Instantaneous or **tankless electric water heaters** have almost no storage capacity and heat water as it flows once through the water heater. Heating rate required varies with water flow rate and needed temperature rise. Tankless electric water heaters for residential applications are available in heating capacities from a low of about 1.5 kW to a high of about 60 kW. Smaller-capacity units (typically 12 kW or less, but this varies with geographic location and entering cold-water temperature) are sometimes used in lavatory (sink) and other point-of-use applications such as remote low-use showers, small hot tubs, whirlpool baths, and other low-flow-rate applications. Larger sizes (above 18 kW) can sometimes be used in whole-house applications, depending on geographic location (and hence entering cold water temperature) and site hot-water use profiles (see Table 15). Tankless water heaters can, if equipped with appropriate controls, be used in booster and/or recirculating water-heating systems. Note that not all models can be used to heat already partially warmed water: this capability varies among models.

Heat pump water heaters (HPWHs) use a vapor-compression or sorption refrigeration cycle to extract energy from an air, ground, or water source to heat water. HPWHs may be designed as a single package with the refrigeration system and storage water tank as an integral system; or as the refrigeration system alone, sometimes referred to as an "add-on" water heater, which is connected to a separately specified storage water tank, the size of which is generally dependent upon the application requirements. HPWHs can generate hot-water temperatures up to 60°C, with some models capable of outlet temperatures in the 82°C range. Where a higher delivery temperature is required than the HPWH can produce, a supplemental or booster water heater downstream of the storage tank should be used. HPWHs function most efficiently where inlet water temperature is low and the heat source temperature is warm. HPWHs frequently benefit from greater storage tank capacity than standard water heaters for the application because that enables the use of smaller HPWHs with lower first cost. The use of greater storage can also reduce conventional back-up energy use, though it may also increase space requirements. One of the most significant benefits of HPWHs is their ability to produce two to three times more heat output energy per unit of input energy than standard resistance and fossil-fueled water heaters. An air-source HPWH also provides potentially useful supplemental air cooling and dehumidification for occupants, and should be taken into account when defining the energy balance for the application. Cooling output should be directed to provide occupant comfort and avoid interfering with temperature-sensitive equipment (EPRI 1990).

Demand-controlled water heating can significantly reduce the cost of heating water electrically. Demand controllers operate on the principle that a building's peak electrical demand exists for a short period, during which heated water can be supplied from storage rather than through additional energy applications. Shifting the use of electricity for service water heating from peak demand periods allows water heating at the lowest electric energy cost in many electric rate schedules. The building electrical load must be detected and compared with peak demand data. When the load is below peak, the control device allows the water heater to operate. Some controllers can program deferred loads in steps as capacity is available. The priority sequence may involve each of several banks of elements in (1) a water heater, (2) multiple water heaters, or (3) water-heating and other equipment having a deferrable load, such as pool heating and snow melting. When load controllers are used, hot-water storage must be sized appropriately.

Electric off-peak storage water heating is a water-heating equipment load management strategy whereby electrical demand to a water-heating system is time-controlled, primarily in relation to the building or utility electrical load profile. This approach may require increased tank storage capacity and/or stored-water temperature to accommodate water use during peak periods.

Sizing recommendations in this chapter apply only to water heating without demand or off-peak control. When demand control devices are used, the storage and recovery rate may need to be increased to supply all the hot water needed during the peak period and during the ensuing recovery period. Manian and Chackeris (1974) include a detailed discussion on load-limited storage heating system design.

Indirect Water Heating

In indirect water heating, the heating medium is steam, hot water, or another fluid that has been heated in a separate generator or boiler. The water heater extracts heat through an external or internal heat exchanger.

When the heating medium is at a higher pressure than the service water, the service water may be contaminated by leakage of the heating medium through a damaged heat transfer surface. In the United States, some national, state, and local codes require double-wall, vented tubing in indirect water heaters to reduce the possibility of cross-contamination. When the heating medium is at a lower pressure than the service water, other jurisdictions allow single-wall tubing heaters because any leak would be into the heating medium.

If the heating medium is steam, high rates of condensation occur, particularly when a sudden demand causes an inflow of cold water. The steam pipe and condensate return pipes should be of ample size. Condensate may be cooled by preheating the cold-water supply to the heater.

Corrosion is minimized on the heating medium side of the heat exchanger because no makeup water, and hence no oxygen, is brought into that system. The metal temperature of the service water side of the heat exchanger is usually less than that in direct-fired water heaters. This minimizes scale formation from hard water.

Storage water heaters are designed for service conditions where hot-water requirements are not constant (i.e., where a large volume of heated water is held in storage for periods of peak load). The amount of storage required depends on the load's nature and water heater's recovery capacity. An individual tank or several tanks joined by a manifold may be used to provide the required storage.

External storage water heaters are designed for connection to a separate tank (Figure 9). Boiler water circulates through the heater shell, while service water from the storage tank circulates through the tubes and back to the tank. Circulating pumps are usually installed in both the boiler water piping circuit and the circuits between the heat exchanger and the storage tank. Steam can also be used as the heating medium in a similar scheme.

Instantaneous indirect water heaters (tankless coils) are best used for a steady, continuous supply of hot water. In these units, the water is heated as it flows through the tubes. Because the heating medium flows through a shell, the ratio of hot-water volume to heating medium volume is small. As a result, variable flow of the service water causes uncertain temperature control unless a thermostatic mixing valve is used to maintain the hot-water supply to the plumbing fixtures at a more uniform temperature.

Some indirect instantaneous water heaters are located inside a boiler. The boiler is provided with a special opening through which the coil can be inserted. Although the coil can be placed in the steam space above the water line of a steam boiler, it is usually placed below the water line. The water heater transfers heat from the boiler water to the service water. The gross output of the boiler must be sufficient to serve all loads.

Semi-Instantaneous

These water heaters have limited storage to meet the average momentary surges of hot-water demand. They usually consist of a heating element and control assembly devised for close control of the temperature of the leaving hot water.

Circulating Tank

These water heaters are instantaneous or semi-instantaneous types used with a separate storage tank and a circulating pump. The

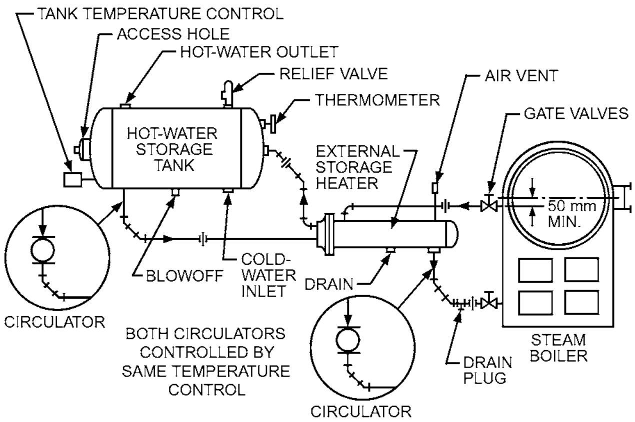

Fig. 9 Indirect, External Storage Water Heater

storage acts as a flywheel to accommodate variations in the demand for hot water.

Blending Injection

These water heaters inject steam or hot water directly into the process or volume of water to be heated. They are often associated with point-of-use applications (e.g., certain types of commercial laundry, food, and process equipment). *Caution*: Cross contamination of potable water is possible.

Solar

Availability of solar energy at the building site, efficiency and cost of solar collectors, system installation costs, and availability and cost of other fuels determine whether solar energy collection units should be used as a primary heat energy source. Solar energy equipment can also be included to supplement other energy sources and conserve fuel or electrical energy.

The basic elements of a solar water heater include solar collectors, a storage tank, piping, controls, and a transfer medium. The system may use natural or forced circulation. Auxiliary heat energy sources may be added, if needed.

Collector design must allow operation in below-freezing conditions, where applicable. Antifreeze solutions in a separate collector piping circuit arrangement are often used, as are systems that allow water to drain back to heated areas when low temperatures occur. Uniform flow distribution in the collector or bank of collectors and stratification in the storage tank are important for good system performance.

Application of solar water heaters depends on (1) auxiliary energy requirements; (2) collector orientation; (3) temperature of the cold water; (4) general site, climatic, and solar conditions; (5) installation requirements; (6) area of collectors; and (7) amount of storage. Chapter 36 has more detailed design information.

Wood Fired

Water heaters are available that use wood, usually in chip or pellet form, as the fuel source.

Waste Heat Use

Waste heat recovery can reduce energy cost and the energy requirement of the building heating and service water-heating equipment. Waste heat can be recovered from equipment or processes by using appropriate heat exchangers in the hot gaseous or liquid streams. Heat recovered is frequently used to preheat water entering the service water heater. A conventional water heater is typically required to augment the output of a waste heat recovery device and to provide hot water during periods when the host system is not in operation.

Refrigeration Heat Reclaim

These systems heat water with heat that would otherwise be rejected through a refrigeration, air-conditioning, or heat pump condenser. Refrigeration heat reclaim uses refrigerant-to-water heat exchangers connected to the refrigeration circuit between the compressor and condenser of a host refrigeration or air-conditioning system to extract heat. Water is heated only when the host is operating. Because many simple systems reclaim only superheat energy from the refrigerant, they are often called **desuperheaters**. However, some units are also designed to provide partial or full condensing. The refrigeration heat reclaim heat exchanger is generally of vented, double-wall construction to isolate potable water from refrigerant. Some heat reclaim devices are designed for use with multiple refrigerant circuits. Controls are required to limit high water temperature, prevent low condenser pressure, and provide for freeze protection. Refrigeration systems with higher run time and lower efficiency provide more heat reclaim potential. Most systems are designed with a preheat water storage tank connected in series with a conventional water heater (EPRI 1992). In all installations, care must be taken to prevent inappropriately venting refrigerants.

Combination Heating

A **combination system** (**combo** or **combi system**) provides hot water for both space heating and domestic use. Most combi systems are one of two types. The first type consists of a water-heating source and a hydronic air handler with a space-heating coil. A space-cooling coil is often included with the air handler to provide year-round comfort. The second type consists of a hydronic space heater with a domestic hot-water loop. The domestic hot-water loop uses an integrated heat exchanger with or without an indirect storage tank. Combi systems can also be subdivided into segregated and nonsegregated systems. A segregated system keeps the potable hot water separate from the fluid used in the heat exchange circuit for space heating, through the installation of additional heat exchangers and pumps if required. A nonsegregated system uses potable hot water to serve both the space-heating circuit and domestic hot-water system. In nonsegregated systems, a means to prevent water stagnation is required; this often involves pumping the water around the circuit or flushing the circuit at regular intervals.

The benefits of combi systems include (1) cost reductions through the use of one heat generator and one vent system, (2) space savings in most applications through having a packaged system delivering more than one function, and (3) efficiency benefits through the use of advanced controls in select systems that can optimize the combi system operation.

