork, such as 16 ga (1.6 mm thickness) within the mechanical room and over noise-sensitive spaces, can also be used.

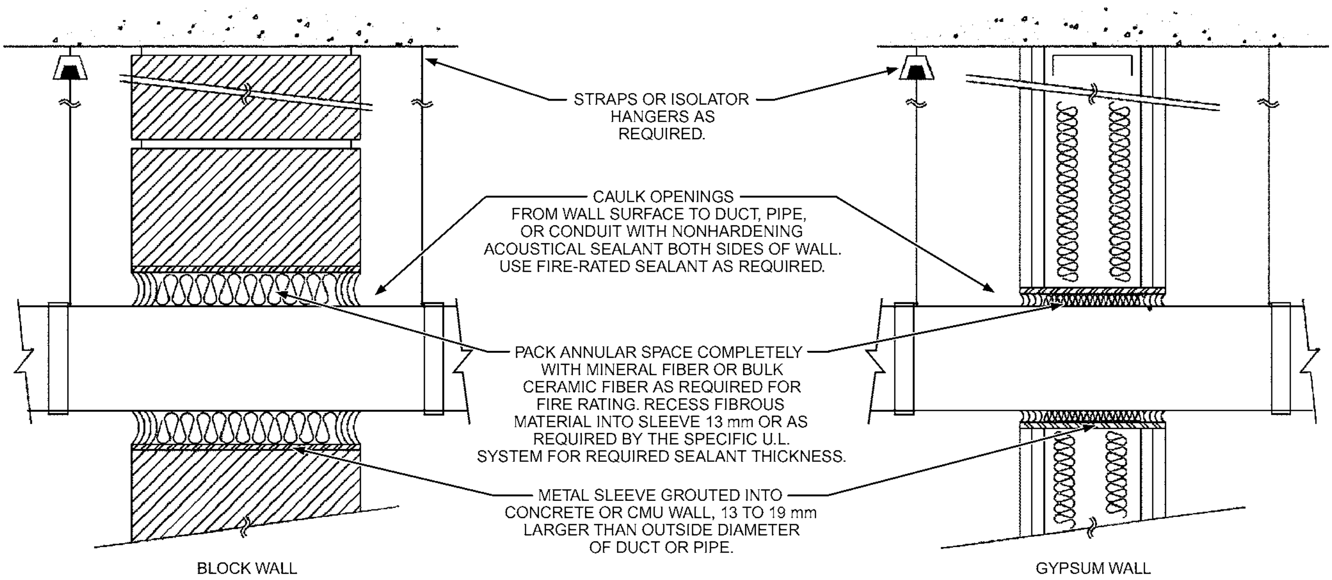

Fig. 35 Duct, Conduit, and Pipe Penetration Details

Table 40 Sound Transmission Class (STC) and Transmission Loss Values of Typical Mechanical Equipment Room Wall, Floor, and Ceiling Types, dB

Room Construction Type	STC	Octave Midband Frequency, Hz 63	125	250	500	1000	2000	4000

150 mm solid concrete floor/ceiling	53	40	40	40	49	58	67	76
150 mm solid concrete floor with 100 mm isolated concrete slab and fiberglass insulation in cavity	72	44	52	58	73	87	97	100
150 mm solid concrete floor with two layers of 16 mm GWB hung on spring isolators with fiberglass insulation in cavity	84	53	63	70	84	93	104	105

Note: Actual material composition (e.g., density, porosity, stiffness) affects transmission loss and STC values.
*CMU = concrete masonry unit; GWB = gypsum wallboard.

Mechanical Chases

Mechanical chases and shafts should be acoustically treated the same way as mechanical equipment rooms, especially if they contain noise-producing ductwork, pipes, and equipment such as fans and pumps. The shaft should be closed at the mechanical equipment room, and shaft wall construction must provide sufficient reduction of mechanical noise from the shaft to noise-sensitive areas to obtain acceptable noise levels. Chases should not be allowed to become "speaking tubes" between spaces requiring different acoustical environments. Crosstalk through the shaft must be prevented. Pipes, ducts, conduits, or equipment should be vibration isolated so that mechanical and structureborne noise is not transmitted to the shaft walls and into the building structure.

When mechanical equipment rooms are used as supply or return plenums, all openings into the equipment room plenum space may require noise control treatment, especially if any sound-critical space is immediately adjacent. This is particularly true if the space above an acoustical tile ceiling just outside the equipment room is used as a return air plenum. Most acoustical tile ceilings are almost acoustically transparent at low frequencies.

Often, supply ducts are run inside a chase that is also used for return air. It is best to attenuate supply and return paths at the fan rather than let duct breakout noise require additional noise control at the chase return air inlets. Take care to prevent turbulent noise generation in the supply duct through proper supply duct design.

Special Construction Types

Sound transmission loss values for some typical constructions are given in Table 40. These data are compiled from controlled laboratory tests and represent a condition typically superior to that found in field installations, because the in situ acoustical performance of any wall, floor, or ceiling is adversely affected by flanking paths, holes, penetrations, and other anomalies. Flanking paths include intersections of the wall, floor, or ceiling surface with another wall, floor, or ceiling that is structurally connected. Higher levels of sound isolation can be achieved by decoupling the surfaces and using double-walled, floating floor, or barrier-ceiling constructions.

Floating Floors and Barrier Ceilings

Correctly installed floating floors and barrier ceilings can provide very high levels of sound isolation, allowing mechanical equipment rooms to be placed adjacent to noise-sensitive spaces. Like double-walled construction, these configurations decouple two surfaces by providing separate supporting structures. However, these types of construction can add significant cost and coordination complexity and should be carefully evaluated.

In a floating floor, the upper floor slab is typically a 100 mm concrete slab resting on spring, neoprene, and/or fiberglass vibration isolators supported by the subfloor (typically another concrete slab of appropriate thickness). An air gap is maintained between the two slabs and resilient materials are used around the upper slab's perimeter to decouple it from surrounding walls. Air gap and upper slab thickness both affect noise isolation performance and should be considered. Any heavy equipment should be properly supported to account for additional loading and possible short circuiting.

Because natural frequencies for floating floor systems are limited by the dynamic response of the air trapped between the floating and structural slabs, these types of systems are not recommended to control structureborne vibration. It is extremely difficult on a floating floor to achieve a natural frequency of less than 15 Hz. While this is low enough to have a significant impact on audible frequencies, it is not low enough to control the vibrations generated by common equipment types.

Mounting equipment directly to a floating floor can reduce flanking paths and result in some acoustic benefits. However, ensure that adequate damping is provided in the floating floor and that there are no common natural frequencies present between the floating floor isolation system and any equipment isolation mounted to it. Improper selection can increase the transmitted vibration rather than reduce it.

Similarly, barrier ceilings are typically composed of multiple layers of gypsum wallboard attached to a frame suspended from the structure above with vibration-isolating hangers. A sound barrier ceiling's construction is influenced by its purpose. If the ceiling isolates two vertically adjacent spaces, mechanical equipment should be placed below the ceiling to ensure a continuous drywall barrier. If noise levels in the occupied space below the sound barrier ceiling are critical, mechanical equipment should be placed above with minimal ceiling penetrations that are properly sealed. Regardless, ductwork, piping, and other equipment require careful coordination of hangers and supports to ensure no rigid contact with the ceiling. Ceiling penetrations should be minimized, because these reduce barrier ceiling performance. In the case of recessed lighting, it is often necessary to use a gypsum wallboard enclosure around the entire fixture so that it does not serve as a flanking path for noise.

Design and selection of the floating floor or ceiling should be carefully considered to properly support the dead and live loads it must carry. *The floating system (floor or ceiling) is not meant as a means of equipment vibration isolation and serves primarily to con-*

trol airborne sound transmission. Acoustical performance of the floating system depends greatly on construction quality, which requires careful coordination between all trades. All penetrations and intersections with other surfaces must allow the floor or ceiling to float without any rigid connections. This typically entails maintaining clearances of at least 6 mm and filling all gaps with resilient materials such as nonhardening caulk.

Sound Transmission in Return Air Systems

The fan return air system provides a sound path (through ducts or a ceiling plenum) between a fan and occupied rooms. Where there is a direct opening to the mechanical equipment room from the ceiling plenum, sound levels in adjacent spaces can be high, originating from the fan and other sources in the mechanical equipment room. Low system attenuation between the mechanical equipment room and adjacent spaces exacerbates the problem.

Fan intake sound power levels control sound in ducted return air systems; sound power levels of the fan intake and casing-radiated noise components affect plenum return air systems. In some installations, sound from other equipment located in the mechanical equipment room may also radiate through the wall opening and into adjacent spaces. Good design yields room return air system sound levels that are approximately 5 dB below the corresponding room supply air system sound levels.

When sound levels in spaces adjacent to mechanical equipment rooms are too high, noise control measures must be provided. The controlling sound paths between the mechanical equipment room and adjacent spaces must be identified. Ducted return air systems can be modified using methods applicable to ducted supply systems. Ceiling plenum return systems should only be used for spaces that are remote from mechanical equipment rooms.

Ceiling plenum systems may require additional modifications. Prefabricated silencers can be effective when installed at the mechanical equipment room wall opening or at the suction side of the fan. Improvements in ceiling transmission loss are often limited by typical ceiling penetrations and lighting fixtures. Modifications to the mechanical equipment room wall can be effective for some constructions. Adding acoustical absorption in the mechanical equipment room reduces build-up of reverberant sound energy in this space; however, this typically reduces high-frequency noise by a maximum of 4 dB and low-frequency noise only slightly in areas near the return opening.

Sound Transmission Through Ceilings

When terminal units, fan-coil units, air-handling units, ducts, or return air openings to mechanical equipment rooms are located in a ceiling plenum above a room, sound transmission through the ceiling system can be high enough to cause excessive noise levels in that room. There is no standard test procedure for measuring direct transmission of sound through ceilings from sources close to the ceiling. As a result, ceiling product manufacturers rarely publish data that can be used in calculations. The problem is complicated by the presence of light fixtures, diffusers, grilles, and speakers that reduce the ceiling's transmission loss. Experiments have shown that, for ceiling panels supported in a T-bar grid system, leakage between the panels and grid is the major transmission path; differences among panel types are small, and light fixtures, diffusers, etc., have only a localized effect.

To estimate room sound pressure levels associated with sound transmission through the ceiling, sound power levels in the ceiling plenum must be adjusted to account for the transmission loss of the ceiling system and plenum. Measured data must also be adjusted to account for sound absorption in the room. The procedures given here are based on ASHRAE research (Warnock 1998):

1. Obtain octave band radiated sound power levels of device.

Table 41 Environmental Correction to Be Subtracted from Device Sound Power

Octave Band Frequency, Hz						
63	125	250	500	1000	2000	4000
4	2	1	0	0	0	0

Table 42 Compensation Factors for Source Area Effect

Area range, m^2			
63 Hz	125 Hz	250 Hz	Adjustment, dB
<0.24	<0.20		–3
0.26 to 0.46	0.22 to 0.43	<0.21	–2
0.47 to 0.67	0.46 to 0.66	0.25 to 0.56	–1
0.69 to 0.87	0.68 to 0.88	0.62 to 0.96	0
0.90 to 1.09	0.91 to 1.12	0.99 to 1.33	1
1.11 to 1.30	1.13 to 1.34	1.37 to 1.70	2
1.32 to 1.52	1.36 to 1.56	1.74 to 2.07	3
1.53 to 1.72	1.59 to 1.79		4
1.75 to 1.93	1.81 to 2.02		5
1.95 to 2.15			6

Note: Find correct area in each frequency column and read adjustment from last column on right.

2. Subtract environmental correction from Table 41.
3. Calculate surface area of bottom panel of source closest to ceiling tiles (m^2).
4. From Table 42, find adjustment to be subtracted from sound power values at three frequencies given there.
5. Select ceiling/plenum attenuation from Table 43 according to ceiling type in use. Note that these values include a typical room effect, so when using these data in analysis, there is no additional line item from Equation (20) or (30).
6. Subtract the three sets of values, taking account of sign where necessary, from sound power values. The result is the average sound pressure level in the room.
7. The sound field in the room may be assumed as uniform up to distances of 5 m from the source.

Example 7. A terminal unit with an area of 1.3 m^2 and a known sound power level is to be used above a standard 16 mm thick mineral fiber ceiling system in a T-bar grid. What room sound pressure levels can be expected?

Solution:

Step	Octave Band Frequency, Hz						
	63	125	250	500	1000	2000	4000
1 Sound power	71	71	65	55	54	53	45
2 Environmental (Table 41)	–4	–2	–1	0	0	0	0
4 Area adjustment (Table 42)	–2	–2	–1	0	0	0	0
5 Ceiling/plenum (Table 43)	–13	–15	–17	–19	–25	–30	–33
6 Room sound pressure levels, dB	52	52	46	36	29	23	12

2.9 HVAC NOISE-REDUCTION DESIGN PROCEDURES

These HVAC system design procedures address the 63 to 4000 Hz octave band midfrequency range. Although it is desirable to extend this frequency range down into the 31.5 Hz octave band, acoustical calculations below the 125 Hz octave band are generally not reliable. With a few exceptions, if acoustical design criteria are met at 4000 Hz, then the 8000 Hz requirements are also met. Guidelines in this chapter and other guides maximize the probability of meeting acoustical design criteria in the 31.5 to 8000 Hz octave bands.

There is reasonable probability that the acoustical design criteria will be met when the following requirements are satisfied:

Table 43 Ceiling/Plenum/Room Attenuations in dB for Generic Ceiling in T-Bar Suspension Systems

Tile Type	Approximate Density, kg/m²	Tile Thickness, mm	Octave Midband Frequency, Hz						
			63	125	250	500	1000	2000	4000
Mineral fiber	4.9	16	13	16	18	20	26	31	36
	2.4	16	13	15	17	19	25	30	33

- Systems are designed in accordance with the equipment selection, placement, and integration guidelines in this chapter, other ASHRAE guides, and manufacturers' application notes and bulletins.
- Acoustical calculations based on the information included in this chapter and the information provided by the equipment manufacturer indicate that the system will not exceed the selected acoustical design criteria values in the 63 to 4000 Hz octave band frequency range.

The following suggested design procedure uses the Noise Criteria (NC) method, which is the most commonly used. Other criteria, such as NCB or RC, may be used. (See the Criteria Descriptions section of this chapter or Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals* for detailed explanations of these methods.) However, it is often difficult to acquire low-frequency sound data, and low-frequency acoustical calculations for HVAC system components are not reliable.

1. Determine the design goal for HVAC system noise for each critical area according to its use and construction. Choose the desirable NC criterion from Table 1.
2. Select equipment and fittings (e.g., air inlet and outlet grilles, registers, diffusers, and air terminal and fan-coil units that radiate sound directly into a room) that are operating comfortably with their specified duty and are quiet for the class of equipment in question. The appropriate selection of equipment and fitting will generally result in an efficient acoustic design to meet design goals.
3. Complete initial design and layout of the HVAC system. Include typical duct lining where appropriate. Provide space for duct sound attenuators. Confirm that the airflow velocities are compliant with the specified rates in Tables 8 and 9 of the Aerodynamically Generated Sound in Ducts section of this chapter.
4. Calculate sound pressure level in the room of interest:

   (a) Acquire sound power data from manufacturers for equipment such as air-handling units, packaged rooftop units, exhaust fans, variable-air-volume terminal units, fan-powered terminal units, etc. If manufacturers' data are not available, estimate sound power level based on methods in this chapter or other authoritative sources.

   (b) Calculate sound attenuation and regenerated sound power of duct elements in the air distribution system of interest.

   (c) Tabulate sound power and attenuation for each component in each sound transmission path. Start at the supply air fan or packaged air-conditioning unit and end at the room. Investigate both the supply and return air paths in similar ways. Investigate possible duct sound breakout when fans are adjacent to, or roof-mounted fans are above, the room of interest. Combine sound power levels from all paths. See Example 8 for calculation procedures for supply and return air paths, including duct breakout noise contributions. Include a placeholder for the duct sound attenuator so that it is a simple matter to include in calculations later.

   (d) Convert sound power levels to corresponding sound pressure levels in the room using the ASHRAE room correction procedure. (See the Receiver Room Sound Correction section of this chapter.)

5. If the mechanical equipment room is adjacent to the room of interest, determine sound pressure levels in the room of interest that are associated with sound transmitted through the mechanical equipment room wall. Air-handling units, ventilation and exhaust fans, chillers, pumps, electrical transformers, and instrument air compressors are typical equipment to consider. Make sure that noise transmission from adjacent external spaces outside the room in question, such as cooling towers or air-cooled chillers, is also considered. Also consider the vibration isolation requirements for equipment, piping, and ductwork. (See Egan [1988] or Reynolds and Bledsoe [1991] for calculation procedure.)
6. Combine on an energy basis the sound pressure levels in the room of interest that are associated with all sound paths between the mechanical equipment room or roof-mounted unit(s) and the room of interest. Establish the controlling noise-transmission paths.
7. Determine the corresponding NC level associated with the calculated total sound pressure levels in the room of interest. Take special note of unbalanced sound spectra and tonal characteristics.
8. If the NC level satisfies the criteria established in step 1, analysis is complete. If the NC level exceeds the design goal, determine the octave frequency bands in which the corresponding sound pressure levels are exceeded and the sound paths associated with these octave frequency bands as determined in step 6. If the resulting noise levels are high enough to cause perceivable vibration, consider both airborne and structureborne noise.
9. Redesign the system:

   (a) Reselect the offending noise source. This is typically the least costly, most energy-efficient, and most effective change, but is not always possible.

   (b) Add sound attenuation to paths that contribute to excessive sound pressure levels in the room of interest. This may be achieved by using thicker internal acoustic-grade insulation or proprietary silencers. Note that silencers preferably should be inserted at the penetration of the mechanical equipment room (MER) walls or external building elements to minimize breakout before the silencer.

   (c) Consider increasing the length of ductwork or introducing bends or a plenum to increase the sound attenuation. Care needs to be taken to ensure that the breakout noise path(s) are still acceptable where additional ductwork is introduced.

   (d) Increase the sound transmission loss properties of building elements where this is the controlling noise path. This may be achieved by installing additional mass (e.g., thicker walls or filled concrete masonry units [CMUs]) or by introducing an air gap with a secondary layer (e.g., double glazing).

(e) Consider installing noise barriers around the external plant to minimize the direct line of sight between plant and critical spaces. The manufacturers' requirements for access and airflow around equipment must be carefully considered where noise barriers are used.

(f) If resultant noise levels are high enough to cause perceivable vibration, then major redesign and possibly use of supplemental vibration isolation for equipment and building systems are often required.

(g) Reference should also be made to this chapter's sections on Acoustical Design of HVAC Systems and Basic Acoustical Design Techniques.

10. Repeat steps 4 to 9 until the desired design goal is achieved. Involve the complete design team where major problems are found. Often, simple design changes to building architectural and equipment selection can eliminate potential problems once the problems are identified. Ensure that all valid noise-transmission paths are assessed.
11. Repeat steps 3 through 10 for every room that is to be analyzed.
12. Make sure that environmental noise radiated by outdoor equipment such as air-cooled chillers, exhaust fans, condensers, and cooling towers does not disturb adjacent properties or interfere with criteria established in step 1 or any applicable building or zoning noise ordinances.

Example 8. This example shows step 4 in the design process. Previous examples demonstrate how to calculate equipment- and air distribution system airflow-generated sound power levels and attenuation values. Here, the individual elements are combined to determine sound pressure levels associated with a specific HVAC system. Only a summary of tabulated results is listed rather than showing complete calculations for each element. Calculations for each element are strictly based on the methods in this chapter or manufacturers' data. Noise transmission via the roof structure has not been considered in this example.

Air is supplied to the HVAC system by the rooftop unit shown in Figure 36, with a supply and return layout as in Figure 37. The receiver room is directly below the unit. The room has the following dimensions: length = 6.1 m, width = 6.1 m, and height = 2.75 m. Assume that the roof penetrations for supply and return air ducts are well sealed and there are no other roof penetrations. In this example, it is assumed that breakout noise (upstream of the supply air silencer) is negligible. The supply side of the rooftop unit is ducted to a VAV terminal control unit serving the room in question. Although these units can create both ductborne and radiated noise, only the ductborne noise has been considered in this example. A return air grille conducts air to a common ceiling return air plenum. The return air is then directed to the rooftop unit through a short rectangular return air duct.

The following three sound paths are to be examined. Note that in this example, neither noise transmission via the roof structure nor any other breakout noise upstream of the silencer has been considered. Those paths, plus VAV unit-radiated noise and other potential breakout noise paths, have been excluded from the analysis for simplification. In critical applications, each of those separate elements must also be considered.

Path 1. Fan airborne supply air sound that enters the room from the supply air system through the ceiling diffuser

Calculation Procedure

Analysis for each path begins at the rooftop unit and proceeds through the different system elements to the receiver room. The element numbers in the tables correspond to those in Figure 37. The source of each element calculation is listed in Table 44. Sound data for the rooftop unit (supply and return openings), VAV terminal, diffuser, and duct sound attenuator are manufacturers' data.

A spreadsheet was used to perform the calculations associated with this example. This type of calculation is often performed iteratively, as described in the preceding design procedure, but using a well-crafted spreadsheet (e.g., the one supplied as an extra feature in the ASHRAE Handbook Online version of this chapter) increases the speed and accuracy of calculations.

Calculation tables for paths 1, 2, and 3 are organized with an element in each row. Three spectra (63 Hz to 4000 Hz) are shown for each element. The first and second spectra (sound power attenuation and regenerated sound power) are either calculated based on the equations and tables in this chapter or acquired from a manufacturer. It is important to note that sound power data and not sound pressure data must be used in these calculations.

The spreadsheet subtracts the sound attenuation spectrum, band by band, from the path sound power spectrum in the previous row. Then, the resultant sound power is logarithmically added per band to the element sound power. This calculation is performed for each element (row).

$$L_w = 10 \log\left(10^{L_{w1}/10} + 10^{L_{w2}/10}\right) \tag{33}$$

The last element in each path is either the ASHRAE room sound correction or the ceiling/plenum/room attenuations outlined in Table 43, which is entered as an attenuation spectrum as it is subtracted directly from the final path sound power spectrum.

3. VIBRATION ISOLATION AND CONTROL

Mechanical vibration and vibration-induced noise are common sources of occupant complaints in modern buildings. Low-mass construction in buildings provides conditions that can result in

vibration-related problems. Mandates for energy conservation have resulted in many buildings being designed with variable air volume systems with variable-speed equipment. As rotating equipment spins slower, its forcing frequency approaches the structure's resonant frequency, which can amplify vibration-induced noise and generate vibration at the structure's resonant frequency. Mechanical equipment is often located in penthouses or on the roof, where structures are typically the most susceptible to inducing vibration-related problems. Mechanical equipment rooms are typically located on intermediate level floors, close to the occupied areas they serve.

Occupant complaints associated with building vibration typically take one or more of three forms:

- The level of vibration perceived by building occupants is of sufficient magnitude to cause annoyance, concern, or alarm
- Vibration energy from mechanical equipment, which is transmitted to the building structure, is transmitted to various parts of the building and then is radiated as structureborne noise
- Vibration in a building may interfere with proper operation of sensitive equipment or instrumentation

The following sections present basic information to properly select and specify vibration isolators and to analyze and correct field vibration problems.

3.1 VIBRATION MEASUREMENT

Understanding the vibratory characteristics of HVAC equipment can be of great use in diagnosing the sources of both tonal and broadband sound or vibration. The advent of low-cost vibration measurement systems has made detailed vibration evaluation much more practical and commonplace. At the same time, it is important

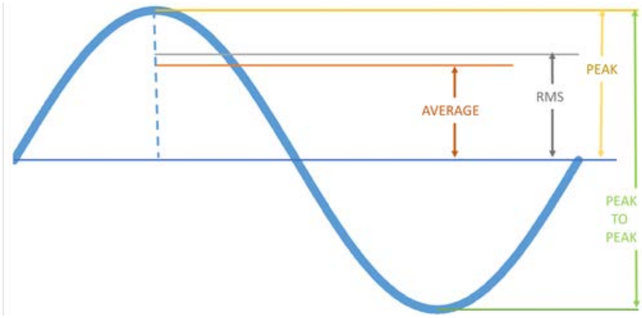

Fig. 39 Vibration Amplitude Terminology

to bear in mind that vibration measurement is a specialty that is best done by, or at least overseen by, a specialist.

Components of a vibration measurement system include the following:

- A **transducer**, which outputs an electrical signal proportional to its vibration level. The most common transducer, called an **accelerometer**, measures vibratory acceleration at its point of attachment to the structure. As explained in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*, accelerometers are the preferred transducers in most situations. They are compact, relatively rugged, capable of a wide measurement range in terms of both vibration level and frequency, and are easy to install (depending on the frequency range of interest).
- A **preamplifier** for the transducer, which amplifies the signal to a level suitable to the data acquisition system and for the signal conditioner. Depending on the transducer and analyzer type, a preamplifier may not needed.
- An **analyzer**, or **vibration meter**, with a display showing the vibration level. The most basic analyzers measure the overall vibration amplitude across a specified frequency range, which does not by itself yield enough analytical detail for troubleshooting. Many are capable of measuring vibration as a function of frequency, with constant frequency spacing. These so-called "narrowband," or fast Fourier transform (FFT), analyzers display the vibration frequency spectrum with a very high degree of resolution. Alternative analyzers of the constant-percentage bandwidth type display the vibration spectrum across a number of frequency bands, the widths of which increase proportionally to the center frequency of each band. These often display vibration at octave, 1/3rd octave, or 1/12th octave frequencies.

Any steady-state vibration, such as that generated by a machine operating at a fixed speed, can be expressed as acceleration, velocity, or displacement. By integrating the acceleration signal, it is possible to convert each of these quantities to the others. Integrating the velocity signal yields the displacement. Note that many transducers cannot measure vibration below a minimum frequency associated with the transducer. The practical implication of that limitation is that, in many cases, measured acceleration cannot be fully converted to displacement, and can never be used to quantify static displacement. For that reason, where very-low-frequency vibration measurements are required, specially designed displacement transducers are needed.

Vibration measurements must specify how the amplitudes are expressed. These can be either peak (maximum level), peak-to-peak (the range between minima and maxima), or rms (root mean square). For a sine wave, the peak-to-peak value is twice the peak, and the rms is the peak divided by the square root of two (Figure 39).

Several factors must be considered when making vibration measurements. One of these is transducer attachment to the vibrating object. An extremely rigid attachment method, such as dental cement, or a screwed connection with oil between the surfaces, is required for accurate measurement at very high frequency (about 5 kHz). Epoxies or other high-quality glues tend to be somewhat more limited but are acceptable in nearly all situations up to 1 kHz. Using magnetic attachments, though convenient and fully acceptable in many cases, limits the upper frequency range of accurate data (typically about 1 kHz). Another common but frequency-limited method of attachment is wax, typically reliable up to 80 Hz. In any case, it is essential to validate that the attachment used in a given application is capable of measuring vibration to the needed degree of accuracy. It is best to contact transducer/analyzer manufacturers to ensure frequency limits can be accurately measured.

Several data processing factors must be considered for narrowband (FFT) measurement. These significantly affect the quality of spectral data and how they are interpreted. Among them are the window type, number of averages, window overlap, frequency resolution, and sampling frequency. Again, guidance from a specialist should be sought when establishing these factors for a given measurement.

Typical applications of vibration measurement include

- Comparison of overall vibration levels (the total across a defined frequency range) with general guidelines representing typical levels to be expected from various classes of machinery. This most basic measurement is often used in connection with routine machinery maintenance or monitoring.
- Comparison of vibration spectral values with either equipment specifications, building specifications, or general guidelines. These more complete data, sometimes defined in terms of octave or 1/3 octave frequencies, provide more detailed guidance for machinery health monitoring, equipment qualification, or building certification.
- Comparison of vibration spectral values above and below vibration isolators, such as pads or springs, to determine if they are providing the anticipated vibration reduction. Note that, as explained in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*, interpretation of the results of these measurements may not be straightforward, especially for multiple-degree-of-freedom systems.
- Using a narrowband measurement system, determination of exact frequencies of tonal vibration sources. This information can be critical in identifying the specific machine or vibration component responsible for excessive vibration or noise. In some cases, a high degree of measurement resolution is required to separate closely spaced tones. For example, in 60 Hz applications, twice the motor or compressor running speeds are typically close to 118 Hz, while twice the electrical line frequency is 120 Hz. Clearly, while the difference between these frequencies is inaudible, knowing which source is responsible for a problem is essential to developing a solution.

Finally, it is noted that many specialized applications of vibration and dynamic measurement require advanced data acquisition equipment, data analysis software, and associated training. Examples are

- Transient vibration measurement
- Impact/frequency response measurement
- Modal testing
- Rotating equipment balancing
- Direct displacement measurement (e.g., rotating shaft orbit analysis)

3.2 EQUIPMENT VIBRATION

Any vibrating, reciprocating, or rotating equipment should be mounted such that it does not transmit significant levels of vibration into the surrounding or supporting structure. Vibrations transmitted via machine mounts or attached piping, ductwork, or electrical connections can result in vibrating walls, floors, and/or ceilings, which in turn radiate sound and/or vibration. Hence, it is important to provide vibration isolation for all attachments to a vibrating machine, including structural mounts and the connections to piping, ductwork, and the electrical system. It is also important to mitigate residual vibrations in attached piping and ductwork, even when equipment is properly isolated.

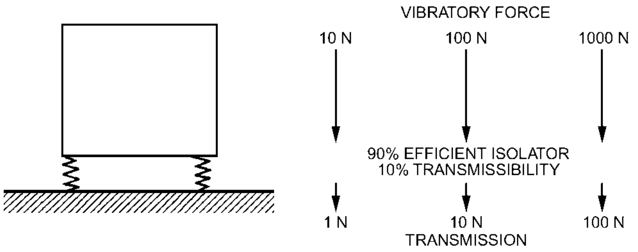

Fig. 40 Transmission to Structure Varies as Function of Magnitude of Vibration Force

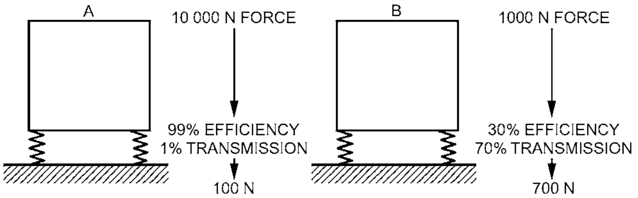

Fig. 41 Interrelationship of Equipment Vibration, Isolation Efficiency, and Transmission

Vibration can be isolated or reduced to a fraction of the original force with resilient mounts between the equipment and the supporting structure, provided that the supporting structure has sufficient stiffness and mass. Isolation transmissibility is the percentage of the vibratory force transmitted to the support. **Isolation efficiency** is the percentage of vibratory force *not* transmitted to the support structure. Figure 40 shows that 90% efficiency results in 10% of the vibration force being transmitted. In this case, the magnitude of transmission to the building is a function of the magnitude of the vibration force. Figure 41 shows the effect of different efficiency levels. See Equation (48) in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*, for a more detailed explanation of isolation transmissibility and efficiency.

Transmissibility and isolation efficiency are a function of the frequency of the transmitted (disturbing) force, and the natural frequency of the isolation system. The transmissibility is given by

$$T = \left| \frac{1}{1 - \left(\dfrac{f_d}{f_n} \right)^2} \right| \times 100\% \qquad (34)$$

where f_d is the frequency of the disturbing force and f_n is the natural frequency of the isolator. The efficiency is given by

$$E = 100\% - T \qquad (35)$$

where T is the transmissibility given by Equation (34).

3.3 VIBRATION CRITERIA

For the HVAC designer, vibration criteria are specified relative to three areas: (1) human response to vibration, (2) vibration levels associated with potential disruption to the use of sensitive equipment in a building, and (3) vibration severity of an operating machine.

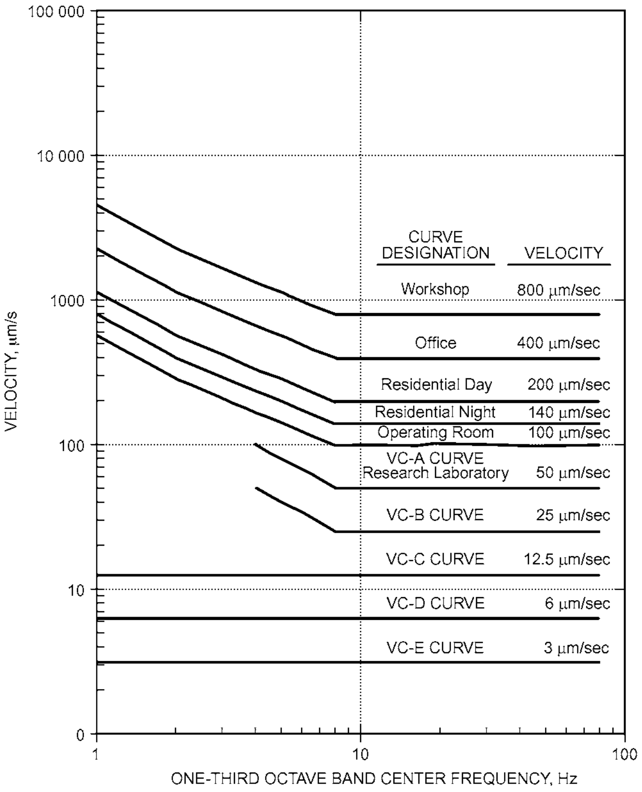

Fig. 42 Building Vibration Criteria for Vibration Measured on Building Structure

Figure 42 and Table 45 present recommended acceptable criteria for vibration in a building structure (IEST 2007; Murray et al. 1997). The vibration values in Figure 42 are measured in one-third octave bands using vibration transducers (usually accelerometers) placed on the building structure near vibrating equipment or in areas containing occupants or sensitive equipment. Occupant vibration criteria are based on guidelines recommended in ANSI *Standard* S2.71-1983 (R2006) and ISO *Standard* 2631-2. For sensitive equipment, acceptable vibration values specified by equipment manufacturers should be used. If none are available, then criteria from IEST (2007), as reflected in Figure 42 and Table 45, can be used.