A method of testing combi systems is given in ASHRAE *Standard* 124. The test procedures allow the calculation of combined annual efficiency (CAE), as well as space- and water-heating efficiency factors. Kweller (1992), Pietsch and Talbert (1989), Pietsch et al. (1994), Subherwal (1986), and Talbert et al. (1992) provide additional design information on noncondensing combi systems. Butcher (2011), Schoenbauer et al. (2012), and Thomas (2011) provide guidance for condensing combi systems.

8. BUILDING APPLICATIONS

Service hot water may be used in various ways in residential, commercial, institutional, and industrial buildings. In some buildings, such as retail stores and office buildings, hot water is predominately used at lavatory sinks for hand washing and, to a lesser amount, at service sinks for floor-cleaning purposes. In other commercial and institutional buildings, hot-water use is process dominated for operations such as commercial kitchens, laundry, and manufacturing, while hot-water use is minimal for hand washing. Residential facilities use hot water in their kitchen, bathroom, and laundry, and the usage is more balanced. The following section identifies some of the common types of facilities that use service hot water. Each facility type is characterized in terms of type of hot-water use, and metrics are provided for average and peak hot-water use.

Dormitories. Hot-water requirements for college dormitories generally include showers, lavatories, service sinks, and clothes washers. Peak demand usually results from the use of showers. Load profiles and hourly consumption data indicate that peaks may last 1 or 2 h and then taper off substantially. Peaks occur predominantly in the evening, mainly around midnight. The figures do not include hot water used for food service.

Military Barracks. Design criteria for military barracks are available from the engineering departments of the U.S. Department of Defense. Some measured data exist for hot-water use in these facilities. For published data, contact the U.S. Army Corps of Engineers or Naval Facilities Engineering Command.

Motels. Domestic hot-water requirements are for tubs and showers, lavatories, and general cleaning purposes. Recommendations are based on tests at low- and high-rise motels located in urban, suburban, rural, highway, and resort areas. Peak demand, usually from shower use, may last 1 or 2 h and then drop off sharply. Food service, laundry, and swimming pool requirements are not included.

Nursing Homes. Hot water is required for tubs and showers, wash basins, service sinks, kitchen equipment, and general cleaning. These figures include hot water for kitchen use. When other equipment, such as that for heavy laundry and hydrotherapy purposes, is to be used, its hot-water requirement should be added.

Office Buildings. Hot-water requirements are primarily for cleaning and lavatory use by occupants and visitors. Older office buildings often use hot-water recirculation-loop systems and are thus good candidates for water-heating distribution system efficiency upgrades through more modern controls and/or addition of point-of-use water heaters. Hot-water use for food service in office buildings is not included.

Food Service Facility. Commercial kitchens can be separated into five major stand-alone food service facility types: coffee/specialty, bar/tavern, deli/sandwich, quick-service restaurant, and full-service restaurant. Commercial kitchens are found in eight major facility types, including nursing/residential care, K-12 schools, supermarkets, office buildings, hotels/casinos with kitchens, hospitals, colleges/universities, and correctional facilities. The three largest segments are coffee/specialty shops, quick-service restaurants and full-service restaurants, together roughly accounting for 75% of all commercial kitchens. Hot-water use intensity in facilities can be distinguished by types of wares used in the dining room. Many smaller facilities, such as coffee shops, sandwich shops, and quick-service restaurants, use disposable wares (e.g., plates, cups), and therefore have much lower use intensity, whereas larger facilities, such as full-service restaurants and cafeterias, use reusable wares and utensils. Hot water is used primarily for ware washing (e.g., dishes, cups, cutting boards). Other uses include food preparation, floor and equipment cleaning, and hand washing.

Apartments. Hot-water requirements for both garden-type and high-rise apartments are for one- and two-bath apartments, for showers, lavatories, kitchen sinks, dishwashers, clothes washers, and general cleaning purposes. Clothes washers can be either in individual apartments or centrally located. These data apply to central water-heating systems only.

Elementary Schools. Hot-water requirements are for lavatories, cafeteria and kitchen use, and general cleaning purposes. When showers are used, their additional hot-water requirements should be added. Recommendations include hot water for dishwashers but not for extended school operation such as evening classes.

High Schools. Senior high schools, grades 9 or 10 to 12, require hot water for showers, lavatories, dishwashers, kitchens, and general cleaning. Junior high schools, grades 7 to 8 or 9, have requirements similar to those of senior high schools. Junior high schools without showers follow the recommendations for elementary schools.

Requirements for high schools are based on daytime use. Recommendations do not take into account hot-water use for additional activities, such as night school. In such cases, the maximum hourly demand remains the same, but the maximum and average daily use increase, usually by the number of additional people using showers and, to a lesser extent, eating and washing facilities.

An important consideration in design of water heating and hot water distribution systems in K-12 schools is that schools have low average occupancy levels. Because of holidays, weekends, and other non-use periods (e.g. night), most K-12 schools are unoccupied approximately 75% of all hours of the entire year. This makes use of recirculation loops (RL) range from less desirable to highly undesirable from both energy use and first-cost perspectives in such applications. K-12 schools often both use less energy and have lower first cost if loads are served by multiple smaller water heaters located near end uses, eliminating the need for recirculation loops (Hiller 2002, 2005c; Hiller et al. 2002, 2004).

9. HOT-WATER LOAD AND EQUIPMENT SIZING

Methods for sizing storage water heaters vary. Those using recovery versus storage curves are based on extensive research. All methods provide adequate hot water if the designer allows for unusual conditions. To serve a hot-water load adequately, the needs of both the peak energy withdrawal rate and total integrated energy delivery for end uses must be met. Meeting these needs can be done either by providing a heating rate large enough to meet the peak energy withdrawal rate of the system (and modulating that heating input for smaller loads), or by providing a lower heating rate combined with storage (from which the peak rates can be satisfied). Lower costs are usually achieved by using at least some storage. A variety of different heating rate/storage volume combinations can be used to meet the needs of a given water-heating load profile (Hiller 1998).

Load Diversity

The greatest difficulty in designing water-heating systems comes from uncertainty about design hot-water loads, especially for buildings not yet built. Although it is fairly simple to test maximum flow rates of various hot-water fixtures and appliances, actual flow rates and durations are user-dependent. Moreover, the timing of different hot-water use events varies from day to day, with some overlap, but almost never will all fixtures be used simultaneously. As the number of hot-water-using fixtures and appliances grows, the percent of those fixtures used simultaneously decreases.

Some of the hot-water load information in this chapter is based on limited-scale field testing combined with statistical analysis to estimate load demand or **diversity** factors (percent of total possible load that is ever actually used at one time) versus number of end use points, number of people, etc. Much of the work to provide these diversity factors dates from the 1930s to the 1960s and is therefore outdated; it remains, however, the best information currently available (with a few exceptions, as noted). Of greatest concern is the fact that most of the data from those early studies were for fixtures that used water at much higher flow rates than modern energy-efficient fixtures (e.g., low-flow shower heads and sink aerators, energy-efficient washing machines and dishwashers). Some research has provided limited information on hot-water use by more modern fixtures, and on their use diversity (Becker et al. 1991; Goldner 1994a, 1994b; Goldner and Price 1999; Hiller 1998; Hiller and Johnson 2015; Hiller and Lowenstein 1996, 1998; Thrasher and DeWerth 1994), but much more information in a variety of applications is needed before the design procedures can be updated. Using the older load diversity information usually results in a water-heating system that adequately serves the loads, but often results in substantial oversizing. Oversizing can be a deterrent to using modern high-efficiency water-heating equipment, which may have higher first cost per unit of capacity than less efficient equipment. Sustainable design must consider these effects.

Residential

Table 3 shows typical hot-water usage in a residence, including usage rates of modern ultralow-use appliances and fixtures. It is more difficult to show typical values for newer devices, because some automatically adjust the amount of hot water they use based on sensed load or cycle setting. In its *Minimum Property Standards for Housing*, the U.S. Department of Housing and Urban Development (HUD 1994) established minimum permissible water heater sizes (Table 4). Storage water heaters may vary from the sizes shown if combinations of recovery and storage are used that produce the required 1 h draw.

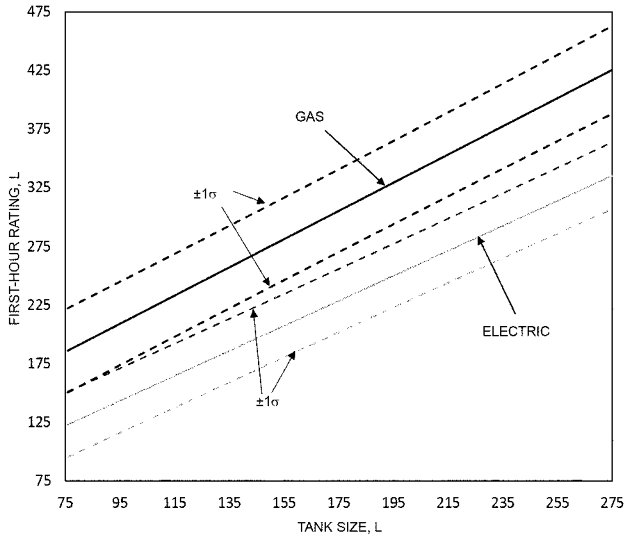

Fig. 10 First-Hour Rating (FHR) Relationships for Residential Water Heaters

Table 3 Typical Residential Use of Hot Water

Use	High Flow, Litres/Task	Low Flow (Water Savers Used), Litres/Task	Ultralow Flow, Litres/Task
Food preparation	19	11	11
Hand dish washing	15	15	11
Automatic dishwasher	57	57	11 to 38
Clothes washer	121	80	19 to 57
Shower or bath	76	57	38 to 57
Face and hand washing	15	8	4 to 8

The first-hour rating (FHR) is a measure of the maximum amount of hot water that a water heater can supply in 1 h of operation when started from operational temperature under specific test conditions (DOE 2014). The linear regression lines shown in Figure 10 represent the FHR for 45 electric heaters (both resistance and heat pump) and 150 gas heaters (DOE 2017). Regression lines are not included for oil-fired heaters because of limited data. The FHR represents water-heater performance characteristics that are similar to those represented by the 1 h draw values listed in Table 4. Residential water-heating equipment sizing is frequently driven by amounts of water used over periods of considerably less than 1 h, often as short as 15 minutes (Hiller 1998). Over these short periods, storage tank volume is a better indicator of hot-water delivery capability than FHR for residential applications. Water heater FHRs changed (generally become lower) because of changes in the DOE test and rating conditions that went into effect in 2015.

Another factor to consider when sizing water heaters is the set-point temperature. At lower storage tank water temperatures, the tank volume and/or energy input rate may need to be increased to meet a given hot-water demand. Currently, manufacturers ship residential water heaters with a recommendation that the initial set point be approximately 50°C to minimize the potential for scalding. Reduced set points generally lower standby losses and increase the water heater's efficiency and recovery capacity, but may also reduce the amount of hot water available.

The structure and lifestyle of a typical family (variations in family size, age of family members, presence and age of children, hot-water use volume and temperature, and other factors) cause hot-water consumption demand patterns to fluctuate widely in both magnitude and time distribution.