If acceptable vibration values are not available from equipment manufacturers, the values specified in Figure 43 can be used. This figure gives recommended equipment vibration severity ratings based on measured rms velocity values (IRD 1988). The vibration values in Figure 43 are measured by vibration transducers (usually accelerometers) mounted directly on equipment, equipment structures, or bearing caps. Vibration levels measured on equipment and components can be affected by equipment unbalance, misalignment of equipment components, and resonance interaction between a vibrating piece of equipment and the floor on which it is placed. If a piece of equipment is aligned and balanced within acceptable tolerances and excessive vibration levels still exist, the equipment and installation should be checked for possible resonant conditions Table 46 gives maximum allowable rms velocity levels for selected pieces of equipment.

Vibration levels measured on equipment structures should be in or below the "good" region in Figure 43. Machine vibration levels in the "fair" or "slightly rough" regions may indicate potential problems requiring maintenance. Machines with vibration levels in these regions should be monitored to ensure problems do not arise. Machine vibration levels in the "rough" and "very rough" regions indicate a potentially serious problem; immediate action should be taken to identify and correct the problem.

Table 45 Human Comfort and Equipment Vibration Criteria (in rms velocity) from Continuous Vibration

Human Comfort[a]	Time of Day	8 to 80 Hz Curve,[a,b] mm/s rms
Workshops	All	0.813
Office areas	All[c]	0.406
Residential (good environmental standards)	0700-2200[c]	0.203
	2200-0700[c]	0.144
Hospital operating rooms and critical work areas	All	0.102
Equipment Requirements (For critical, highly sensitive situations, consult manufacturer's requirements)		**Curve[c]**
Adequate for computer equipment, probe test equipment, and microscopes less than 40×		0.203
Bench microscopes up to 100× magnification; laboratory robots		0.102
Bench microscopes up to 400× magnification; optical and other precision balances; coordinate measuring machines; metrology laboratories; optical comparators; microelectronics manufacturing equipment; proximity and projection aligners, etc.		0.051
Microsurgery, eye surgery, neurosurgery; bench microscopes at magnification greater than 400×; optical equipment on isolation tables; microelectronic manufacturing equipment, such as inspection and lithography equipment (including steppers) to 3 mm line widths[d]		0.025
Electron microscopes up to 30 000× magnification; microtomes; magnetic resonance imagers; microelectronics manufacturing equipment, such as lithography and inspection equipment to 1 mm detail size[d]		0.013
Electron microscopes at magnification greater than 30 000×; mass spectrometers; cell implant equipment; microelectronics manufacturing equipment, such as aligners, steppers, and other critical equipment for photolithography with line widths of 1/2 µm; includes electron beam systems[d]		0.0064
Unisolated laser and optical research systems; microelectronics manufacturing equipment, such as aligners, steppers, and other critical equipment for photolithography with line widths of 1/4 µm; includes electron beam systems[d]		0.0032

[a]Any acoustical noise caused by vibrating walls is not considered.
[b]See Figure 41 for corresponding curves.
[c]In areas where individuals are sensitive to vibration, use Residential Day curve.
[d]Classes of microelectronics manufacturing equipment.

Pumps	3.3
Centrifugal compressors	3.3
Fans (vent sets, centrifugal, axial)	2.3

3.4 SPECIFICATION OF VIBRATION ISOLATORS

Vibration isolators must be selected not only to provide required isolation efficiency but also to ensure that the natural frequency of the isolated system is not close to the natural frequency of the floor. If vibration isolators are not correctly selected, the isolator may actually amplify the force transmitted. Floor spans, equipment operating speeds, equipment power, damping, and other factors are considered in Table 47.

Note that floor spans in Table 47 are for general reference. In fact, isolators should be selected after establishing the slab's static

Base Types:
A. No base, isolators attached directly to equipment (Note 28)
B. Structural steel rails or base (Notes 29 and 30)
C. Concrete inertia base (Note 30)
D. Curb-mounted base (Note 31)

Isolator Types:
1. Pad, rubber, or glass fiber (Notes 20 and 21)
2. Rubber floor isolator or hanger (Notes 20 and 25)
3. Spring floor isolator or hanger (Notes 22, 23, and 26)
4. Restrained spring isolator (Notes 22 and 24)
5. Thrust restraint (Note 27)
6. Air spring (Note 25)

Notes for Table 47: Selection Guide for Vibration Isolation

These notes are keyed to the column titled *Reference Notes* in Table 47 and to other reference numbers throughout the table. Although the guide is conservative, cases may arise where vibration transmission to the building is still excessive. If the problem persists after all short circuits have been eliminated, it can almost always be corrected by altering the support path (e.g., from ceiling to floor), increasing isolator deflection, using low-frequency air springs, changing operating speed, improving rotating component balancing, or, as a last resort, changing floor frequency by stiffening or adding more mass. Assistance from a qualified vibration consultant can be very useful in resolving these problems.

Note 1. Isolator deflections shown are based on a reasonably expected floor stiffness according to floor span and class of equipment. Certain spaces may dictate higher levels of isolation. For example, bar joist roofs may require a static deflection of 38 mm over factories, but 64 mm over commercial office buildings.

Note 2. For large equipment capable of generating substantial vibratory forces and structureborne noise, increase isolator deflection, if necessary, so isolator stiffness is less than one-tenth the stiffness of the supporting structure, as defined by the deflection due to load at the equipment support.

Note 3. For noisy equipment adjoining or near noise-sensitive areas, see the section on Mechanical Equipment Room Sound Isolation.

Note 4. Certain designs cannot be installed directly on individual isolators (type A), and the equipment manufacturer or a vibration specialist should be consulted on the need for supplemental support (base type).

Note 5. Wind load conditions must be considered. Restraint can be achieved with restrained spring isolators (type 4), supplemental bracing, snubbers, or limit stops. Also see Chapter 56.

Note 6. Certain types of equipment require a curb-mounted base (type D). Airborne noise must be considered.

Note 7. See section on Resilient Pipe Hangers and Supports for hanger locations adjoining equipment and in equipment rooms.

Note 8. To avoid isolator resonance problems, select isolator deflection so that resonance frequency is 40% or less of the lowest normal operating speed of equipment (see Chapter 8 in the 2017 *ASHRAE Handbook—Fundamentals*). Some equipment, such as variable-frequency drives, and high-speed equipment, such as screw chillers and vaneaxial fans, contain very-high-frequency vibration. This equipment creates new technical challenges in the isolation of high-frequency noise and vibration from a building's structure. Structural resonances both internal and external to the isolators can significantly degrade their performance at high frequencies. Unfortunately, at present no test standard exists for measuring the high-frequency dynamic properties of isolators, and commercially available products are not tested to determine their effectiveness for high frequencies. To reduce the chance of high-frequency vibration transmission, add a minimum 20 mm thick elastomeric pad (type 1, Note 20) to the base plate of spring isolators (type 3, Note 22, 23, 24). For some sensitive locations, air springs (Note 25) may be required. If equipment is located near extremely noise-sensitive areas, follow the recommendations of an acoustical consultant.

Note 9. To limit undesirable movement, thrust restraints (type 5) are required for all ceiling-suspended and floor-mounted units operating at 500 Pa or more total static pressure.

Note 10. Pumps over 55 kW may need extra mass and restraints.

Note 11. See text for full discussion.

Isolation for Specific Equipment

Note 12. Refrigeration Machines: Large centrifugal, screw, and reciprocating refrigeration machines may generate very high noise levels; special attention is required when such equipment is installed in upper-story locations or near noise-sensitive areas. If equipment is located near extremely noise-sensitive areas, follow the recommendations of an acoustical consultant.

Note 13. Compressors: The two basic reciprocating compressors are (1) single- and double-cylinder vertical, horizontal or L-head, which are usually air compressors; and (2) Y, W, and multihead or multicylinder air and refrigeration compressors. Single- and double-cylinder compressors generate high vibratory forces requiring large inertia bases (type C) and are generally not suitable for upper-story locations. If this equipment must be installed in an upper-story location or at-grade location near noise-sensitive areas, the expected maximum unbalanced force data must be obtained from the equipment manufacturer and a vibration specialist consulted for design of the isolation system.

Note 14. Compressors: When using Y, W, and multihead and multicylinder compressors, obtain the magnitude of unbalanced forces from the equipment manufacturer so the need for an inertia base can be evaluated.

Note 15. Compressors: Base-mounted compressors through 4 kW and horizontal tank-type air compressors through 8 kW can be installed directly on spring isolators (type 3) with structural bases (type B) if required, and compressors 10 to 75 kW on spring isolators (type 3) with inertia bases (type C) with a mass 1 to 2 times the compressor mass.

Note 16. Pumps: Concrete inertia bases (type C) are preferred for all flexible-coupled pumps and are desirable for most close-coupled pumps, although steel bases (type B) can be used. Close-coupled

Notes for Table 47: Selection Guide for Vibration Isolation (*Continued*)

pumps should not be installed directly on individual isolators (type A) because the impeller usually overhangs the motor support base, causing the rear mounting to be in tension. The primary requirements for type C bases are strength and shape to accommodate base elbow supports. Mass is not usually a factor, except for pumps over 55 kW, where extra mass helps limit excess movement due to starting torque and forces. Concrete bases (type C) should be designed for a thickness of one-tenth the longest dimension with minimum thickness as follows: (1) for up to 20 kW, 150 mm; (2) for 30 to 55 kW, 200 mm; and (3) for 75 kW and up, 300 mm.

Pumps over 55 kW and multistage pumps may exhibit excessive motion at start-up ("heaving"); supplemental restraining devices can be installed if necessary. Pumps over 90 kW may generate high starting forces; consult a vibration specialist.

Note 17. Packaged Rooftop Air-Conditioning Equipment: This equipment is usually installed on low-mass structures that are susceptible to sound and vibration transmission problems. The noise problems are compounded further by curb-mounted equipment, which requires large roof openings for supply and return air.

The table shows type D vibration isolator selections for all spans up to 6 m, but extreme care must be taken for equipment located on spans of over 6 m, especially if construction is open web joists or thin, low-mass slabs. The recommended procedure is to determine the additional deflection caused by equipment in the roof. If additional roof deflection is 6 mm or less, the isolator should be selected for up to 10 times the additional roof deflection. If additional roof deflection is over 6 mm, supplemental roof stiffening should be installed to bring the roof deflection down below 6 mm, or the unit should be relocated to a stiffer roof position.

For mechanical units capable of generating high noise levels, mount the unit on a platform above the roof deck to provide an air gap (buffer zone) and locate the unit away from the associated roof penetration to allow acoustical treatment of ducts before they enter the building.

Some rooftop equipment has compressors, fans, and other equipment isolated internally. This isolation is not always reliable because of internal short-circuiting, inadequate static deflection, or panel resonances. It is recommended that rooftop equipment over 135 kg be isolated externally, as if internal isolation was not used.

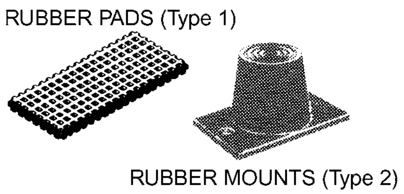
Note 18. Cooling Towers: These are normally isolated with restrained spring isolators (type 4) directly under the tower or tower dunnage. High-deflection isolators proposed for use directly under the motor-fan assembly must be used with extreme caution to ensure stability and safety under all weather conditions. See Note 5.

Note 19. Fans and Air-Handling Equipment: Consider the following in selecting isolation systems for fans and air-handling equipment:

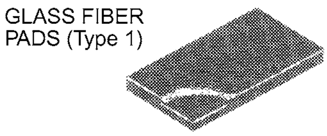
1. Fans with wheel diameters of 560 mm and less and all fans operating at speeds up to 300 rpm do not generate large vibratory forces. For fans operating under 300 rpm, select isolator deflection so the isolator natural frequency is 40% or less than the fan speed. For example, for a fan operating at 275 rpm, 0.4 × 275 = 110 rpm. Therefore, an isolator natural frequency of 110 rpm or lower is required. This can be accomplished with a 75 mm deflection isolator (type 3).
2. Flexible duct connectors should be installed at the intake and discharge of all fans and air-handling equipment to reduce vibration transmission to air duct structures.
3. Inertia bases (type C) are recommended for all class 2 and 3 fans and air-handling equipment because extra mass allows the use of stiffer springs, which limit heaving movements.
4. Thrust restraints (type 5) that incorporate the same deflection as isolators should be used for all fan heads, all suspended fans, and all base-mounted and suspended air-handling equipment operating at 500 Pa or more total static pressure. Restraint movement adjustment must be made under normal operational static pressures.

Vibration Isolators: Materials, Types, and Configurations

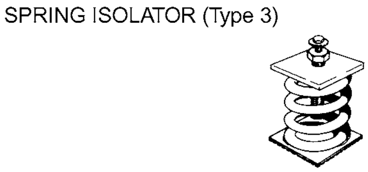
Notes 20 through 32 include figures to assist in evaluating commercially available isolators for HVAC equipment. The isolator selected for a particular application depends on the required deflection, life, cost, and compatibility with associated structures.



Note 20. Rubber isolators are available in pad (type 1) and molded (type 2) configurations. Pads are used in single or multiple layers. Molded isolators come in a range of 30 to 70 durometer (a measure of stiffness). Material in excess of 70 durometer is usually ineffective because durometers are not a measure of stiffness of an isolator. Isolators are designed for up to 13 mm deflection, but are used where 8 mm or less deflection is required. Solid rubber and composite fabric and rubber pads are also available. They provide high load capacities with small deflection and are used as noise barriers under columns and for pipe supports. These pad types work well only when they are properly loaded and the mass load is evenly distributed over the entire pad surface. Metal loading plates can be used for this purpose.



Note 21. Glass fiber with elastic coating (type 1). This type of isolation pad is precompressed molded fiberglass pads individually coated with a flexible, moisture-impervious elastomeric membrane. Natural frequency of fiberglass vibration isolators should be essentially constant for the operating load range of the supported equipment. Mass load is evenly distributed over the entire pad surface. Metal loading plates can be used for this purpose.



Note 22. Steel springs are the most popular and versatile isolators for HVAC applications because they are available for almost any deflection and have a virtually unlimited life. Spring isolators may have a rubber acoustical barrier to reduce transmission of high-frequency vibration and noise that can migrate down the steel spring coil. They should be corrosion protected if installed outdoors or in a corrosive environment. The basic types include the following:

Note 23. *Open spring isolators* (type 3) consist of top and bottom load plates with adjustment bolts for leveling equipment. Springs should be designed with a horizontal stiffness of at least 80% of the vertical stiffness (k_x/k_y) to ensure stability. Similarly, the springs should have a minimum ratio of 0.8 for the diameter divided by the deflected spring height.

Notes for Table 47: Vibration Isolators: Materials, Types, and Configurations (*Continued*)

RESTRAINED SPRING ISOLATOR (Type 4) 	**Note 24.** *Restrained spring isolators* (type 4) have hold-down bolts to limit vertical as well as horizontal movement. They are used with (a) equipment with large variations in mass (e.g., boilers, chillers, cooling towers) to restrict movement and prevent strain on piping when water is removed, (b) outdoor equipment, such as condensing units and cooling towers, to prevent excessive movement due to wind loads, and (c) with any equipment subject to seismic forces. Spring criteria should be the same as open spring isolators, and snubbers should have adequate clearance so that they are activated only when a temporary restraint is needed. See Chapter 56 for typical snubber types. *Closed mounts* or *housed spring isolators* consist of two telescoping housings separated by a resilient material. These provide lateral snubbing and some vertical damping of equipment movement, but do not limit the vertical movement. Additional vertical snubbers must be used where vertical travel must be limited (see Chapter 56). Care should be taken in selection and installation to minimize binding and short circuiting.
AIR SPRINGS (Type 6)  ROLLING LOBE BELLOWS	**Note 25.** Air springs (type 6) can be designed for any frequency, but are economical only in applications with natural frequencies of 1.33 Hz or less (150 mm or greater deflection). They do not transmit high-frequency noise and are often used to replace high-deflection springs on problem jobs (e.g., large transformers on upper-floor installations). A constant air supply (an air compressor with an air dryer) and leveling valves are typically required.
 RUBBER HANGER (Type 2) SPRING HANGER (Type 3) 	**Note 26.** Isolation hangers (types 2 and 3) are used for suspended pipe and equipment and have rubber, springs, or a combination of spring and rubber elements. Criteria should be similar to open spring isolators, though lateral stability is less important. Where support rod angular misalignment is a concern, use hangers that have sufficient clearance and/or incorporate rubber bushings to prevent the rod from touching the housing. Swivel or traveler arrangements may be necessary for connections to piping systems subject to large thermal movements. *Precompressed spring hangers* incorporate some means of precompression or preloading of the isolator spring to minimize movement of the isolated equipment or system. These are typically used on piping systems that can change mass substantially between installation and operation.
THRUST RESTRAINT (Type 5) 	**Note 27.** Thrust restraints (type 5) are similar to spring hangers or isolators and are installed in pairs to resist the thrust caused by air pressure. These are typically sized to limit lateral movement to 6.4 mm or less.
DIRECT ISOLATION (Type A)	**Note 28.** Direct isolation (type A) is used when equipment is unitary and rigid and does not require additional support. Direct isolation can be used with large chillers, some fans, packaged air-handling units, and air-cooled condensers. If there is any doubt that the equipment can be supported directly on isolators, use structural bases (type B) or inertia bases (type C), or consult the equipment manufacturer.
STRUCTURAL BASES (Type B) 	**Note 29.** Structural bases (type B) are used where equipment cannot be supported at individual locations and/or where some means is necessary to maintain alignment of component parts in equipment. These bases can be used with spring or rubber isolators (types 2 and 3) and should have enough rigidity to resist all starting and operating forces without supplemental hold-down devices. Bases are made in rectangular configurations using structural members with a depth equal to one-tenth the longest span between isolators. Typical base depth is between 100 and 300 mm, except where structural or alignment considerations dictate otherwise.
STRUCTURAL RAILS (Type B) 	**Note 30.** Structural rails (type B) are used to support equipment that does not require a unitary base or where the isolators are outside the equipment and the rails act as a cradle. Structural rails can be used with spring or rubber isolators and should be rigid enough to support the equipment without flexing. Usual practice is to use structural members with a depth one-tenth of the longest span between isolators, typically between 100 and 300 mm, except where structural considerations dictate otherwise.
CONCRETE BASES (Type C) 	**Note 31.** Concrete bases (type C) are used where the supported equipment requires a rigid support (e.g., flexible-coupled pumps) or excess heaving motion may occur with spring isolators. They consist of a steel pouring form usually with welded-in reinforcing bars, provision for equipment hold-down, and isolator brackets. Like structural bases, concrete bases should be sized to support piping elbow supports, rectangular or T-shaped, and for rigidity, have a depth equal to one-tenth the longest span between isolators. Base depth is typically between 150 and 300 mm unless additional depth is specifically required for mass, rigidity, or component alignment.
CURB ISOLATION (Type D) 	**Note 32.** Curb isolation systems (type D) are specifically designed for curb-supported rooftop equipment and have spring isolation with a watertight, and sometimes airtight, assembly. *Rooftop rails* consist of upper and lower frames separated by nonadjustable springs and rest on top of architectural roof curbs. *Isolation curbs* incorporate the roof curb into their design as well. Both kinds are designed with springs that have static deflections in the 25 to 75 mm range to meet the design criteria described in type 3. Flexible elastomeric seals are typically most effective for weatherproofing between the upper and lower frames. A continuous sponge gasket around the perimeter of the top frame is typically applied to further weatherproof the installation.

spanned slab's resonant frequency of the spanned slab, and using an isolator with a deflection 10 times greater than that of the slab. Mechanical equipment should not operate at frequencies near or below resonance.

Also note that each item has reference notes to detail isolator selection and installation. The extra spreadsheet in the ASHRAE Handbook Online version of this chapter gathers onto one page all the notes and graphics pertaining to each equipment type.

In specifying isolator deflection rather than isolation efficiency or transmissibility, a designer can compensate for floor stiffness and building resonances by selecting isolators that have more deflection than the supporting floor. Isolator deflection is related to the natural frequency of the isolators, and in turn, to the isolator efficiency. Vibration isolators are described in terms of maximum **static deflection**, which is the amount that a spring compresses under the weight of the equipment. If a spring is 50 mm long when unloaded and compresses to 25 mm when loaded, it has 25 mm of static deflection. Static deflection is directly related to vibration isolation efficiency: 25 mm static deflection equates to about 88% isolation of vibration energy, and 12 mm static deflection isolates roughly 50%. Static deflection is also related to the lowest frequency of vibration. Isolating very low frequencies (less than 20 Hz) requires very large static deflections of 100 mm or more. Beyond a certain point, springs can no longer do the job, in which case two-stage isolators or special air isolators are needed. The relationship between deflection and the natural frequency of the isolated system is given by Equation (36):

$$f_n = \frac{15.77}{\sqrt{d_{st}}} \tag{36}$$

where d_{st} is the static deflection in millimetres.

To apply the information from Table 47, base type, isolator type, and minimum deflection columns are added to the equipment schedule. These isolator specifications are then incorporated into mechanical specifications for the project.

Minimum deflections in the table are based on the experience of acoustical and mechanical consultants and vibration control manufacturers. Recommended isolator type, base type, and minimum static deflection are reasonable and safe recommendations for most HVAC equipment installations. The selections are based on concrete equipment room floors 100 to 300 mm thick with typical floor stiffness. The type of equipment, proximity to noise-sensitive areas, and type of building construction may alter these choices, especially in such cases as steel buildings with lightweight floors.

The following method develops isolator selection for specific applications:

1. Use Table 47 for floors specifically designed to accommodate mechanical equipment.
2. Use recommendations from the 6 m span column for equipment on ground-supported slabs adjacent to noise-sensitive areas.
3. For roofs and floors constructed with open web joists; thin, long span slabs; wooden construction; and any unusual light construction, evaluate all equipment with a mass of more than 140 kg to determine the additional deflection of the structure caused by the equipment. Isolator deflection should be up to 10 times the additional deflection or the deflection shown in Table 47, whichever is greater. If the required spring isolator deflection exceeds commercially available products, consider air springs or two-stage isolation, stiffen the supporting structure, or change the equipment location.
4. When mechanical equipment is adjacent to noise-sensitive areas, it is important to not only provide adequate vibration isolation but also to coordinate the construction of the surrounding floors, ceilings, and walls to isolate mechanical equipment room noise.

Selecting Vibration Isolators to Meet Isolator Deflection Requirements

An overview of the procedure to select vibration isolators is as follows:

1. Establish total mass of equipment to be supported. This includes all equipment and support framework. The mass of piping connected to equipment may also need to be considered, because this may be partly supported from the equipment.
2. Establish operating mass (e.g., mass of water in a chiller or cooling tower).
3. Determine the location of supporting springs.
4. Calculate the distribution of weight onto each of the supporting springs using static force distribution methods.
5. Consider any dynamic forces that may change the mass distribution over the supporting springs.
6. Select vibration isolators to achieve the minimum deflection based on the vibration-isolator spring constant as advised by the manufacturer.

Note that the preceding procedure does not satisfy seismic restraint requirements, which must be considered in vibration isolator selection to meet applicable codes and standards.

Where requested or for sensitive projects, the following calculations may be presented for review:

1. Dry and operating masses (including any thrust forces)
2. Operating masses at each of the support points, considering the operating condition of the equipment
3. Isolator at each of the support points, given the selected vibration isolator spring constant
4. Wind forces, if installed outdoors.

3.5 VIBRATION- AND NOISE-SENSITIVE FACILITIES

Vibration-sensitive facilities identified in the section on Vibration Criteria are likely to require detailed assessment. Table 47 reflects typical application of vibration isolators in buildings to satisfy human comfort requirements. A specialist should be engaged to design vibration isolators for facilities with sensitive noise and vibration requirements, such as concert halls or facilities with electron microscopes or other diagnostic imaging equipment. The specialist will select vibration isolators based on the proximity to sensitive areas, structural design of the facility, and type and operating duty of vibration sources. Vibration propagation through soil may also need to be considered for any facilities close to rail lines or other vibration-generating sources.

3.6 INTERNAL VERSUS EXTERNAL ISOLATION

Vibration isolators are most effective if the isolator base is attached directly to the building structure at a support point that is highly stiff compared to the isolator. In many cases, the vibrating equipment (e.g., internal components of air-handling units) can be effectively isolated with internal vibration isolators, where only the moving parts (e.g., fan/motor assembly) are supported by the isolators. This approach can reduce the load supported by the isolators and thus can reduce the cost of isolation. The other primary advantage of internal isolation is reduction of vibration and structure-borne noise into the air-handling unit housing. Disadvantages of internal isolation can include the following:

- The isolator is often not easily visible in the field to verify that it is functioning properly.
- The isolator support point may be near the middle of a beam, which often provides inadequate stiffness for optimum isolator performance.

- Short circuiting of housed isolators, caused by horizontal thrust of the fan, can occur.
- Commonly provided isolators are not selected based on building support structure or noise criteria, and may not provide sufficient vibration control.
- Internal isolation does nothing to reduce vibration in equipment casing and structure caused by air movement.

Typically, vibration isolation devices should be applied to either the internal components or the external casing, but not both.

It is possible to use both internal and external vibration isolation on the same air-handling unit, but isolator stiffness selection must avoid resonances at or near normal fan and motor rotational speeds. There are multiple resonance frequencies to consider: if the fan or motor operates at or near one of these frequencies, vibration levels could become excessive. The probability of such an interaction increases significantly if the fan and motor are driven by a variable-frequency drive. Implementing both internal and external vibration isolation on the same unit should only be attempted with the guidance of an experienced vibration consultant.

3.7 ISOLATING VIBRATION AND NOISE IN PIPING SYSTEMS

All piping systems have mechanical vibration generated by the equipment and impeller-generated and flow-induced vibration and noise, which is transmitted by the pipe wall and the water column. In addition, equipment supported by vibration isolators exhibits some motion from pressure thrusts during operation. Vibration isolators have even greater movement during start-up and shutdown as equipment vibration passes through the isolators' resonance frequency. The piping system must be flexible enough to (1) reduce vibration transmission along the connected piping, (2) allow equipment movement without reducing the performance of vibration isolators, and (3) accommodate equipment movement or thermal movement of the piping at connections without imposing undue strain on the connections and equipment.

Flow noise and vibration in piping can be reintroduced by turbulence, sharp pressure drops, and entrained air; however, this can be minimized by sizing pipe so that velocities are 1.2 m/s maximum for pipe 50 mm and smaller and using a pressure drop limitation of 400 Pa per m of pipe length, with a maximum velocity of 3 m/s for larger pipe sizes. Take care not to exceed these limits.

Resilient Pipe Hangers and Supports

Resilient pipe hangers and supports may be used to prevent vibration and noise transmission from the piping system to the building structure and to provide flexibility in the piping.

Suspended Piping. Isolation hangers described in Note 26 of Table 47 should be used for all piping in equipment rooms and up to 15 m from vibration-isolated equipment and pressure-regulating valve (PRV) stations. To avoid reducing the effectiveness of equipment isolators, at least the first three hangers from the equipment should provide the same deflection as the equipment isolators, with a maximum limitation of 50 mm deflection; the remaining hangers should be spring or combination spring and rubber with 20 mm deflection.

The first two hangers adjacent to the equipment should be the positioning or precompressed type, to prevent load transfer to equipment flanges when the piping system is filled. The positioning hanger aids in installing large pipe, and many engineers specify this type for all isolated pipe hangers for piping 200 mm and larger.

Piping over 50 mm in diameter that is suspended below or within 15 m of noise-sensitive areas should be hung with isolation hangers. Hangers adjacent to noise-sensitive areas should be the spring and rubber combination type 3.

Floor-Supported Piping. Floor supports for piping in equipment rooms and adjacent to isolated equipment should use vibration isolators as described in Table 47. They should be selected according to the guidelines for hangers. The first two adjacent floor supports should be the restrained spring type, with a blocking feature that prevents load transfer to equipment flanges as the piping is filled or drained. Where pipe is subjected to large thermal movement, a slide plate (PTFE, graphite, or steel) should be installed on top of the isolator, and a thermal barrier should be used when rubber products are installed directly beneath steam or hot-water lines. Temperatures above 60°C can affect rubber isolators.

Riser Supports, Anchors, and Guides. Many piping systems have anchors and guides, especially in the risers, to permit expansion joints, bends, or pipe loops to function properly. Anchors and guides are designed to eliminate or limit (guide) pipe movement and must be rigidly attached to the structure; this is inconsistent with the resiliency required for effective isolation. The engineer should try to locate the pipe shafts, anchors, and guides in noncritical areas, such as next to elevator shafts, stairwells, and toilets, rather than adjoining noise-sensitive areas. Where concern about vibration transmission exists, some type of vibration isolation support or acoustical support is required for pipe supports, anchors, and guides.

Because anchors or guides must be rigidly attached to the structure, the isolator cannot deflect in the sense previously discussed, and the primary interest is that of an acoustical barrier. Heavy-duty rubber pads that can accommodate large loads with minimal deflection can provide such an acoustical barrier. Figure 44 shows some arrangements for resilient anchors and guides. Similar resilient supports can be used for the pipe.

Resilient supports for pipe, anchors, and guides can attenuate noise transmission, but they do not provide the resiliency required to isolate vibration. Vibration must be controlled in an anchor guide system by designing flexible pipe connectors and resilient isolation hangers or supports.

Completely spring-isolated riser systems that eliminate the anchors and guides have been used successfully in many instances and give effective vibration and acoustical isolation. In this type of isolation system, the springs are sized to accommodate thermal growth as well as to guide and support the pipe. These systems provide predictable load transfer because of thermal expansion and contraction, but require careful engineering to accommodate movements encountered not only in the riser but also in the branch takeoff to avoid overstressing the piping.

Piping Penetrations. HVAC systems typically have piping that must penetrate floors, walls, and ceilings. If these penetrations are not properly treated, they provide a path for airborne noise, which can destroy the acoustical integrity of the occupied space. Seal openings in pipe sleeves between noisy areas, such as equipment rooms, and occupied spaces with an acoustical barrier such as fibrous material and resilient acoustical caulking, or with engineered pipe penetration seals as shown in Figure 45.

Flexible Pipe Connectors. Flexible pipe connectors (1) provide piping flexibility to allow isolators to function properly, (2) protect equipment from strain caused by misalignment and expansion or contraction of piping, and (3) attenuate noise and vibration transmission along the piping (Figure 46). Connectors are available in two configurations: (1) hose type, a straight or slightly corrugated wall construction of either rubber or metal; and (2) arched or expansion-joint type, a short-length connector with one or more large-radius arches, of rubber, PTFE, or metal. Metal expansion joints are acoustically ineffective and are seldom successfully used for vibration and sound isolation in HVAC systems; they should not be expected to substitute for conventional pipe vibration isolators.

To accommodate pressure thrust, flexible connectors require an end restraint, which is either (1) added to the connector, (2) incor-

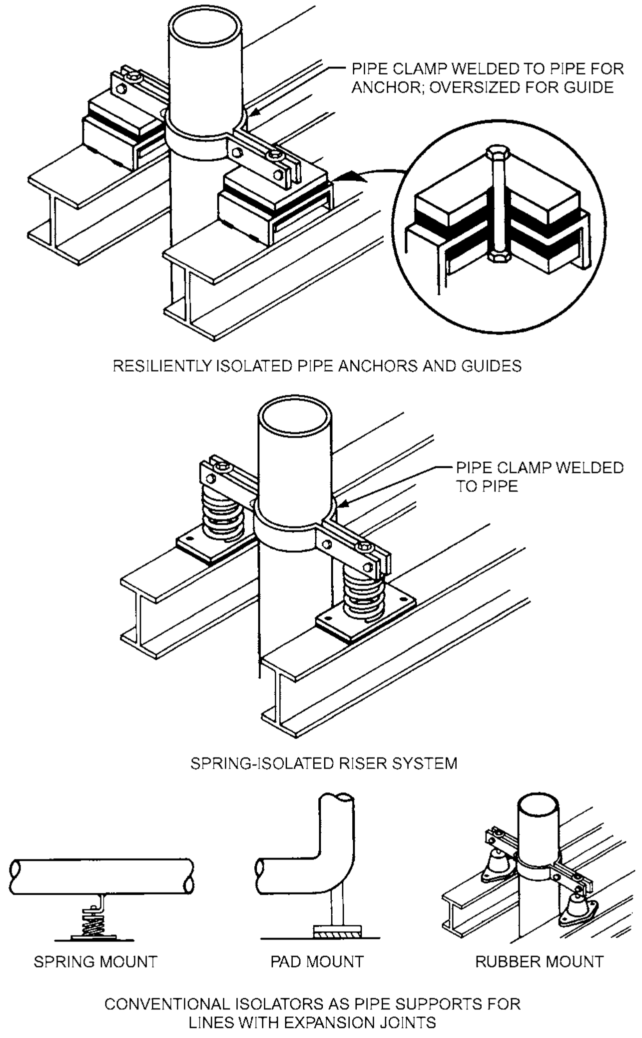


Fig. 44 Resilient Anchors and Guides for Pipes

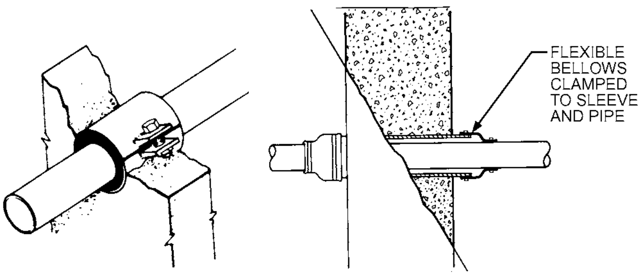

Fig. 45 Acoustical Pipe Penetration Seals

porated by its design, (3) added to the piping system (anchoring), or (4) built in by the stiffness of the system. Connector extension caused by pressure thrust on isolated equipment should also be considered when flexible connectors are used. Overextension causes failure. Manufacturers' recommendations on restraint, pressure, and temperature limitations must be strictly observed. Sometimes these restraint systems almost eliminate the effects of the flexible connector.