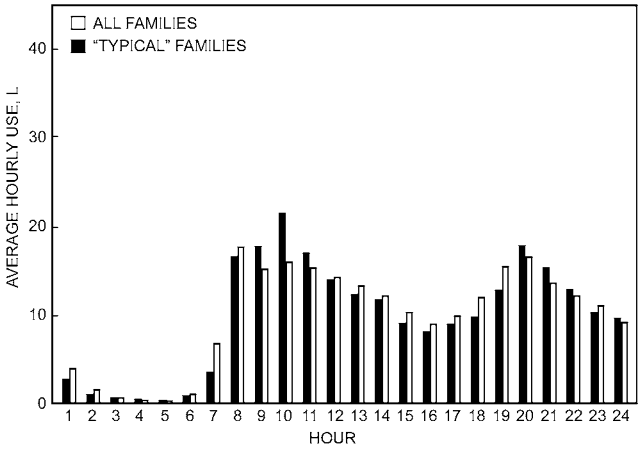

Fig. 11 Residential Average Hourly Hot-Water Use

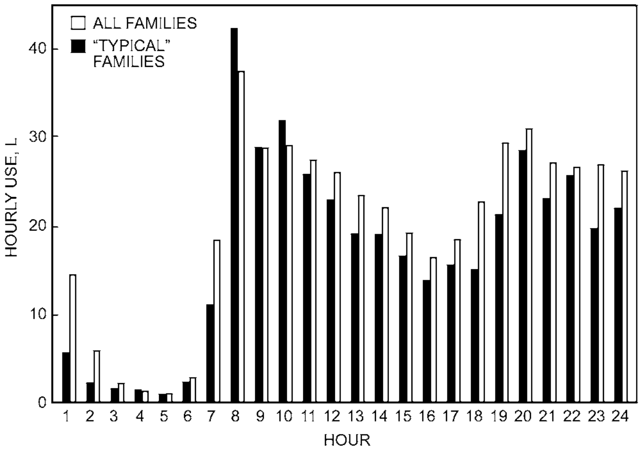

Fig. 12 Residential Hourly Hot-Water Use, 95% Confidence Level

Perlman and Mills (1985) developed the overall and peak average hot-water use volumes shown in Table 5. Average hourly patterns and 95% confidence level profiles are shown in Figures 11 and 12. Samples of results from the analysis of similarities in hot-water use are given in Figures 13 and 14.

Commercial and Institutional

Most commercial and institutional establishments use hot or warm water. The specific requirements vary in total volume, flow rate, duration of peak load period, and temperature. Water heaters and systems should be selected based on these requirements.

This section covers sizing recommendations for central storage water-heating systems. Hot-water usage data and sizing curves for dormitories, motels, nursing homes, office buildings, food service establishments, apartments, and schools are based on EEI-sponsored research (Werden and Spielvogel 1969a, 1969b). Caution must be taken in applying these data to small buildings. Also, within any given category there may be significant variation. For example, the motel category encompasses standard, luxury, resort, and convention motels.

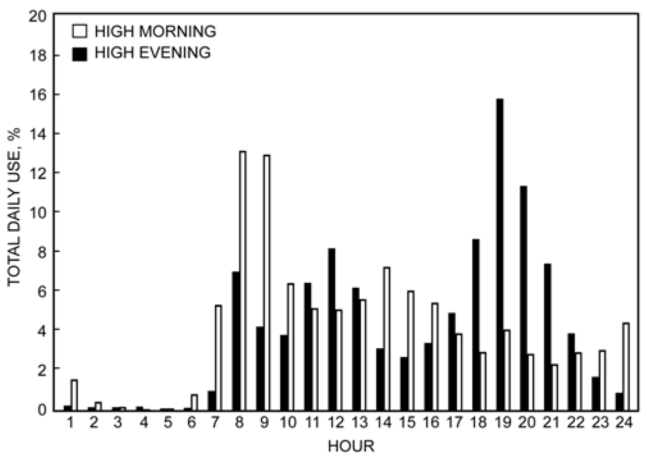

Fig. 13 Residential Hourly Hot-Water Use Pattern for Selected High Morning and High Evening Users

When additional hot-water requirements exist, increase the recovery and/or storage capacity accordingly. For example, if there is food service in an office building, the recovery and storage capacities required for each additional hot-water use should be added when sizing a single central water-heating system.

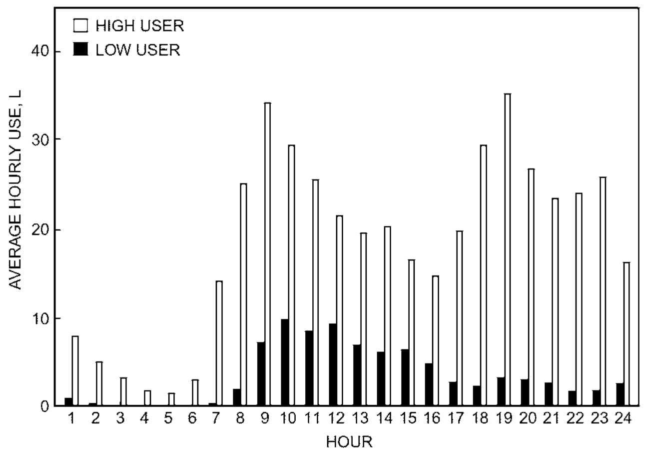

Fig. 14 Residential Average Hourly Hot-Water Use Patterns for Low and High Users

Peak hourly and daily demands for various categories of commercial and institutional buildings are shown in Table 6. These demands for central-storage hot water represent the maximum flows metered in this 129-building study, excluding extremely high and very infrequent peaks. Table 6 also shows average hot-water consumption figures for these buildings. Averages for schools and food service establishments are based on actual days of operation; all others are based on total days. These averages can be used to estimate monthly consumption of hot water, but are not intended for sizing purposes because they do not show the time distribution of draws.

Research conducted for ASHRAE (Becker et al. 1991; Thrasher and DeWerth 1994) and others (Goldner 1994a, 1994b) included a compilation and review of service hot-water use information in

Table 6 Hot-Water Demands and Use for Various Types of Buildings*

Type of Building	Maximum Hourly	Maximum Daily	Average Daily
Men's dormitories	14.4 L/student	83.3 L/student	49.7 L/student
Women's dormitories	19 L/student	100 L/student	46.6 L/student
Motels: Number of units[a]			
20 or less	23 L/unit	132.6 L/unit	75.8 L/unit
60	20 L/unit	94.8 L/unit	53.1 L/unit
100 or more	15 L/unit	56.8 L/unit	37.9 L/unit
Nursing homes	17 L/bed	114 L/bed	69.7 L/bed
Office buildings	1.5 L/person	7.6 L/person	3.8 L/person
Food service establishments:			
Type A: Full-meal restaurants and cafeterias	5.7 L/max meals/h	41.7 L/max meals/day	9.1 L/average meals/day[b]
Type B: Drive-ins, grills, luncheonettes, sandwich and snack shops	2.6 L/max meals/h	22.7 L/max meals/day	2.6 L/average meals/day[b]
Apartment houses: Number of apartments			
20 or less	45.5 L/apartment	303.2 L/apartment	159.2 L/apartment
50	37.9 L/apartment	276.7 L/apartment	151.6 L/apartment
75	32.2 L/apartment	250 L/apartment	144 L/apartment
100	26.5 L/apartment	227.4 L/apartment	140.2 L/apartment
200 or more	19 L/apartment	195 L/apartment	132.7 L/apartment
Elementary schools	2.3 L/student	5.7 L/student	2.3 L/student[b]
Junior and senior high schools	3.8 L/student	13.6 L/student	6.8 L/student[b]

[a]Interpolate for intermediate values. [b]Per day of operation.

commercial and multifamily structures along with new monitoring data. Some of this work found consumption comparable to those shown in Table 6; however, many of the studies showed higher consumption.

Additional Data.

Fast Food Restaurants. Hot water is used for food preparation, cleanup, and rest rooms. Dish washing is usually not a significant load. In most facilities, peak usage occurs during the cleanup period, typically soon after opening and immediately before closing. Hot-water consumption varies significantly among individual facilities. Fast food restaurants typically consume 1000 to 2000 L per day (EPRI 1994).

Supermarkets. The trend in supermarket design is to incorporate food preparation and food service functions, substantially increasing the usage of hot water. Peak usage is usually associated with cleanup periods, often at night, with a total consumption of 1100 to 3800 L per day (EPRI 1994).

Apartments. Table 7 shows cumulative hot-water use over time for apartment buildings, taken from a series of field tests by Becker et al. (1991), Goldner (1994a, 1994b), Goldner and Price (1999), and Thrasher and DeWerth (1994). These data include use diversity information, and enable use of modern water-heating equipment sizing methods for this building type, making it easy to understand the variety of heating rate and storage volume combinations that can serve a given load profile (see Example 1). Unlike Table 6, Table 7 presents low/medium/high (LMH) guidelines rather than specific singular volumes, and gives better time resolution of peak hot-water use information. The same information is shown graphically in Figure 15. Note that these studies showed that occupants on average use more hot water when water-heating costs are included in the rent, than if the occupants pay directly for water-heating energy use.

The low-use peak hot-water consumption profile represents the lowest peak profile seen in the tests, and is generally associated with apartment buildings having mostly a mix of the following occupant demographics:

- All occupants working
- One person working, while one stays at home
- Seniors
- Couples
- Middle income
- Higher population density

Table 7 Hot-Water Demand and Use Guidelines for Apartment Buildings (Litres per Person at 49°C Delivered to Fixtures)

Guideline	Peak Minutes 5	15	30	60	120	180	Maximum Daily	Average Daily
Low	1.5	3.8	6.4	10.6	17.0	23.1	76	53
Medium	2.6	6.4	11.0	18.2	30.3	41.6	185	114
High	4.5	11.4	19.3	32.2	54.9	71.9	340	204

The medium-use peak hot-water consumption profile represents the overall average highest peak profile seen in the tests, and is generally associated with apartment buildings having mostly a mix of the following occupant demographics:

- Families
- Singles
- On public assistance
- Single-parent households

The high-use peak hot-water consumption profile represents the highest peak profile seen in the tests, and is generally associated with apartment buildings having mostly a mix of the following occupant demographics:

- High percentage of children
- Low income
- On public assistance
- No occupants working
- Families
- Single-parent households

In applying these guidelines, the designer should note that a building may outlast its current use. This may be a reason to increase the design capacity for domestic hot water or allow space and connections for future enhancement of the service hot-water system. Building management practices, such as the explicit prohibition (in the lease) of apartment clothes washers or the existence of bath/kitchen hook-ups, should be factored into the design process.

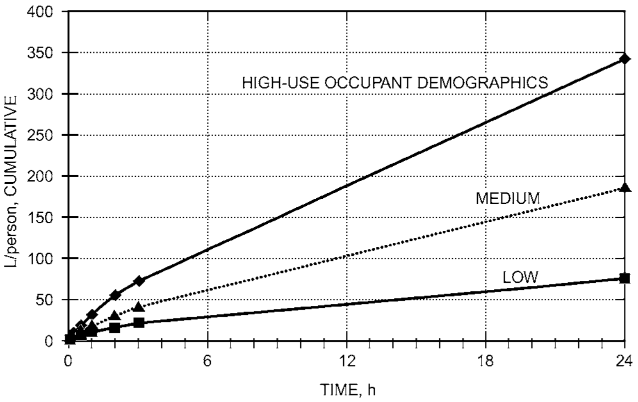

Fig. 15 Apartment Building Cumulative Hot-Water Use Versus Time (from Table 7)

A diversity factor that lowers the probability of coincident consumption should also be used in larger buildings.

The information in Table 7 and Figure 15 generates a water-heating equipment sizing method for apartment buildings. The cumulative total hot-water consumption versus time (which includes all necessary load diversity information) can be used to select a range of heating rate and storage volume options, all of which will satisfy the load. The key is that plots of cumulative total hot-water consumption versus time as shown in Figure 15 also represent, by the slope of a line drawn from zero time through the cumulative volume used at any given time, the average hot-water flow rate up to that point in time. Up to any point in time, the minimum average heating rate needed to satisfy the load is one that can heat the average hot-water flow rate through that time from the local entering cold-water temperature to the water-heating system delivery temperature. (More accurately, the heating rate needed is determined by the local slope of the hot-water use versus time curve, not the average slope. This is because storage can supply the hot water supplied up to a selected time, and the heating rate only needs to provide the additional energy after storage is depleted. Eventually, however, storage needs to be reheated, which must also be considered. See the two methods shown in Example 1.) The storage volume needed for that heating rate is the total cumulative flow through that time (Hiller 1998). To evaluate the range of minimum required heating rates and their corresponding minimum required storage tank volumes, it is easiest to pick various volumes in Figure 15 or Table 7, then determine the heating rate and time period that correspond to them, as shown in Example 1. Final selection of water-heating system heating rate and storage size is then made by examining the first and operating costs of the various combinations.

Hotels. Hotel hot water uses tend to be grouped into three major categories: (1) guest room circuit, (2) laundry circuit, and (3) food service/commercial kitchen circuit. Guest room circuits tend to have the following hot water loads: (1) guest showers and baths, (2) guest room sink use, (3) guest room cleaning, and (4) common area cleaning. Bathing (showers and baths) is the largest single hotel hot-water use category, often exceeding all other hot-water uses combined. Research results from Hiller and Johnson (2015, 2016a, 2016b, 2016c, 2017a, 2017b) present findings on a study of a large conference hotel and a roadside travel hotel. The work provides guidance on sizing of the water heating system, including storage volumes and heating rates of water heaters, based on these two studies. ASHRAE members can obtain copies of RP-1544 reports at no cost via the ASHRAE Technology Portal (technologyportal.ashrae.org).

Sizing Examples

Example 1. Evaluate the range of water-heating system heating-rate and storage volume combinations that can serve a 58-unit apartment building occupied by a mix of families, singles, and middle-income couples in which most adults work. The peak expected number of building occupants is 198, based on the assortment of apartment sizes in the building. Assume a water-heating system delivery temperature of 50°C, design entering cold-water temperature of 4°C, and heating device thermal efficiency of 80%.

Simplified Method.

Solution: The stated occupant demographics represent a medium load. Multiplying the volume per person versus time from the medium values in Table 7 by the number of occupants gives the cumulative amount needed at any point in time and the average flow rate (and hence heating rate) required through that time.

At 5 min, the peak design cumulative volume is (2.6 L/person) × (198 people) = 515 L. The average flow rate over 5 min is (515 L)/(5 min)/(60 s/min) = 1.7 L/s. The required heating rate is thus, from Equation (1) and dividing by the input efficiency,

$$q = (1.7 \text{ L/s})(1 \text{ kg/L})[4.1868 \text{ kJ/(kg·K)}] \times (50 - 4°\text{C})/0.8 = 409 \text{ kW}$$

Assuming 70% of the storage tank volume can be extracted at a useful temperature (the other 30% being degraded by mixing in the tank), the required tank volume for this heating rate is

$$V = 515 \text{ L}/0.7 = 736 \text{ L}$$

Note that, because the heating rate divided by storage capacity (555 W/L) exceeds 300 W/L, this system is considered an instantaneous water heater.

At 60 min, 18.2 L/person)(198 people) = 3604 L. Average flow rate = (3604 L/60 min)/(60 s/min) = 1 L/s.

$$q = (1 \text{ L/s})(1 \text{ kg/L})[4.1868 \text{ kJ/(kg·K)}] \times (50 - 4°\text{C})/0.8 = 240 \text{ kW}$$

$$V = 3604 \text{ L}/0.7 = 5149 \text{ L}$$

Doing these calculations at other volumes and times yields the combinations of heating rate and storage volume that can serve the load (Table 8).

More Accurate Method.

The preceding simplified method calculates the needed heating rate by computing the average water flow rate from the beginning of all draws for the day. In reality, because some storage is present, the water-heating device only needs to provide a heating rate computed from the local slope of the hot-water use curve, not the average slope. In other words for example, the flow over the first 5 min could have been provided entirely from storage without any heat input at all. The water heater only needs to heat in real time the amount of hot water needed over succeeding time periods. Consequently, the simplified heating rate computational method works, but results in some degree of heating rate oversizing.

Solution: Using the more accurate heating rate sizing method is similar to using the simplified method, except the local slope of the hot-water use curve versus time must be found at each time interval to determine the necessary heating rate.

At 5 min, the peak design cumulative volume (Table 8) is 515 L. At 15 min, the peak design cumulative volume (Table 8) is 1267 L. The incremental flow rate (representing the local slope of the hot water use line) is hence (1267 – 515 L)/600 s =1.25 L/s. The needed heating rate is thus more accurately computed as

$$Q = (1.25 \text{ L/s})(1 \text{ kg/L})[4.1868 \text{ kJ/(kg·K)}] (50°\text{C} - 4°\text{C})/0.8 = 303 \text{ kW}$$

Note that heating rate divided by storage capacity (411 W/L) exceeds 300 W/L, so the more accurately sized system is still considered an instantaneous water heater.

From Table 8, the peak design cumulative volume at 120 min is 5999 L, and is 8237 L at 180 min. The incremental flow rate slope is thus ((8237 – 5999 L)/3600 s = 0.62 L/s. The heating rate needed when using 5999 L of storage is more accurately computed as

$$Q = (0.62 \text{ L/s})(1 \text{ kg/L})[4.1868 \text{ kJ/(kg·K)}](50°\text{C} - 4°\text{C})/0.8 = 151 \text{ kW}$$

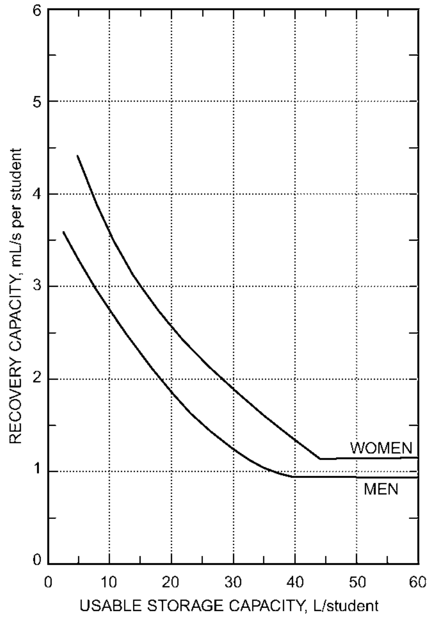

Fig. 16 Dormitories

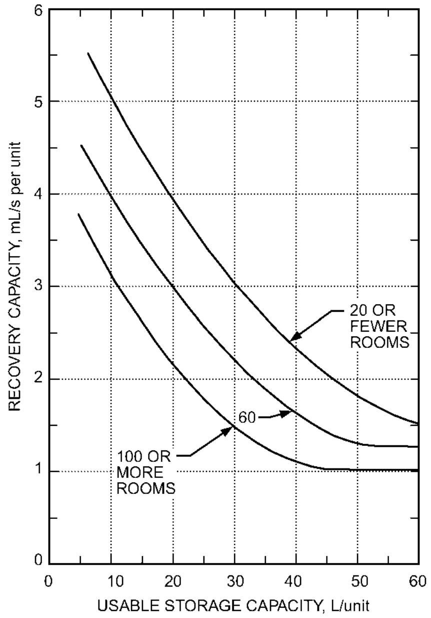

Fig. 17 Motels

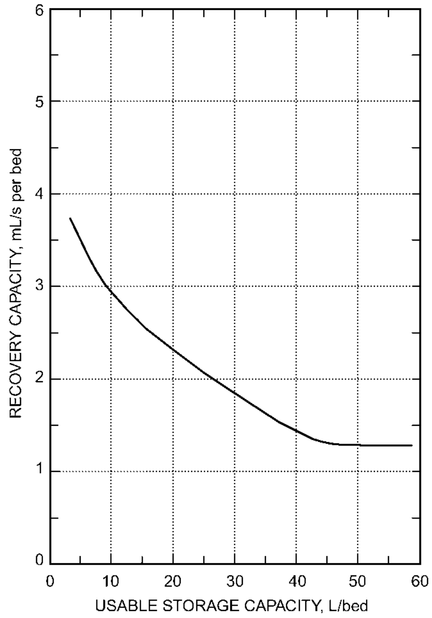

Fig. 18 Nursing Homes

Table 8 Example 1, Simplified Method: Heating Rate and Storage Volume Options

Time, min	Litres per Person	Total Litres for 198 People	Average Litres per Second	Heating Rate, kW	Storage Volume, L
5	2.6	515	1.7	409	736
15	6.4	1 267	1.4	337	1810
30	11.0	2 178	1.2	288	3111
60	18.2	3 604	1.0	240	5149
120	30.3	5 999	0.83	200	8570
180	41.6	8 237	0.76	183	11 767
1440	185.5	36 729	0.43	103	52 470

From Table 8, the peak design cumulative volume at 180 min is 8237 L, and at 1440 min is 36 729 L. Consequently, the incremental flow rate slope is (36 729 – 8237 L)/75 600 s = 0.38 L/s. The heating rate needed when using 8237 L of storage is thus more accurately computed as

Q = (0.38 L/s)(1 kg/L)[4.1868 kJ/(kg·K)](50°C – 4°C)/0.8 = 91.5 kW

It is important to recognize, however, when using this more accurate heating rate sizing method, that storage must eventually be reheated. The minimum heating rate used should therefore not be less than that computed using the 24 h average flow rate.

Doing these calculations at other volumes and times yields the more accurate combinations of heating rate and storage volume that can serve the load, as shown in Table 9.

There are several techniques to size water-heating systems using the more limited draw profile information in older data. Figures 16 to 23 show relationships between recovery and storage capacity for various building categories. Any combination of storage and recovery rate that falls on the proper curve satisfies building requirements. Using the minimum recovery rate and maximum storage capacity on the curves yields the smallest hot-water capacity able to satisfy the building requirement. The higher the recovery rate, the greater the 24 h heating capacity and the smaller the storage capacity required. Note that the data in Figures 16 to 23 predate modern low-flow fixtures and appliances.