Hose Connectors. Hose connectors accommodate lateral movement perpendicular to length and have very limited or no axial movement capability. Rubber hose connectors can have

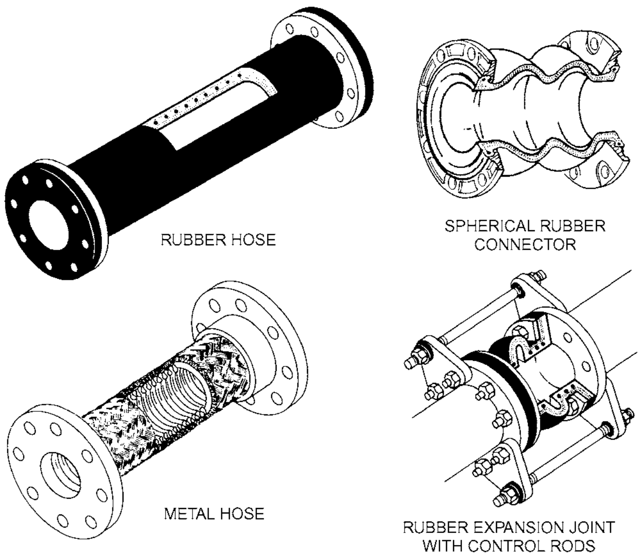

Fig. 46 Flexible Pipe Connectors

Table 48 Recommended Live Lengths[a] of Flexible Rubber and Metal Hose

Nominal Diameter, mm	Length,[b] mm	Nominal Diameter, mm	Length,[b] mm
20	300	100	450
25	300	125	600
40	300	150	600
50	300	200	600
65	300	250	600
80	450	300	900

[a]Live length is end-to-end length for integral flanged rubber hose and is end-to-end less total fitting length for all other types.
[b]Per recommendations of Rubber Expansion Division, Fluid Sealing Association.

molded or hand-wrapped construction with wire reinforcing, and are available with metal-threaded end fittings or integral rubber flanges. Application of threaded fittings should be limited to 75 mm and smaller pipe diameter. The fittings should be the mechanically expanded type to minimize the possibility of pressure thrust blowout. Flanged types are available in larger pipe sizes. Table 48 lists recommended lengths.

Metal hose is constructed with a corrugated inner core and a braided cover, which helps attain a pressure rating and provides end restraints that eliminate the need for supplemental control assemblies. Short lengths of metal hose or corrugated metal bellows, or pump connectors, are available without braid and have built-in control assemblies. Metal hose is used to control misalignment and vibration rather than noise and is used primarily where temperature or pressure of flow media precludes the use of other material. Table 48 provides recommended lengths.

Expansion Joint or Arched Connectors. Expansion joint or arched connectors have one or more convolutions or arches and can accommodate all modes of axial, lateral, and angular movement and misalignment. When made of rubber, they are commonly called expansion joints, spool joints, or spherical connectors; in PTFE, they are known as couplings or expansion joints.

Rubber expansion or spool joints are available in two basic types: (1) hand-wrapped with wire and fabric reinforcing, and (2) molded with fabric and wire or with high-strength fabric only (instead of metal) for reinforcing. The handmade type is available in a variety of materials and lengths for special applications. Rubber spherical connectors are molded with high-strength fabric or tire cord reinforcing instead of metal. Their distinguishing characteristic is a large-radius arch. The shape and construction of some designs allow use without control assemblies in systems operating to 1 MPa, and are the most effective for minimizing vibration transmission. Where thrust restraints are not built in, they must be used as described for rubber hose joints.

PTFE expansion joints and couplings are similar in construction to rubber expansion joints with reinforcing metal rings.

In evaluating these devices, consider temperature, pressure, and service conditions as well as each device's ability to attenuate vibration and noise. Metal hose connections can accommodate misalignment and attenuate mechanical vibration transmitted through the pipe wall, but do little to attenuate noise. This type of connector has superior resistance to long-term temperature effects. Rubber hose, expansion joints, and spherical connectors attenuate vibration and impeller-generated noise transmitted through the pipe wall. Be-cause rubber expansion joint and spherical connector walls are flexible, they can grow volumetrically and attenuate noise and vibration at blade-pass frequencies. This is a particularly desirable feature in uninsulated piping systems, such as for condenser or domestic water, which may run adjacent to noise-sensitive areas. However, high pressure has a detrimental effect on the ability of the connector to attenuate vibration and noise.

Because none of the flexible pipe connectors control flow or velocity noise or completely isolate vibration and noise transmission to the piping system, resilient pipe hangers and supports should be used; these are shown in Note 26 for Table 47 and are described in the Resilient Pipe Hangers and Supports section.

Isolating Duct Vibration

Flexible canvas and rubber duct connections should be used at fan intake and discharge. However, they are not completely effective because they become rigid under pressure, allowing the vibrating fan to pull on the duct wall. To maintain a slack position of the flexible duct connections, thrust restraints (see Note 27, Table 47) should be used on all equipment as indicated in Table 47.

Although vibration transmission from ducts isolated by flexible connectors is not common, flow pulsations within the duct can cause mechanical vibration in the duct walls, which can be transmitted through rigid hangers. Spring or combination spring and rubber hangers are recommended wherever ducts are suspended below or near a noise-sensitive area.

3.8 SEISMIC PROTECTION

Seismic restraint requirements are specified by applicable building codes that define design forces to be resisted by the mechanical system, depending on building location and occupancy, location of the system in the building, and whether it is used for life safety. Where required, seismic protection of resiliently mounted equipment poses a unique problem, because resiliently mounted systems are much more susceptible to earthquake damage from overturning forces, the impact limits of bare restraints, and resonances inherent in vibration isolators.

A deficiency in seismic restraint design or anchorage may not become apparent until an earthquake occurs, with possible catastrophic consequences. Adequacy of the restraint system and anchorage to resist code design forces must be verified before the event, by either equipment tests, calculations, or dynamic analysis, depending on the item, with calculations or dynamic analysis performed under the direction of a professional engineer. These analysis items may be supplied as a package by the vibration isolation vendor.

Restraints for floor-mounted equipment should be designed with adequate clearances so that they are not engaged during normal operation of the equipment. Contact surfaces (snubbers) should be protected with resilient pad material to limit shock during an earthquake, and restraints should be strong enough to resist the forces in any direction. The integrity of these devices can be verified by a comprehensive analysis, but is more frequently verified by laboratory tests.

Calculations or dynamic analyses should have an engineer's seal to verify that input forces are obtained in accordance with code or specification requirements. Additionally, a professional engineer should make the anchorage calculations in accordance with accepted standards. For more information, see Chapter 56.

3.9 VIBRATION INVESTIGATIONS

Theoretically, a vibration isolation system can be designed to mitigate even the most extreme sources of mechanical vibration. However, isolators should not be used to mask a condition that should be corrected before it damages the equipment and its operation. High vibration levels can indicate a faulty equipment operating condition in need of correction, or they can be a symptom of a resonance interaction between a vibrating piece of equipment and the structure(s) on which it is supported or to which it is attached.

Vibration investigations can include

- Measurement of vibration levels on vibrating equipment (see Figure 43 for recommended vibration criteria)
- Measurement of vibration levels in building structures to which vibrating equipment is connected, such as a building floor, piping systems, etc. (see Figure 42 and Table 45 for recommended building vibration criteria)
- Examination of equipment vibration generated by system components, such as bearings, drives, pumps, etc.
- Measurement of the natural frequencies (resonances) of vibrating equipment or connected structure(s)
- Examination of equipment installation factors, such as equipment alignment, vibration isolator placement, etc. (see Table 47)
- Measurement of the unbalance of reciprocating or rotating equipment components

4. COMMISSIONING

In the initial design and final commissioning phases of an HVAC system, sound criteria are needed to determine the degree of noise impact and the amount of noise and vibration reduction required for acceptable background sound and vibration levels based on occupancy usage. This chapter is intended primarily to assist with the design phase and provide limited assistance with diagnosing problems. Detailed diagnosis of problems may require the assistance of a vibration consultant or an engineer experienced in HVAC system noise and vibration analysis. Consult the section on Testing for Sound and Vibration in Chapter 39 for the commissioning phase.

5. TROUBLESHOOTING

Despite all precautions, situations may arise where there is disturbing noise and vibration. Problems can be identified and corrected by

- Determining which equipment or system is the source of the problem
- Determining whether the problem is one of airborne sound, structureborne noise, or vibration
- Applying appropriate solutions

Troubleshooting can be time consuming, expensive, and difficult, and use of an experienced acoustical consultant is often warranted. Proper diagnosis of the problem is most critical to allow for developing the right solution. Once a noise or vibration transmission problem exists, occupants become more sensitive and require greater reduction of the sound and vibration levels than would initially have been satisfactory. The need for troubleshooting should be minimized by properly designing, installing, and testing the system as soon as it is operational and before the building is occupied.

5.1 DETERMINING PROBLEM SOURCE

A simple, accurate method of determining the problem source is to turn individual pieces of equipment on and off until the vibration or noise is eliminated. Because the source of the problem is often more than one piece of equipment or the interaction of two or more systems, it is always good practice to double check by shutting off the system and operating the equipment individually. Reynolds and Bevirt (1994) and Schaffer (2005) provide practical information on the measurement and assessment of sound and vibration in buildings.

5.2 DETERMINING PROBLEM TYPE

Once the source is identified, the next step is to determine whether the problem is one of noise or vibration. Clearly perceptible vibration is often a clue that vibration transmission is the major cause of the problem. The possibility that low-mass wall or ceiling panels are excited by airborne noise should be considered. However, even if the vibration is not readily perceptible, the problem may still be one of vibration transmission causing structureborne noise. This can be checked using the following procedure:

- If a sound level meter is available, some readings should be taken. If the difference between C-weighted and overall (unweighted or linear) readings is greater than 6 dB, or if the slope of the acoustic spectrum is steeper than 6 dB per octave at low frequencies (below 63 Hz), vibration is likely a contributing factor.
- If excessive noise is found close to the equipment and/or main ductwork, airborne noise is probably the main contributor.
- If the affected area is remote from source equipment, there is no problem in intermediary spaces, and noise does not appear to be coming from the duct system or diffusers, structureborne noise is probably the cause.

One important step in diagnosing many noise or vibration problems, particularly if the affected area is close to the mechanical equipment room, is to check the equipment's vibration isolation system. A simple test is to have one person listen in the affected area while another shouts loudly in the equipment room. If the voice cannot be heard, the problem is likely one of structureborne noise. If the voice can be heard, check for openings in the wall or floor separating the areas. If no such openings exist, the structure separating the areas does not provide adequate transmission loss. In these situations, see the section on Mechanical Equipment Room Sound Isolation for possible solutions.

Noise Problems

If ductborne sound (i.e., noise from grilles or diffusers or duct breakout noise) appears to be the problem, measure the sound pressure levels and compare them with the design criteria (NC, RC, etc.). It is often helpful to obtain sound data with and without terminal devices installed. Comparison of the two results shows how much noise a given terminal device contributes. If this reveals the responsible components, the engineer can analyze each sound source using the procedures presented in this chapter to determine whether sufficient attenuation has been provided.

If the sound source is a fan, pump, or similar rotating equipment, an important question is whether it is operating near the most efficient part of its operating curve, where most equipment operates best and generates predictable levels of sound and vibration as published by equipment manufacturers and used in the building design. Excessive vibration and noise can occur if a fan or pump is trying to move too little or too much air or water. Check that vanes, dampers, and valves are in the correct operating position and that the system has been properly balanced.

Vibration Problems

Vibration and structureborne noise problems can be caused by

- Equipment improperly specified or installed, poorly balanced, misaligned, or operating outside of design conditions
- Equipment with inadequate or improper vibration isolation
- Flanking transmission paths such as rigid pipe or duct connections, obstructions under the base of vibration-isolated equipment, improperly installed equipment seismic restraints shorting vibration isolation, or shipping blocks not removed after the equipment has been installed and in operation
- Excessive floor flexibility indicative of improper structural support conditions for equipment or inadequate or improper vibration isolation
- Resonances in equipment, vibration isolation system, building structure, or connected structures (e.g., piping)

Most field-encountered problems result from improperly selected or installed isolators and flanking paths of transmission, which can be simply evaluated and corrected. If the equipment lacks vibration isolators, in many cases it is possible to add isolators (see Table 47) without altering connected ducts or piping by using structural brackets. Floor flexibility and resonance problems are sometimes encountered and usually require analysis by experts. However, the procedures in the following sections can help identify such problems.

Testing Vibration Isolation Systems. Improperly functioning vibration isolation systems are the cause of most field-encountered problems and can be evaluated and corrected by the following procedures:

1. Ensure that the system is free floating by bouncing the base, which should cause the equipment to move up and down freely and easily. Note that this may not be practical on very heavy equipment. On floor-mounted equipment, check that there are no obstructions between the base and the floor that would short circuit the isolation system. This is best accomplished by passing a rod under the equipment. A small obstruction might allow the base to rock, giving the impression that it is free floating when it is not. On suspended equipment, make sure that rods are not touching the hanger box. Rigid connections such as pipes and ducts can prevent equipment from floating freely, prohibit isolators from functioning properly, and provide flanking paths for vibration transmission.
2. Determine whether isolator static deflection is as specified or required, changing it if necessary, as recommended in Table 47. A common problem is inadequate deflection caused by underloaded isolators. Overloaded isolators are not generally a problem as long as the system is free-floating and there is space between the spring coils.

With most commonly used spring isolators, static deflection can be determined by measuring the operating height and comparing it to free-height information available from the manufacturer. Once the actual isolator deflection is known, determine its adequacy by comparing it with the recommended deflection in Table 47.

If a transmission problem exists, it may be caused by (1) excessively rough equipment operation, (2) the system not being free floating or flanking path transmission, or (3) a resonance or floor stiffness problem.

It is easy to determine the natural frequency of spring isolators from the static deflection determined by spring height measurements, but these measurements are difficult with pad and elastomeric isolators and are often not accurate in determining their natural frequencies. Although such isolators can theoretically provide natural frequencies as low as 4 Hz, they typically provide higher natural frequencies and generally do not provide the desired isolation efficiencies for upper floor equipment locations. Therefore, it is recommended to avoid using elastomeric mounts in general for (1) equipment on elevated floors, (2) major equipment, (3) critical applications, and (4) equipment on variable-speed operation; in all such cases, spring isolation should be considered and properly specified.

In general, it is very difficult to determine whether vibration isolation efficiencies intended in design have been achieved in field installations using field vibration measurements. However, vibration measurements can readily be made on vibrating equipment, equipment supports, floors supporting vibration-isolated equipment, and floors in adjacent areas to determine whether vibration criteria specified in Table 45 or in Figure 42 have been achieved.

Floor Flexibility Problems. Floor flexibility problems can occur with heavy equipment installed on long-span floors or thin slabs and with rooftop equipment installed on light structures of open web joist construction. If floor flexibility is suspected, the isolators should be one-tenth or less as stiff as the floor to eliminate the problem. Floor stiffness can be determined by calculating the additional floor deflection caused by a specific piece of equipment.

For example, if a 5000 kg piece of equipment causes floor deflection of an additional 2.5 mm, floor stiffness is 19.6 MN/m, and an isolator combined stiffness of 1.96 MN/m or less must be used. Note that floor stiffness or spring rate, not total floor deflection, is determined. In this example, the total floor deflection might be 25 mm, but if the problem equipment causes 2.5 mm of that deflection, 2.5 mm is the factor that identifies floor stiffness of 19.6 MN/m.

As a general guideline, limiting the additional floor deflection (not total deflection) caused by equipment mass to 7.5 mm is advisable, even when the equipment is provided with proper vibration isolation. This may need to be further reduced for vibration in acoustically critical adjacencies.

Resonance Problems. These problems occur when the equipment's operating speed is the same as or close to the resonance frequency of (1) an equipment component such as a fan shaft or bearing support pedestal, (2) the vibration isolation system, or (3) the resonance frequency of the floor or other building component, such as a wall. Vibration resonances can cause excessive equipment vibration levels, as well as objectionable and possibly destructive vibration transmission in a building. These conditions must always be identified and corrected. Note that, if building structures have resonant frequencies, it is important to isolate equipment to avoid energizing those frequencies in the structure. Structural changes can also reduce susceptibility to other excitation sources (e.g., walking, rhythmic activity).

When vibrating mechanical equipment is mounted on vibration isolators on a flexible floor, there are two resonance frequencies that must be considered: that of the floor and that of the isolated equipment. The lower frequency should be controlled by the stiffness (and consequently the static deflection) of the vibration isolators. This frequency should be significantly less than the normal operating speed (or frequency) of the mechanical equipment and is generally not a problem. The higher resonance frequency is associated with and primarily controlled by the stiffness of the supporting structure. This resonance frequency is usually not affected by increasing or decreasing the static deflection of the mechanical equipment vibration isolators.

Sometimes, when the floor under mechanical equipment is flexible (as occurs with some long-span floor systems and with roof systems supporting rooftop packaged units), the operating speed of the mechanical equipment can coincide with the floor resonance frequency. When this occurs, changing the static deflection of the vibration isolators may not solve the problem. Alternatives include changing the rotating speed of the equipment, stiffening the structure, or adjusting a variable-frequency drive to avoid the resonant frequency. Also, adding mass such as a housekeeping pad in concrete under the isolator could be a possible solution.

Vibration Isolation System Resonance. Always characterized by excessive equipment vibration, vibration isolation system rigid-body resonance (characterized by the mass of the equipment vibrating on the stiffness of the isolators) usually results in objectionable transmission to the building structure. However, transmission might not occur if the equipment is on grade or on a stiff floor. Vibration isolation system rigid-body resonances can be measured with instrumentation or, more simply, by determining the isolator's natural frequency (as described in the section on Testing Vibration Isolation Systems) and comparing this figure to the operating speed of the equipment.

When a vibration isolation system resonance problem exists, the system natural frequency must be changed using the following guidelines:

- If equipment is installed on excessively stiff pad or rubber elastomeric mounts, isolators with the deflection recommended in Table 47 should be installed.
- If equipment is installed on spring isolators and there is objectionable vibration or noise transmission to the structure, determine whether the isolator is providing the designed static deflection. For example, an improperly selected or installed nominal 50 mm deflection isolator could be experiencing only 3 mm deflection under its static load, which would be in resonance with equipment operating at 500 rpm. If this is the case, the isolators should be replaced with ones having enough capacity to provide the requisite 50 mm deflection. However, if there is no transmission problem with the isolators, it is not necessary to use greater-deflection isolators than can be conveniently installed.
- If equipment is installed on spring isolators and there is objectionable noise or vibration transmission, replace the isolators with springs of the deflection recommended in Table 47.
- If equipment is installed on spring isolators of the recommended stiffness and there is objectionable high-frequency (200 Hz or greater) noise or vibration, it is possible that resonances internal to the spring are the culprit. These resonances, sometimes called **surge frequencies**, can be important in applications where equipment (e.g., screw compressors, inverters) generates high-frequency noise. To control their adverse effects, many isolator designs incorporate an elastomeric pad under the spring. It may also be possible to identify an elastomeric mount that can provide the desired static deflection; these typically have better high-frequency characteristics than springs.

Building Resonances. These problems occur when some part of the building structure has a resonance frequency coincident with the disturbing frequency (often the operating speed) of some of the equipment. These problems can exist even if the isolator deflections recommended in Table 47 are used. The resulting objectionable noise or vibration should be evaluated and corrected. Often, the resonance problem is associated with the floor on which the equipment is installed, but it can also occur in a remotely located floor, wall, or other building component. If a noise or vibration problem has a remote source that cannot be associated with piping or ducts, building resonance must be suspected.

Building resonance problems can be resolved by the following:

- Reduce the vibration force by balancing the equipment. This is not a practical solution for a true resonance problem. However, it is effective when the disturbing frequency is close to the floor's natural frequency, as evidenced by the equal displacement of the floor and the equipment, especially when the equipment is operating with excessive vibration.

- Change the disturbing frequency by changing the equipment operating speed. This is practical only for belt-driven equipment, or equipment driven by variable-frequency drives.
- Modify the structure to shift the structural response. Although this requires upsizing the structure and can be costly, if feasible it is often the most effective means of resolving vibration issues.

CHAPTER 50

WATER TREATMENT: DEPOSITION, CORROSION, AND BIOLOGICAL CONTROL

WATER QUALITY AND ITS SOURCES 50.1
Water Characteristics 50.1
Water Sources 50.2
WATER TREATMENT 50.4
Control 50.4
Corrosion and Corrosion Control 50.7
Biological Growth Control 50.12
Nonchemical and Physical Water Treatment Methods 50.15
Water Systems 50.16
TERMINOLOGY 50.23

THIS chapter covers the fundamentals of water treatment and conditioning. It provides guidance on the treatment of water and water-based fluids used in heating, air-conditioning, refrigeration, and process systems, with a focus on the control of corrosion, scale, fouling, and biological growth. Proper treatment improves the performance and energy efficiency of these systems while helping to protect human health and safety. Water treatment extends the life of equipment in both open- and closed-loop systems. Water treatment can help conserve water resources as well as enable the use of alternative sources of water. All of these benefits help to promote a healthier, more sustainable environment.

1. WATER QUALITY AND ITS SOURCES

1.1 WATER CHARACTERISTICS

Water has unique properties that make it ideal for heating, cooling, and steam generating processes. Water is the only common substance that exists in all three states of matter (solid [ice], liquid [water], and gas [steam]) at normal earth temperatures. Water absorbs more heat for a given temperature rise than any other common inorganic substance. Water expands 1600 times as it evaporates to form water vapor and steam at atmospheric pressure. Steam can carry large quantities of heat. Such qualities position water as the ideal material for heating, cooling, and power generating processes.

Water supplies contain varying amounts of impurities that can lead to scale formation, corrosion, and other problems in industrial equipment. Starting with rain, water accumulates impurities from its surroundings, dissolving minerals and picking up various substances from the air, soil, vegetation, and other materials. For this reason, water is often referred to as the **universal solvent**. Falling rain dissolves carbon dioxide and oxygen from the atmosphere. As carbon dioxide breaks up in water, it forms carbonic acid (H_2CO_3). When carbonic acid makes contact with soil or rock strata containing limestone ($CaCO_3$), it slowly dissolves the calcium to form highly soluble calcium bicarbonate. This process occurs in soil or rock strata where temperatures are relatively cool (less than 21°C). Unfortunately, bicarbonate does not remain stable as water warms, and the limestone dissolution can be quickly reversed to reform calcium carbonate when hard water is heated. Calcium carbonate that reforms in water used in heating or air-conditioning applications can eventually become scale, which can increase energy costs, maintenance time, and equipment shutdowns, and can eventually lead to the need for equipment replacement.

Water's composition can change as it is transported in pipelines, heated to make steam, or evaporated for cooling or other heat exchange processes. Impurities in water may reach a solubility limit and be deposited along the way, or the impurities in water may act to corrode the metal equipment containing it. The actions of water in HVAC systems depend on the types of impurities and the temperatures and pressures to which it is subjected, among other factors.

The following definitions present the most relevant terms chemical and physical terms, properties or characteristics of water relevant to water treatment and that affect its use in HVAC and other applications.

Parts per million (ppm) is a dimensionless ratio, used in water treatment to express concentration (e.g., one gram in a million grams, one mL per L). Dissolved minerals and impurities commonly found in water are present at very low concentration (e.g., milligrams in a full glass of water). The most convenient ratio to express concentration is then milligrams per million milligrams, or milligrams per litre (L), of water (the mass of a litre of water is almost equivalent to 1,000,000 milligrams). In water treatment, ppm concentration is almost always expressed in mg/L.

Hardness refers to the amount of calcium and magnesium (typically expressed in ppm as $CaCO_3$) in the water. It is a historical term referring to the potential for formation of hard calcium and magnesium carbonate scales, such as those found in improperly treated boilers and cooling-water systems. Harder water contributes to scale formation because heating encourages deposition of calcium carbonate, or lime scale. Solubility of most calcium and magnesium salts decreases with an increase in temperature, so these salts tend to form scale on heat transfer surfaces where the metal skin temperature is greater than the bulk water temperature. Boiler and cooling-water treatment programs are designed to control deposition of hardness salts through pretreatment removal of hardness (e.g., water softening by ion exchange) or internal chemical additive conditioning to solubilize, remove, or otherwise control deposition.

Alkalinity is a measure of the capacity of water to neutralize strong acids and bases, defined in a specific water testing procedure. This procedure uses a measurable amount of a dilute acid solution of known concentration to change the color of two specific indicators, phenolphthalein and methyl orange. Alkalinity is the measured carbonate and bicarbonate minerals (calculated as calcium carbonate [$CaCO_3$]), and refers to the primary alkaline earth minerals. Alkalinity also includes hydroxide ion (OH^-), when present. All natural waters contain some alkalinity. The presence of alkalinity contributes to scale formation, because it can contribute carbonate ions, driving formation of calcium carbonate. In natural waters, alkalinity almost always consists of bicarbonate, although some carbonate alkalinity may also be present. Borate, hydroxide, phosphate, and other constituents, if present, are included in the alkalinity measurement in treated waters.

Alkalinity is measured using two different end-point indicators. The **phenolphthalein alkalinity (P alkalinity)** measures the strong alkali present, including carbonate and hydroxide, and the **methyl orange alkalinity (M alkalinity)**, or **total alkalinity**, measures the total alkalinity in the water. Note that total alkalinity includes the phenolphthalein alkalinity. For most natural waters, the actual

The preparation of this chapter is assigned to TC 3.6, Water Treatment.

Table 1 Alkalinity Relationship Based on P and M Tests

Situation	Hydroxyl	Level of Alkalinity Contributed by Carbonate	Bicarbonate
P = M	M	0	0
P > 1/2M	2P – M	2 (M – P)	0
P = 1/2M	0	M	0
P < 1/2M	0	2P	M – 2P
P = 0	0	0	M

P = P alkalinity = phenolphthalein alkalinity
M = M alkalinity = methyl orange (total) alkalinity

chemical species present can be estimated after performing two specific alkalinity tests. Treated waters may also include the hydroxide alkalinity contributed by OH^- (Table 1).

pH is a measure of the concentration of hydrogen ions (the acid strength) of a solution. Mathematically, it is defined as the negative logarithm of the hydrogen ion concentration (pH of 1 is very acidic; pH of 14 is very basic; a pH of 7 is neutral at ambient temperature.) The pH concept is fundamental to an understanding of water chemistry and to control of pretreatment systems, boilers, and cooling towers. All water systems depend on either pH control or maintaining pH above a specified minimum level. Unexpected changes in pH (~1.0 to 1.5 pH increase or decrease) are usually a warning of problems that must be corrected.

Chlorides are the total of dissolved chloride components of salts such as sodium chloride, potassium chloride, calcium chloride, magnesium chloride, etc. Sodium chloride and calcium chloride ($CaCl_2$) are the most common chloride salts found in water. Chlorides do not ordinarily contribute to scale, because they are very soluble. However, chlorides are corrosive and can be excessively so when present in high concentration, as in seawater, because of their ability to react with and weaken the natural protective oxide films present on most metals. Determining the concentration of chlorides in water is a useful measuring tool in evaporative systems for determining cycles of concentration. Most water constituents change in concentration when common treatment chemicals are added or due to chemical changes that take place in normal operation. Chlorides are not affected by such changes, so, with few exceptions, only evaporation affects chloride concentration. Therefore, the ratio of chlorides in a water sample from an operating system to those of the makeup water provides a measure of how much the water has been concentrated. (*Note:* Chloride levels will change if the system is treated with chemicals releasing chloride.)

Conductivity, or **specific conductance,** measures the ability of water to conduct electrical current and act as an electrolyte. Conductivity increases with an increase in total dissolved solids (ions) present in the water. Specific conductance can be used to estimate total dissolved solids.

Dissolved solids consist of salts, including water hardness, and other materials that combine with water as a solution. They can affect the formation of corrosion and scale. Total dissolved solids are referred to as **TDS**. Dissolved solids content is most commonly determined instrumentally based on the electrical conductivity of water or the weight of residue after water is totally evaporated.

Suspended solids include both organic and inorganic solids suspended in water (particularly unpurified water from surface sources or those that have been circulating in open equipment). Organic matter in surface supplies may be colloidal (homogeneously suspended). Naturally occurring compounds such as lignin and tannins are often colloidal. At high velocities, hard suspended particles can abrade equipment. Settled suspended matter of all types can contribute to corrosion, as it fosters corrosive microbiology. Total suspended solids are referred to as TSS and should not include TDS.

Silica is dissolved sand or silica-bearing rock (such as quartz) through which the water flows. Silica is the cause of very hard and tenacious scales that can form in heat transfer systems. These deposits can be particularly hard to remove if allowed to concentrate. Fortunately, silicate deposition is less common than other deposits.

Soluble iron in water can originate from metal corrosion in water systems or as a contaminant in the makeup water supply. The iron can form heat-insulating deposits by precipitation as iron hydroxide or iron phosphate in the presence of phosphate-based water treatment or phosphate in the makeup water.

Sulfates are the dissolved sulfate salts of sodium, potassium, calcium, and magnesium in the water. Their presences is the product of dissolution of sulfate-bearing rock, such as gypsum. Calcium and magnesium sulfate scale is very hard and difficult to remove and greatly interferes with heat transfer. Sulfates also contribute to scale formation in high-calcium waters. Calcium sulfate scale, however, forms at much higher concentrations than the more common calcium carbonate scale. High sulfates also contribute to increased corrosion because of their high conductivity and support of **microbiologically influenced corrosion (MIC)**.

Turbidity is the amount of opacity caused by suspended matter and is often described as cloudiness or haziness in water. It should not be confused with color. Water may be dark in color but still clear and not turbid. Turbidity is caused by suspended matter, in a finely divided state, which can scatter and deflect incoming light. Clay, silt, organic matter, microscopic organisms, and similar materials are common causes of turbidity. Although suspended matter and turbidity are closely related, they are not synonymous. Suspended matter is the quantity of insoluble material in water that can be removed by filtration. Levels of suspended matter and turbidity will likely change based on the dynamics of water flow or lack of flow. Turbidity of water used in HVAC systems should be as low as possible, particularly for steam boiler feedwater. Turbidity can concentrate in the boiler and settle as sludge or mud. It can also cause increased boiler blowdown, plugging, overheating, priming, and foaming.

Biological matter such as bacteria, algae, and fungi can be present in water, and their growth in water systems can cause operating, maintenance, and health problems. Microbial growth should be assumed to occur in most water systems below 65°C. Problems caused by biological materials range from green algae growth in cooling towers to bacterial slime formations. This growth can plug equipment, drastically reduce heat exchanger (transfer) efficiencies, and cause microbial corrosion.

Holding time index (HTI) is defined as the time required to completely exchange the volume of a system via bleed off. It calculated by dividing system volume by the rate of system bleed off, or blowdown. HTI is reflective of the amount of aging within a system.

Dispersant is a term used to express an additive's ability to aid in suspending very small particles, so they do not readily agglomerate, settle, or adhere to surfaces. Dispersants are typically chain-like compounds (polymers) that can attach to and engulf very small particles. Dispersive polymers are designed to include area of electrical negative charge to impart repulsive activity between polymer-engulfed particles.

1.2 WATER SOURCES

Potable Water Sources

Municipal water sources in the United States are generally of high quality and in compliance with federal government (EPA) standards as well as state and local requirements. Depending on the primary source, water properties may be quite constant, as where water is drawn from the Great Lakes or fixed-strata deep wells. In contrast, some properties are quite variable in the more arid parts of the

United States, where water may be obtained from rivers, lakes, or wells as season and water demand dictate. Highly variable water properties can be particularly challenging in management of boiler and cooling tower treatment programs (e.g., obtaining desired response from treatment control equipment, maintaining proper function of water conditioning equipment such as water softeners, dealing with water that varies between being corrosive and being scale forming). Municipal supplies, though free of contaminants initially, can pick up iron corrosion debris from miles-long delivery mains leading to episodes of iron-rich "red water." Municipal water should also not be presumed microbiologically sterile. Water mains typically possess biofilm of significant thickness.

Corporate, public, and private water well sources of potable water are generally have lower quality, consistency of chemical properties, or reliability of supply. In addition, issues of odor, taste, or turbidity may arise, and contaminants typically not found in municipally processed water may be present.

Alternative Water Sources

Facilities are under continuous pressure to reduce costs and operate in a more environmentally responsible manner. Historically, energy conservation has overshadowed water conservation in these efforts. However, in many locations, the reduced availability and increased cost of water now make water conservation much more attractive. More facilities are subject to limits on water consumption and the amount of wastewater that can be discharged. Although there are energy source alternatives to oil and gas, there is no substitute for fresh water. The economic and environmental payback on reducing water usage is greater than ever.

As a large consumer of potable water, evaporative cooling-water systems, including cooling towers, are an obvious target for water conservation efforts. Because of supply and cost pressures, more facilities are considering alternative makeup water sources, such as air handler condensate, rainwater, and reclaim water. In some cases, alternative water sources are blended with potable water to improve water use efficiency. Using one or more of these alternative water sources for cooling tower makeup conserves fresh water for other uses and can provide significant cost savings.

Evaluating an Alternative Water Source. It is important to understand the impurities in an alternative makeup water source and how they affect cooling tower operation before substituting for potable water. Some water sources can be successfully used without further treatment, whereas others require additional treatment measures to control problems related to corrosion, scale, and microbiological growth.

Air Handler Condensate. In warm, humid climates, the normal operation of air-conditioning equipment produces large quantities of condensate from the air handler cooling coils. This cold, near-distilled-quality water is typically sent to the drain. In some cases, this water can be readily recovered for other uses, including cooling tower makeup. Because air handler condensate does not contain the dissolved mineral impurities present in potable water, using this cold, nearly pure water for cooling tower makeup also allows operation at lower bleed rates.

Because the quantity of condensate generated by a cooling coil is a direct function of the airflow rate and change in the relative humidity, it varies considerably throughout the year. For example, a 3517 kW cooling load in a commercial facility with 25% outdoor air produces 0.30 L/s of condensate when the outdoor air temperature is 29°C with 80% relative humidity (rh) and 0.17 L/s with 60% rh. Case studies have shown that 10 to 40% of cooling tower makeup requirements can often be met with air handler condensate in facilities that operate in warm, humid climates.

Depending on the location of the air-handling units and the cooling towers, the collection system can be as simple as a gravity-fed tank with a level controller and pump. Corrosion-resistant tanks and piping are recommended because of the corrosivity of such pure water. Typically, an oxidizing biocide is added to the condensate storage tank to prevent microbiological problems. Each facility is different, but the water savings and payback on using air handler condensate for cooling tower makeup water can be significant. The need for cooling tower makeup and the availability of it from cooling coils are generally simultaneous, thus minimizing storage costs.

Rainwater. Although unpredictable, rainwater is a good alternative source in some areas. Approximately 1 litre of water can be recovered per millimetre of rain per square metre of collection surface. For a 200 m^2 roof, this translates to about 200 litres of water per millimetre of rain.

A typical rainwater recovery system directs rainwater from the roof to a storage tank rather than a storm sewer. This cache can then be used for various purposes throughout a facility, including irrigation and cooling tower makeup. Parking decks can also be used to harvest rainwater; however, special media filters are required to remove oil and other contaminants before use.