These curves can be used to select recovery and storage requirements to accommodate water heaters that have fixed storage or recovery rates. Where hot-water demands are not coincident with peak electric, steam, or gas demands, greater heater inputs can be selected if they do not create additional energy system demands, and the corresponding storage tank size can be selected from the curves.

Ratings of gas-fired water-heating equipment are based on sea-level operation and apply up to 600 m. For operation above 600 m, and in the absence of specific recommendations from the local authority, equipment ratings should be reduced by 4% for each 300 m above sea level before selecting appropriately sized equipment.

Recovery rates in Figures 16 to 23 represent the actual hot water required without considering system heat losses. Heat losses from storage tanks and recirculating hot-water piping should be calculated and added to the recovery rates shown. Storage tanks and hot-water piping must be insulated.

The storage capacities shown are net usable requirements. Assuming that 60 to 80% of the hot water in a storage tank is usable, the actual storage tank size should be increased by 25 to 66% to compensate for unusable hot water.

Figure 24 shows hourly flow profiles for a sample building in each category, so that readers may better understand the nature of energy withdrawal rate profiles that may need to be met in such applications. These buildings were selected from actual metered tests, but are not necessarily typical of all buildings in that category. Figure 24 should not be used for sizing water heaters, because a design load profile for a real building may vary substantially from these limited test cases.

Example 2. Determine the required water heater size for a 300-student women's dormitory for the following criteria:

a. Storage with minimum recovery rate

b. Storage with recovery rate of 2.6 mL/s per student

c. With the additional requirement for a cafeteria to serve a maximum of 300 meals per hour for minimum recovery rate, combined with item *a*; and for a recovery rate of 1.9 mL/s per maximum meals per hour, combined with item *b*

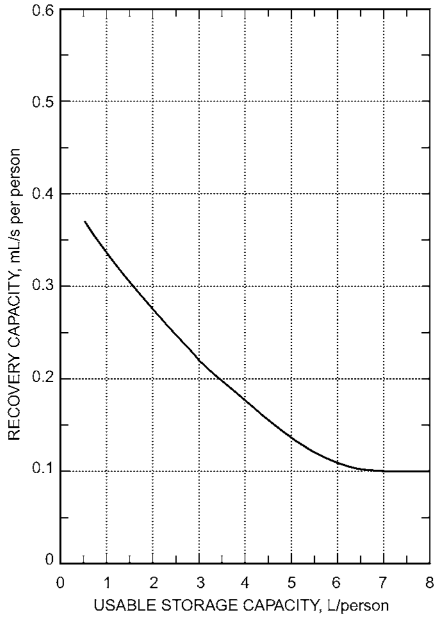

Fig. 19 Office Buildings

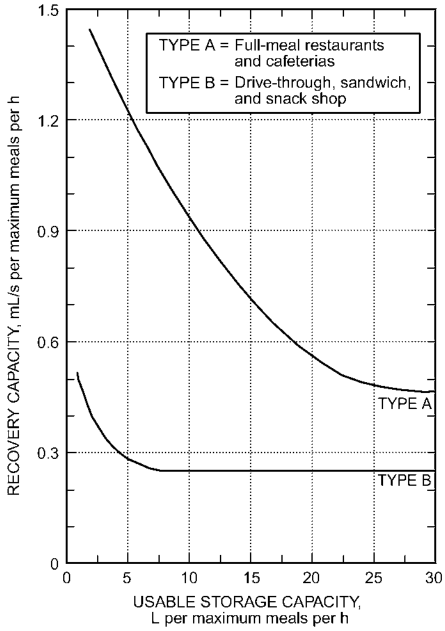

Fig. 20 Food Service

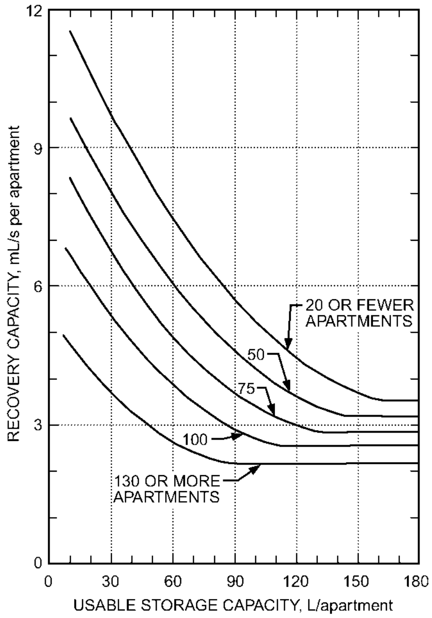

Fig. 21 Apartments

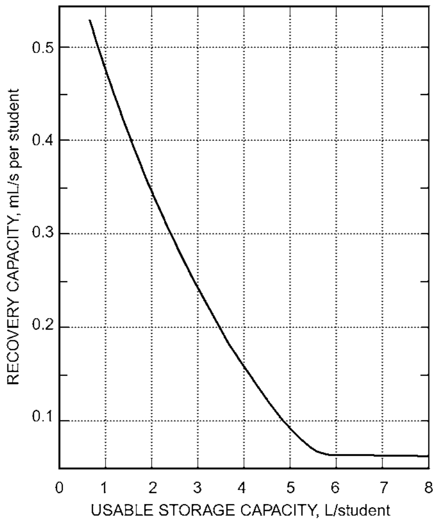

Fig. 22 Elementary Schools

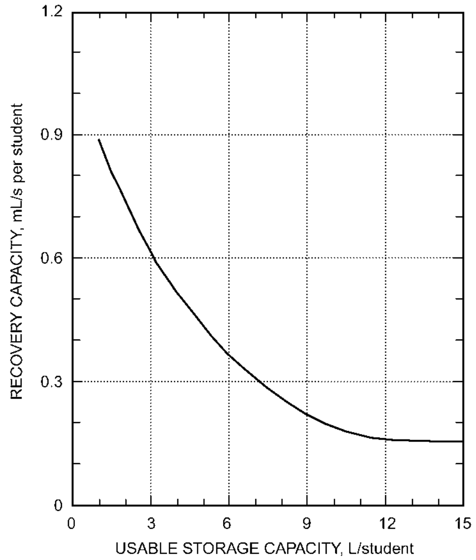

Fig. 23 High Schools

Solution:

a. The minimum recovery rate from Figure 16 for women's dormitories is 1.1 mL/s per student, or 330 mL/s total. At this rate, storage required is 45 L per student or 13.5 m^3 total. On a 70% net usable basis, the necessary tank size is 13.5/0.7 = 19.3 m^3.

b. The same curve shows 20 L storage per student at 2.6 mL/s recovery, or 300 × 19 = 5700 L storage with recovery of 300 × 2.6 = 780 mL/s. The tank size is 5700/0.7 = 8140 L.

c. Requirements for a cafeteria can be determined from Figure 20 and added to those for the dormitory. For the case of minimum recovery rate, the cafeteria (Type A) requires 300 × 0.47 = 140 mL/s recovery rate and 300 × 26.5/0.7 = 11.4 m^3 of additional storage. The entire building then requires 330 + 140 = 470 mL/s recovery and 19.3 + 11.4 = 30.7 m^3 of storage.

With 1.0 mL/s recovery at the maximum hourly meal output, the recovery required is 300 mL/s, with 300 × 7.5/0.7 = 3260 mL/s of additional storage. Combining this with item *b,* the entire building requires 780 + 300 = 1080 mL/s recovery and 8140 + 3260 = 11 400 L = 11.4 m^3 of storage.

Note: Recovery capacities shown are for heating water only. Additional capacity must be added to offset system heat losses.

Example 3. Determine the water-heater size and monthly hot-water consumption for an office building to be occupied by 300 people under the following conditions:

a. Storage with minimum recovery rate

b. Storage with 3.8 L per person storage

c. Additional minimum recovery rate requirement for a luncheonette open 5 days a week, serving a maximum of 100 meals per hour and an average of 200 meals per day

d. Monthly hot-water consumption

Solution:

a. With minimum recovery rate of 0.1 mL/s per person from Figure 19, 30 mL/s recovery is required; storage is 6 L per person, or