Like air handler condensate, rainwater is relatively pure. Once collected from a roof and filtered, it can be used as cooling tower makeup water with little treatment beyond adding an oxidizing biocide to the storage tank to minimize microbiological growth.

Reclaimed Water. Reclaimed water, or recycled water, is highly treated wastewater from a wastewater treatment plant. This nonpotable water source is delivered to a facility through purple or lavender piping to distinguish it from potable water supplies. It is suitable for irrigation, deep well injection, and possibly for open recirculating cooling systems.

Compared to potable water, reclaimed water contains a higher concentration of hardness and alkalinity, which increases the tendency to form scale deposits. It can also contain appreciable levels of phosphate and ammonia, components not normally present in significant amounts in potable water.

The increased phosphate content in reclaimed water also makes calcium phosphate scale formation in heat exchange equipment a concern, unless the proper treatment measures are taken, such as operating the cooling tower at a higher bleed rate, using sulfuric acid for pH control, and/or adding a phosphate specific polymeric dispersant.

Although reclaimed water is disinfected to control pathogenic microorganisms, there is an increased potential for microbiological problems when used in cooling tower systems. In part, this is related to the presence of ammonia and other nitrogen compounds, which are nutrients that support bacteria growth. Reclaimed water also has higher background bacteria levels than potable water. Because of the increased potential for corrosion and deposit problems related to bacteria growth, additional biocides are usually required. A combination of oxidizing and nonoxidizing biocides usually works best. Chlorine dioxide is an excellent biocide because of its nonionic nature, and is better at penetrating biofilm than chlorine or bromine. New technologies greatly simplify chlorine dioxide generation and application, making this an attractive alternative biocide.

Blended Water. Blending one or more alternative water sources can reduce overall water consumption and costs associated with operating a cooling tower system. In some applications, it may be necessary to blend potable water with reclaim water to provide a makeup water quality suitable for use in cooling towers. Where there is excess water softener or reverse osmosis (RO) capacity, blending with high-alkalinity, high-hardness potable water can allow a cooling tower to operate at greatly reduced bleed rates. Alternative water streams such as RO reject water may also be suitable for use as tower makeup with blending.

Consistent blending is important when considering a blended water supply for cooling tower makeup. It is difficult to control the bleed rate and treatment levels when the makeup quality varies widely. Equipment systems can be engineered to correctly blend two or more water supplies.

2. WATER TREATMENT

2.1 CONTROL

Deposition

Several different types of deposits can form in boiler and cooling-water systems, and terms such as scale, fouling, deposit, film, coating, precipitate, and others are sometimes used interchangeably in the industry to describe these materials. However, it is important to use the correct term in describing these phenomena, because the operating procedures and chemical treatments used to help prevent these various deposits from forming, and to remove them when necessary, depend on the specific composition of the deposits.

Deposit refers to any material formed on either the internal or external surfaces of components in contact with water.

Fouling describes the condition of a system in which deposits have formed, including microbiological fouling. Microbiological fouling is slime or biofilm that accumulates by incorporating inorganic particulate matter such as calcium carbonate, silica, and corrosion products.

Scale is formed from minerals, formerly dissolved in water, deposited from the water onto heat transfer surfaces or pipes. As water is evaporated in a cooling tower, the concentration of dissolved solids becomes greater, and the solubility of particular scale-causing mineral salts can be exceeded. When this situation occurs in an untreated cooling-water system, scale will form on any surface in contact with the water, especially on heat transfer surfaces. The most common scaling minerals are (1) calcium carbonate, (2) calcium phosphate, (3) calcium sulfate, and (4) silica, usually in that order. Formation of magnesium silicate scale is also possible under certain conditions. Most salts, including silica, are more soluble in hot water than in cold water; however, most calcium and magnesium salts, including calcium phosphate and calcium carbonate, are more soluble in cold water. This is called **reverse solubility**. As recirculating water passes through the cooling system, the water temperature increases. As a result, calcium and magnesium scales may form anywhere in the system, but most likely on heated surfaces such as heat exchangers or surface condensers. Silica forms in areas having the lowest water temperature, such as in the cooling tower fill.

Minerals such as calcium and magnesium are relatively insoluble in water and can form scale deposits when exposed to conditions commonly found in cooling-water systems. A layer of scale as thin as 0.40 mm can reduce heat exchanger capacity by 15%.

Several key factors influence whether scale forms:

- Temperature
- pH
- Alkalinity
- Hardness (amount of scale-forming salts)
- Total dissolved solids (influence of other dissolved materials, which may or may not be scale-forming)

As any of these factors changes, so do scaling tendencies. Changes in pH or alkalinity can greatly affect scale formation. For example, as pH or alkalinity increases, calcium carbonate becomes less soluble and deposits on surfaces.

Some materials, such as silica (SiO_2), are less soluble at lower alkalinities. When the amount of scale-forming material dissolved in water exceeds its saturation point, scale may result. In addition, other dissolved solids may influence scale-forming tendencies. In general, a higher level of scale-forming dissolved solids results in a greater chance for scale formation.

Calcium Carbonate Formation (Hard Lime Scale)

The progression of calcium carbonate deposition and scale formation is fundamentally a reversal of the process of creating hard water (when carbonic acid in rainwater dissolves limestone). However, this bond is easily undone once water is put to practical use, because the bicarbonate component of hard water is thermally unstable:

$$2HCO_3^{-} + \text{heat} \rightarrow CO_3^{-2} + CO_2$$

Alkalinity breakdown produces carbonate ion and carbon dioxide (easily lost from a system as a gas). The percentage of bicarbonate broken down grows so long as heat continues to be added to water.

The solubility of calcium bicarbonate is more than 10 000 mg/L. The solubility of calcium carbonate at 24°C is roughly 10 mg/L: 4 mg/L calcium ions and 6 mg/L carbonate ions. Basic chemistry dictates that, for aqueous salts of limited solubility, any effort to increase the concentration of one constituent must cause the concentration of the other constituent to fall. Expressed mathematically, when a soluble salt such as calcium carbonate is dissolved in water, multiplying the concentration of each constituent produces a fixed number K_{sp} (or solubility product or constant).

Hard water typically contains roughly two bicarbonate ions for every calcium ion. Cooling tower and boiler makeup water supplies frequently hold up to 300 mg/L hardness or more, which may be further concentrated several times by evaporation in a cooling tower or boiler. Calcium and bicarbonate concentrations may easily approach several hundred mg/L each. Alkalinity breakdown can then lead to levels of 100 mg/L or greater of carbonate ions combined with a near equal concentration of calcium ions to form a very highly supersaturated solution of calcium carbonate, in violation of the solubility product limit.

Scale and sludge are not produced instantly when hard water is introduces into a cooling tower or boiler, because calcium carbonate precipitates only very slowly from a supersaturated solution of calcium and carbonate ions. Such supersaturated solutions are termed **metastable**, in that there is great potential for precipitation to occur, but time is required for its initiation. The mechanism of initiation is complex and beyond the scope of this chapter; it is mainly important to note that the process of calcium carbonate formation starts with alkalinity breakdown and CO_2 loss from a boiler or cooling tower system. A metastable condition is then created throughout the entire bulk phase of cooling or boiler water, and nucleated crystals of calcium carbonate (limestone) eventually form. As surface nucleation occurs, various conditions in a cooling tower or boiler system dictate where deposits form within the system, along with the extent and physical character of the deposit. For example, hotter heat transfer surfaces speed nucleation and promote formation of the densest crystal structure (calcite), biofilm in cooling water systems captures microcrystals to form calcium-carbonate-rich mud and sludge, and carbonate-rich deposits can form on cooling tower fill at wet/dry boundaries due to hypersaturation.

Deposition, Scale, and Suspended-Solids Control

Whether dealing with a boiler or cooling tower, treatment strategy is dictated by makeup chemical properties and the “stress” and operating constraints placed on water. Treatment of an HVAC type cooling tower fed with makeup water of relatively low hardness is usually quite different than that for an industrial process cooling tower fed with high hardness makeup water. In some instances, local water resource conservation or discharge regulations may dramatically affect the treatment strategy used.

Steam Boilers:

- Makeup water conditioning:

- Ion exchange (softening) to remove calcium and magnesium.
- Reverse osmosis (RO) to remove almost all dissolved solids including calcium and magnesium.
- Deionization (DI) to remove all dissolved solids.
- Deaerator to aid control of carbonate species and pH.

• Direct chemical treatment of boiler water:
  - Various chemical additives such as sodium hydroxide, sodium carbonate, phosphates, dispersive agents, etc. may be added to "soften" boiler water, but this practice is considered out of date, and makeup water conditioning is favored. Chemical additives are typically used to address low level hardness not removed by makeup conditioning or due to external contamination.

• Maintain good internal boiler and steam condensate protection against corrosion to control iron deposition on internal boiler surfaces.

Cooling Towers:

• Makeup water conditioning:
  - Ion exchange (softening) to remove calcium and magnesium.
  - Ion exchange to remove alkalinity using weak cation exchange resin followed by degasification.
  - Reverse osmosis (RO) to remove almost all dissolved solids including calcium and magnesium.
  - Deionization (DI) to remove virtually all dissolved solids.

• Add acid to cooling tower water to remove alkalinity and control carbonate ion formation

• Add scale inhibitors and dispersives to dramatically slow rate of particle nucleation and agglomeration.

Scaling Indices

To help determine the tendency of water to form or dissolve calcium carbonate scale, several scaling indices have been developed. These indices are only for predicting calcium carbonate scale, not scale of other calcium compounds (such as calcium sulfate). The indices are calculated using the pH, alkalinity, calcium hardness, temperature, and total dissolved solids of the water.

Langelier Saturation Index (LSI). This index was developed to calculate the calcium carbonate scale-forming and scale-dissolving tendencies of drinking (potable) water at or near ambient temperatures (Langelier 1936). Using a water's calcium hardness, total alkalinity, and total dissolved solids measurements, along with the water's pH and temperature values, the pH of saturation **pH(s)** is calculated. Subtracting the water's pH(s) from its actual pH then results in the LSI. If the water's measured pH (**pH [actual]**) is greater than its pH(s) (i.e., positive LSI value), the water has a scale-forming tendency. If the water's pH (actual) is less than its pH(s) (i.e., negative LSI value), the water will have a scale-dissolving tendency. The water's equilibrium or neutral value is at an LSI of zero. Because this index was originally designed to predict calcium carbonate scale in potable water, there are serious deficiencies in the accuracy of this index when applied to evaporative cooling water, heating water, or potable hot water.

The temperature component in the LSI calculation is considered appropriate for water that is carried at ambient soil temperatures through buried distribution piping. However, this was later deemed insufficient for process water used for cooling towers or boilers where values tended almost always to be positive, yet indications of deposition of calcium carbonate were absent. Experience shows that the LSI can be used as a trending value in process water systems to indicate changes in stability, rather than an absolute condition.

The LSI is calculated as

$$\text{LSI} = \text{pH(actual)} - \text{pH(s)}$$

where

$\text{pH(s)} = (9.3 + A + B) - (C + D)$

$A = [\log(\text{TDS}) - 1] / 10$

$B = -13.12 \times \log[\text{temp } °\text{C} + 273] + 34.55$

$C = \log[Ca^{2+}] - 0.4$

$D = \log[\text{alkalinity}]$

Note: All log values are base 10; alkalinity is the total alkalinity measured as mg/L $CaCO_3$; Ca^{2+} is the calcium measured as mg/L $CaCO_3$; and TDS is total dissolved solids measured in mg/L.

Ryznar Stability Index (RSI). This index is a more accurate formula for predicting calcium carbonate scale (Ryznar 1944). Ryznar altered the LSI by measuring scale thickness in distributed water systems and comparing the calculated LSI with field results. With this information, he made revisions to the LSI. With his formula, an RSI value of 6.0 is considered neutral water, with values > 6.0 indicating a tendency to dissolve calcium carbonate, and values < 6.0 a tendency to deposit calcium carbonate. RSI gives more accurate results than LSI in waters with a pH less than 7.8, but still gives an indication of scale formation at higher pH values. Regardless, the RSI was useful for the era's acid feed water treatment programs, which operated at pH < 7.8.

The RSI is calculated as

$$\text{RSI} = 2 \times \text{pH(s)} - \text{pH(actual)}$$

where pH(s) is calculated as in the LSI.

Practical (Puckorius) Scaling Index (PSI). Puckorius and Brooke (1991) presented a modified version of the RSI that gives a more accurate and consistent indication of the calcium carbonate scaling potential of cooling water. The PSI takes into consideration the effect of the type of total alkalinity of the cooling water on the measured pH(actual). The measured pH does not always relate correctly to bicarbonate alkalinity, because of the buffering effect of other ions. Rather than using the measured pH in calculating the PSI, an adjusted, or equilibrium pH **pH(eq)** is used. As with the RSI, a PSI value of 6 indicates stable water, and a value lower than 6 indicates a scale-forming tendency. Without scale control treatment, a cooling tower with a PSI of 6 to 7 should operate scale free. Use of the PSI is most applicable when cooling-water pH is above 7.5.

The PSI is calculated as

$$\text{PSI} = 2 \times \text{pH(s)} - \text{pH(eq)}$$

where pH(s) is as calculated in the LSI, and $\text{pH(eq)} = 1.465 \times \log[\text{alkalinity as } CaCO_3] + 4.54$.

Simple models and calculators and more information on these indices can be found online from various sources.

Scale and Deposit Formation Control

Methods used to control scale and deposit formation include the following:

• Limit the concentration of scale-forming minerals, impurities, and contaminants in a steam boiler or evaporative cooling-water system by intentionally wasting (removing) water from the system via blowdown (bleed-off). This, in effect, lowers concentration that tends to increase during the continuing evaporation of steam or cooling water from these systems. Scale control is thus achieved through operation of the system at subsaturated conditions.

• Remove scale-forming minerals, impurities, and contaminants before they enter the boiler or cooling-water system, using external or pretreatment systems. This can be done using (1) softened water, blending soft or RO water with other makeup water to achieve a desired saturation index, (2) cycles of concentration, or (3) both methods.

• Make mechanical changes in the system, such as increasing water flow or surface areas of heat exchangers, to reduce tendencies and potential for scale/deposit formation.

- Feed acid to reduce alkalinity and keep common scale-forming minerals such as calcium carbonate in solution.
- Implement a water treatment program designed to control scale and deposit formations in the boiler or cooling-water system.

Retention Time. Controlling cycles of concentration also controls the time that minerals, as well as treatment chemicals and other water constituents, are held within a system. Evaporative-cooling-water systems have a load and volume dependent water residence or turnover time referred to as the **holding time index (HTI)**, also called the **retention time** of the system. HTI is the measure of time that it takes for an analyte in the cooling-water system to decrease to 50% of its original value through the process of system losses (blowdown and drift) plus the addition of makeup water to the system. The greater the HTI of the system, the longer water is held in the system and the greater the probability that dissolved, scale-forming minerals will nucleate to produce deposits. At the same time, the greater the HTI of the system, the longer a biocide dosage is held in the system water for a greater contact time to promote microbial kill or control.

HTI for a cooling-water system is calculated as follows:

$$\text{HTI} = 0.693 \times V/\text{BD}$$

where

V = volume of system
BD = blowdown rate for system ≈ evaporation rate (ER)/[cycles of concentration (CC) – 1]

Mechanisms. Water treatment chemical scale inhibitors work by the following mechanisms:

- **Threshold inhibition chemicals** control scale formation by dramatically extending the time required for deposit nucleation. If nucleation time is extended beyond a system's HTI, mineral deposits fail to form. The most commonly used threshold scale inhibitors are organophosphorus compounds (phosphonates) and low-molecular-weight acrylate polymers. Both classes of materials function as threshold inhibitors; however, the polymeric materials are more effective as dispersants.
- **Scale conditioners** modify the crystal structure of scale forming minerals as the nucleate, creating a bulky, transportable sludge instead of a hard deposit. Scale conditioners include lignin, tannins, and polymeric compounds.

Suspended Solids and Deposition Control

Strainers, filters, and separators may be used to reduce suspended solids to an acceptable level. Generally, if the screen has openings ≥0.076 mm (200 mesh), it is called a strainer; if it is finer than 200 mesh, it is called a filter.

Strainers. A strainer is a closed vessel with a cleanable screen designed to remove and retain foreign particles down to 0.025 mm diameter from fluids. Strainers extract material to protect equipment downstream from constrictions or damage, and to allow saving the extracted product if it is valuable. Strainers are available as single-basket or duplex units, manual or automatic cleaning units, and may be made of cast iron, bronze, stainless steel, copper-nickel alloys, or plastic. Supplemental magnetic inserts are available where microscopic iron or steel particles are present in the fluid.

Cartridge Filters. These are typically used as final or tertiary filters to remove nearly all suspended particles from about 0.102 to 0.00102 mm or smaller. Cartridge filters are typically disposable (i.e., once plugged, they must be replaced). The frequency of replacement, and thus the economic feasibility of their use, depends on the concentration of suspended solids in the fluid, the size of the smallest particles to be removed, and the removal efficiency of the cartridge filter selected.

In general, cartridge filters are ideal for systems where contamination levels are less than 0.01% by mass (<100 mg/L). They are available in many different materials and configurations. Filter media materials include yarns, felts, papers, nonwoven materials, resin-bonded fabric, woven wire cloths, sintered metal, and ceramic structures. The standard configuration is a cylinder with an overall length of approximately 254 mm, an outside diameter of approximately 63.5 to 69.85 mm, and an inside diameter of about 25.4 to 38.1 mm, where the filtered fluid collects in the perforated internal core. Overall lengths from 101.6 to 1016 mm are readily available.

Cartridges made of yarns, resin-bonded, or melt-blown fibers normally have a structure that increases in density near the center. These depth-type filters capture particles throughout the total media thickness. Thin media, such as pleated paper (membrane types), have a narrow pore size distribution design to capture particles at or near the surface of the filter. Surface-type filters can normally handle higher flow rates and provide higher removal efficiency than equivalent depth filters. Cartridge filters are rated according to manufacturers' guidelines. Surface-type filters have an absolute rating, whereas depth-type filters have a nominal rating that reflects their general classification function. Higher-efficiency, melt-blown depth filters are available with absolute ratings as needed.

Bag-Type Filters. These filters are composed of a bag of mesh or felt supported by a removable perforated metal basket, placed in a closed housing with an inlet and outlet. The housing is a tubular pressure vessel with a hinged or clamped cover on top for access to the bag and basket. The inlet can be in the cover, in the side (above the bag), or in the bottom. The side inlet is the simplest type. In any case, the liquid enters the top of the bag. The outlet is located at the bottom of the side (below the bag). Pipe connections can be threaded or flanged. Single-basket housings can handle up to 14 L/s, multibaskets up to 221 L/s.

The support basket is usually of 304 stainless steel perforated with 3 mm holes. (Heavy wire mesh baskets also exist.) The baskets can be lined with fine wire mesh and used by themselves as strainers, without adding a filter bag. Some manufacturers offer a second, inner basket (and bag) that fits inside the primary basket. This provides for two-stage filtering: first a coarse filtering stage, then a finer one. The benefits are longer service time and possible elimination of a second housing to accomplish the same function.

Filter bags are made of many materials: cotton, nylon, polypropylene, and polyester, with a range of size ratings from <0.00102 to 0.838 mm. Felted materials are most common because of their depth-filtering quality, which provides high dirt-loading capability, and their fine pores. Mesh bags are generally coarser, but are reusable and, therefore, less costly. The bags have a support ring sewn into their opening; this holds the bag open and seats it on top of the basket rim. They can be configured with lift handles, thermal sealed edges instead of sewn stitches, and glazed (thermal pressed) finish to prevent release of fibers. In operation, the liquid enters the bag from above, flows out through the basket, and exits the housing, cleaned of particulate down to the desired size. The contaminant is trapped inside the bag, making it easy to remove without spilling any downstream.

Sand Filters. A downflow filter is used to remove suspended solids from a water stream. The degree of suspended solids removal depends on the combinations and grades of the medium being used in the vessel. During the filtration mode, water enters the top of the filter vessel. After passing through a flow impingement plate, it enters the quiescent (calm) freeboard area above the medium.

In multimedia downflow vessels, various grain sizes and types of media are used to filter the water. This design increases the suspended solids holding capacity of the system, which in turn increases the backwashing interval, which conserves water. Multimedia vessels might also be used for low-suspended-solids applications, where chemical additives may be required.

Sand filters for cooling-water systems are usually high rate (13.58 L/[s·m^2]), with filter media rated from 0.00051 to 0.0102 mm. Some filter vessels are configured to allow water to enter at an angle to create a vortex-shaped filter bed and enhance removal efficiency. Total filtration rate is determined by either system volume turnovers or percent of circulation flow rate. Filter vessels are usually installed sidestream with a booster pump. When they are installed next to cooling towers, filter piping is used to sweep clean tower basin floors at a rate of 0.68 to 1.02 L/(s·m^2) via sweep nozzles. This usually calls for a bigger booster pump to create the sweeping action.

When the vessel has retained enough suspended solids to develop a substantial pressure drop, the unit must be backwashed (either manually or automatically) by reversing the direction of flow. This operation removes the accumulated solids out through the top of the vessel. The Handbook Online version of this chapter features separator animations.

Centrifugal-Gravity Separators. In this type of separator, liquids enter the unit tangentially, which sets up a circular cyclone flow path. The liquids are accelerated into the separation chamber. Centrifugal forces toss particles heavier than the liquid to the perimeter of the separation chamber. Solids drop along the perimeter and into the quiescent collection chamber in. A low-solids liquid is then drawn into the separator vessel vortex (low-pressure area) and up through the separator outlet at the top of the vessel. Solids are either purged periodically by a manual or automatic timed purge, or continuously bled from the separator to a solids collection/filter chamber. Advantages of separators include a constant pressure drop even as solids are collected, a negligible water loss in the purge cycle, and no backwash or interruption of service. Disadvantages are that they will not remove particles with lower density than the primary liquid (e.g., cottonwood seeds).

Notes: In specifying filtration systems, third-party testing by an accredited or independent agency should be specified. The test report documentation should include a description of methods, piping diagrams, performance data, and certification.

Filters described in this section may also be used where industrial process cooling water is involved. For this type of service, consultation with the filtration equipment manufacturer is essential to ensure proper application.

2.2 CORROSION AND CORROSION CONTROL

Corrosion is the destruction of a material, usually a metal or alloy, through chemical or electrochemical reaction with its environment. This is the mechanism by which a metal reverts to an oxide (hydroxide) of sulfide state. Pure metals fall into two practical groups when considering their interaction with pure neutral-pH water: those that can react and those that do not. Common examples of those that can react are magnesium, aluminum, zinc, chromium, iron, tin-nickel, and lead. Examples of pure metals that should not react include copper, silver, platinum, and gold. Exceptions exist depending on the character of metal oxide surface films. Very tenacious surface oxide film can block corrosion of a metal that is theoretically very reactive with water (aluminum, chromium, and nickel, or austenitic stainless steels). Corrosion is therefore a two-step process: (1) penetrating any protective oxide surface film (depolarization) and (2) establishing a continuing reaction between water and metal in a depolarized state.

Depolarization involves a chemical reaction that fully or partially removes or weakens protective surface oxide film, thereby exposing base metal. Acidic conditions tend to dissolve protective films and produce uniform metal loss. High chloride tends to weaken protective film on steel so that subsequent corrosion is more irregular.

In most instances, the second reaction is electrochemical in nature, much like that in an electric battery. For corrosion to occur, a corrosion cell consisting of an anode, a cathode, an electrolyte, and an electrical connection must exist. Metal ions dissolve into the electrolyte (water) at the anode, leaving behind electrons. These electrons flow through the metal (electric connection) to other points (cathodes) where electron-consuming reactions occur. The result of this activity is the loss of metal and often the formation of a deposit. The rapidity of corrosion depends on the rate of flow of the electrons. Mechanisms for various types of corrosion are shown in Figure 1.

Types of Corrosion

Corrosion is often divided into three broad categories: (1) uniform (general), (2) localized (pitting), and (3) galvanic (dissimilar metal corrosion). Many other types of corrosion associated with these three main categories are of concern in water treatment and commonly encountered in boiler and cooling water systems for both HVAC and processes, including stress, fatigue, crevice, erosion, and microbiologically influenced corrosion. Corrosion in practical systems is rarely of one type but the result of an aggregate of several forms.

Uniform (general) corrosion (Figure 1D) is the most common type and is caused by a chemical or electrochemical reaction that results in the deterioration of the entire exposed surface of a metal. It is essentially due to general attack, removal, or weakening of whatever protective metal oxide surface film may be present on a metal. Wetted metal surfaces below 66°C are typically coated by biofilm. Beneath biofilm, pH is lower than in bulk phase water by virtue of microbiological metabolism. This lower relative pH tends to weaken protective oxide surface film and expose subsurface elements to corrosive hydrogen ions. Biological activity in and beneath biofilm also produces enzymes reactive with protective metal oxide surface film. Low pH and high chloride are primary contributors to the removal of protective iron oxide films from steel. Ultimately, metal can deteriorate to the point of failure. Uniform attack corrosion accounts for the greatest amount of metal destruction by corrosion, but is considered a normal condition when metals are exposed to water based fluids, because it is (1) evenly distributed over a given metal surface throughout a system and (2) predictable, manageable, and often preventable. Uniform corrosion can be compensated for by using corrosion-resistant construction materials, applying protective coatings, or providing appropriate cathodic corrosion protection. In some (but not all) cases, uniform corrosion can be controlled by changing the chemical environment. Raising pH and reducing chloride and total dissolved solids can reestablish protective surface oxide films on steel and ferrous alloys. The effects of uniform corrosion can be anticipated through measurement of material specimens exposed to the anticipated operating environment in a corrosion coupon rack. Coupons are inserted in the rack for a predetermined exposure before being removed, cleaned, weighed, and examined to determine rates of corrosion.

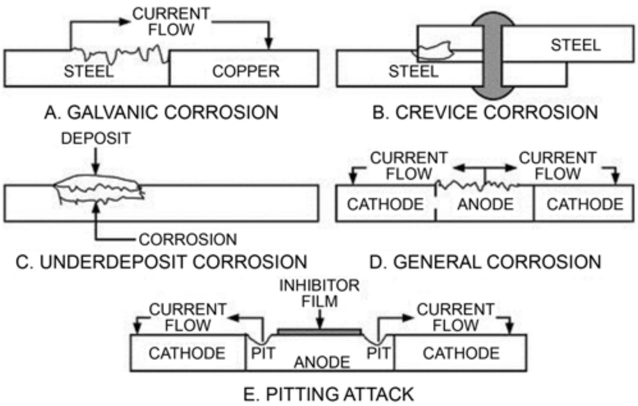

Fig. 1 Corrosion Types and Mechanisms

Localized (pitting) corrosion (Figure 1E) results when a small defect or hole forms in protective metal oxide surface film, usually as the result of inconsistent inhibitor film formation at that location. This area becomes electrochemically anodic, while part of the remaining metal becomes cathodic, producing a localized galvanic reaction, often referred to as a **concentration cell**. The deterioration of this small area penetrates the metal and can quickly lead to failure. This form of corrosion is often difficult to detect because it is usually relatively small and may be covered and hidden by corrosion-produced compounds (corrosion byproducts). Pitting is the most serious form of corrosion, because the action is concentrated in a small area. Pits often appear with roughly equal depth and diameter. Continued corrosion reaction in pits of ferrous metals can cause the appearance of hollow, tube-like growths above the metal surface, called **tubercles**. These are formed by layering deposits of iron oxide species, a by-product of the pit formation at the base of the tubercle. Like corrosion cells, pits may reach an autocatalytic stage of rapid corrosion, though not always. Tubercles, however, are always the result of an autocatalytic process. Unlike crevice corrosion, pitting is thought to be self-initiated in otherwise unmarred surfaces by the presence of deposits and chloride salts. The pit then concentrates chlorides in the hollow. The process is accelerated by the presence of oxygen, which creates a localized adjacent cathode to the anodic surface of the pit, forcing concentrated anodic deterioration and enlarging the pit.

Galvanic (dissimilar metal) corrosion (Figures 1A and 2) occurs when two different metals are located together in an electrolyte (solution). A galvanic couple forms between the two metals, where one metal becomes the anode and the other the cathode. The anode, or sacrificial metal, corrodes and deteriorates faster than it would alone, while the cathode deteriorates more slowly than it would otherwise. Galvanic corrosion is limited to the immediate area of the juncture of the two dissimilar metals. Deterioration of the anodic metal is most severe at the point of contact and diminishes markedly with distance. Galvanic corrosion rarely extends more than a few inches from where dissimilar metals make contact.

Three conditions must exist for galvanic corrosion to occur:

- Electrochemically dissimilar metals must be present.
- The metals must be in intimate electrical contact.
- The metals must be exposed to an electrolyte.

Common examples of galvanic corrosion in water systems are metal-to-metal contacts between steel and copper alloys (brass); aluminum and steel; zinc and steel; and zinc coated galvanized steel; and carbon steel or stainless steel. If galvanic corrosion

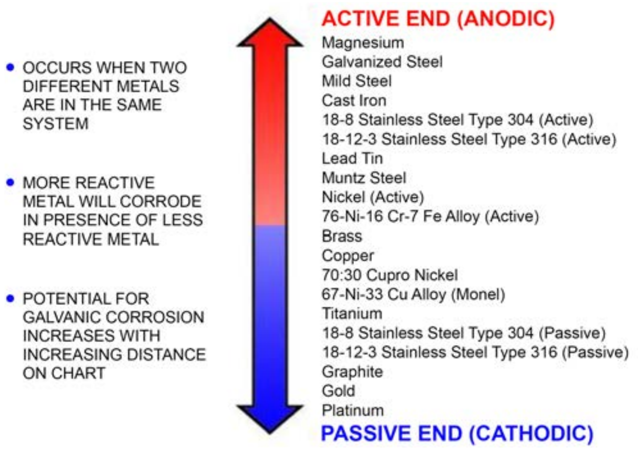

Fig. 2 Galvanic Corrosion

occurs, the metal named first is the anode and experiences the corrosion.

Stress corrosion cracking (SCC), or environmental cracking, can result from a combination of environmental conditions affecting the metal and in alloys subject to tensile stress. The stress may be applied, residual (from processing), or a combination. The resulting crack formation is generally intergranular.

Corrosion fatigue may occur by one of two mechanisms. In the first, cyclic stresses (e.g., from rapid heating and cooling) are concentrated at points where surface defects are present and corrosion has roughened or pitted the metal surface. In the second type, cracks often initiate because of the action of applied cyclic stresses where a magnetite film fails on metal surfaces.

Caustic cracking occurs when metal is stressed in a fluid with a high caustic content, and a mechanism of concentration occurs.

Crevice corrosion (Figure 1B) occurs in the void between a metal and another surface. These opposing surfaces can be metal (similar or dissimilar), gaskets, organic residue, or scale deposits. In this void, and usually in the presence of a stagnant solution, a localized corrosion environment is created. Also referred to as **underdeposit corrosion**, it is similar to concentration cell corrosion issues. As in pitting, the crevice allows the concentration of chlorides in the void, and the presence of oxygen enhances the reaction.

Erosion corrosion (flow-accelerated corrosion) occurs as a result of flow or impact that can physically remove inhibitor films and the protective metal oxide surface. This type of corrosion usually occurs because of altered flow patterns or a flow rate that is above design. Suspended solids in a solution can greatly contribute to erosion corrosion. Control of suspended solids can reduce erosion in systems and enhance material life cycle and durability.

Cavitation corrosion, a form of erosion corrosion, is caused by the rapid formation and collapse of vapor bubbles during a change in fluid pressures in a solution and adjacent to a metal surface.

Microbiologically influenced corrosion (MIC), also called **microbial corrosion, bacterial corrosion,** or **biocorrosion**, involves the reaction of microbiological species with metals. It is caused or promoted by microorganisms, usually chemoautotrophs, which are microbes that can produce corrosive acids and enzymes as a part of their cellular metabolism. Bacteria do not attack metal or protective metal oxide surface films. The acids, enzymes, cause attack and other metabolic byproducts produced by bacteria, especially when bacteria create a biofilm. MIC can be a very serious problem in building HVAC recirculating water systems, involving many forms, mechanisms, and types of microbiological organisms, including the following.

- **Iron-related bacteria (IRB),** such as *Gallionellea ferrugine* and *Ferrobacillus* species, cause corrosion of iron and steel in recirculating water systems by direct metabolism of iron. Some of these organisms consume iron as a part of their metabolic process and then deposit it in the form of hydrated ferric hydroxide along with mucous secretions. Iron bacteria are commonly found in all types of cooling systems, especially in low-flow areas.
- **Sulfate-reducing bacteria (SRB)** are the best known group of organisms involved in MIC. These anaerobic organisms (i.e., they live without metabolizing oxygen) metabolize sulfur in one form or another. The most widely known, *Desulfovibrio*, is often found in cooling systems, especially where oil or sludge is present. Metabolic processes involve the transfer of electrons from a "food source" to an electron acceptor (oxidizing agent) for the purpose of obtaining energy and the building blocks for continued cell growth. The principle electron acceptor under aerobic (oxygen rich) conditions is oxygen. When oxygen is depleted or absent, SRBs can use sulfate as an alternative electron acceptor to oxygen. In the process, sulfate is converted to corrosive hydrogen sulfide.

Table 2 Corrosion Rate Guidelines

Open Recirculating HVAC Cooling-Water Systems			
Description	**Carbon Steel**	**Copper Alloys**	**Stainless Steel***
Negligible or excellent	≤0.0254 mm	≤0.00254 mm	Acceptable <0.00254 mm
Mild or very good	0.0254 to.0762 mm	0.00254 to 0.00635 mm	Unacceptable >0.00254 mm
Good	0.0762 to 0.127 mm	0.00635 to 0.00889 mm	—
Moderate to fair	0.127 to 0.2032 mm	0.00889 to 0.0127 mm	—
Poor	0.2032 to 0.254 mm	0.0127 to 0.0254 mm	—
Very poor to severe	>0.254 mm	>0.0254 mm	—
Closed Recirculating HVAC Water Systems (Hot, Chilled, and Tempered Loops)			
Description	**Carbon Steel**	**Copper Alloys**	**Aluminum***
Excellent	≤0.00508 mm	≤0.00254 mm	<0.00127 mm
Good	0.00508 to 0.0127 mm	0.00254 to 0.00889 mm	0.00127 to 0.00254 mm
Moderate	0.0127 to 0.02032 mm	0.00635 to 0.00889 mm	0.00254 to 0.00508 mm
Poor	0.02032 to 0.0254 mm	0.00635 to 0.0127 mm	0.00508 to 0.00762 mm
Very poor to severe	≥0.0254 mm	≥0.0127 mm	>0.00762 mm

Source: Boffardi (2000). *Not an AWT Guideline.