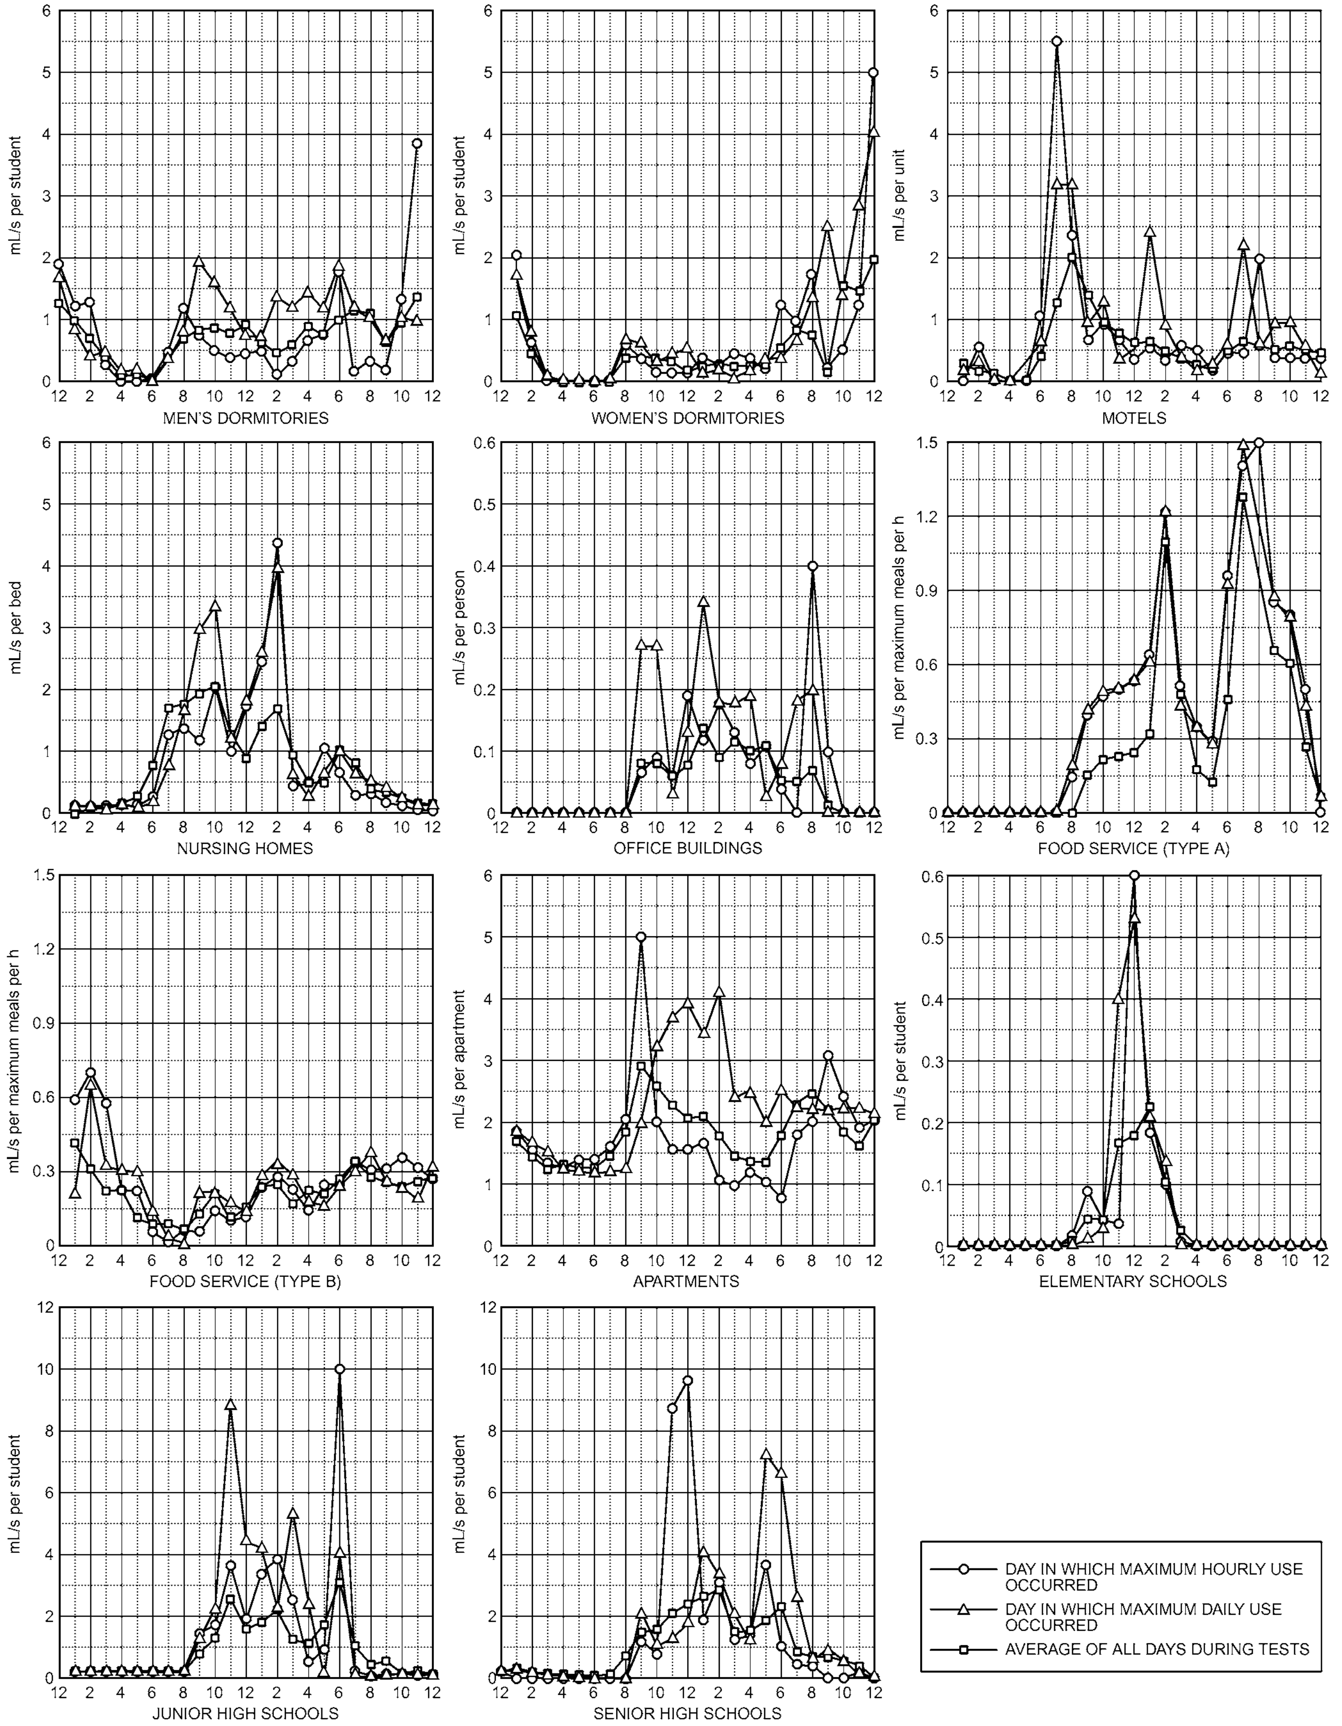

Fig. 24 Hourly Flow Profiles for Various Building Types

Table 9 Example 1, More Accurate Method: Heating Rate and Storage Volume Options

Time, min	Litres per Person	Total Litres for 198 People	Local Slope of Incremental Litres per Minute	Heating Rate, kW	Storage Volume, L
5	2.6	515	1.2	303	736
15	6.4	1 267	0.97	233	1 810
30	11.0	2 178	0.77	191	3 111
60	18.2	3 604	0.65	162	5 149
120	30.3	5 999	0.61	151	8 570
180	41.6	8 237	0.37	103*	11 767
1440	185.5	36 729	0.43	103	52 470

*Heating rate should not be lower than that needed to satisfy load on a 24 h basis.

Table 10 Hot Water Demand per Fixture for Various Types of Buildings

(Litres of water per hour per fixture, calculated at a final temperature of 60°C)

	Apartment House	Club	Gymnasium	Hospital	Hotel	Industrial Plant	Office Building	Private Residence	School	YMCA
1. Basin, private lavatory	7.6	7.6	7.6	7.6	7.6	7.6	7.6	7.6	7.6	7.6
2. Basin, public lavatory	15	23	30	23	30	45.5	23	—	57	30
3. Bathtub[c]	76	76	114	76	76	—	—	76	—	114
4. Dishwasher[a]	57	190-570	—	190-570	190-760	76-380	—	57	76-380	76-380
5. Foot basin	11	11	46	11	11	46	—	11	11	46
6. Kitchen sink	38	76	—	76	114	76	76	38	76	76
7. Laundry, stationary tub	76	106	—	106	106	—	—	76	—	106
8. Pantry sink	19	38	—	38	38	—	38	19	38	38
9. Shower	114	568	850	284	284	850	114	114	850	850
10. Service sink	76	76	—	76	114	76	76	57	76	76
11. Hydrotherapeutic shower				1520						
12. Hubbard bath				2270						
13. Leg bath				380						
14. Arm bath				130						
15. Sitz bath				114						
16. Continuous-flow bath				625						
17. Circular wash sink				76	76	114	76		114	
18. Semicircular wash sink				38	38	57	38		57	
19. DEMAND FACTOR	0.30	0.30	0.40	0.25	0.25	0.40	0.30	0.30	0.40	0.40
20. STORAGE CAPACITY FACTOR[b]	1.25	0.90	1.00	0.60	0.80	1.00	2.00	0.70	1.00	1.00

Note: Data sources predate low-flow fixtures and appliances.
[a]Dishwasher requirements should be taken from this table or from manufacturers' data for model to be used, if known.
[b]Ratio of storage tank capacity to probable maximum demand/h. Storage capacity may be reduced where unlimited supply of steam is available from central street steam system or large boiler plant.
[c]Whirlpool baths require specific consideration based on capacity. They are not included in the bathtub category.

300 × 6 = 1800 L. If 70% of the hot water is usable, the tank size is 1800/0.7 = 270 L.

b. The curve also shows 3.8 L storage per person at 0.18 mL/s per person recovery, or 300 × 0.18 = 54 mL/s. The tank size is 300 × 3.8/0.7 = 1630 L.

c. Hot-water requirements for a luncheonette (Type B) are in Figure 20. With a minimum recovery capacity of 0.26 mL/s per maximum meals per hour, 100 meals per hour requires 26 mL/s recovery, and the storage is 7.6 L per maximum meals per hour, or 100 × 7.6/0.7 = 1090 L storage. The combined requirements with item *a* are then 56 mL/s recovery and 3660 L storage.

Combined with item *b,* the requirement is 80 mL/s recovery and 2720 L storage.

d. Average day values are found in Table 6. The office building consumes an average of 3.8 L per person per day × 30 days per month × 300 people = 34.2 m^3 per month and the luncheonette will consume 2.6 L per meal × 200 meals per day × 22 days per month = 11.4 m^3 per month, for a total of 45.6 m^3 per month.

Note: Recovery capacities shown are for heating water only. Additional capacity must be added to offset the system heat losses.

Example 4. Determine the water heater size for a 200-unit apartment house under the following conditions:

a. Storage with minimum recovery rate
b. Storage with 4.2 mL/s per apartment recovery rate
c. Storage for each of two 100-unit wings
1. Minimum recovery rate
2. Recovery rate of 4.2 mL/s per apartment

Solution:

a. The minimum recovery rate, from Figure 21, for apartment buildings with 200 apartments is 2.2 mL/s per apartment, or a total of 440 mL/s. The storage required is 90 L per apartment, or 18 m^3. If 70% of this hot water is usable, the necessary tank size is 18/0.7 = 25.7 m^3.

b. The same curve shows 19 L storage per apartment at a recovery rate of 4.1 mL/s per apartment, or 200 × 4.2 = 840 mL/s. The tank size is 200 × 19/0.7 = 5.43 m^3.

c. Solution for a 200-unit apartment house having two wings, each with its own hot-water system.

1. With minimum recovery rate of 2.6 mL/s per apartment (see Figure 21), a 260 mL/s recovery is required, and the necessary storage is 106 L per apartment, or 100 × 106 = 10.6 m^3. The required tank size is 10.6/0.7 = 15.2 m^3 for each wing.

2. The curve shows that, for a recovery rate of 4.2 mL/s per apartment, storage is 50 L per apartment, or 100 × 50 = 5 m^3, with recovery of 100 × 4.2 = 420 mL/s. The necessary tank size is 5/0.7 = 7.2 m^3 in

a. Storage with minimum recovery rate
b. each wing.

Note: Recovery capacities shown are for heating water only. Additional capacity must be added to offset the system heat loss.

Example 5. Determine the water-heater size and monthly hot-water consumption for a 2000-student high school under the following conditions:

a. Storage with minimum recovery rate

b. Storage with 15 m^3 maximum storage capacity
c. Monthly hot-water consumption

Solution:

a. With the minimum recovery rate of 0.16 mL/s per student (from Figure 23) for high schools, 320 mL/s recovery is required. The storage required is 11.5 L per student, or 2000 × 11.5 = 2.3 m^3. If 70% of the hot water is usable, the tank size is 2.3/0.7 = 32.9 m^3.

b. Net storage capacity is 0.7 × 15 = 10.5 m^3, or 5.25 L per student. From the curve, a recovery capacity of 0.41 mL/s per student or 2000 × 0.41 = 820 mL/s is required.

c. From Table 6, monthly hot-water consumption is 2000 students × 1.86.8 L per student per day × 22 days = 299 m^3.

Note: Recovery capacities shown are for heating water only. Additional capacity must be added to offset the system heat loss.