- **Acid-producing bacteria (APB)** include the slime-forming bacteria *Pseudomonas*, *Aerobacter*, and *Bacillus*, which exude compounds such as formic, acetic, and oxalic acids in their metabolic processes. These organic acids cause low-pH conditions at local sites, resulting in corrosion. *Thiobacillus* is a common APB that oxidizes sulfur compounds into sulfuric acid, which is extremely corrosive and leads to localized underdeposit and pitting corrosion, often resulting in pinholes in system piping.
- **Biological deposits (BD)** such as algae, yeast, molds, fungi, and bacterial slimes can also cause MIC. Even in the absence of specific corrosive organisms, biological deposits establish an environment for corrosion by establishment of concentration cells and lowering pH, resulting in underdeposit corrosion. Biological deposits also act as traps providing food for other organisms, accelerating metabolism and growth. This complex matrix sets up a corrosion potential between adjacent areas of a metal surface that may have different type of deposits. In general, the longer it is allowed to flourish, the more difficult, time consuming, and expensive it is to bring under control.

To control and/or prevent MIC, it is important to understand the processes that cause it. An effective control and prevention program must address all types of biological growths in recirculating water systems.

Factors Affecting Corrosion

All cooling-water system metals of construction will corrode at some rate. Therefore, the rate of corrosion is of prime importance. This rate is commonly expressed in terms of penetration (thickness of metal lost) as millimetres. Table 2 provides guidelines for categorizing corrosion rates.

The following paragraphs describe the effects of various factors on corrosion.

Moisture. Corrosion does not occur in dry environments. However, some moisture is present as water vapor in most environments. In pure oxygen, almost no iron corrosion occurs at relative humidity up to 99%. However, when contaminants such as sulfur dioxide or solid particles of charcoal are present, corrosion can proceed at relative humidity of 50% or more. The corrosion reaction proceeds on surfaces of exposed metals such as iron and unalloyed steel as long as the metal remains wet. Many alloys develop protective corrosion-product films or oxide coatings and are thus unaffected by moisture.

Oxygen. Oxygen dissolved in water (DO) does not lead to corrosion of active metals such as aluminum, chromium, nickel, or zinc because these metals form protective oxide surface films acting as polarizing barriers that separate potentially oxygen-reactive metal from DO. Basic ferrous metals (steel and iron) unfortunately form only semiprotective oxide films susceptible to depolarization by numerous chemical and mechanical influences. While oxygen is frequently blamed for corrosion of basic ferrous metals, this is untrue in the strict sense. Once depolarization of surface film on steel occurs, DO perpetuates the attack unless the film can be repaired by corrosion inhibitors (which reestablish film integrity). Ironically, molybdate, a commonly used corrosion inhibitor, requires the presence of oxygen to work effectively.

pH. The acidic or basic (alkaline) nature of a solution is quantified by pH; a neutral solution has a pH of 7. Acidic solutions are below 7, and basic solutions are above 7. The pH of cooling water influences the potential of most metals to corrode. Corrosion tends to increase as pH levels decrease (become more acidic) because protective surface film tends to weaken or dissolve as pH falls below 7.0. However, different metals show different corrosion curves with respect to pH. Basic solutions are generally less corrosive to ferrous systems because they tend to make surface oxide film less soluble. It is practical in many water systems to minimize corrosion by adding caustic or alkaline buffering agents to raise and stabilize the pH at 9 or higher. Aluminum can corrode above a pH of 8.5 because its protective film weakens or dissolves; this reduces the acceptable range of pH in systems that contain both steel and aluminum.

Chlorides. Chloride is nonvolatile, commonly found in water, easily concentrated as water evaporates. Chloride ions can combine with the iron of protective surface film, weakening the film and making steel progressively more vulnerable to pitting and general corrosion, as chloride concentration rises and/or pH falls. Once protective film is depolarized, exposed elemental iron is free to react with oxygen. Because depolarization establishes an electrochemical circuit, the rate of reaction depends not only on the amount of oxygen present but also on the electrical conductance of the water; the higher the chloride and all other ionic species such as sulfate, sodium, potassium, etc., the more readily electrochemical activity proceeds.

Increasing the amount of dissolved solids increases the conductivity of the electrolyte (water). Because a corrosion cell depends on the ability of the electrolyte to conduct the flow of electrons, the presence of more dissolved solids increases corrosion. For the corrosion reaction to proceed, a potential difference between anodic and cathodic areas is required. The potential difference between locations on a metal surface is caused by variations in solute concentration in the localized environment. The increase in corrosion caused by such conditions is called **concentration cell corrosion**. Crevices, cracks, pits, and foreign deposits on the metal surface can create conditions that contribute to corrosion. The anodic area, where corrosion proceeds, is in the crevice or pit, or under the deposit. Whether the process is metal ion or oxygen concentration based, available chlorides accelerate the reactions. The process turns into an autocatalytic reaction, resulting in rapid destruction of the metal alloy. Though slow to start, once chlorides are introduced, this series of events leads to rapid failure of the metal unless the process is mechanically repaired or properly inhibited.

Galvanic (Dissimilar Metal) Corrosion. Another factor that accelerates corrosion is the difference in potential of dissimilar metals coupled together and immersed in an electrolyte. The following factors control the severity of corrosion resulting from such dissimilar metal coupling:

- **Relative differences in position (potential) in the galvanic series,** with reference to a standard electrode (see Figure 2): the greater the difference, the greater the driving force of the reaction.
- **Relative area or mass relationship between anode and cathode areas:** because the amount of current flow (and therefore total metal loss) is determined by the potential difference and resistance of the circuits, a small anodic area corrodes more rapidly in the presence of a large cathodic area or mass. A larger anodic area or mass relative to the cathode reduces the penetration rate.
- **Intentional polarization of either cathodic or anodic areas:** technology is available to create polarization to reduce the potential difference between components of piping systems, large storage tanks, and various metal structures and thus reduce the rate of attack at points of naturally occurring anodic activity.
- **Ionic content of water or electrolyte:** as the concentration of the ionic components of the electrolyte increases, the resulting higher electrical conductivity increases the rate of galvanic corrosion because the resistance to electron flow through water is reduced.

Stress. Stresses in metallic structures rarely have significant effects on the uniform corrosion resistance of metals and alloys. Stress may be due to mechanical loading, vibration, large or cyclic temperature swings, repeated impact, or chemical or MIC gouging (acting alone or in combination). Stresses in some metals and alloys can cause corrosion cracking when the metals are exposed to specific corrosive environments. The cracking can have catastrophic effects. Almost all metals and alloys exhibit susceptibility to stress corrosion cracking in at least one environment. Common examples are steels in hot caustic solutions, high-zinc-content brasses in ammonia, and stainless steels in hot chlorides. Metal manufacturers have technical details on specific materials and their resistance to stress corrosion.

Temperature. Higher temperatures speed up chemical reactions and weaken protective surface films. Thus, corrosion rates are greatest in areas where temperatures are the hottest. Even temperature variations within a single piece of metal cause the warmer areas to become anodic to the cooler areas and corrode.

An increase in temperature may increase the corrosion rate, but only to a point. Oxygen solubility decreases as temperature increases and, in an open system, may approach zero as water boils. Beyond a critical temperature level, the corrosion rate may decrease because of a decrease in oxygen solubility. However, in a closed system, where oxygen cannot escape, the corrosion rate may continue to increase with an increase in temperature until the oxygen is used up. For those alloys that depend on oxygen in the environment for maintaining a protective oxide film (e.g., stainless steel), the reduction in oxygen content caused by an increase in temperature can accelerate the corrosion rate by preventing oxide film formation.

Temperature can affect corrosion potential by causing a salt dissolved in the environment to precipitate on the metal surface as a protective layer of scale. One example is calcium carbonate scale in hard waters. Temperature can also affect the nature of the corrosion product, which may be relatively stable and protective in certain temperature ranges and unstable and nonprotective in others. An example of this is zinc in distilled water: the corrosion product is nonprotective from 60 to 88°C but reasonably protective at other temperatures.

Pressure. Where dissolved gases such as oxygen and carbon dioxide affect the corrosion rate, pressure on the system may increase their solubility and thus increase corrosion. Similarly, a vacuum on the system reduces the solubility of the dissolved gas, thus reducing corrosion. In a heated system, pressure may rise with temperature. It is impractical to control system corrosion by pressure control alone.

Flow Velocity. The impact of flow velocity on corrosion rate depends on several factors, including

- Amount of oxygen in the water
- General chemical environment (e.g., low pH, high chlorides, high MIC potential due to sulfates)
- Temperature
- Suspended solids in the water
- Type of metal exposed (copper and iron are both susceptible)
- Flow rate

In metal systems where corrosion products retard corrosion by acting as a physical barrier, high flow velocities may remove those protective barriers and increase the potential for corrosion. A turbulent environment may cause uneven attack, from both erosion and corrosion. This corrosion is called **erosion corrosion**. It is commonly found in piping with sharp bends where the flow velocity is high. Copper and softer metals are more susceptible to this type of attack. When flow velocity is low (less than 1 m/s), suspended solids can drop out and cause deposition as well as underdeposit corrosion, including concentration cell corrosion and microbial corrosion. Low flow velocity can also affect transport of corrosion inhibitors and polarization of corrosion cells.

Solids Management. The presence of solids, either suspended or deposited, in the waters of HVAC and process systems can cause abrasion, enhance corrosion, and reduce heat transfer. Suspended solids in flowing waters increase erosion corrosion. Underdeposit corrosion can form under dust, dirt, rust, silt, and other solids introduced into evaporative cooling-water systems; mud, rust, and silts can deposit in closed-loop piping systems, especially in dead legs, storage and heat exchanger tanks, end bells, or cast iron boiler sections. See the section on Deposition, Scale, and Suspended-Solids Control for further discussion of control.

Other major factors affecting corrosion include those discussed in the microbiological and fouling control sections. They center on the contaminants and/or conditions that work to

- Prevent inhibitors from reaching the metal surface
- Remove inhibitors and/or the protective films from the metal surface
- Promote the formation of biofilm and/or deposits under which corrosion can occur

Such conditions are common in systems with high suspended matter and/or poor microbiological control programs, as well as those systems with process contamination and/or poor deposit control programs, including poor corrosion control programs contributing corrosion debris (byproducts) as deposits.

Corrosion Preventive and Protective Measures

Materials Selection. Any piece of heating or air-conditioning equipment can be made of metals that are virtually corrosionproof under normal and typical operating conditions. However, economics usually dictate common material choices. When selecting construction materials, the following factors should be considered:

- Corrosion resistance of the metal in the operating environment.
- Corrosion products that may be formed and their effects on equipment operation.
- Ease of construction using a particular material.
- Design and fabrication limitations on corrosion potential.
- Economics of construction, operation, and maintenance during the projected life of the equipment. Expenses may be minimized in the long run by paying more for a corrosion-resistant material and avoiding regular maintenance.
- Use of dissimilar metals should be avoided. Where dissimilar materials must be used, insulating gaskets and/or applied coatings must be used to prevent galvanic corrosion.
- Compatibility of chemical additives with materials in the system.

Protective Coatings. The operating environment has a significant role in the selection of protective coatings. The suitability of a coating for a particular environment also depends on the surface preparation of the metal to be protected, coating thickness, and coating application technique. Coating durability depends on the adhesion between the coating and the metal. Adhesion depends greatly on surface preparation, including cleaning, degreasing, and the application of primers.

Defects in a coating are difficult to prevent. These defects can be flaws introduced into the coating during application or mechanical damage sustained after application. To maintain corrosion protection, defects must be repaired both in the fabrication process and in the operational environment. Defects in coatings, called **holidays**, can lead to significant localized corrosion of the base metal, most commonly in the form of oxide lifting or cathodic disbondment. **Oxide lifting** occurs when anodic corrosion products accumulate under a coating adjacent to holidays, lifting the coating from the protected surface. **Cathodic disbondment** is the result of the cathodic reduction of dissolved oxygen, which, along with water, migrates under the coating from holidays. Once under the coating, blistering occurs, separating the coating from the protected surface.

Cycles of Concentration. Some corrosion control may be achieved by optimizing the cycles of concentration (the degree to which soluble mineral solids in the makeup water have increased in the circulating water because of evaporation). Generally, adjustment of the blowdown rate and pH to produce a slightly scale-forming condition (see the section on Scale and Deposit Formation Control) results in an optimum condition between excess corrosion and excess scale.

Chemical Methods. Historically, several chemicals have been used to inhibit corrosion. It is important that the inhibitor not interfere with the heat transfer or other functions of the metal. In general, corrosion inhibitors function in one of three ways:

- **Passivation:** these inhibitors form a thin protective oxide film on the metal surface. Nitrites and molybdates work in this way.
- **Precipitation:** these inhibitors contain materials that are precipitated out of solution to form protective films at sites in a corrosion cell. Zinc and phosphates work this way.
- **Adsorption:** these inhibitors are directly adsorbed onto the metal surface, where they form a protective layer. Organics usually function in this manner.

Many inhibitors work best when initially applied at two to three times their normal dosage for several weeks. This **pretreatment procedure** improves corrosion control by rapidly establishing the protective inhibitor films to new metal surfaces. This procedure should also be repeated for start-ups that follow shutdowns and any time pH or other deviations occur.

Film-forming chemical inhibitors reduce or stop corrosion by interfering with the corrosion mechanism. Inhibitors usually affect either the anode or the cathode. The most common inhibitors are molybdates, phosphates, zinc, phosphonates, silicates, nitrite-borates, aromatic azoles, and organics. Although very effective, chromate inhibitors are severely restricted because of their environmental toxicity and federal laws that have banned their use. The most important factor in an effective corrosion inhibition program is consistent control of both the corrosion inhibition chemicals and the key water characteristics. No program will be effective without controlling these factors.

Anodic corrosion inhibitors establish a protective film at the anode. They stop the corrosion cell by blocking the electrochemical reaction at the anodic site and reestablishing polarization. Though these inhibitors can be very effective, they can also be very dangerous if insufficient anodic inhibitor is present, because the entire corrosion potential can be focused at unprotected anode sites. Severe localized pitting attack can occur at unprotected anodic sites if insufficient inhibitor is present.

Cathodic corrosion inhibitors retard oxygen reduction at the cathode and slow overall electrochemical activity. Cathodic inhibitors are not as effective as fully deployed anodic inhibitors, but are commonly used in conjunction with anodic inhibitors to reduce anodic inhibitor dosage requirement.

General corrosion inhibitors protect by forming a film on all metal surfaces, whether anodic or cathodic. Optimum corrosion inhibition is typically obtained through use of one or more anodic and/or cathodic inhibitor(s).

Filming inhibitors are chemical additives that form a molecular film on metals to create a barrier to corrosion (analogous to paint but much thinner). A filming inhibitor bonds to metal through direct molecular charge interaction between the inhibitor and the metal's surface due to opposite electrical charge. Such bonding is quite strong. The class of copper corrosion inhibitors termed azoles is a good example.

Cathodic Protection. Sacrificial anodes reduce galvanic attack by providing a metal (such as zinc or magnesium) that is more active (anodic) in the galvanic series than two metals in a galvanic couple. A sacrificial anode becomes anodic to the surface metal and supplies electrons to relatively cathodic surfaces, thereby limiting the corrosion of the more anodic metal in the galvanic couple. Proper design and placement of anodes is important. When properly used, they can reduce loss of steel from the tube sheet of exchangers using copper tubes. Sacrificial anodes have helped supplement chemical programs in many cooling-water and process water systems.

Impressed-current protection is a similar corrosion control technique that reverses the corrosion cell's normal current flow by impressing a stronger current of opposite polarity. Direct current is applied to an anode (inert [platinum, graphite] or expendable [aluminum, cast iron]), reversing the galvanic flow and converting the steel from a corroding anode to a protective cathode. The method is very effective in protecting essential equipment such as elevated water storage tanks, steel tanks, or buried pipelines and structures.

Corrosion Measurement

Uniform, or general, corrosion can be quantitatively measured. Localized corrosion, by definition, may only be observed in some cases, and is unobservable in most cases. Although the process of localized corrosion itself is not measurable, damage to metals by localized corrosion attack can be assessed through various means, such as eddy current testing of chiller tubes.

Corrosion Coupons. Using corrosion coupons is an accepted method for evaluating uniform corrosion rates in both closed- and open-loop systems. Coupon specimens can sometimes exhibit results of localized attack, most frequently from underdeposit and/or microbiologically influenced corrosion. Evidence of excessive localized attack on a coupon specimen may invalidate the coupon specimen from further inclusion in a test or series evaluation. Careful selection, handling, placement, alignment, and recording of coupon specimens is required for accurate test results. Flow rates and velocities of the fluid through the coupon rack are also essential: velocity of 1 m/s is normally used, and velocities in excess of 1.5 m/s may influence erosion, particularly of soft metals such as copper. Ideally, constant flow should be maintained throughout the test period and variable-flow piping systems should use pressure-independent flow control devices in the coupon rack piping. Coupon specimens should not be disturbed during a test.

Mild steel and copper are commonly used as coupons; admiralty grades of brass and various grades of stainless steel are less common. Regardless, coupon selection should reflect system metallurgy. Placement of the least noble coupon specimen should precede progressively more noble coupons in the rack in the direction of fluid flow.

Because of high initial corrosion rates of the specimen coupon metals, long-duration tests of coupons (60 to 90 days) yield more accurate results in operating systems than shorter tests (15 to 30 days). For comparison and trend analysis, a series of tests should be conducted using the same or similar exposure lengths.

Electronic corrosion sensors or probes can be used to determine uniform corrosion rates in a system or to augment a corrosion coupon program. Many different types of probes and systems are available, including electric resistance and inductive resistance probes. Linear polarization resistance probes give real-time feedback of corrosion rates. However, because rates of uniform corrosion are rarely consistent over time, the readings from linear polarization devices should be monitored or logged to assess trends in the corrosion rates and system stability. Electronic sensors do not exhibit the clear differences between uniform and localized attack that may be observable on coupon specimens. Consult a water treatment professional about the proper type of probe for the specific application and water treatment program.

2.3 BIOLOGICAL GROWTH CONTROL

Heating equipment operates above normal biological temperature limits and therefore has fewer microbial problems. Hydronic systems operated below about 50°C provide conditions for growth and proliferation of microorganisms: abundant water, aeration, a possible supply of nutrients, and surfaces upon which to attach. Nutrients may include inorganic and organic compounds added directly to fight corrosion/scale/foam (e.g. nitrites) or introduced as a process or operational contaminant. Problems associated with the uncontrolled growth of microorganisms in cooling or low-temperature heating water systems can be categorized in the following four areas:

- Plugging and fouling by biological slime (biofilm/biomass)
- Biodeterioration (e.g., wood rot)
- Microbiologically influenced/induced corrosion (MIC)
- Potential health/safety issues (e.g., disease-causing bacteria)

Generally speaking, microbiological activity depends on, and reacts to, the specific conditions of a given water system. Clean, municipally treated, drinking (potable) water likely has extremely low biological activity. Wastewater and sewage are most likely highly biologically active. There are a vast number of different biological entities that can potentially be found in water, and the topic of microbiology is far too complex for involved discussion in this context, but there are a few key microbiological concepts very important to water treatment:

- All practical water systems have some degree of biological activity.
- Carbon is the primary component of biological activity, along with nitrogen and phosphorous.
- Biological activity appears in two forms: freely circulating organisms (planktonic) and organisms attached to surfaces (sessile); the same organism types may be found circulating or in biofilms.
- Sessile organisms form biofilm, which is present in all water conduits to a degree (even human arteries and in the human digestive tract).
- Metabolism is an oxidation/reduction process involving transfer of electrons from an electron source (food/nutrient) to an electron acceptor, most commonly oxygen. Through this process, an organism obtains energy and the building blocks for growth and reproduction.
- Metabolism is fostered by biological catalysts (enzymes).
- Metabolism produces inorganic and organic waste products, which tend to be acidic/corrosive.
- Some organisms (aerobic) require oxygen to maintain metabolism and die or go dormant in the absence of oxygen (**obligate aerobes**).
- Some organisms (anaerobic) only use other electron acceptors (oxidizing agents), such as sulfate, and die or go dormant in the presence of oxygen (**obligate anaerobes**).
- Some organisms can metabolize with or without oxygen (**facultative anaerobes**).
- Chemical/biochemical conditions (e.g., pH, oxygen level, enzyme presence) may be considerably different under biofilm than in general water circulation (bulk phase water).
- Biofilm mass depends on nutrient availability, temperature, and oxygen.
- Small particles of biofilm, containing a large number of cells, freely detach from biofilm to migrate within a system and promote biofilm extension

Biological Categories

Microorganisms found in cooling-water systems generally fall into one of three categories: (1) bacteria, (2) algae, or (3) fungi. These organisms can enter a cooling system in various ways: through the makeup water supply; from the atmosphere during normal operation; or from accumulations of environmental organic matter such as insects, bird droppings, grass clippings, and construction debris. Microbial growth can interfere with a cooling operation by causing fouling or corrosion, and may pose a health hazard.

Bacteria. When considering biological growth in a cooling system, it is important to distinguish between planktonic (free-living) and sessile (attached) microorganisms:

- **Planktonic bacteria** are suspended in the water and sometimes referred to as “free floaters” or “swimmers.” These are aerobic bacteria that thrive in an oxygenated environment. They are not harmful to the cooling system, because they do not directly cause deposits or corrosion, but they can provide nutrients for other microorganisms. Generally speaking, the count of planktonic bacteria increases with increasing organic carbon nutrient as measured by the water’s chemical oxygen demand (COD) or its total organic carbon (TOC) content. In addition, some planktonic bacteria, such as *Legionella pneumophila*, are pathogenic and can present a significant human health risk.
- **Sessile bacteria** are nonswimming (attached) bacteria, sometimes called “stickers.” Sessile organisms cause the majority of the corrosion problems in cooling-water systems, because they are not detected in total bacteria counts and tend to be overlooked until problems arise. They establish themselves by attaching to contact surfaces to develop microcolonies with dense biomatrix

structures. Sessile bacteria types include slime formers and anaerobic (corrosive) bacteria. Slime formers can grow and form gelatinous deposits on almost any surface in contact with the cooling water. These deposits can grow so large that they restrict water flow and interfere with heat transfer; they also may promote underdeposit corrosion. Usually, if slime formers are present in the system, deposits can be felt on the sides of the cooling tower basin just below the water level. Anaerobic bacteria thrive in oxygen-deprived environments and often establish colonies beneath slime deposits or under other types of deposits. Surface microbial measurements using special coupons and/or other monitoring devices can be used to monitor sessile bacteria.

Biological fouling can be caused by a wide variety of organisms that produce biofilm and slime masses. Slimes can be formed by bacteria, algae, yeasts, or molds and frequently consist of a mixture of these organisms combined with organic and inorganic debris. Among the problematic bacterial species, sulfate-reducing bacteria (SRB) and iron-related bacteria (IRB) are the most concerning species (after *Legionella*). Their presence suggests a potential for severe corrosion and fouling. IRB are commonly found in tubercles and account for assimilation of ferrous ions to form mounds of ferric hydroxide, whereas SRB are usually found in the bottom of tubercles with black iron sulfides and sometimes elemental sulfur. The sulfur products give off a rotten egg smell. They signal the presence of acid-producing bacteria and deep penetrating pits.

Because biofilm microorganisms can dramatically enhance, accelerate, and, in some cases, initiate localized corrosion (pitting), they are tested and monitored for critical heat transfer operations. Monitoring methods include the following:

- Visual and tactile inspection
- Water analysis for ammonia, chemical oxygen demand (COD), total organic carbon (TOC), adenosine triphosphate (ATP), bacteria speciation’s, and planktonic plate counts
- Online biofilm monitors, including corrosion-resistant coupons, disks/plugs, electrochemical sensors, thermal gradient sensors, and sidestream devices to track hydrodynamic pressure differential and heat transfer

Microorganisms can influence localized corrosion directly by their metabolism or indirectly by the deposits they form. Corrosion may not be mediated by simply killing the planktonic microorganisms. Biofilm removal through chemical and/or mechanical cleaning is usually necessary. Corrosion can be substantially mediated by inhibiting microorganism metabolism with proper choice of a biocide program.

Algae uses energy from the sun to convert bicarbonate or carbon dioxide into biomass. Algal mass can block piping, distribution holes, and nozzles.

Control Measures

Eliminating sunlight from wetted surfaces such as distribution troughs, cooling media, and sumps significantly reduces algae growth. A distribution deck cover, which drastically reduces the sunlight reaching the algae, is one of the most cost effective control devices for a cooling tower.

Eliminating dead legs and low-flow areas in the piping and the cooling loop reduces biological growth in those areas. Careful selection of materials of construction can remove nutrient sources and environmental niches for growth and also helps mitigate corrosion. Maintaining a high-quality makeup water supply with low bacterial counts reduces biological growth. Equipment should be designed with adequate access for inspection, sampling, and manual cleaning.

Mechanical aids include submicron filter media, fine strainers, scrapers/brushes, and flow and temperature control. Nonchemical treatment approaches include biocidal paint, ultraviolet light, sonication with ultrasound, and modification of contact surface material.

Sometimes, effective control of slime and algae requires a combination of mechanical and chemical treatments. For example, when a system already contains a considerable accumulation of slime, a preliminary mechanical cleaning makes the subsequent application of a biocidal chemical more effective in killing the growth and more effective in preventing further growth. A build-up of scale deposits, corrosion products, and sediment in a cooling system also reduces the effectiveness of chemical biocides. Routine disinfection of cooling towers, including the use of high-level chlorination and a biodispersant, helps control *Legionella* as well as other microorganisms. Sidestream filtration and monitoring devices such as corrosion coupons, test spools, and biofilm sensors can enhance control of biofilm growth. Alternating two different types of biocide can overcome resistance developed by bacteria against a single biocide. The two different types should include two different kill mechanisms.

More cooling-water treatment programs fail because of lack of microbiological control than from any other treatment problem. Scale, corrosion, and fouling are often symptoms of poor microbiological control. Corrosion often occurs under bacterial slime layers. Inorganic foulants are trapped in slime layers, compounding problems. The effects of uncontrolled microbiological activity and fouling may negate the effectiveness of even the best programs for scale prevention and corrosion inhibition. Appropriate biocides must be selected to handle the most prevalent problems first, perhaps in conjunction with dispersants to penetrate and remove deposits. Effective microbiological control is an absolute necessity for a open cooling-water program to be successful.

An effective microbicide (biocide) program has four steps:

- Identify the types and concentrations of microorganisms present in the system.
- Select proper biocides based on system design, discharge restrictions, and types of microorganisms.
- Implement proper application, dosage, contact time, and control of the selected biocides.
- Perform seasonal disinfection cleanings.

Microbicides. Chemical biocides used to control biological growth in cooling systems fall into two broad categories: oxidizing and nonoxidizing. There are numerous options commercially available. Some address a broad spectrum of organisms, whereas others are used to target specific types of organisms such as algae, SRBs, or fungi. Selection of the biocides should always be left to water treatment professionals.

Effective biocide treatment is usually a combination of an oxidizing biocide with a nonoxidizing biocide. The oxidizer may be fed continuously or intermittently. Nonoxidizing biocide may be introduced with either oxidizing biocide strategy. Oxidizing biocides provide quick-kill results and are best used to control biofilm; nonoxidizers are relatively slow acting and best used to suppress MIC activity. A biodispersant (surfactant) is often also incorporated to enhance biocide performance.

Oxidizing Biocides. These substances (chlorine, bromine, ozone, iodine, chlorine dioxide, and halogen-releasing compounds such as bromochlorodimethylhydantoin [BCDMH or BCD]) are among the most effective biocide chemicals used in water treatment. However, they are not always effective or appropriate for use in cooling-water systems with high organic loading, high temperatures, and/or systems with corrosion or contaminant (compatibility) issues. Chlorine dioxide is probably the one oxidizing biocide least affected by high chemical oxygen demand (COD) and total organic carbon (TOC). In air washers, the odor may become offensive to building/facility occupants, or the exit air (to the building/facility) may be too corrosive for the environment. In wooden cooling towers, high levels of oxidizing biocides can cause delignification.

Overdosing of oxidizing biocides may cause corrosion issues with metallic components in any system. Accurate feed and control of oxidizing biocides for the most effective, efficient, and safe application requires using appropriate feed and control equipment. In many systems, the most effective use of oxidizing biocides is to maintain a constant, low-level residual in the system. However, if halogen-based oxidizing biocides are fed intermittently (slug dosed), a pH below 8 is most advantageous, because of the pH-dependent dissociation curve where the halogen (particularly chlorine) is more prevalent in the more biocidal active (hypohalous acid) form. The residual oxidizing biocide concentration should be tested on a routine basis. Most halogenation programs can benefit from using dispersants or surfactants to penetrate and break up microbial masses and biofilm.

Chlorine has been the oxidizing biocide of choice for many years, either as chlorine gas, or in liquid form as sodium hypochlorite. Other forms of chlorine are available, such as powders, pellets, or calcium hypochlorite sticks; chlorine-releasing compounds (e.g., chloramines, chloroisocyanurates). It can also be produced electrolytically with brine on site. Use of chlorine gas is declining because of health and safety concerns involved in handling it and because of environmental pressures concerning the formation of EPA-regulated halogenated disinfection by-products. In hot-water systems, including potable hot-water systems, chlorine loses efficacy up to 70% at temperatures of 60 to 71°C.

Bromine is usually produced through reactions of an oxidizer such as sodium hypochlorite with sodium bromide on site, or by release from solids of chlorobromohydantoin compounds. Bromine has certain advantages over chlorine: it is less volatile, and bromamines break down more rapidly than chloramines in the environment. Also, when slug feeding biocide in high-pH systems, hypobromite ions may have an advantage because their biocidal power is better than that of hypochlorite ions. This effect is less important when biocides are fed continuously at low dosage. Like chlorine, bromine can affect the environment with formation of EPA-regulated halogenated disinfection by-products.

Ozone is a gaseous form of oxygen consisting of three oxygen atoms (O_3). As a biocide, it has several advantages compared to chlorine: it does not produce halogenated disinfection by-products, it breaks down to nontoxic compounds rapidly in the environment, it is more potent than chlorine in destructing biofilms, and it requires significantly less chemical handling. The disadvantages of ozone are its short half-life, instability for storage, and reaction by-products that are more biodegradable than their precursors. Use of ozone-generating equipment in an enclosed space requires safety protocols to protect operators from the toxic gas.

Water conditions should be reviewed to determine the need for scale and corrosion inhibitors and then, as with all oxidizing biocides, inhibitor chemicals should be carefully selected to ensure compatibility. To maximize the biocidal performance of ozone, the injection equipment should be designed to provide adequate contact of the ozone with the circulating water. In larger systems, ensure that the ozone is not depleted before ozonated water has circulated through the entire system.

Iodine is provided in pelletized form, often from a rechargeable cartridge. Iodine is a relatively expensive chemical for use on cooling towers and is probably only suitable for use on smaller systems.

Chlorine dioxide gas is effective in low concentrations (0.2 to 0.5 mg/L residual). It must be generated on site. Unlike ozone, it is not affected by pH, and has a longer half-life and therefore a higher penetrating power because of lower oxidizing potential. It is usually generated with sodium chlorite precursor by either an electrolytic generator or reactions with acids. Its drawbacks are instability in storage, costly generating equipment, and precursors and acid salt in the end-product solution.

Hydrogen peroxide (H_2O_2) is a liquid that is usually available in concentrations of 50% or less, by mass, in water. Hydrogen peroxide is considered one of the most environmentally friendly oxidizing biocides, because it degrades to water; however, concentrated hydrogen peroxide reacts in a violent manner when it comes into contact with organic chemicals and materials.

Nonoxidizing Biocides. These biocides destroy organisms either by poisoning the organism, blocking its ability to uptake energy, or disrupting its protective coating (cellular membranes) and exposing the organism to a hostile environment. Most nonoxidizers are also known as **biostats,** which means they inhibit growth of microorganisms.

When selecting a nonoxidizing biocide, many factors must be considered for its effective and efficient use, including system pH and relevant water chemistry, chemical compatibility with other treatment products and system contaminants, and the system turnover rate, or holding time index (HTI), for adequate microbial contact time. Common nonoxidizing biocides include the following:

- Quaternary ammonium compounds
- Polyquats
- Methylene bis(thiocyanate) (MBT)
- Isothiazolones
- Tetrahydro-3,5-dimethyl-2H-1,3,5-thiadiazine-2-thione (Thione)
- Tributyl tetradecyl phosphonium chloride (TTPC)
- Bis(tributyltin) oxide (TBTO)
- Carbamates/Dithiocarbamates
- 2-(Decylthio)ethanamine (DTEA)
- Glutaraldehyde
- Dodecylguanidine (Guanides)
- Tetrakis(hydroxymethyl)phosphonium sulfate (THPS, TKHPS)
- 2-(tert-butylamino)-4-chloro-6-(ethylamino)-s-triazine (TBZ,Tertbuthylazine)
- 2-2-Dibromo-3-nitrilopropionamide (DBNPA)
- 2-Bromo-4-hydroxyacetophenone (BHAP)
- 2-Bromo-2-nitropropane-1,3-diol (Bronopol)
- Bromo-nitrostyrene (BNS)
- Proprietary blends
- Aldehyde release treatments
- Organosulfur compounds

How nonoxidizing biocides are fed is important. Sometimes, the continuous feeding of low dosages is neither effective nor economical. Slug feeding large concentrations to achieve a toxic level of the chemical in the water long enough to kill the organisms present can show better results. Water blowdown rate and biocide hydrolysis (chemical degradation) rate affect the required dosage. The hydrolysis rate of the biocide is affected by the type of biocide, along with the temperature and pH of the system water. Dosage rates are proportional to system volume; dosage concentrations should be sufficient to ensure that the contact time of the biocide is long enough to obtain a high kill rate of microorganisms before the minimum inhibitory concentration of the biocide is reached. The period between nonoxidizing biocide additions should be based on the system half-life, with sequential additions timed to prevent regrowth of bacteria in the water. When two nonoxidizing biocides are used, it is important to select the two biocides based on two different kill modes to overcome resistance developed by microbes.

Other Biocides. Ultraviolet (UV) irradiation deactivates microorganisms as the water passes around a quartz tube containing the UV lamp. The intensity of the light and thorough contact with the water are critical in obtaining a satisfactory kill of microorganisms. Suspended solids in the water or deposits on the quartz tube significantly reduce the effectiveness of this treatment method. Therefore, a filter is often installed upstream of the UV lamp to minimize these problems. Because ultraviolet light leaves no residual biocide in the water, sessile organisms and organisms that do not pass the light source are not affected by the ultraviolet treatment. Ultraviolet irradiation may be effective on humidifiers and air washers where the application of biocidal chemicals is unacceptable and where 100% of the recirculating water passes the lamp. It is less effective where all microorganisms cannot be exposed to the treatment, such as in cooling towers. Ultraviolet lamps require replacement after approximately every 9000 h of operation because, although they will light much longer, the quartz glass slowly becomes opaque to UV light.

Copper (Cu) and silver (Ag) ions can effectively control microbial populations in water systems when the ionization systems that produce them are properly maintained, operated, and applied. Ions are released into the water via electrochemical means to generate 0.4 to 0.8 mg/L of copper and/or 40 to 80 μg/L of silver. The ions assist in the control of bacterial populations. Copper, in particular, effectively controls algae.

Handling Biocides. All biocides must be handled with care to ensure personal safety. In the United States, cooling-water biocides are approved and regulated through the EPA and, by law, must be handled in accordance with labeled instructions. Maintenance staff handling the biocides must read the safety data sheets (SDS) and be provided with all appropriate safety equipment to handle the substance. An automatic feed system is preferred, to minimize and eliminate handling of biocides by maintenance personnel.

Legionella and Legionnaires' Disease

Legionellosis is any disease caused by *Legionella* bacteria. **Legionnaires' disease**, a form of legionellosis, is a potentially fatal, pneumonia-like illness primarily caused by *Legionella pneumophila* serogroup 2, one of the more than fifty known species of *Legionella*.

Legionella are common warm-water microorganisms that are mostly found in surface waters (lakes, ponds, rivers, streams) but can also be found in groundwater sources, including some soils. They tend to grow in biofilm or slime on the surfaces of lakes, rivers, and streams. *Legionella* adapt to conditions in water distribution systems, thereby sometimes escaping municipal water plant disinfection (chlorination). They can, therefore, be found in domestic (potable) water plumbing and associated building water systems such as cooling towers, spas, water fountains, and other water-use systems. Within these systems, *Legionella* can find favorable conditions for growth and amplification, and pose a risk for human disease.

The mere presence of *Legionella* does not necessarily result in disease. Several conditions and factors must occur: primarily, there must be a sufficient quantity and/or virulent form of the bacteria made transmittable and then transmitted to a susceptible host. Transmission occurs when a host inhales tiny water droplets (mists or vapor aerosols) containing *Legionella* from a water-aerosolizing source. Aspiration of water can also occur during normal drinking and swallowing due to choking or gag reflex. Inhalation can bring infectious *Legionella* to the deep, distal parts (alveoli) of the lungs, where they take over and promote the pneumonia of Legionnaires' disease. The dose of *Legionella pneumophila* (or other species of *Legionella*) required to infect humans is not known, and is most probably influenced by host susceptibility.

Legionella grow well and amplify in warm water environments and systems that provide favorable conditions for bacterial growth and the formation of biofilm. The optimum temperature range for growth is 32 to 41°C. The subsequent use of water from such systems harboring *Legionella*, through faucets, shower sprays, humidifying, aerosolizing (misting) devices, or other spray or drift mechanisms of the system may transmit the bacteria to susceptible hosts.

Legionella pneumophila was first identified in 1977, following an outbreak of disease associated with a Philadelphia host hotel for an American Legion bicentennial convention in 1976. Since then, surveillance systems and research studies have been established around the world. In recent years, with improved capabilities and changes in clinical methods of diagnosis, there has been an upsurge in reported cases in many countries. Environmental studies continue to provide information and identify novel sources of infection, leading to regular revisions of guidelines and regulations. As of reports in 2014, an estimated 8000 to 18 000 people are hospitalized with Legionnaires' disease each year in the United States, according to the Centers for Disease Control and Prevention (CDC), and the disease has a 5 to 30% mortality rate (www.cdc.gov/legionella/about/).

Outbreaks of Legionnaires' disease receive media attention. However, this disease more often occurs as single, isolated cases not associated with any recognized outbreak. When outbreaks occur, they are usually in the summer and early autumn, though cases may occur at any time of year.

Water treatment microbial control programs should also include a risk assessment for *Legionella* control and disease prevention. This includes the effectiveness of treatment products and the program to control *Legionella* and the conditions favorable for its growth and amplification, including the accumulation of biofilm (slime/biomass), the presence of amoebae and other protozoans that harbor it, as well as the potential of the water system to produce aerosols and provide routes of aerosol transmission to susceptible human populations.

See ASHRAE *Standard* 188-2015 and ASHRAE *Guideline* 12-2000 for further information.

2.4 NONCHEMICAL AND PHYSICAL WATER TREATMENT METHODS

Nonchemical water treatment has been used for boiler water, cooling water, potable water, and other process applications for decades. There are multiple classifications of such treatment methods and equipment systems. Adherence to manufacturers' recommendations and the proper application of these technologies is critical to achieving successful results. As with traditional methods of water treatment, the ability to achieve successful results should be adequately evaluated for the water treatment system as well as regularly monitored for effective control of scale, corrosion, and biological contamination. Water treatment technologies, published papers, and case histories should be evaluated in light of water supply chemistry, operating environment, duty, and industry standard performance metrics.

Several nonchemical and physical water treatment equipment technologies are classified in the following paragraphs, along with brief summaries of their basic claims and theoretical mechanisms of action.

Magnetic, or **fixed-field magnetic, systems** are designed to cause scale-forming minerals to precipitate on suspended solids as opposed to heat exchanger surfaces. This mechanism produces nonadherent particles, often classified as the aragonite form of calcium carbonate versus the hard, adherent calcite. The precipitated particles can then be removed by blowdown, mechanical means, or physical flushing.

Electromagnetic systems induce either a constant or variable magnetic flux density (or both), thereby inducing a localized, variable electric field in the bulk water. **Pulsed-power** and **electrodynamic** field systems generate a combination of variable magnetic flux density with a variable electric field at frequencies greater than the incoming line signal. The induced electric fields alter the surface charge on suspended solids and particulate and force precipitation on these surfaces in the bulk water.

Cavitation systems can cause formation and sudden collapse of low-pressure bubbles in a water stream by means of a mechanical force. The collapse of the bubbles imparts a shock wave and resultant heat locally within the water flow. The energy created during the implosion of bubbles promotes precipitation of minerals in the water stream.

Ionization rods create a static electric field that disperses scale-producing foulants, thereby inhibiting precipitation of minerals on equipment surfaces. The dispersion created by the device's electric field also inhibits biological growth.

Electrolysis systems pass an electric current between two electrodes. Precipitation of minerals occurs at the cathode. Biological growth is inhibited by formation of chlorine gas at the anode; the gas combines with water to form hypochlorite.

Ultrasonic systems impart high-frequency acoustic energy in the ultrasonic range to a stream of water. The sound wave produced by ultrasonic devices can cause mechanical damage to bacteria cell walls. Similar to cavitation devices, ultrasonic energy can also produce low-pressure bubbles, which can collapse and damage bacterial cell walls.

Ultraviolet light systems irradiate a water stream with ultraviolet light. Exposing microorganisms to ultraviolet light inhibits their biological growth. The ability to effectively and efficiently control microbial populations throughout a cooling-water system with a point-of-use ultraviolet light system must be evaluated for any given system.

Ozone systems inject ozone created by coronal plasma, by ultraviolet lamps, or by chemical reaction, into the bulk water. When contact is made with microorganisms, ozone can be a very effective disinfectant for their control. However, it is difficult to maintain an effective residual of ozone throughout a cooling-water system because of its high reactivity and fast dissipation. Ozone is very volatile and can be lost from the system as the water passes through the cooling tower fill. Successful application of ozone for biological control requires that sufficient ozone-generating capacity be provided to sustain a level of ozone residual that will control microbial contamination throughout the cooling-water system.

ASHRAE Research Projects

ASHRAE research projects RP-765 (Nasrazadani and Chao 1996) and RP-747 (Gan et al. 1996) found ozone only marginally effective in scale and corrosion inhibition, respectively. Ozone has been shown to have a very limited and unpredictable effect on calcium carbonate scale, and a limited effect to inhibit corrosion of most metals. It provides some reduction of mild steel corrosion, but increases the corrosion rates of copper and copper alloys. It is also known to attack galvanized steel, and increasing the level of ozone in water increases the corrosiveness of the water.

ASHRAE research project RP-1155 (Cho 2002) studied physical water treatment with respect to scale prevention and/or mitigation. For the study, a physical water treatment (PWT) device was defined as a nonchemical method of water treatment for scale prevention or mitigation. Bulk precipitation on colloidal surfaces was proposed as the mechanism of scale prevention. Three different PWT devices (permanent magnets, a solenoid coil device, and a high-voltage electrode) were tested under laboratory conditions. Fouling resistance data obtained in a heat transfer test section supported the benefit of all three devices when configured in optimum conditions in the laboratory-scale test system.

ASHRAE research project RP-1361 (Vidic et al. 2010) studied physical water treatment and microbial control. In this study, a PWT device was defined as a nonchemical method of water treatment for microbial control. Five different PWT devices (magnetic, pulsed electric field, electrostatic, ultrasonic, and hydrodynamic cavitation) were tested in a pilot-scale cooling tower. No statistically significant difference in planktonic and sessile microbial concentrations was observed in the (test) pilot-scale cooling tower for any of the devices, as compared to an untreated control tower.

Copies of ASHRAE research project final reports can be obtained from technologyportal.ashrae.org, and are free to ASHRAE members.

2.5 BOILER WATER SYSTEMS

Steam and hot-water systems can be classified into three broad groups: (1) steam and hot water for space heating and humidity control in commercial and residential HVAC systems and many industrial plants; (2) steam for industrial process heating and for use as a process reactant in chemical plants, paper mills, etc.; and (3) steam to drive turbines for electric power generation. The American Society of Mechanical Engineers (ASME) classifies boilers into three basic types: fire-tube, water-tube, and electric (ASME 2015). Boilers are also classified according to pressure, materials of construction, size, heat source, or circulation. A general understanding of boiler design and classifications, as well as requirements of the system, is essential to ensure the system receives proper care to maintain reliability. One of the most important classifications of boiler systems is the end use of the steam or hot water. The focus of this section is on steam and hot-water boiler systems for space heating and humidity control in commercial and residential HVAC systems and some industrial plants.

Hot-water heating and low-pressure (103 kPa or less) steam systems with >95% condensate return are similar to closed-loop cooling systems, except with reversed heat-exchange processes. The hot water or steam adds heat to an HVAC system or to an industrial process. The hot-water temperature is maintained either by heat exchange with a steam source or electric elements, or by direct firing in a hot-water-heating boiler.

Steam generators range from small heating boilers to very large and complex systems generating steam for industrial plants and electric utility stations. All steam boilers operate on certain basic principles. Water is heated to produce steam at a desired pressure. The steam does work by heating a building or a commercial/industrial process. To conserve water and energy, waste steam is condensed after use and a portion of the condensate is returned to the boiler as feedwater, along with required fresh makeup water. All parts of this system, including feedwater preparation, the boiler, and the condensate system, require chemical treatment to protect the equipment, maintain boiler efficiency, and prepare steam with the required quality and purity.

Selection of Water Treatment. As discussed in previous sections, many methods are available to prevent or correct water-caused problems. Selection of the proper water treatment method, and the chemicals and equipment necessary to apply that method, depend on many factors. The chemical characteristics of the water, which change with the operation of the equipment, are most important. Other factors contributing to the selection of proper water treatment are

- Economics
- Chemistry control mechanisms
- Dynamics of the operating system
- Design of major components
- Number of operators available
- Training and qualifications of personnel
- Preventive maintenance program
- Control instrumentation and remote monitoring

The two most significant factors in setting up an economically viable and effective cooling water treatment program are the chemical properties of the water supply and cooling capacity (i.e., rated tonnage).

Open Systems

Systems classified as open are routinely or continuously in contact with the atmosphere. Examples include steam systems which breathe in and exhale air, and condenser water systems that spray the water in an airstream. Open systems are constantly exposed to oxygen (a major corrosive element), local trace gases, and debris entrained in the air. These systems require significant effort and cost to establish and maintain desired conditions.

Steam Systems

Scale in boilers is a direct result of precipitation of the calcium, magnesium, iron, and silica from the boiler feedwater. Scale can be prevented by removing a portion of the scale-forming ingredients prior to the boiler with external equipment, or within the boiler itself with internal boiler water treatment.

One of the most troublesome deposits frequently encountered in steam boilers is iron and combinations of iron with calcium and phosphate used in boiler water treatment. These sticky, adherent sludge deposits are caused by excessive amounts of iron entering the boiler with the feedwater. This iron is in the form of iron oxide or iron carbonate corrosion products. It is a result of corrosion taking place in sections prior to the boiler, such as steam and condensate lines, condensate receivers, deaerators, and boiler feedwater lines. A program for preventing scale deposits must include treatment to prevent this troublesome type of sludge deposit.

Many treatment methods are available for steam-producing boilers; the method selected depends on

- Makeup water quality
- Makeup water quantity (or percentage condensate return)
- Pretreatment equipment
- Boiler operating conditions
- Steam purity requirements
- Economics

When possible, the removal of scale-forming minerals and other objectionable minerals from the water before it enters the boiler system is preferred to internal boiler treatment. The internal boiler treatment program should be designed as a polishing tool to ensure clean heat transfer surfaces.

External Boiler Water Pretreatment (Water Conditioning)

The selection of the proper pretreatment system depends on boiler type, size, source water mineral content, and the desired operator involvement in system operation. This section discusses typical pretreatment solutions for steam boilers in HVAC applications. Some of the pretreatment system components will have a positive effect on water and energy usage. Some components will also require chemical additives and conditioners as consumables. Selection criteria should include the effects of all components, as well as local water type and sanitary discharge regulations.

The most common sources of corrosion in boiler systems are dissolved gases: oxygen, carbon dioxide, and ammonia. Of these, oxygen is the most aggressive potentially leading to pitting of boiler tubes. Dissolved oxygen is undesirable because it can cause major corrosion damage in the boiler system and greatly increases treatment chemical requirements. The importance of eliminating oxygen as a source of pitting and iron deposition cannot be overemphasized. Even small concentrations of this gas can cause serious corrosion problems.

Deaerators and feedwater heaters function on the principle that the dissolved gases are decreasingly soluble as the temperature of their solution is raised. However, even the most efficient deaerators cannot remove all of the dissolved oxygen. Although deaerators can reduce dissolved oxygen to about 7 μg/L, trace amounts are still present and can cause corrosion. Chemical oxygen scavengers then must be added to the feedwater, preferably in the storage section of the deaerator or feedwater tank, to remove the final traces of dissolved oxygen. The most commonly used oxygen scavenger is sodium sulfite. It is very effective and can be easily measured in the water.

In smaller steam boilers, mixing of makeup water and condensate normally occurs in an unpressurized vessel called a feedwater tank. Although much less sophisticated and efficient than a deaerator, a feedwater tank serves much the same purpose, which is to preheat the feedwater and promote removal of harmful dissolved gases. Whether a deaerator or a feedwater tank is used, its proper operation is important to the overall success of the water treatment program. Unless proper treatment measures are taken, dissolved gases can cause major corrosion damage in feedwater lines, economizers, boiler internals, steam-operated equipment, and condensate return piping.

Types of pretreatment for boilers include the following:

- **Ion Exchange Resin.** Ion exchange resin allows for specific ions or groups of ions to be removed from the water and be exchanged for another ion that will have a less negative effect on the steam system. These resin beads then require regeneration to remove the objectionable ions to drain and replenish the reaction sites with the appropriate ions. Ion exchange resins can be classified in two groups: anion exchanger and cation exchanger.
  - **Zeolite softeners** are cation exchangers that remove calcium and magnesium (and some dissolved iron) from the water and replace them with sodium ions, effectively removing the scaling minerals from the makeup water. The resin is regenerated with sodium chloride salt (NaCl) solution. It is also possible to regenerate with potassium chloride salt (KCl) to minimize sodium effluent during regeneration. Water softeners have negligible effect on the total dissolved solids of the water.
  - **Chloride cycle dealkalizers** are anion exchangers that remove carbonates from the water and replace them with chloride ions. This minimizes carbonic acid formation in the condensate network, and reduces chemical consumption. Reducing the carbonate alkalinity of the incoming water may also offer opportunities to reduce boiler blowdown rates, resulting in water and energy savings. The resin is regenerated with sodium chloride salt (NaCl) solution and sodium hydroxide (caustic soda, NaOH). A chloride cycle dealkalizer must be installed downstream of a water softener.
- **Deionizers** use both anion and cation resin. Ions are removed through a mixed-bed deionizer or individual anion and cation exchanger vessels in series. Deionization removes virtually all anions and cations in the incoming water, replacing them with H^+ and OH^-, which in turn form water. Deionizers are often regenerated off site by a third-party service, although large systems (microchip manufacturers) may have automatic regeneration with acid and caustic soda, which requires increased operator involvement. The water produced by a deionizer is extremely low in dissolved solids and offers significant reductions in boiler blowdown requirements, leading to water and energy savings. This water quality also minimizes carbonic acid formation in the condensate network, and reduces chemical consumption. Deionizers are typically seen in clean-steam applications.
- **Membrane separation** allows water to pass through a semipermeable membrane while preventing most dissolved minerals from passing through with the water. This is done by cross-flow filtration. The dissolved mineral ions are flushed to drain via a concentrate (reject) stream. Membrane separation increases total pretreatment system water input by 20 to 50% because of the

increased water requirement of the concentrate stream, although it may be possible to reuse this stream for other applications on site.

- **Reverse osmosis (RO)** produces the highest quality (lowest dissolved mineral content) of all membrane separation technologies. Typical removal rates are >95%. The water quality produced by RO systems is very low in dissolved solids and offers significant reductions in boiler blowdown requirements, leading to energy savings. This water quality also minimizes carbonic acid formation in the condensate network, and reduces chemical consumption.
- **Mechanical deaeration (deaerators)** (1) remove oxygen, carbon dioxide, and other noncondensable gases from steam boiler feedwater; and (2) heat the incoming makeup water and return condensate to an optimum temperature for minimizing solubility of the undesirable gases, providing the highest temperature water for injection to the boiler. A deaerator is a vessel specifically designed to preheat the feedwater to remove dissolved gases, primarily oxygen.

Boiler Feedwater

After pretreatment to remove hardness and other problem impurities, the makeup water is combined with returned condensate to become boiler feedwater. In larger boilers, the mixing of makeup water and condensate normally takes place in the deaerator.

Makeup water introduces appreciable amounts of oxygen into the system. Oxygen can also enter the feedwater system via the condensate return system. Possible return line sources are direct air leakage on the suction side of pumps, systems under vacuum, the breathing action of closed condensate receiving tanks, open condensate receiving tanks, and leakage of non-deaerated water used for condensate pump seal and/or quench water.

Boiler Internal Treatments

Even after the best external treatment of the water source, boiler feedwater (including return condensate) still contains impurities that could adversely affect boiler operation. Internal boiler water treatment is then applied to minimize potential problems and avoid catastrophic failure, regardless of external treatment malfunction.

Prevention of Scale. After the feedwater is pretreated, scale is controlled with phosphates, acrylates, polymers, chelates, and coagulation programs. Chelates, polymers, and acrylates work by binding the hardness, thereby preventing precipitation and scale formation. Phosphates and coagulation programs work in combination with sludge conditioners (tannins, lignin, starches, and synthetic polymers) to produce a softened precipitate that is removed by blowdown of the steam boiler.

Prevention of Corrosion and Oxygen Pitting. Although steam boilers can corrode as the result of low boiler water pH or misuse of certain chemicals, corrosion is primarily caused by oxygen. After mechanical deaeration, boiler feedwater must be treated chemically to remove the final traces of dissolved oxygen in the feedwater. An oxygen scavenger, such as catalyzed sodium sulfite, should then be fed to react with the residual feedwater oxygen. Oxygen scavengers provide added protection not only to the boiler, but also to the steam and condensate systems. Oxygen at levels as low as 0.005 mg/L can cause oxygen pitting in the steam and condensate system if not chemically reduced by oxygen scavengers.

Steam Boiler Lay-Up. Most of the corrosion damage to boilers and associated equipment occurs during idle periods. The corrosion is caused by the exposure of wet metal to oxygen in the air or water. For this reason, special precautions must be taken to prevent corrosion while boilers are out of service.

Although sulfite introduction to remove oxygen is the most common form of treatment for steam boilers, it is not always the most effective for various operational reasons that prevent adequate maintenance of the required continuous sulfite residual. Sulfite maintenance can be particularly difficult in low-pressure heating boilers, most often operated without feedwater deaeration. To deal with this situation, boiler corrosion-inhibitor treatment strategies have been developed that do not primarily remove dissolved oxygen, but act to restore a stable protective oxide surface film on steel. Various chemicals such as nitrite, chromate, molybdate, hydrazine, erythorbate, diethyl-hydroxylamine and others act to prevent oxygen attack by creating a stable oxide film on steel.

Wet Boiler Lay-Up (Steam Boiler). This is a method of storing boilers full of water so that they can be returned to service. It involves adding extra chemicals (usually something to increase alkalinity, an oxygen scavenger, and a dispersant) to the boiler water. Along with the boiler water additives, vapor-phase corrosion inhibitors can also be used for wet storage. The water level is raised in the idle boiler to eliminate air spaces, and the boiler is kept completely full of treated water. Superheaters require special protection. Nitrogen gas can also be used on airtight boilers to maintain a positive pressure on the boiler, thereby preventing oxygen in-leakage.

Dry Boiler Lay-Up. This method of lay-up is usually for longer boiler outages. It involves draining, cleaning, and drying the boiler. A material that absorbs moisture, such as hydrated lime or silica gel, is placed in trays inside the boiler. Vapor-phase corrosion inhibitors can also be used for dry storage. The boiler is then sealed carefully to keep out air. Periodic inspection and replacement of the drying chemical are required during long storage periods.

Boiler Blowdown Control. As a steam boiler produces steam, the dissolved and suspended solids, as well as the nonvolatile treatment chemicals, stay in the boiler (bulk water). As more steam is produced and feedwater is introduced, the concentration of these dissolved and suspended solids increases (and with it, sludge formation). The increased alkalinity and dissolved minerals decrease boiler water surface tension. This leads to the formation of water droplets that can carry over with the steam, causing wet steam. Wet steam can cause water hammer, erosion corrosion of the steam network, and increased condensate drainage from drip traps. Implementing blowdown can decrease the concentration of dissolved and suspended solids. There are two types of boiler blowdown: continuous (or surface) blowdown and manual (or bottom) blowdown.

Continuous (or surface) blowdown uses a calibrated valve and a blowdown tap near the boiler water surface. As the name implies, it continuously takes water from the top of the boiler (just beneath the surface water level) at a predetermined rate. Continuous blowdown is not included on all boilers. Dissolved solids tend to concentrate near the water surface in the steam drum. Therefore, surface blowdown is most effective in reducing the concentration of dissolved solids.

By code (ASME 2015), all steam boilers must include a means for **manual (bottom) blowdown**. Manual blowdown allows removal of solids that settle at the bottom (mud-drum or belly) of the boiler. Bottom blowdown is used to remove precipitated sludge from the boiler mud drum. There is no absolute rule for frequency of bottom blowdown. It can vary between once per shift to once or twice a week. The required frequency depends on the boiler, feedwater quality, and type of chemical treatment program. A precipitating treatment program reacts with hardness in the feedwater to form a sludge that must be removed through bottom blowdown. A solubilizing treatment program keeps hardness in solution and creates little in the way of sludge.

Boiler Blowdown Guide. Blowdown results in the loss of heated water and treatment chemicals. Economical operation requires careful control of blowdown to maintain safe solids levels, while minimizing both heat and chemical losses. Contact the boiler manufacturer for the recommended blowdown procedures. If none are available, the following can be used as a general guide:

1. Open the blowdown valve nearest the boiler (note that this should be a quick-opening valve)
2. Slowly open the downstream valve until the line is hot
3. Continue opening the downstream valve at a steady rate to drop the water level in the sight glass by approximately 13 mm
4. Close the downstream valve quickly, making sure that the hand wheel is backed off slightly from fully closed to relieve any potential strain on the valve packing
5. Close the valve nearest the boiler

Manual blowdown should be done with the boiler under a light load when possible.

Controlling the continuous blowdown rate is important to prevent the problems associated with high levels of dissolved and suspended solids, while minimizing the amount of water energy and treatment (waste) being sent to drain. Automated boiler blowdown controllers can measure the conductivity of the boiler water (a proxy for total dissolved solids), and control blowdown valves to maintain the correct boiler water cycles of concentration. These systems also have data-logging capability and communication functionality with cloud-based applications and building automation systems.

Steam and Condensate Network

Other problems associated with steam and condensate systems include general corrosion and pitting corrosion. Naturally occurring bicarbonate alkalinity in the boiler water breaks down to form carbonate ions and carbon dioxide (CO_2). CO_2 leaves the boiler with the steam. As the steam condenses and becomes condensate, it dissolves some of the CO_2 to form carbonic acid, lowering the condensate pH. To prevent condensate corrosion, these systems must be protected from acidic conditions and oxygen, which lead to general and pitting corrosion respectively. Protection can be mechanical (deaeration/ dealkization), chemical, or include both means. The following methods are commonly used for condensate system protection.

Protection from General Corrosion.

Mechanical. Reduce alkalinity from boiler feedwater to minimize the amount of CO_2 in the system. As discussed in the boiler water pretreatment section, alkalinity can be reduced by dealkalization, demineralization, and reverse osmosis. In many cases, mechanical reduction of alkalinity is not needed because of low-alkalinity makeup water and/or feedwater.

Chemical. Feed volatile neutralizing amines to the boiler system. Neutralizing amines are high-pH chemicals that neutralize the carbonic acid formed in the condensate (acid attack). The three most commonly used neutralizing amines are morpholine, diethylaminoethanol (DEAE), and cyclohexylamine. Neutralizing amines cannot protect against oxygen attack; however, they help keep oxygen less reactive by maintaining an alkaline pH. Neutralizing amines may be fed to the storage section of the deaerating heater, directly to the boiler with the internal treatment chemicals, or into the main steam header. Some steam distribution systems may require more than one feed point to allow proper distribution. Neutralizing amines are usually fed based on maintaining the condensate system pH > 8 and measured corrosion rates. These amines may be fed neat (undiluted), diluted with condensate or demineralized water, or mixed in low concentrations with the internal treatment chemicals. Different amines have different basicity, neutralizing capacity, and distribution ratios. The proper blend is critical to ensure protection of the entire steam and condensate system, especially in larger and more complex buildings and campuses.

Protection from Oxygen Corrosion.

Mechanical. Reduce oxygen from all steam boiler feedwater to prevent oxygen carryover to the steam and condensate system (via mechanical methods and chemical oxygen scavengers).

Chemical. One method includes feeding filming amines to the steam to form a thin, hydrophobic barrier (film) on the condensate system surfaces. Filming amines are various chemicals that form a protective layer on the condensate piping to protect it from both oxygen and acid attack. The two most common filming amines are octadecylamine (ODA) and ethoxylated soya amine (ESA). The filming amines should be continuously fed into steam headers at points that allow proper distribution. Combining neutralizing and filming amines is a successful alternative to protect against both acid and oxygen attack.

Another practice is to feed a volatile oxygen scavenger to the steam. The need for chemical treatment can be reduced by designing and maintaining tight return systems so that the condensate is returned to the boiler and less makeup is required in the boiler feedwater. The greater the amount of makeup, the more the system requires increased chemical treatment.

Boiler Water Treatment Chemical Feed Methods

A properly designed water treatment program should be automated to feed the appropriate amounts of treatment proportional to the varying loads of the steam system. Meter-initiated chemical feed pumps or more complex control packages with chemical level feedback mechanisms should be considered. Proper injection points for treatment chemicals are important in attaining optimal results from the water treatment program. The chemical handling, delivery, and disposal of containers must be considered. Onsite mixing of chemicals should be avoided. Chemicals should be fed directly from preblended shipping containers or from microbulk double-wall containment tanks that are refilled by the water treatment vendor.

Condenser Water Systems

Cooling Tower Treatment. The following guidelines are for start-up (or recommissioning) and shutdown of cooling tower systems.

Start-Up and Recommissioning for Drained Systems

1. Inspect tower interior for airborne debris and storm or weather related damages, and determine the extent of cleaning and repairs needed.
2. Clean all debris, such as leaves and dirt, from the cooling tower.
3. Close building air intakes in the area of the cooling tower to prevent entrainment of biocide and biological aerosols in the building's air-handling system.
4. Fill the system with water. While operating the condensing water pump(s) and *before operating the cooling tower fans*, execute one of the following two biocidal pretreatment programs:
   - Resume treatment with the biocide that had been used before shutdown. Use the services of the water treatment supplier. Maintain the maximum recommended biocide residual for the specific biocide for a period sufficient to bring the system under good biological control (residual and time varies with the biocide).
   - Treat the system with sodium hypochlorite at a level of 4 to 5 mg/kg free chlorine residual at a pH of 7.0 to 7.6. The residual level of free chlorine should be held at 4 to 5 mg/kg for 6 h.
5. Once the biocide pretreatment program has been successfully completed, turn on the fan and then put the system in service. The standard water treatment program (including biocide treatment) should be resumed at this time.

Start-Up and Recommissioning for Undrained (Stagnant) Systems

When water remains stagnant for more than about 24 h, dissolved oxygen may disappear and microbiological conditions may change unfavorably. The environment may become increasingly favorable to MIC activity. Likelihood of this occurring increases if sulfates and COD are high, or if significant amounts of silt or sludge are present. It is always best to clean a cooling tower system at the end of a cooling season rather than waiting until the start of a new season.

1. Inspect tower interior for airborne debris and storm or weather related damage, and determine the extent of cleaning and repairs needed.
2. Remove accessible solid debris from bulk water storage vessel (cooling tower sump, draindown tank, etc.).
3. Close building air intakes in the area of the cooling tower to prevent entrainment of biocide and biological aerosols in the building's air-handling system.
4. Perform one of the two biocide pretreatment procedures (described in the section on Start-Up and Recommissioning for Drained Systems) directly to the bulk water storage vessel.
5. Avoid circulating stagnant bulk cooling water over cooling tower fill or operating cooling tower fans during pretreatment.
6. Stagnant cooling water may be circulated with condenser water pumps if tower fill is bypassed. Otherwise, add approved biocide directly to the bulk water and mix with manual or sidestream flow methods to evenly distribute the dosage. Take care to prevent creating aerosol spray from the stagnant cooling water from any point in the cooling-water system.
7. When the biocidal pretreatment is successfully completed, the cooling water should be circulated over the tower fill. Once the biocide treatment has been maintained at a satisfactory level for at least 6 h, the cooling tower fans may then be operated safely.

Shutdown

When the system is to be shutdown for an extended period, the entire system (cooling tower, system piping, heat exchangers, etc.) should be flushed and drained using the following procedure:

1. Add a dispersant and biocide to the system and recirculate for 12 to 24 h. Confer with a water treatment consultant for suitable chemicals and dosage levels.
2. For dry lay-up, shut down pumps and completely drain all water distribution piping and headers, as well as the cooling loop. Remove water and debris from dead legs and low areas in the piping, which may not have completely drained.
3. Rinse silt and debris from the sump. Pay special attention to corners and crevices. Add a mild solution of detergent and disinfectant to the sump and rinse. If the sump does not completely drain, pump out the remaining water and residue.
4. If the equipment cannot be completely drained and is exposed to cold temperatures, freeze protection may be required.
5. Significant protection can be afforded to drained piping and systems with nitrogen blanketing or vapor-phase corrosion inhibitors.

White Rust on Galvanized Steel Cooling Towers

White rust is a zinc corrosion product that forms on galvanized surfaces. It appears as a white, waxy, or fluffy deposit composed of loosely adhering crystalline form of zinc carbonate hydroxide. There is some debate in the literature as to the specific chemical composition of white rust and that of the desirable passivated, durable zinc surface, though they are deemed to be very similar in composition, if not identical. For the purposes of this chapter, and to clearly differentiate the two, white rust is referred to as zinc carbonate hydroxide and the desired passivated surface as zinc carbonate.

The most damaging white rust forms on submerged and consistently wetted galvanized surfaces. This loose crystal structure of zinc carbonate hydroxide allows continued access of the electrolytic fluid (water) to quickly expose successive layers of the zinc coating over carbon steel sheet or plate, in effect accelerating the zinc anodic reaction locally. This unusually rapid reduction of zinc allows corrosion of the exposed carbon steel, which can affect the life cycle of galvanized steel cooling towers under certain conditions. These conditions are generally accepted to be found in waters with pH below 6 or above ~8.5, and with carbonate (P-alkalinity > 0) and hydroxide alkalinity species present in the solution. Further acceleration of white rust formation can be caused by calcium hardness below 50 mg/L (3 grains as $CaCO_3$), requiring the evaluation of the use of water softeners on makeup water during passivation.

Contemporary cooling tower treatment programs generally involve the addition of phosphate-polymer-based scale and corrosion inhibitors and operating cooling-water systems at alkaline pH. Water chemistry at these higher pH levels (>8 to 9+) is naturally less corrosive to steel and copper, but can create an environment where white rust on galvanized steel can occur. Also, some scale prevention programs soften the water to reduce hardness, rather than use acid to reduce alkalinity. Resulting soft waters with <50 mg/L hardness (as $CaCO_3$) can also be corrosive to galvanized steel.

White Rust Prevention. White rust can be prevented in new galvanized cooling towers by promoting the formation of a nonporous surface layer of basic zinc carbonate. This barrier layer is formed during a process called **passivation** and normally protects the galvanized steel for many years. Passivation is best accomplished by controlling pH during initial operation of the cooling tower. Controlling the cooling-water pH in the range of 7 to 8 for 45 to 60 days usually allows passivation of galvanized surfaces to occur. Excursions of cooling-water pH (<7 and >8) during passivation is undesirable, and consistent monitoring and control are essential to prevent white rust formation. In addition to pH control, initial operation during passivation with moderate hardness levels of 100 to 300 mg/L as $CaCO_3$ and alkalinity levels of 100 to 300 mg/L as $CaCO_3$ promote passivation. Where pH control is not possible or practical (e.g., makeup water is >8 pH), phosphate-based inhibitors may help protect galvanized steel. Using an inhibitor in lieu of initial passivation by pH control may later expose the galvanized surfaces to white rust formation should the inhibitor fall below recommended residuals and the pH exceed 8. A water treatment company should be consulted for specific formulations.