Table 10 can be used to determine the size of water-heating equipment from the number of fixtures. However, caution is advised when using this table, because its data are very old, taken well before the introduction of modern low-flow fixtures and appliances. To obtain the probable maximum demand, multiply the total quantity for the fixtures by the demand factor in line 19. Note that, as the number of fixtures becomes very small (e.g., for a water heater to serve a single small apartment), the demand (diversity) factors listed in Table 10 are no longer valid. In all cases, total demand is never less than the demand for the largest single fixture. The heater or coil should have a water-heating capacity equal to this probable maximum demand. The storage tank should have a capacity equal to the probable maximum demand multiplied by the storage capacity factor in line 20.

Example 6. Determine heater and storage tank size for an apartment building from a number of fixtures.

Solution:

60 lavatories	×	7.6	=	46 L/h
30 bathtubs	×	76	=	2280 L/h
30 showers	×	114	=	3420 L/h
60 kitchen sinks	×	38	=	2280 L/h
15 laundry tubs	×	76	=	1140 L/h
Possible maximum demand			=	9576 L/h
Probable maximum demand	=9576 × 0.30=	2870 L/h		
Heater or coil capacity	=2870/3600=0.80 L/s			
Storage tank capacity	=2870 × 1.25=3590 L/s			

Showers. In many housing installations such as motels, hotels, and dormitories, peak hot-water load is usually from shower use. Table 10 indicates the probable hourly hot-water demand and recommended demand and storage capacity factors for various types of buildings. Hotels could have a 3 to 4 h peak shower load. Motels require similar volumes of hot water, but peak demand may last for only a 2 h period. In some types of housing, such as barracks, fraternity houses, and dormitories, all occupants may take showers within a very short period. In this case, it is best to find the peak load by determining the number of shower heads and rate of flow per head; then estimate the length of time the shower will be on. It is estimated that the average shower time per individual is 7.5 min (Meier 1985).

Flow rate from a shower head varies depending on type, size, and water pressure. At 280 kPa water pressure, available shower heads have nominal flow rates of blended hot and cold water from about 160 to 380 mL/s. In multiple-shower installations, flow control valves on shower heads are recommended because they reduce flow rate and maintain it regardless of fluctuations in water pressure. Flow can usually be reduced to 50% of the manufacturer's maximum flow rating without adversely affecting the spray pattern of the shower head. Flow control valves are commonly available with capacities from 95 to 250 mL/s.

If the manufacturer's flow rate for a shower head is not available and no flow control valve is used, the following average flow rates may serve as a guide for sizing the water heater:

Small shower head	160 mL/s
Medium shower head	280 mL/s
Large shower head	380 mL/s

Note that the maximum flow rate allowed by U.S. federal energy efficiency standards is **160 mL/s**, as of 1992. However, higher-flowrate models are still sold.

Food Service. These establishments are required to provide a sufficient supply of hot water to meet the peak hot-water demand requirements set forth by the overseeing regulatory body, usually the county health department. Cities and counties adopt or modify state or federal hot-water sizing guidelines for food service establishments to meet the needs of their locality. The procedure for sizing water heaters for restaurants typically includes the following steps:

1. List all hot-water end-use fixtures by type and by count.
2. Characterize each fixture for maximum hot-water use per hour and per minute.
3. Calculate the peak hot-water demand for water heaters with and without storage.
4. Obtain the water heater temperature rise required for winter.
5. Calculate the minimum water heater input rate.
6. Select the water heater type, input rate, and storage capacity (in a few jurisdictions).

It is important to note that the hot-water requirements for various fixtures presented in Table 11 are based on various resources (see the table notes), which are currently used by food service facilities and health departments to size hot-water heaters. Some equipment flow data in these guidelines predates current low-flow fixtures used in kitchens. Specifically, the flow rate requirements for prerinse spray valves have dropped from 315 mL/s to a federally mandated maximum flow rate of 100 mL/s, and, similarly, flow rate requirements for aerators on public hand sinks have dropped from 140 mL/s to 30 mL/s.

Note that the sizing guidelines required by local mandate for commercial food service applications specify only the required heating rates; they do not address the storage volume requirements of storage water heaters. Because of this, it is not really possible to size storage water heaters with the information specified. Although for some types of storage water heaters it may be possible to provide the storage water heater heating rate specified, there is no way to know how large the tank needs to be with that information alone. More information is needed regarding the time spacing of draws throughout the day before adequate storage volume can be specified. It is possible to design or select storage water heating systems that will perform adequately but do not have as high a heating rate as may be specified in local mandates, as long as adequate amounts of storage are provided. In this regard, the outdated practice of specifying needed storage water heater heating requirements without regard to storage volume used is an impediment to use of newer higher efficiency technologies, such as gas- or electric heat pump water heaters and solar water heating systems. Such systems would normally be provided with lower heating rates and more storage when meeting loads, to minimize first costs.

The intent of the heating rate sizing guidelines for storage heaters is an attempt to ensure that hot water is available during operating hours to meet the food preparation and sanitation needs of the facility for food safety reasons. Thus, the food service sizing guideline is the minimum bar that some localities may accept for specified heating rates. However, this differs from the combination of heating rate and storage volume that may actually work for a given installation. The sizing guidelines are limited in that they only focus on calculating the energy input rate to the water heater without providing guidance on minimum hot-water storage requirements (except for North Carolina), and hot-water delivery performance considerations

Table 11 Hot-Water Requirements for Various Commercial Kitchen Uses

Equipment[a]	Storage, mL/s	Tankless, mL/s
Hand sink or lavatory	5.3	30
One-compartment food preparation or utility sink	5.3	125
Two-compartment food preparation or utility sink	11	125
Large three-compartment sanitation sink (610 × 610 × 360 mm	110[b]	125[c]
Standard three-compartment sanitation sink (460 × 460 × 250 mm)	44[b]	125[c]
Bar three-compartment sanitation sink (250 × 360 × 250 mm)	19[b]	125
Mop sink or can wash facility	16	125[c]
Prerinse spray valve	47	Varies
Dishwasher	Varies[d]	Varies

Source: CCDEH (1995), FDA (2000), NCPH (2001).
[a]Refer to manufacturer's specifications for other end-use fixtures that use hot water.
[b]Equation to calculate storage heater hot water demand requirements for sanitation sinks:

mL/s = Sink size (mm^3) × Number of compartments × 0.001 (mL/(h·mm^3) ÷ 3600 s/h

Certain jurisdictions, including the FDA and North Carolina, use a compartment fill factor, which is 75% of the sink size, to calculate the hot water requirements of sanitation sinks.
[c]A flow rate of 320 mL/s is recommended for compartment sink or hose bibb fill operations.
[d]Certain jurisdictions, including the FDA and North Carolina, use a rack loading efficiency factor, which is 70% of the dishwasher manufacturer's listed hourly rinse water use, to calculate hot-water demand.

(e.g., performance limitations of tankless heaters with door-type dishwashers). The food safety sizing guidelines for water heaters also do not consider after-hours cleanup, when the peak hourly hot-water use occurs in some facilities; this may cause emptying of the tank on a nightly basis. Rapidly using hot water and filling the tank with cold water can cause thermal fatiguing of the tank, greatly reducing the operating life in gas storage heaters (Fisher-Nickel 2010). There is no current method for calculating the minimum storage requirement for a food service facility or sizing storage heaters based on the ratio of storage capacity and energy input rate. This is a difficult task, because hot-water use on an average daily, peak hourly, or per-minute basis greatly varies between food service facilities, especially in larger facilities, even of equal size and type. Variations in staff operating practices (e.g., after-hours store cleaning), equipment maintenance, and other operations between two identical facilities can cause large differences in hot-water consumption. This sizing guideline and associated examples are intended to clarify the prevailing food safety sizing guidelines, which in many cases are not comprehensive and are difficult to follow.

After the maximum flow rate has been calculated using Table 11, the required heater(s) may be sized using manufacturers' specification sheets that cross-reference temperature rise and flow rate, or using Equation (11):

$$q_i = Q_h c_p \rho \Delta t / \eta \quad (11)$$

where

q_i = heater input, W
Q_h = flow rate, mL/s
c_p = specific heat of water = 4.1868 kJ/(kg·K)
ρ = density of water = 1.0 kg/L
Δt = temperature rise, K
η = heater efficiency

Sizing water heater input rate in food service may require following local food safety department water-heater sizing guidelines, which typically provide end-use fixture flow rates, temperature rise, and heater efficiency values to calculate minimum flow rate or recovery rate. An alternative to using these input rate sizing guidelines requires the commercial kitchen to hire a professional engineer to submit for approval an alternative water-heater sizing calculation. This latter method is typically too costly and time consuming in the build-out or renovation of most commercial kitchens.

Table 12 Range in Water Heater Flow Rate Requirements to Satisfy Dishwasher Rinse Operation of Various Units

Type of Dishwasher	Flow Rate for Heaters Without Storage,[a] mL/s	Hourly Demand for Heaters with Storage,[b] mL/s
Undercounter (low-temperature)	130 to 280	23 to 68
Undercounter (high-temperature)	200 to 420	20 to 54
Door type (low-temperature)	120 to 320	35 to 72
Door type (high-temperature)	170 to 450	29 to 97
Rack conveyor (low-temperature)	80 to 300	80 to 300
Rack conveyor (high-temperature)	45 to 300	50 to 300
Flight conveyor (high-temperature)	65 to 380	60 to 380

[a]Based on flow rate during rinse operation period.
[b]Based on dishwasher operation at 100% of mechanical capacity.

Dishwashers in food service facilities typically dictate the water heater outlet temperature required. Dishwashers generally require delivery of 60°C water for rinse operation, but inlet temperature can range from a minimum of {50°C for a low-temperature dishwasher to 82°C for a high-temperature dishwasher without a booster heater. For a typical hot-water system distribution line, heat losses require the water heater thermostat to be set at an elevated temperature (typically between 63 to 66°C) to deliver 60°C water to the dishwasher or booster heater.

In restaurants, bacteria are killed by rinsing washed dishes with 82 to 90°C water for several seconds. In addition, an ample supply of general-purpose hot water, usually at 60 to 65°C, is required for the wash cycle of dishwashers. Although a water temperature of 60°C is reasonable for dish washing in private dwellings, in public places, the NSF (e.g., *Standard* 3) or local health departments require 82 to 90°C water in the rinsing cycle. However, the NSF allows a lower temperature of 50 to 60°C when low temperature or fill and dump machines are used with the use of a chemical sanitizing rinse. The two-temperature hot-water requirements of food service establishments present special problems. The lower-temperature water is distributed for general use, but the 82°C water should be confined to the equipment requiring it and should be obtained by boosting the temperature. It is dangerous to distribute 82°C water for general use. ANSI/NSF *Standard* 3-2001 covers the design of dishwashers and water heaters used by restaurants.