Once-Through Cooling-Water Systems

Economics is an overriding concern in treating water for once-through systems (in which a very large volume of water passes through the system only once). Protection can be obtained with relatively little treatment per unit mass of water, because the water does not change significantly in composition while passing through equipment. However, the quantity of water to be treated is usually so large that any treatment other than simple filtration or the addition of a few milligrams per litre of a polyphosphate, silicate, or other inexpensive chemical may not be practical or affordable. Intermittent treatment with polyelectrolytes can help maintain clean conditions when the cooling water is sediment laden. In such systems, it is generally less expensive to invest more in corrosion-resistant construction materials than to attempt to treat the water.

Open Recirculating Cooling-Water Systems

In an open recirculating system with chemical treatment, more chemical must be present, because the water composition changes significantly by evaporation. Corrosive and scaling constituents are concentrated. However, most chemicals are also concentrated by evaporation; therefore, after the initial dosage, only moderate dosages maintain the higher level of treatment needed. The selection of a water treatment program for an open recirculating system depends on the following major factors:

- Economics

- Water quality
- Performance criteria (e.g., corrosion rate, bacteria count, etc.)
- System metallurgy
- Available staffing
- Automation capabilities
- Environmental requirements
- Water treatment supplier

An open recirculating system is typically treated with a scale inhibitor, corrosion inhibitor, oxidizing biocide, nonoxidizing biocide, and possibly a dispersant. The exact treatment program depends on the previously mentioned conditions. A water treatment control scheme for a cooling tower might include

- Chemistry and cycles of concentration control using a conductivity controller
- Alkalinity control using automatic injection of sulfuric acid based on pH
- Scale control using contacting water meters, proportional feed, or traced control technology
- Oxidizing biocide control using an ORP (oxidation-reduction potential) controller
- Nonoxidizing biocide control using timers and pump systems

Air Washers and Sprayed-Coil Units

A water treatment program for an air washer or a sprayed-coil unit is usually complex and depends on the purpose and function of the system. Some systems, such as sprayed coils in office buildings, are used primarily to control temperature and humidity. Other systems are intended to remove dust, oil vapor, and other airborne contaminants from an airstream. Unless the water is properly treated, the fouling characteristics of the contaminants removed from the air can cause operating problems.

Scale control is important in air washers or sprayed coils providing humidification. The minerals in the water may become concentrated enough (by evaporation) to cause problems. Inhibitor/dispersant treatments commonly used in cooling towers are often used in air washers to control scale formation and corrosion. Suitable dispersants and surfactants are often needed to control oil and dust removed from the airstream. The type of dispersant depends on the nature of the contaminant and the degree of contamination. For maximum operating efficiency, dispersants should produce minimal amounts of foam.

Control of slime and bacterial growth is also necessary in the treatment of air washers and sprayed coils. The potential for biological growth is enhanced, especially if the water contains contaminants that are nutrients for the microorganisms. Because of variations in conditions and applications of air-washing installations and the possibility of toxicity problems, individual treatment options should be discussed with water treatment experts before a program is chosen.

Closed Systems

Common Elements. All closed loops need a mechanism to introduce chemicals into the system. Pot feeders are the most common tool used for small to medium sized systems, but chemical pumps can also be used to introduce the chemicals.

- **Filter feeders:** Newer systems or pot feeder replacements should use filter feeders. These units have a stainless steel sleeve strainer that is inserted into the specially designed pot feeder and allows the unit to become a filter once a filter bag or cartridge is added. Filtration can occur down to submicron (<0.5 μm) levels.
- **Corrosion coupon racks:** Closed loops should be outfitted with a two- to four-position corrosion coupon rack with a flow meter to verify that the flow rate through the rack is appropriate and representative of the system (generally 0.9 to 1.5 m/s).
- **Water meters:** Each closed-loop system should be outfitted with a water meter to measure the amount of water fed into the system. A log of the readings should be kept; this helps in detecting leaks.
- **Filtration:** New pipe has varying degrees of moderately loose iron oxide based mill scale. Over time, and with repeated expansion and contraction due to temperature change, mill scale is eroded and adds small particles of highly abrasive debris to flowing water. This material can cause roughening of valve seats, scoring of valve stems, and abrasive damage to packings and mechanical seals. Sidestream filtration is recommended to reduce possible abrasive to working surfaces within closed loop systems. When filtration is needed, the easiest solution for smaller systems is replacing the pot feeder with a filter feeder. Filtration down to 5 μm size is desirable; however, dirty systems should start with >25 μm size filtration to allow cheaper coarse filters to do their work first. The optimum size can be determined by a particle size distribution analysis. Pressure gages and a flow meter at the filter outlet should be placed on the filter unit to help identify when the bags, cartridges, or media need to be changed or cleaned, based on the inlet and outlet pressure differentials. Aluminum condensing boilers need filtration because of (1) their high ratios of metal surface to water volume and (2) their ribbed and textured aluminum alloy surfaces required for efficient heat transfer.

Closed Recirculating Systems (Closed Hydronic Loops). These systems use a water-based solution to transfer heat. The most common distinction defining a closed system is the fact that the method of cooling is not evaporative. Minimal water loss/makeup and minimal air contact are two additional conditions typically associated with closed loops.

In a closed recirculating system, water composition remains fairly constant, with very little loss of either water or treatment chemical. Closed systems are often defined as those requiring less than 5% makeup per year. The need for water treatment in such systems (e.g. heating water, chilled water, combined cooling and heating, closed-loop condenser water systems) is often ignored based on the rationalization that the total amount of scale from the water initially filling the system would be insufficient to interfere significantly with heat transfer, and that corrosion would not be serious. However, leakage losses are common, and corrosion products can accumulate sufficiently to foul heat transfer surfaces. Therefore, all systems should be adequately treated to control corrosion. Systems with high makeup rates should be treated to control scale as well. One of the most problematic challenges for closed-loop systems is contamination from glycol-based antifreeze used to “winterize” air handler coils. Although the amount of antifreeze contamination amounts to just a a few hundred milligrams per 1000 litres of system volume, fermentation-like breakdown of glycols can produce enough acidic byproducts to lower pH throughout the recirculating water and establish system-wide corrosive conditions.

The selection of a treatment program for closed systems should consider the following factors:

- Economics
- System metallurgy
- Operating conditions
- Makeup rate
- System size

Before new systems are treated, they must be cleaned and flushed. Grease, oil, construction dust, dirt, and mill scale are always present in varying degrees and must be removed from the metallic surfaces to ensure adequate heat transfer and to reduce the opportunity for localized corrosion. Detergent cleaners with organic dispersants are available for proper cleaning and preparation of new closed systems.

Some of the most serious corrosion damage is done to new systems because of improper start-up procedures. In almost all cases, filling a system with untreated water for the purpose of performing pressure tests causes this problem. Typically, the system is then left stagnant, sometimes for many months, until it is ready to be commissioned. During that time, anoxic conditions persist, promoting MIC and underdeposit corrosion. MIC will waste system metals, sometimes considerably.

New systems should never be filled with untreated water and should not be left stagnant for long periods of time, even when treated. New systems should be thoroughly cleaned and flushed with an appropriate pretreatment chemistry as early as possible, preferably with the initial filling.

After a system has been cleaned and thoroughly flushed of pretreatment chemicals, it should be immediately refilled with water and treated with the recommended corrosion inhibitor and microbiological control products. The system should not be allowed to sit empty for any length of time, unless extraordinary effort is made to ensure that it is completely dry.

Corrosion inhibiting treatments for closed water systems are usually composed of several constituents and typically contain molybdate, nitrite, or other inhibitor compounds as a control parameter, reviewed at least annually. The chemical manufacturer's recommendations should be followed as to the amount of inhibitor maintained in the system.

HVAC Closed Loops Containing Aluminum. These loops must be treated primarily to control corrosion and sometimes biological fouling, but may also need cleanup programs to remove new or old corrosion products.

There are several important water treatment issues that must be addressed in a mixed-metallurgical system:

- The pH must be considered for amphoteric metals, such as aluminum and zinc, that can corrode in both acid and alkaline pH environments. Manufacturer specifications should be followed (generally not to exceed 8.5 pH).
- Free copper should generally be maintained <0.1 mg/L with a copper inhibitor.
- Total aerobic bacteria counts should be controlled to less than 1000 colony-forming units per millilitre (cfu/mL).

Mixed-metallurgy corrosion inhibitors should contain appropriately dedicated corrosion inhibitors for the metal composition of the system.

Water-Heating Systems

Secondary and Low Temperature. Closed, chilled-water systems that are converted to secondary water heating during winter and primary low-temperature water heating, both of which usually operate in the range of 38 to 93°C, require sufficient inhibitors to control corrosion. For more information on treatment selection for these systems, see the section on Corrosion and Corrosion Control.

Environment and High Temperature. Water-heating systems (121 to 177°C) and high-temperature, high-pressure hot-water systems (above 177°C) require careful consideration of treatment for corrosion and deposit control. Makeup water for such systems should be demineralized or softened to minimize scale deposits. For corrosion control, oxygen scavengers such as sodium sulfite can be added to remove dissolved oxygen.

Electrode boilers are sometimes used to supply low- or high-temperature hot water. Such systems use heat generated from the electrical resistance of the water between electrodes. The conductivity of the recirculating water must be in a specific range depending on the voltage used. Treatment of this type of system for corrosion and deposit control varies. In some cases, oil-based corrosion inhibitors that do not contribute to the conductivity of the recirculating water are used.

Table 3 Freeze and Burst Protection by Volume

Temperature, °C	Ethylene Glycol, % by Volume		Propylene Glycol, % by Volume	
	Freeze	Burst	Freeze	Burst
–6.7	17.3	11.9	18.0	12.0
–12.2	27.1	18.4	29.0	20.0
–18.0	25.7	23.8	36.0	24.0
–23.3	42.2	28.1	42.0	28.0
–28.9	47.6	32.5	46.0	30.0
–34.4	51.9	32.5	50.0	33.0
–40.0	56.3	32.5	54.0	35.0
–45.6	60.6	32.5	57.0	35.0

Glycol Systems

Glycol systems are closed-loop water systems that usually contain over 20% (by mass) of either propylene glycol or ethylene glycol (aka antifreeze). For most HVAC applications, inhibited nontoxic propylene glycol replaces inhibited toxic ethylene glycol as antifreeze and for burst protection. It is commonly used as an all year coolant in closed evaporative cooler circuits, and in chilled- and hot-water circuits that are exposed to freezing temperatures.

In geothermal cooling and heating systems, if not using food-grade propylene glycol, sometimes a mixture of water and alcohol is used, typically ethanol rather than methanol or propanol (because ethanol is safer than methanol and has lower freeze point and viscosity than propanol).

To protect against freezing during seasonal lay-ups, glycol may be added at the end of a cooling season into parts of closed water systems that are vulnerable to burst failures from freezing. These vulnerable system parts are isolated and filled with 25 to 50% glycol in fall (before seasonal shutdown) to prevent freezing. They are then drained and flushed before summer start-up to resume normal operation. Inhibited glycol, when diluted to below 20%, loses its antiseptic and pH stabilizing (buffering) abilities, turns acidic after decomposition by oxygen and heat, becomes corrosive to metals, and can be a food source for microbes. Most glycol manufacturers recommend keeping inhibited glycol above 25% concentration, and using glycol tank makeup systems to prevent dilution of the bulk water. Flushing without testing for trace glycol can lead to trace glycol contamination, which can cause high turbidity, corrosiveness, and repulsive odor. See Table 3 for data on glycol and freeze protection.

Treating antifreeze systems is similar to treating closed-loop water systems. It requires pretreatment (start-up) cleaning with alkaline low-foaming detergent. When aluminum and/or galvanized steel are present, chemically neutral low-foaming detergent is used to protect those metals. Phosphate-based detergent is also preferred over silicate base, because residual silicate can become a source of foulants to the piping when pH turns from neutral to acidic. In addition to controlling freezing points with different concentrations of antifreeze, corrosion is controlled with either demineralized makeup water or preblended inhibited glycol. Makeup should only be fed by an automatic antifreeze (glycol) feeder. If a standard hydronic water makeup connection is used, the glycol concentration may be diluted below 20% and it may ferment (like wine). A domestic water feed will also dilute inhibitor levels. Use only industrial glycol. Automotive glycol contains much less corrosion inhibitor. Do not change glycol products without verifying the corrosion inhibitors they use. Most glycols use a phosphate inhibitor, but at least one vendor uses nitrite. Makeup water quality with total hardness <50 mg/L. as $CaCO_3$, chloride as Cl^- <25 mg/L., and sulfate as SO_4 <25 mg/L. is preferred for control of corrosion. When inhibitor levels are out of balance, inhibitors may be fed with a bypass filter feeder to control pH, alkalinity, turbidity, and copper and ferrous inhibitors levels. An inhibitor program protects multimetal materials, steel, cast iron, copper, brass, and solder with buffered pH between 8 and 10.5;

phosphates are common buffering agents with concentrations between 2000 and 4000 mg/L. Nitrite borate and silicate are less preferred because of potential for unfavorable reactions with glycol. New glycol shall comply with ASTM *Standard* D1384 (less than 0.5 mL annual penetration of all system metals).

Thermal Storage Systems

Thermal storage systems require the same attention as other systems for corrosion, scale, and biological control. As with other systems, it is important to begin with a clean system. The system should be properly cleaned and passivated after construction and before operation, and then treated with appropriate corrosion inhibitors and biocides. The large volume typical of thermal storage systems can result in periodically stagnant conditions and solids accumulation. The system should be equipped with a filter to facilitate solids removal. Either a physical or instrumental method of corrosion monitoring should also be used to ensure that acceptable corrosion rates are maintained.

Perhaps most important regarding large chilled-water thermal storage (CWTS) systems is having a clear understanding of the treatments recommended. Because water and water treatment additives remain in a CWTS system for many years, the eventual fate of all additive components should be clearly detailed and understood prior to addition. Proposed organic compounds should receive special consideration by virtue of their potential biological nutrient value (i.e., biochemical oxygen demand [BOD]).

Brine Systems

Systems containing brine, a strong solution of sodium chloride or calcium chloride, must be treated to control corrosion and deposits. Sodium nitrite, at a minimum 3000 mg/L in calcium brines or 4000 mg/L in sodium brines, and a pH between 7.0 and 8.5, should provide adequate protection. Organic inhibitors are available that may provide adequate protection where nitrites cannot be used. Molybdates should not be used with calcium brines because insoluble calcium molybdate will precipitate.

3. TERMINOLOGY

The following terms are commonly used in the water treatment industry as they pertain to corrosion, scale, deposit, fouling, and microbiological control. Additional terms are defined in the section on Water Characteristics.

Alkalinity. The sum of bicarbonate, carbonate, and hydroxide ions in water. Other ions, such as borate, phosphate, or silicate, also contribute to alkalinity.

Anion. A negatively charged ion of an electrolyte that migrates toward the anode influenced by an electric potential gradient. Common examples are chloride (Cl^{-1}), sulfate (SO_4^{-2}), bicarbonate (HCO_3^{-1}), carbonate (CO_3^{-2}), and phosphate (PO_4^{-3}).

Anode. The positive electrode of an electrolytic cell at which oxidation occurs.

Biological deposits. Water-formed deposits of biological organisms or the products of their life processes. Examples include barnacles, algae, or bacterial slime (biofilm). Biofilm formation can be found in the arterial and digestive systems of animals and people.

Bleed off/blowdown. Water intentionally discharged from a system to limit buildup of dissolved solids.

Cathode. The negative electrode of an electrolytic cell at which reduction occurs.

Cation. A positively charged ion of an electrolyte that migrates toward the cathode influenced by an electric potential gradient. Common examples are calcium ion (Ca^{+2}), magnesium ion (Mg^{+2}), sodium ion (Na^{+1}), potassium ion (K^{+1}), and ferric iron (Fe^{+3}).

Corrosion. The deterioration of a material, usually a metal, by reaction with its environment.

Cycles of concentration. Water vapor lost from a cooling tower or steam or condensate lost from a boiler system is pure water free of dissolved solids and must quickly be replaced by makeup water to sustain system operation. The incoming water has dissolved solids; the lost water was free of dissolved solids; therefore, dissolved solids accumulate in retained system water. Cycles of concentration can be defined as the ratio of dissolved solids in cooling tower or boiler water to dissolved solids in makeup water. More precisely stated, it is the ratio of the volume of makeup to the volume of bleed off/blowdown.

Electrolyte. A solution through which an electric current can flow. Water without ions present in it will not conduct electricity. Ions dissolved in water create an electrolyte and allow current to flow. The more concentrated the ions, the easier it is for current to flow.

Filtration. Process of passing a liquid through a porous material in such a manner as to remove suspended matter from the liquid.

Galvanic corrosion. Corrosion resulting from the contact of two dissimilar metals in an electrolyte or from the contact of two similar metals in an electrolyte of nonuniform concentration.

Hardness. The sum of the calcium and magnesium ions in water; usually expressed in mg/kg or mg/L as $CaCO_3$.

Inhibitor. A chemical substance that reduces the rate of corrosion, scale formation, fouling, or slime production.

Ion. A positive (cation) or negative (anion) electrically charged atom or group of atoms.

Makeup. Water added to a cooling tower or boiler system to replace evaporation or steam loss.

Passivity. The tendency of a metal to become inactive in a given environment. Noble metals such as gold, silver, and platinum are inherently passive or unreactive with respect to water. Water reactive (active) metals such as iron, aluminum, nickel, and zinc acquire varying degrees of passivity because of natural and inhibitor-enhanced formation of an extremely thin, protective oxide surface film.

pH. The logarithm of the reciprocal of the hydrogen ion concentration of a solution [$-\log 10 = \log(1/H^+)$]. pH values below 7 are increasingly acidic; those above 7 are increasingly alkaline. Each whole unit change in pH represents a 10-fold change in hydrogen ion concentration.

Polarization. The deviation from the open circuit potential of an electrode resulting from the passage of current. Also used to describe the absence of electron flow where corrosion of an active metal is possible. Depolarization implies passage of electron flow and likely corrosion activity.

Potable. Safe to drink. In the U.S., this normally means water that complies with the *National Primary Drinking Water Regulations* (NPDWR; EPA 2009). The NPDWR document is also an excellent source of information about the adverse effects and sources of each regulated contaminant. Some states may also adopt the *National Secondary Drinking Water Regulations*, which are shown at the end of the NPDWR document and affect cosmetic issues and taste, but not health.

ppm. Parts per million by mass. In water, ppm are essentially the same as milligrams per liter (mg/L); 10 000 mg/L = 1%.

Scale. (1) The formation at high temperature of thick corrosion product layers on a metal surface. (2) The precipitation of water-insoluble constituents on a surface.

Sludge. A sedimentary water-formed deposit, originating from (1) biological sources, (2) capture of suspended particles from the air, and/or (3) in-system formation hardness or corrosion debris. Note, sludge deposits can harden over time, or upon drying, and take on the appearance of scale.

Tuberculation. The formation over a surface of scattered, knob-like mounds of localized corrosion products.

Water-formed deposit. Any accumulation of insoluble material derived from water or formed by the reaction with water on surfaces in contact with it.

WATER HEATING energy use is second only to space conditioning in most residential buildings, and is also significant in many commercial and industrial settings. In some climates and applications, water heating is the largest energy use in a building. Moreover, quick availability of adequate amounts of hot water is an important factor in user satisfaction. Both water and energy waste can be significant in poorly designed service water-heating systems: from over- or undersizing pipes and equipment, from poor building layout, and from poor system design and operating strategies. Good service water-heating system design and operating practices will reduce operating costs and can often reduce first costs. The information in this chapter is thus critical for the sustainable design and operation of many buildings.

Research documenting hot-water use in modern systems is limited to certain segments. Some of the data in this chapter on hot-water demands for some types of buildings, applications, and fixtures may be outdated. Nevertheless, these data are provided for guidance, because they are often still the best available; however, these demand values are not intended for use as designers' sole references for hot-water system sizing purposes.

1. SYSTEM ELEMENTS

A service water-heating system has (1) one or more heat energy sources, (2) heat transfer equipment, (3) a distribution system, and (4) end-use fixtures.

Heat energy sources may be (1) fuel combustion; (2) electrical conversion; (3) solar energy; (4) geothermal, air, or other environmental energy; and/or (5) recovered waste heat from sources such as flue gases, ventilation and air-conditioning systems, refrigeration cycles, and process waste discharge.

Heat transfer equipment is direct, indirect, or a combination of the two. For direct equipment, heat is derived from combustion of fuel or direct conversion of electrical energy into heat and is applied within the water-heating equipment. For indirect heat transfer equipment, heat energy is developed from remote heat sources (e.g., boilers; solar energy collection; air, geothermal, or other environmental source; cogeneration; refrigeration; waste heat) and is then transferred to the water in a separate piece of equipment. Storage tanks may be part of or associated with either type of heat transfer equipment.

Distribution systems transport hot water produced by water-heating equipment to end-use fixtures. For locations where constant supply temperatures are desired, circulation piping or a means of heat maintenance must be provided.

End-use fixtures are plumbing faucets, accessories, and equipment requiring hot water that may have periods of irregular flow, constant flow, and no flow. These patterns and their related water usage vary with different buildings, process applications, and personal preference. Examples of end-use accessories are prerinse spray valves, faucet aerators, showerheads, washdown sprayers, and hose bibbs. Examples of end-use equipment are dishwashers, clothes washers, and pressure washers.

The preparation of this chapter is assigned to TC 6.6, Service Water Heating Systems.

2. WATER-HEATING TERMINOLOGY

Distribution system efficiency. Heat contained in the water at points of use divided by heat delivered at the heater outlet during flow periods.

Energy factor. The delivered efficiency of a residential water heater when operated as specified in U.S. Department of Energy (DOE) test procedures (DOE 2001). See also ASHRAE *Standard* 118.2.

First-hour rating. An indicator of the maximum amount of hot water a residential water heater can supply in 1 h when starting with a tank that is up to temperature. This rating is used by the U.S. Federal Trade Commission (FTC) for comparative purposes and by the U.S. Department of Energy (DOE) for selecting the appropriate draw profile when testing for the uniform energy factor. Because peak draws taken over periods less than 1 h frequently drive residential equipment sizing, first-hour rating alone should not be used for equipment sizing. As for larger systems, storage tank volume and heating rate also play important roles.

Fixture unit. A number, on an arbitrarily chosen scale, that expresses the load-producing effects on the system of different kinds of fixtures.

Heat trap. A device to counteract the natural convection of heated water in a vertical pipe. Commercially available heat traps for large equipment are generally 360° loops of tubing; heat traps can also be constructed of pipes connected to the water heater (inlet or outlet) that direct flow downward before connecting to the vertical supply or hot-water distribution system. Tubing or piping heat traps should have a loop diameter or length of downward piping of at least 300 mm. Various prefabricated check-valve-like heat traps are available for residential-sized equipment, using balls, flexible flaps, or moving disks.

Input efficiency. Heat entering water in the heating device divided by energy input to the heating unit over a specific period of steady-state conditions, or while heating from cold to hot, depending on how stated (steady-state versus average input efficiency); it does not include heat losses from the water heater jacket and/or tank. When used with fossil-fuel-fired equipment, this is commonly called **combustion efficiency**.

Operating efficiency. Heat delivered at the heater outlet ($Q_{out} = mc_p[T_{hot\ out} - T_{cold\ in}]$) divided by heat input to the heating unit (includes heat losses from water heater jacket and/or tank) for any selected period for systems without recirculation pumps. For distribution systems with recirculation pumps, heat losses include recirculation line losses, because hot water at a reduced temperature is returned back to the heater. Thus, operating efficiency equals the heat delivered to the middle of the distribution line ($Q_{out} = mc_p[(T_{hot\ out} + T_{hot\ return})/2 - T_{cold\ in}]$) divided by heat input to heating unit. The operating efficiency of water heaters in systems with continuous recirculation can be further reduced by loss of stratification in storage heaters. Elevated return temperatures associated with continuous recirculation systems further reduce the operating efficiency of condensing water heaters (see Figures 1 and 2). This is also referred to the heater's real-world efficiency, which can be easily measured and used to estimate the energy use or operating cost. A system with higher operating efficiency may not always equate to a higher-performing system, because operating efficiency considers water temperature leaving the tank, not water temperature reaching the fixtures. A system with extremely long hot-water distribution piping and no recirculation may show a high operating efficiency, but hot water may never reach the farthest fixtures.

Overall system efficiency. Heat energy in the water delivered at points of use divided by the total energy supplied to the heater for any selected period.

Recovery efficiency. Heat absorbed by the water divided by heat input to the heating unit during the period that water temperature is raised from inlet temperature to final temperature (includes heat losses from water heater jacket and/or tank).

Recovery rate. The amount of hot water that a water heater can continually produce, usually reported as flow rate in litres per hour that can be maintained for a specified temperature rise through the water heater.

Standby loss. As applied to a tank water heater (under test conditions with no water flow), the average hourly energy consumption divided by the average hourly heat energy contained in stored water, expressed as a percent per hour. This can be converted to the average watts energy consumption required to maintain any water/air temperature difference by taking the percent times the temperature difference, times 1.15 kWh/($m^3 \cdot K$) (a nominal specific heat for water), times the tank capacity, and then dividing by 100.

Standby loss coefficient. The heat input (in W/K) into a storage water heater when operated as specified in U.S. Department of Energy (DOE) test procedures (DOE 2001). This value is essentially the standby loss divided by the difference in temperature between the average stored water temperature and the surrounding air temperature. Care should be taken to understand whether a quoted standby loss coefficient includes the heat input efficiency of the heating device. It is possible to directly measure the heat lost from a storage water heater independently of how that water is heated. Sometimes, the reported standby loss coefficient represents only the heat lost; at other times, it represents the amount of energy to make up that heat loss, and considers the heat input efficiency of the heating device.

System standby loss. The amount of heat lost from the water heating system and the auxiliary power consumed during periods of nonuse of service hot water.

Thermal efficiency. Heat in water flowing from the heater outlet divided by the energy input to the heating unit over a specific period of steady-state conditions (includes heat losses from the water heater jacket and/or tank).

Uniform energy factor. The delivered efficiency of a residential water heater when operated as specified in U.S. Department of Energy (DOE) test procedures (DOE 2014).

3. SYSTEM PLANNING

The goals of system planning are to (1) size the system properly; (2) optimize system efficiency; and (3) minimize first, operating, and overall life-cycle costs. It is important to design systems so that they perform well from both functional (hot-water delivery) and energy-use perspectives. Flow rate, temperature, and total flow over specific time periods are the primary factors to be determined in the design of a water-heating and piping system for delivering adequate amounts of hot water. Operating pressures, time of delivery, and water quality are also factors to consider. Presently, separate procedures are used to select water-heating equipment and to design the piping system. However, water-heating equipment sizing and piping system design should be considered together for best system design. Oversized or excessively long piping exacerbates delivery delay and/or energy waste.

Water-heating equipment, storage facilities, and piping should (1) have enough capacity to provide the required hot water while minimizing waste of energy or water and (2) allow economical system installation, maintenance, and operation.

Water-heating equipment types and designs are based on the (1) energy source, (2) heat exchange method, and (3) control method used to deliver the necessary hot water at the required temperature under varying water demand conditions. Application of water-heating equipment within the overall design of the hot-water system is based on (1) location of the equipment within the system, (2) related temperature requirements, (3) volume of water to be used, and (4) flow rate. Consideration of electricity demand charges on the utility bill is also of growing importance. Additional planning is required when the system providing the potable hot water is also used for space heating or other purposes. Some special water heater designs, made for this purpose, are known as combination space- and water-heating systems.

Energy Sources

Choice of energy source(s) is influenced by local availability of the various energy sources, equipment type, space considerations, locations of water heaters in structures, initial cost, operating cost, maintenance requirements, and other factors. A life-cycle cost analysis is highly recommended.

In making energy conservation choices, consult ASHRAE *Standards* 90.1 and 90.2, or the sections on Service Water Heating Systems of ASHRAE *Standard* 100, as well as the section on Design Considerations in this chapter.

4. DESIGN CONSIDERATIONS

Hot-water system design should consider the following:

- Water heaters of different sizes and insulation may have different standby losses, thermal efficiency, or energy factors.
- A distribution system should be properly laid out, sized, and insulated to deliver adequate water quantities at temperatures satisfactory for the uses served. This reduces standby loss and improves distribution system efficiency. Locating fixtures or usage devices close to each other and to the water-heating equipment is particularly important for minimizing piping lengths and diameters, and thus reducing wait times as well as water and energy waste.
- Heat traps between recirculation mains and infrequently used branch lines reduce convection losses to these lines and improve distribution system efficiency. In small residential systems, heat traps can be applied directly to the water heater for the same purpose.
- Controlling circulating pumps to operate only as needed to maintain proper temperature at the end of the main reduces losses on return lines.
- Provision for shutdown of circulators during building vacancy reduces standby losses.

For most large water heating systems, providing some amount of redundant water heating capacity is a good idea, such that water heating loads can still be met when other water heaters in the system are not operational or require regular maintenance. When water heaters are installed in flow parallel, they should be the same size heating rate and other design characteristics to help simplify flow and energy (run time) balancing. Moreover, when heaters are separate from storage tanks, multiple heaters can be installed in flow parallel with each other, but serving a single storage tank. Alternatively, they can each serve a separate (equal-sized) storage tank, with each of the storage tanks in flow parallel. To provide back-up heating, a water heater having a heating capacity equal to the other water heaters in the system should be provided, allowing peak loads to be met when any one water heater and/or storage tank is out of commission. If design-day peak needed heating rate is Q, then for N equal-sized water heaters, each water heater needs to have a design day heating rate of $Q/(N - 1)$, resulting in having an additional back-up heating capacity amounting to $1/(N - 1)$ of the total design day load. For example, for $N = 5$, each water heater needs to have a design-day heating capacity of 1/4 of the design-day total needed heating rate. Four water heaters are needed to serve the design-day load, and the fifth provides a back-up capacity of another 1/4 of the design-day total needed heating rate. Workable combinations of total design-day needed heating rate and storage volume are determined the same way as for all systems.

Design Path for Savings

Reducing hot-water consumption not only results in lower water and sewer costs, it is the most effective way to reduce water-heating energy use. Designing in a reverse direction, starting with the hot-water-using equipment and moving back to the water heater, is an effective thought process to achieve higher system efficiency and performance.

Step 1: Specify high-performance equipment and accessories that use less hot water, or alternative processes that eliminate the need for hot water for that particular task.

Step 2: Locate sinks and equipment in proximity to each other and to the water heater, and optimize the plumbing layout; these are key factors to the efficiency and performance of the overall system. Delivering hot water more efficiently yields permanent energy savings and improved hot-water delivery performance. Consider distributed generation or point-of-use heating for distant sinks where it does not make sense to extend the primary system's distribution system.

Step 3: Specify high-efficiency water heaters that are compatible with the distribution system and end-use fixtures. This is imperative.

Step 4: Before the hot-water system design is finalized, consider integrating preheating technologies such as heat recovery or solar heating.

Step 5: Verify proper installation of the system, including simple monitoring equipment, which can play an important role in commissioning and maintaining the system.

5. END-USE FIXTURES

Advanced end-use fixtures play an important role in reducing the size of the primary water heater(s) and simplifying the distribution system design. Use of high-efficiency, low-water-use equipment and fixtures, such as faucet aerators, reduced-flow (but still adequate) showerheads, and advanced clothes washers and dishwashers, achieves multiple benefits, including the ability to use lower water temperatures and lowered total hot water consumption. Thus, in many instances, it is practical to provide localized heating devices, either near or built into the fixture or device, thereby additionally reducing distribution system heat losses and piping first costs. Providing localized heating devices also reduces demands on piping diameter and length for the remaining hot-water distribution system, and may reduce or eliminate the need for hot-water recirculation loops in some applications.

The U.S. Energy Policy Act of 1992 established a maximum flow rate requirement for hand sink faucets and showerheads. These maximum flow rates were later revised and lowered to 30 mL/s for public hand sinks and 140 mL/s for private hand sinks. Manufacturers are now making public sink faucet aerators that flow as low as 20 mL/s and private sink faucet aerators that use 95 mL/s. Similarly, manufacturers are now producing showerheads that use 125 mL/s, reduced from the federally mandated 160 mL/s flow rate.

Similar improvements have been made in fixtures and equipment for food-service industry hot-water systems. The U.S. Energy Policy Act of 2005 set a maximum flow rate of a prerinse spray valve at 100 mL/s (DOE 2011), reduced from conventional models rated at 160 to 285 mL/s. Spray valves flowing at 40 to 80 mL/s are now available. Dishwashers are now available with built-in heat recovery capability, which reduces dishwasher total energy and hot-water requirements and, when combined with localized or built-in heating ability, can significantly reduce hot-water demands on a building's central hot-water system. Use of localized booster water heaters to produce the high water temperatures required for sanitization of wares in commercial dishwashers is commonplace and reduces temperatures required from a central hot-water system.

6. DISTRIBUTION

Piping Material

Traditional piping materials include galvanized steel used with galvanized malleable iron screwed fittings. Copper piping and copper water tube types K, L, or M have been used with brass, bronze, or wrought copper water solder fittings. PEX and CPVC piping materials are now used as an alternative in residential applications. Another alternative piping material is stainless steel tube. Particular care must be taken to ensure that the application meets the design limitations set by the manufacturer, particularly regarding temperature and pressure limits, and that the correct materials and methods of joining are used. These precautions are easily taken with new projects, but become more difficult during repairs of existing work. Using incompatible piping, fittings, and joining methods or materials must be avoided, because they can cause severe problems, such as corrosion or leakage caused by differential thermal expansion.

Today, most potable water supplies require treatment before distribution; this may cause the water to become more corrosive. Therefore, depending on the water supply, traditional galvanized steel piping or copper tube may no longer be satisfactory, because of accelerated corrosion. Galvanized steel piping is particularly susceptible to corrosion (1) when hot water is between 60 and 80°C and (2) where repairs have been made using copper tube without a nonmetallic coupling. Note that plumbing can be either piping (relatively thick wall) or tubing (relatively thin wall), although *piping* is used in this chapter for both. Before selecting any water piping material or system, consult the local code authority. The local water supply authority should also be consulted about any history of water aggressiveness causing failures of any particular material.

The Reduction of Lead in Drinking Water Act (effective January 4, 2014) prohibits the use of any pipe, pipe or plumbing fitting or fixture, and associated solder and flux used in all facilities for potable water piping that is not "lead free" as defined in section 1417(d) of the Safe Drinking Water Act, because of possible lead contamination of the water supply (EPA 2013).

Pipe Sizing

Sizing hot-water supply pipes from a hydraulic (pressure drop) perspective involves the same principles as sizing cold-water supply pipes (see Chapter 22 of the 2017 *ASHRAE Handbook—Fundamentals*). The water distribution system must be correctly sized for the total hot-water system to function properly. Hot-water demand

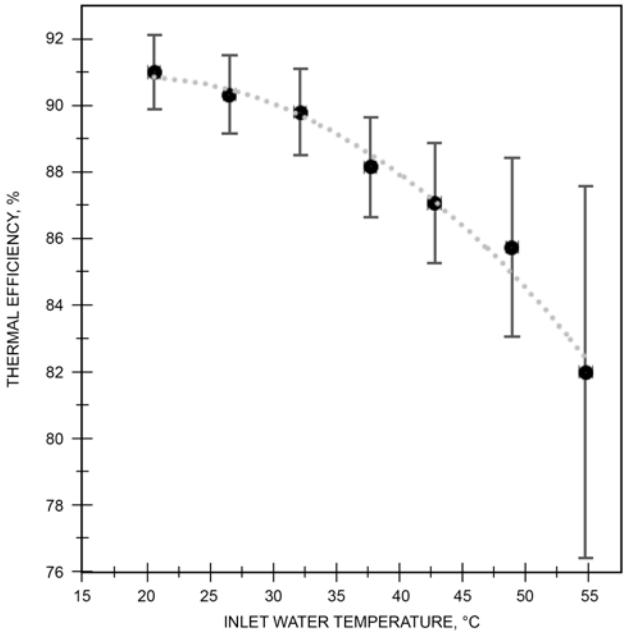

Fig. 1 Effect of Inlet Water Temperature on Thermal Efficiency of Condensing Tankless Heater

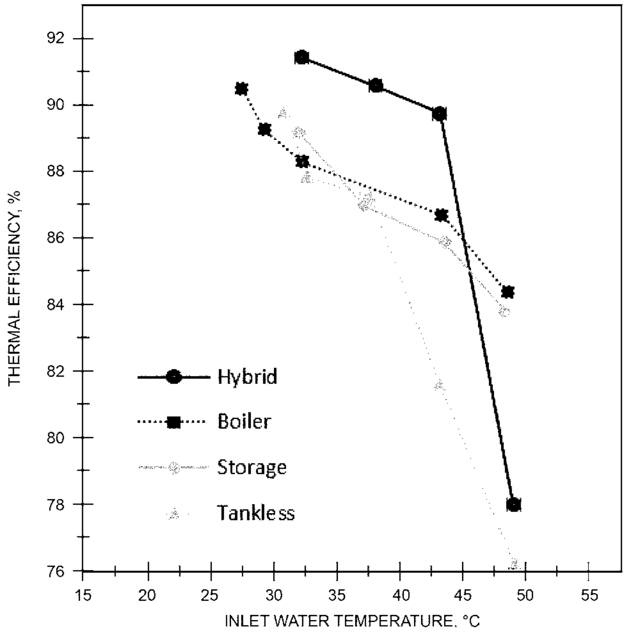

Fig. 2 Effect of Return Water Temperature on Operating Efficiency of Condensing Heaters

varies with the type of establishment, usage, occupancy, and time of day. The piping system should be able to meet peak demand at an acceptable pressure loss. It is important not to oversize hot-water supply pipes, because this adversely affects system heat loss and overall energy use.

Supply Piping

Table 16, Figures 27 and 28, and manufacturers' specifications for fixtures and appliances can be used to determine hot-water demands. These demands, together with procedures given in Chapter 22 of the 2017 *ASHRAE Handbook—Fundamentals*, are used to size the mains, branches, and risers.

Allowance for pressure drop through the heater should not be overlooked when sizing hot-water distribution systems, particularly where instantaneous water heaters are used and where the available pressure is low.

Pressure Differential

Sizing both cold- and hot-water piping requires that the pressure differential at the point of use of blended hot and cold water be kept to a minimum. This is particularly important for tubs and showers, because sudden changes in flow at fixtures cause discomfort and a possible scalding hazard. Pressure-compensating devices are available.

Effect of Distribution Design on Efficiency of Condensing Heaters

The distribution system design and operation can have a significant impact on the efficiency of gas-fired condensing heaters. Laboratory tests have shown a significant reduction in the ability of high-efficiency gas water heaters to maintain full condensing function because of elevated inlet-water temperatures. Figure 1 shows the reduction in thermal efficiency of a condensing tankless heater when inlet water temperatures are increased to simulate preheating equipment such as solar water heating systems and heat recovery devices (Huestis 2013; Johnson et al. 2013). The unit loses all condensing function at inlet temperatures of 54°C, where the thermal efficiency reaches 82%, typical of a standard-efficiency unit.

A second study looked at the effect of continuous recirculation at a narrower band of return water temperatures on the operating efficiency of various heaters (Figure 2) with an outlet temperature of 54°C at 190 mL/s water flow rate (Schoenbauer 2012, 2013). This study shows consistent loss of thermal efficiency with higher return water temperatures observed at varying levels across product categories, though the specific loss of efficiency depends on unit design, specifically heat exchanger surface area and storage volume. The storage heater with a storage volume of 208 L and boiler with a flooded volume of less than 14 L demonstrated a steady decline in efficiency from approximately 90% thermal efficiency at 32°C to 84% efficiency at 49°C (partially condensing). For the hybrid heater with a storage volume of 7.6 L, the unit maintained condensing function with an average efficiency of 90% with a return water temperature from 32 to 43°C, but then the efficiency rapidly dropped to 78% at 49°C return water temperature. The tankless heater performed the worst, with a large drop in operating efficiency from 90% at 31°C to 76% efficiency at 49°C. Both the hybrid and tankless units lost the ability to capture latent heat from the exhaust gases at 49°C. Finding alternatives to the use of continuous recirculation systems, or maintaining a return temperature at 38°C or lower, would significantly improve the efficiency of condensing water heaters.

Piping Heat Loss and Hot-Water Delivery Delays

Good hot-water distribution system layout is very important, for both user satisfaction and energy use. This has become increasingly important with the mandated use of low-flow fixtures, which can cause lengthy delays and increased water waste while waiting for hot water to arrive at fixtures compared to higher-flow designs. In general, it is desirable to put fixtures close to each other and close to the water heater(s) that serve them. This minimizes both the diameter and length of the hot-water piping required. Recent work has shown that energy loss from hot-water piping due to both heat loss and water waste waiting for hot water to arrive at fixtures can be a significant percentage of total water-heating system energy use (Hiller 2005a; Klein 2004a, 2004b, 2004c; Lutz 2005). Energy losses from hot-water distribution systems usually amount to at

Table 1 Piping Heat Loss Factors for Foam In Piping Heat Loss Factors for Foam Insulation with Thermal Conductivity of 0.114 W/(m²·K)

least 10 to 20% of total hot-water system energy use in most potable water-heating systems (Hiller 2005a), and are often as high as 50%; losses of over 90% have been found in some installations (Hiller and Miller 2002; Hiller et al. 2002).

Hiller (2005a, 2005b, 2006a, 2006b) measured both piping heat loss and time, water, and energy waste while waiting for hot water to arrive at fixtures. This research measured piping heat loss *UA* factors for several commonly used piping sizes, types, and insulation levels. See ASHRAE *Standard* 90 series for pipe insulation requirements. $UA_{flowing}$ values are a slight function of water flow rate and temperature difference between the hot water and the surroundings. However, for many practical calculation purposes, *UA* can be considered constant at the values shown in Table 1.

Hiller (2008) found that bare copper piping buried in damp sand (typical of under-slab piping) exhibited heat loss rates over eight times higher than the same pipe in air. This much higher heat loss rate is believed to be caused by moisture in the sand near the pipe behaving like a heat pipe by evaporating, recondensing (thus transferring heat to sand particles a short distance away much faster than conduction would), and then wicking back to the pipe. Adding insulation to buried piping dramatically reduced the heat-pipe effect by lowering the surface temperature seen by the moisture. Hence, as can be seen in Table 1, adding 19 mm foam pipe insulation to copper piping reduces the heat loss rate in air to around one-half of the uninsulated value, but adding the same insulation to pipe buried in damp sand reduces the heat loss rate to only around 6% of its uninsulated value, a reduction by a factor of around 16. Thus adding pipe insulation is highly beneficial for buried piping, and is recommended.

Table 1 also shows that all of the plastic pipes tested to date exhibit moderately to significantly higher heat loss rates than comparably sized copper pipes when tested uninsulated in air. However, when insulated, they exhibit moderately to significantly lower heat loss rates than comparably sized copper pipes with the same insulation. Adding 19 mm foam reduces plastic pipe heat loss rates to around 30% of their uninsulated values when tested in air. This is a reduction in heat loss rate by a factor of three, compared to a factor of two for insulation on copper piping. This result suggests that plastic pipes have higher emissivity for radiation heat loss from the piping than does copper. Theoretical analysis suggests that, for the pipe sizes tested, radiation heat loss from the pipes represents between 30% and 70% of total heat loss rate from the pipes, depending on pipe type and size. It has been suggested that the emissivity of copper pipe may increase with age as the outer surface oxidizes to its normal dull-brown appearance from its original bright, shiny surface. Repeat tests on aged copper pipe have not yet been performed.

The *UA* factors of Table 1 are used in Equations (1) to (8) to determine heat loss rates from piping during both flowing and zero-flow (cooldown) conditions, and to find temperature drop while water is flowing through pipe, and pipe temperature at any time during cooldown. Note that piping heat loss and pipe temperature drop are not constant with length under flowing conditions, because the temperature of each successive length of pipe is less than the one before it. The same is true for zero-flow pipe cooldown with respect to time, because the pipe is at a progressively lower temperature at each successive time interval. The result is that pipe temperatures decay inverse-exponentially with length under flowing conditions and with time under cooldown conditions. This is why log-mean temperature difference must be used in heat loss calculations instead of a simple linear temperature difference (Rohsenow and Choi 1961).

Under flowing conditions,

$$Q = mc_p(T_{hot\ in} - T_{hot\ out}) \tag{1}$$

and

$$Q = UA_{flowing}\, L_{pipe} \Delta T_{lm} \tag{2}$$

For water flowing in pipes in a constant-air-temperature environment,

$$\Delta T_{lm} = \frac{[(T_{hot\ in} - T_{air}) - (T_{hot\ out} - T_{air})]}{\ln[(T_{hot\ in} - T_{air})/(T_{hot\ out} - T_{air})]} \tag{3}$$

When $UA_{flowing}$, water flow rate, air temperature, and entering water temperature are known, Equations (1) to (3) can be combined and rearranged to determine pipe-exiting water temperature as follows:

$$T_{hot\ out} = T_{air} + (T_{hot\ in} - T_{air})e^{-\left[\frac{(UA_{flowing})(L_{pipe})}{(mc_{p_{water}})}\right]} \tag{4}$$

where

ΔT_{lm} = log mean temperature difference, K
Q = heat loss rate, W
m = water flow rate, kg/s
c_p = specific heat of water, 4186.8 J/(kg·K)
$T_{hot\ in}$ = water temperature entering pipe, °C
$T_{hot\ out}$ = water temperature leaving pipe, °C
$UA_{flowing}$ = flowing heat loss factor per metre of pipe, W/(m·K)
L_{pipe} = length of hot-water pipe, m

Note that the quantity $(UA_{flowing})(L_{pipe})/(mc_p)_{water}$ must be nondimensional, so appropriate units must be used.

Under zero-flow cooldown conditions,

$$Q = (Mc_p)_{w,p,i}\,(T_{hot\ t_1} - T_{hot\ t_2})/(t_2 - t_1) \tag{5}$$

$$Q = UA_{zero\text{-}flow}(\Delta T_{lm}) \tag{6}$$

Table 2 Approximate Heat Loss from Piping at 60°C Inlet, 21°C Ambient

Nominal Size, mm	Bare Copper Tubing, W/m	Bare Copper *UA*, W/(m·K)	13 mm Glass Fiber Insulated Copper Tubing, W/m	13 mm Glass Fiber Insulated Copper *UA*, W/(m·K)
19	29	0.74	17.0	0.43
25	37	0.93	19.5	0.50
32	43	1.11	22.5	0.57
38	51	1.32	24.4	0.62
50	63	1.63	28.5	0.73
64	77	1.97	32.5	0.83
75	90	2.32	38.0	0.96
100	115	2.96	46.5	1.19

And for pipe in a constant-air-temperature environment:

$$\Delta T_{lm} = \frac{[(T_{hot\ t_1} - T_{air}) - (T_{hot\ t_2} - T_{air})]}{\ln[(T_{hot\ t_1} - T_{air})/(T_{hot\ t_2} - T_{air})]} \tag{7}$$

$$T_{hot\ t_2} = T_{air} + (T_{hot\ t_1} - T_{air})e^{-\left[\frac{(UA_{zero\text{-}flow})(t_2 - t_1)}{(Mc_p)_{w,p,i}}\right]} \tag{8}$$

where

t_1 = initial time
t_2 = final time
Q = average heat loss rate from time t_1 to time t_2, W/m
$(Mc_p)_{w,p,i}$ = sum of mass times specific heat for water, pipe, and insulation, J/(m·K)
$T_{hot\ t_1}$ = pipe temperature at t_1, °C
$T_{hot\ t_2}$ = pipe temperature at t_2, °C
$UA_{zero\text{-}flow}$ = zero-flow heat loss factor per metre of pipe, W/(m·K)

Note that the quantity $(UA_{zero\text{-}flow})(t_2 - t_1)/(Mc_p)_{w,p,i}$ must be nondimensional, so appropriate units must be used.

Pipe temperature at any time during the cooldown process is determined by Equation (8). Total energy lost from piping during zero-flow cooldown is determined by calculating the pipe temperature at time t_2 and multiplying the average heat loss rate between t_1 and t_2 determined by Equation (5) times the duration of the cooldown period $(t_2 - t_1)$. An alternative is to calculate heat loss over short time periods using Equation (6) and sum the results.

Table 2 contains earlier piping heat loss data, and shows computed piping *UA* values based on those data.

Hiller (2005a, 2005b, 2006b) also produced tables of water/energy wasted while waiting for hot water to arrive at fixtures. Waste is a strong function of pipe material, interior finish, diameter, fittings present, flow rate, initial pipe temperature, and entering hot-water temperature. The amount of water wasted to drain is generally an amount greater than pipe volume because temperature of some of the first hot water traveling through the pipe is degraded to below a usable temperature.

Initial flow of hot water into a pipe full of cooler water often does not behave as predicted by steady-state flow theory, because both hot and cold water are flowing simultaneously in the same pipe (a non-steady-state condition). At least three different flow regimes were identified: (1) stratified flow (at low flow rates in horizontal pipes, hot water flows farther along the top side of the pipe than on the bottom side; this can happen even in small-diameter pipes), (2) normal turbulent flow, and (3) shear flow (a relatively sharp hot/cold interface with little turbulence-induced mixing of hot and cold water because the normal boundary layer is slow to develop under some conditions). These flow regimes are important because each causes different amounts of temperature degradation as hot water flows through the pipe.

For detailed information on time, water, and energy waste while waiting for hot water to arrive at fixtures, see Hiller (2005b). Simply summarized here, the amount of water waste can be expressed as the ratio of the actual amount of water (actual flow or AF) wasted while waiting for hot-enough-to-use water to arrive at fixtures (defined as 40.5°C by Hiller) divided by pipe volume (PV). When the pipe cools below a usable temperature, AF/PV ratios are usually in the range of 1.0 to 2.0, but can go to infinity at low flow rates in long, uninsulated pipe in cold or otherwise adverse (e.g., damp) heat transfer environments. The critical length of pipe at which AF/PV goes to infinity can be calculated for any flow rate and temperature conditions, using the piping $UA_{flowing}$ factors and Equations (1) to (4).

For preliminary engineering design and energy use calculations, Hiller recommends assuming AF/PV values of 1.25 to 1.75. For more refined analyses, accounting better for temperature effects on AF/PV ratio, the data tables in the original reference should be consulted. More such data on a larger variety of pipe sizes, types, and environments would be beneficial, but are not currently available.

Examples 11 to 14 demonstrate how to use piping heat loss and delivery water waste information to calculate hot-water system energy use.

Hot-Water Recirculation Loops and Return Piping

Hot-water recirculation loops are commonly used where piping lengths are long and hot water is desired immediately at fixtures. In recirculation-loop systems, return piping and a circulation device are provided. Some recirculation-loop systems use buoyancy-driven natural convection forces to circulate flow, but most are equipped with circulating pumps to force water through the piping and back to the water heater, thus keeping water in the piping hot.

The water circulation pump may be controlled by a thermostat (in the return line) set to start and stop the pump over an acceptable temperature range. This thermostat can significantly reduce both heat loss and pumping energy in some applications. An automatic time switch or other control should turn water circulation off when hot water is not required. Other, more advanced circulating pump control schemes, such as on-demand types using manual initiation, flow switches, or occupancy sensors, are also available. Because hot water is corrosive, circulating pumps should be made of corrosion-resistant material.

For small installations, a simplified pump sizing method is to allow 3 mL/s for every fixture unit in the system, or to allow 30 mL/s for each 20 or 25 mm riser; 60 mL/s for each 32 or 40 mm riser; and 130 mL/s for each riser 50 mm or larger.

Dunn et al. (1959) and Werden and Spielvogel (1969a, 1969b) discuss heat loss calculations for large systems. For larger installations, piping heat losses become significant. A quick method to size the pump and return for larger systems is as follows:

1. Determine total length of all hot-water supply and return piping.
2. Choose an appropriate value for piping heat loss from Tables 1 or 2 or other engineering data (usually supplied by insulation companies, etc.). Multiply this value by the total length of piping involved.

   A rough estimation can be made by multiplying the total length of covered pipe by 30 W/m or uninsulated pipe by 60 W/m. Table 2 gives actual heat losses in pipes at a service water temperature of 60°C and ambient temperature of 21°C. The values of 30 or 60 W/m are only recommended for ease in calculation.
3. Determine pump capacity as follows:

$$Q = \frac{q}{\rho c_p \Delta t} \tag{9}$$

where

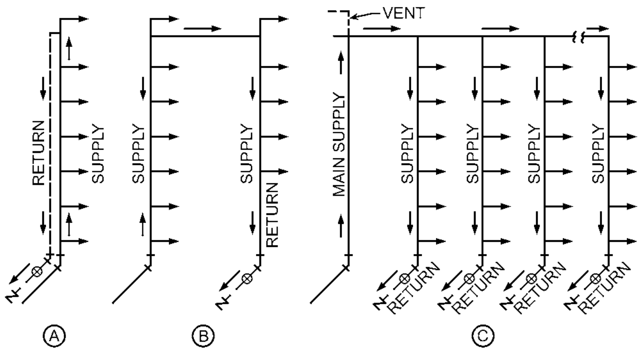

Fig. 3 Arrangements of Hot-Water Circulation Lines

Q_p = pump capacity, L/s
q = heat loss, W
ρ = density of water = 0.99 kg/L (50°C)
c_p = specific heat of water = 4186.8 J/(kg·K)
Δt = allowable temperature drop, K

For a 10 K allowable temperature drop,

$$Q_p(\text{L/s}) = \frac{q}{0.99 \times 4186.8 \times 10} = \frac{q}{41\,450} \quad (10)$$

Caution: This calculation assumes that a 10 K temperature drop is acceptable at the last fixture.

4. Select a pump to provide the required flow rate, and obtain from the pump curves the pressure created at this flow.
5. Check that the pressure does not exceed the allowable friction loss per metre of pipe.
6. Determine the required flow in each circulating loop, and size the hot water return pipe based on this flow and the allowable friction loss from Step 5.

Where multiple risers or horizontal loops are used, balancing valves with means of testing are recommended in the return lines. A swing-type check valve should be placed in each return to prevent entry of cold water or reversal of flow, particularly during periods of high hot-water demand.

Three common methods of arranging circulation lines are shown in Figure 3. Although the diagrams apply to multistory buildings, arrangements (A) and (B) are also used in residential designs. In circulation systems, air venting, pressure drops through the heaters and storage tanks, balancing, and line losses should be considered. In Figures 3A and 3B, air is vented by connecting the circulating line below the top fixture supply. With this arrangement, air is eliminated from the system each time the top fixture is opened. Generally, for small installations, a nominal pipe size (NPS) 15 or 20 mm hot-water return is ample.

All storage tanks and piping on recirculating systems should be insulated as recommended by the ASHRAE *Standard* 90 series and *Standard* 100.

Heat-Traced, Nonreturn Piping

In this system, the fixtures can be as remote as in the hot-water recirculation loops and return piping section. The hot-water supply piping is heat traced with electric resistance heating cable preinstalled under the pipe insulation. Electrical energy input is self-regulated by the cable's construction to maintain the required water temperature at the fixtures. No return piping system or circulation pump is required.

Multiple Water Heaters

Depending on fixture spacing, required pipe lengths, and draw spacing, it may be more energy-efficient (and sometimes provide lower first cost) to use more than one water heater rather than using extensive piping runs. Energy losses from high-efficiency water heaters can be lower than recirculation-loop piping heat losses if the distance from water heaters to fixtures exceeds 10 to 20 m (Hiller 2005a). Although there are considerations beyond energy use, such as installation, maintenance, and space requirements, using more than one water heater should always be evaluated when designing water heating systems, even in residences, because of the potentially large energy savings.

Commercial Dishwasher Piping and Pressure Considerations

Adequate flow rate and rinse pressure must be maintained for automatic dishwashers to achieve efficient dishwashing in commercial kitchens. National Sanitation Foundation (NSF) standards for dishwasher water flow pressure are 100 kPa (gage) minimum, 170 kPa (gage) maximum, and 140 kPa (gage) ideal. Flow pressure is the line pressure measured when water is flowing through the rinse arms of the dishwasher.

Low flow pressure can be caused by undersized water piping, stoppage in piping, or excess pressure drop through heaters. Low water pressure causes an inadequate rinse, resulting in poor drying and sanitizing of the dishes. If flow pressure in the supply line to the dishwasher is below 100 kPa (gage), a booster pump or other means should be installed to provide supply water at 140 kPa (gage).

Flow pressure over 170 kPa (gage) causes atomization of the 82°C rinse water, resulting in excessive temperature drop (which can be as much as 8 K between rinse nozzle and dishes). A pressure regulator should be installed in the supply water line adjacent to the dishwasher and external to the return circulating loop (if used).

To reduce operating difficulties, piping for automatic dishwashers should be installed according to the following recommendations:

- The cold-water feed line to the water heater should be no smaller than NPS 25 mm.
- The supply line that carries 82°C water from the water heater to the dishwasher should not be smaller than NPS 19 mm.
- No auxiliary feed lines should connect to the 82°C supply line.
- A return line should be installed if the source of 82°C water is more than 1.5 m from the dishwasher.
- Forced circulation by a pump should be used if the water heater is installed on the same level as the dishwasher, if the length of return piping is more than 18 m, or if the water lines are trapped.
- If a circulating pump is used, it is generally installed in the return line. It may be controlled by (1) the dishwasher wash switch, (2) a manual switch located near the dishwasher, or (3) an immersion or strap-on thermostat located in the return line.
- A pressure-reducing valve should be installed in the low-temperature supply line to a booster water heater, but external to a recirculating loop. It should be adjusted, with the water flowing, to the value stated by the washer manufacturer.
- A check valve should be installed in the return circulating line.
- If a check-valve water meter or a backflow prevention device is installed in the cold-water line ahead of the heater, it is necessary to install a properly sized diaphragm-type expansion tank between the water meter or prevention device and the heater.
- NSF standards require an NPS 6 mm IPS connection for a pressure gage mounted adjacent to the supply side of the control valve. They also require a water-line strainer ahead of any electrically operated control valve (Figure 4).

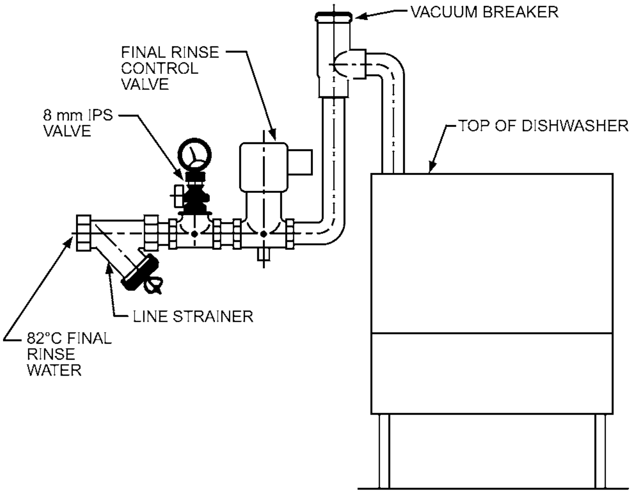

Fig. 4 National Sanitation Foundation (NSF) Plumbing Requirements for Commercial Dishwasher

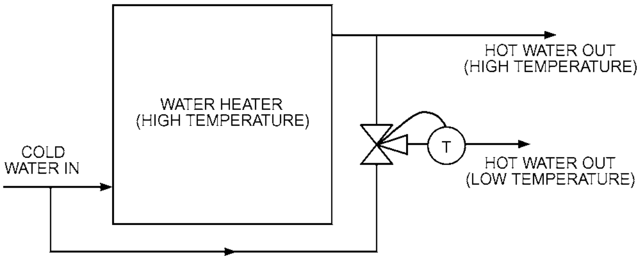

Fig. 5 Two-Temperature Service with Mixing Valve

- NSF standards do not allow copper water lines that are not under constant pressure, except for the line downstream of the solenoid valve on the rinse line to the cabinet.

Two-Temperature Service

Where multiple temperature requirements are met by a single system, the system temperature is determined by the maximum temperature needed. Where the bulk of the hot water is needed at the higher temperature, lower temperatures can be obtained by mixing hot and cold water. Automatic mixing valves reduce the temperature of the hot water available at certain outlets to prevent injury or damage (Figure 5). Applicable codes should be consulted for mixing valve requirements.

Where predominant use is at a lower temperature, the common design heats all water to the lower temperature and then uses a separate booster heater to further heat the water for the higher-temperature service (Figure 6). This method offers better protection against scalding.

A third method uses separate heaters for the higher-temperature service (Figure 7). It is common practice to cross-connect the two heaters, so that one heater can serve the complete installation temporarily while the other is valved off for maintenance. Each heater should be sized for the total load unless hot-water consumption can be reduced during maintenance periods.

Manifolding

Where one heater does not have sufficient capacity, two or more water heaters may be installed in parallel. If blending is needed, a single mixing valve of adequate capacity should be used. It is difficult to obtain even flow through parallel mixing valves.

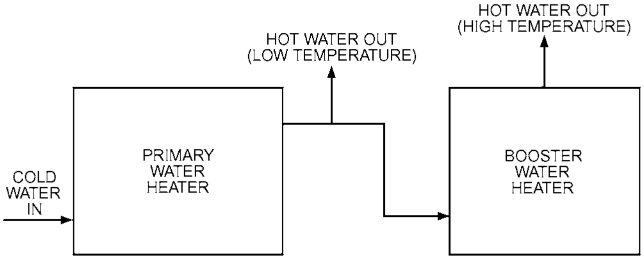

Fig. 6 Two-Temperature Service with Primary Heater and Booster Heater in Series

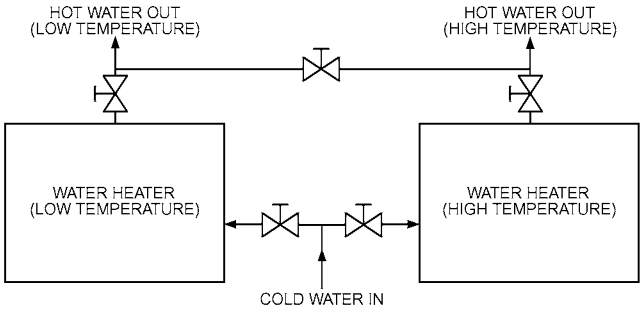

Fig. 7 Two-Temperature Service with Separate Heater for Each Service

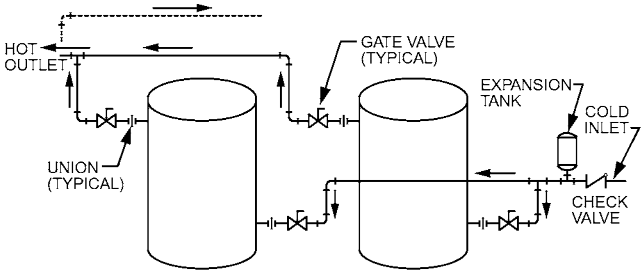

Fig. 8 Reverse/Return Manifold System

Heaters installed in parallel should have similar specifications: the same input and storage capacity, with inlet and outlet piping arranged so that an equal flow is received from each heater under all demand conditions.

An easy way to get balanced, parallel flow is to use reverse/return piping (Figure 8). The unit having its inlet closest to the cold-water supply is piped so that its outlet is farthest from the hot-water supply line. Quite often this results in a hot-water supply line that reverses direction (see dashed line, Figure 8) to bring it back to the first unit in line; hence the name reverse/return.

Care must be used in commissioning heaters in parallel flow. Field testing (Hiller and Johnson 2015) showed that having water heaters in parallel flow can result in each heater having dramatically different numbers of on/off firing cycles: an important consideration in equipment life and maintenance. Having heaters set to even slightly different on/off temperatures can cause the heater set to the highest temperatures to come on first and end up being the only heater to fire to make up most of the heat loss from the storage and distribution system.

7. WATER-HEATING EQUIPMENT

Gas-Fired Systems

Storage water heaters incorporate the burner(s), storage tank, outer jacket, and controls such as a thermostat in a single unit and typically have an input-to-storage capacity ratio of less than 300 W/L.

Instantaneous water heaters are produced in two distinctly different types. Tank-type instantaneous heaters have an input-to-storage capacity ratio of 300 W/L or more and a thermostat to control energy input to the heater. Water-tube instantaneous heaters have minimal water storage capacity. They usually have a flow switch that controls the burner, and may have a modulating fuel valve that varies fuel flow as water flow changes.

Tankless water heaters have almost no storage capacity, and heat water as it flows once through the water heater. Heating rate required varies with water flow rate and needed temperature rise. They are best suited for steady-state operation. Most modern gas-fired tankless water heaters have a flow switch or equivalent to confirm flow before the burner activates. Some have advanced multistage or modulating burners to better control outlet temperature. Some also incorporate fixed or modulating water flow rate controls to ensure that water temperature reaches at least a minimum outlet temperature (i.e., it restricts flow rate, possibly below that which the user requested, to avoid undesirably cool outlet water temperature if burners are already operating at maximum heating rate). Most advanced designs also incorporate electronic ignition controls, thus minimizing standby energy losses compared to having a tank and continuously burning pilot light. Properly applied tankless water heaters thus have lower overall energy use and higher efficiency compared to minimum-efficiency tank types serving the same loads. Note, however, that tankless gas water heaters have on/off cycling-rate-related energy losses that, under water draw events of a small volume, short duration, or intermittent nature may reduce their system efficiency and hot water delivery performance (Glanville et al. 2013). They may also have minimum flow rate requirements before they activate, which may require users to modify their behavior (e.g., use a higher flow rate than they normally would and/or leave water running when they would normally turn it off) to obtain hot water. Sometimes, it may be beneficial to reduce the hot-water delivery temperature to reduce point-of-use mixing with cold water, thereby increasing hot-water flow rate.

Circulating tank water heaters are classified in two types: (1) automatic, in which the thermostat is located in the water heater, and (2) nonautomatic, in which the thermostat is located within an associated storage tank.

Hot-water supply boilers are capable of providing service hot water. They are typically installed with separate storage tanks and applied as an alternative to circulating tank water heaters. Outdoor models are wind- and rain-tested. They are available in most of the classifications previously listed.

Direct-vent models are installed indoors, but are not vented through a conventional chimney or gas vent and do not use ambient air for combustion. They must be installed with the means specified by the equipment manufacturer for venting (typically horizontal) and for supplying combustion air from outside the building.

Power vent equipment uses a powered fan or blower to move combustion products, allowing horizontal as well as vertical venting.

Direct-fired equipment passes cold water through a stainless steel or other heat exchange medium, which breaks up the water into very small droplets. These droplets then come into direct contact with heat rising from a flame, which heats the water directly.

Residential water-heating equipment is usually the automatic storage type, although increasing numbers of tankless water heaters are being installed. For industrial and commercial applications, commonly used types of heaters are (1) automatic storage, (2) circulating tank, (3) instantaneous/tankless and (4) hot-water supply boilers.

Installation guidelines for gas-fired water heaters can be found in the National Fuel Gas Code, NFPA *Standard* 54/ANSI *Standard* Z223.1. This code also covers sizing and installation of venting equipment and controls.

Oil-Fired Systems

Oil-fired water heaters are generally the storage tank type. Models with a storage tank of 200 L or less with an input rating of 30 kW or less are usually considered residential models. Commercial models are offered in a wide range of input ratings and tank sizes. There are models available with combination gas/oil burners, which can be switched to burn either fuel, depending on local availability.

Installation guidelines for oil-fired water heaters can be found in NFPA *Standard* 31/ANSI *Standard* Z95.1.

Electric

Electric water heaters are generally the storage type, consisting of a tank with one or more immersion heating elements. The heating elements consist of resistance wire embedded in refractories having good heat conduction properties and electrical insulating values. Heating elements are fitted into a threaded or flanged mounting for insertion into a tank. Thermostats controlling heating elements may be of the immersion or surface-mounted type.

Residential storage tank water heaters range up to 450 L with input up to 12 kW. They have a primary resistance heating element near the bottom and often a secondary element located in the upper portion of the tank. Each element is controlled by its own thermostat. In dual-element heaters, the thermostats are usually interlocked so that the lower heating element cannot operate if the top element is operating. Thus, only one heating element operates at a time to limit the current draw.

Commercial storage tank water heaters are available in many combinations of element quantity, wattage, voltage, and storage capacity. Storage tanks may be horizontal or vertical. Compact, low-volume models are used in point-of-use applications to reduce hot-water piping length. Locating the water heater near the point of use makes recirculation loops unnecessary.