The data provided in Table 12 shows the range of water heater flow rate and hourly hot-water demand requirements for various types of low- and high-temperature sanitizing dishwashers based on 100% operating capacity of the machines. Loading a dishwasher at 100% capacity is impractical in most commercial kitchens. Some local health departments assume a 70% operating rinse capacity for sizing dishwashers' hot-water demand, except for rackless-type conveyor machines where the fresh-water rinse is continually operating when the machine is in operation. Some dishwashers use only a cold-water supply for rinse and (with some models) for the tank fill, allowing them to operate without any connection to the hot-water line. These undercounter and door-type machines typically use integrated booster heaters and exhaust-air heat recovery to preheat the cold water for the next rinse cycle.

Examples 7, 8, and 9 demonstrate the use of Equation (11) in conjunction with Tables 11 and 12.

Example 7. Determine the maximum hot-water flow rate demand for tankless water heaters and the maximum hourly average hot-water flow rate demand for storage water heaters for a commercial kitchen with a one-compartment food preparation sink, one standard three-compartment sanitation sink, two hand sinks, two lavatories, one mop sink, one prerinse sink with a 70 mL/s spray valve, and one high-temperature door-type dishwasher (3.8 L/rack, 11 s rinse time, 57 racks/h) with a built-in 22 K temperature rise booster heater.

Solution: The end-use fixtures and hot-water demand requirements for sizing the heating rate of storage or tankless water heaters are shown in the following table:

Item	Flow Rate Required, mL/s	Recovery Rate Required, mL/s
One-comp. prep sink	125	5
Three-comp. sink	125	46
Hand sink (2)	65	11
Lavatory (2)	65	11
Mop sink	125	16
Prerinse sink	70	47
Dishwasher	340	60
Total requirements	915	196

The minimum flow rate for sizing the heating rate of a tankless water heater is 915 mL/s. Likewise, the minimum flow rate for sizing the heating rate of a storage water heater is 196 mL/s.

Example 8. Determine the energy input requirements (heating rate) for both a tankless and a storage water heater for the commercial kitchen described in Example 7. Examine both gas and electric resistance energy source options. Assume an operating efficiency of 70% for the noncondensing gas option, 85% condensing for the condensing gas option, 90% for the electric storage option, and 99% for the electric tankless option. Assume the design entering cold-water temperature (winter) is 10°C and the water heater outlet temperature is 66°C. This is a little higher than the 60°C required by the dishwasher booster heater, to account for piping heat losses.

Solution: The temperature rise required is 66 − 10 = 56 K. For a tankless water heater, the required heating rate using Equation (11) is computed as

$$q_i = (0.915 \text{ L/s})(1.0 \text{ kg/L})[4.1868 \text{ kJ/(kg·K)}](56 \text{ K}) = 215 \text{ kW}$$

Thus, for the 70% gas tankless option, the required energy input rate is 215/0.70 = 307 kW. It is common practice to install one or more 58 kW units in parallel in commercial facilities to meet minimum flow rate requirements. Using this approach, six standard-efficiency tankless units, each rated at 58 kW, are required to meet this load. For the 85% gas condensing tankless option, the required heating rate is 215/0.85 = 253 kW, requiring five 58 kW condensing tankless heaters. For the 99% electric tankless option, the required energy input rate is 215/0.99 = 217 kW. Four 54 kW or six 36 kW electric resistance tankless heaters are required to meet the hot-water demand.

Because tankless water heaters have no storage volume, these heating rates are adequate for use in specifying appropriate water heaters.

Sizing tankless heaters using manufacturers' specification sheets data on maximum flow rate at a given temperature rise is a common approach, because the data are readily provided. Flow rate data varies slightly among manufacturers of similar products at the same input rate based on the efficiency of the unit. A 58 kW standard-efficiency heater typically provides a maximum of 210 mL/s of water at a 56 K temperature rise, whereas a condensing heater provides 240 mL/s. To meet the flow requirements of 915 mL/s for this facility, five standard-efficiency 58 kW units installed in parallel for a combined input rate of 292 kW are required to meet the load by providing a maximum combined flow rate of 1040 mL/s. To meet the flow requirements with condensing high-efficiency tankless heaters, four 58 kW units for a combined input rate of 233 kW are required, for a maximum combined flow rate of 960 mL/s. It is important to note that using the manufacturer's stated maximum flow rate at a given temperature rise to calculate the number of tankless units based on the maximum flow rate calculation of 915 mL/s is a less conservative approach, because it relies on the rated thermal efficiency of the heater instead of the typical operating efficiency.

For the storage water heaters, the required heating rate is computed as

$$q_i = (0.196 \text{ L/s})(1.0 \text{ kg/L})[4.1868 \text{ kJ/(kg·K)}](56 \text{ K}) = 46 \text{ kW}$$

Thus, for the 70% gas storage water heater, the required heating rate is 46/0.70 = 66 kW. For the 85% gas condensing storage water heater, the required heating rate is 46/0.85 = 54 kW. For the 90% electric resistance storage water heater, the required heating rate is 46/0.90 = 51 kW.

Note that this information in insufficient to properly specify a storage water heater, because a method for calculating the minimum storage volume is needed. Moreover, once storage is incorporated, note that the loads can be met by using smaller heating rates than those computed here, using larger storage tanks. In this respect, the heating rates mandated by a typical health department become a barrier to using higher-efficiency equipment, such as heat pump water heaters or solar water heating, whose heating capacities are more expensive than standard efficiency equipment, and whose cost-effective system designs therefore favor smaller heating rates and larger storage volumes. Although this is true, the majority of water heaters in commercial kitchens are specified using the food safety guidelines to calculate the minimum input rate of conventional gas or electric water heaters. In doing so, one or more storage heaters may be selected to meet this total requirement. Typically, one 73 kW gas storage heater (or two 37 kW units) rated at 80% thermal efficiency is chosen. An energy-efficient approach is to select a high-efficiency condensing water heater rated at 95% thermal efficiency, which is assumed to be operating at 85% operating efficiency in this kitchen with continuous recirculation. A 58 kW condensing gas storage heater will meet the requirements for this facility and is a better value, because it reduces operating costs and is competitive on first costs. One 54 kW or two 27 kW electric resistance storage heaters could be selected from manufacturers' specification sheets to meet the hot-water demand.

Example 9. For the commercial kitchen described in Example 7, what is the condensing storage water heater input rating if the facility chooses to install a dishwasher that only requires a cold-water hookup? Assume that the facility can benefit by reducing the required outlet temperature by 11 K from 66°C. Also assume that, by removing the need for continuous recirculation, this measure improves the operating efficiency from a nominal 85% to 90%.

Solution: The total hot-water demand calculated in Example 7 drops from 196 mL/s to 136 mL/s when the hot-water demand of the dishwasher on the centralized water heater is eliminated. For the storage water heaters, the required heating rate is computed as

$$q_i = (0.136 \text{ L/s})(1.0 \text{ kg/L})[4.1868 \text{ kJ/(kg·K)}](44 \text{ K}) = 25 \text{ kW}$$

For the 90% gas condensing storage water heater, the required heating rate is 25/0.90 = 28 kW. One 29 kW gas condensing storage heater can be selected to meet the hot water demand using the food safety input rate sizing guidelines. Also, dishwashers that have only a cold water feed typically depend on heat recovery systems to preheat the incoming cold water from the exhaust or drainwater waste streams to a temperature of 43°C. They rely on larger secondary heating systems commonly referred to as booster heaters to heat the water to the 82°C sanitizing rinse temperature on a high-temperature machine. This requires the addition of a 39 K rise booster heater instead of a conventional 22 K booster heater that would be used in conjunction with entering 60°C water from the primary water heater.

Schools. Service water heating in schools is needed for janitorial work, lavatories, cafeterias, shower rooms, and sometimes swimming pools. Hot water used in cafeterias is about 70% of that usually required in a commercial restaurant serving adults and can be estimated by the method used for restaurants. Where NSF sizing is required, follow *Standard* 5. Shower and food service loads are not ordinarily concurrent. Each should be determined separately, and the larger load should determine the size of the water heater(s) and the tank. Provision must be made to supply 82°C sanitizing rinse.

The booster must be sized according to the temperature of the supply water. If feasible, the same water can be used for both needs. If the distance between the two points of need is great, a separate water heater should be used. A separate heater system for swimming pools can be sized as outlined in the section on Swimming Pools/Health Clubs.

Domestic Coin-Operated Laundries. Small domestic machines in coin laundries or apartment house laundry rooms have a wide range of draw rates and cycle times. Domestic machines provide a wash water temperature (normal) as low as 50°C. Some manufacturers recommend a temperature of 70°C; however, the average appears to be 60°C. Hot-water sizing calculations must ensure a supply to both the instantaneous draw requirements of a number of machines filling at one time and the average hourly requirements.

The number of machines drawing at any one time varies widely; the percentage is usually higher in smaller installations. One or two customers starting several machines at about the same time has a much sharper effect in a laundry with 15 or 20 machines than in one with 40 machines. Simultaneous draw may be estimated as follows:

1 to 11 machines	100% of possible draw
12 to 24 machines	80% of possible draw
25 to 35 machines	60% of possible draw
36 to 45 machines	50% of possible draw

Possible peak draw can be calculated from

$$F = 1000NPV_f/T \qquad (12)$$

where

F = peak draw, mL/s
N = number of washers installed
P = number of washers drawing hot water divided by N
V_f = quantity of hot water supplied to machine during hot-wash fill, L
T = wash fill period, s

Recovery rate can be calculated from

$$R = (1000NV_f)/[60(\theta + 10)] = 16.7\,NV_f/(\theta + 10) \qquad (13)$$

where

R = total hot water (machines adjusted to hottest water setting), mL/s
θ = actual machine cycle time, min

Note: (θ + 10) is the cycle time plus 10 min for loading and unloading.

Commercial Laundries. Commercial laundries generally use a storage water heater. The water may be softened to reduce soap use and improve quality. The trend is toward installing high-capacity washer-extractor wash wheels, resulting in high peak demand.

Sizing Data. Laundries can normally be divided into five categories. The required hot water is determined by the mass of the material processed. Average hot-water requirements at 82°C are

Institutional	4.6 mL/(kg·s)
Commercial	4.6 mL/(kg·s)
Linen supply	5.8 mL/(kg·s)
Industrial	5.8 mL/(kg·s)
Diaper	5.8 mL/(kg·s)

Total mass of the material times these values give the average hourly hot-water requirements. The designer must consider peak requirements; for example, a 270 kg machine may have a 1.25 L/s average requirement, but the peak requirement could be 22 L/s.

In a multiple-machine operation, it is not reasonable to fill all machines at the momentary peak rate. Diversity factors can be estimated by using 1.0 of the largest machine plus the following balance:

	Total number of machines				
	2	3 to 5	6 to 8	9 to 11	12 and over
1.0 +	0.6	0.45	0.4	0.35	0.3

For example, four machines have a diversity factor of 1.0 + 0.45 = 1.45.

Types of Systems. Service water-heating systems for laundries are pressurized or vented. The pressurized system uses city water pressure, and the full peak flow rates are received by the softeners, reclaimer, condensate cooler, water heater, and lines to the wash wheels. Flow surges and stops at each operation in the cycle. A pressurized system depends on an adequate water service.

The vented system uses pumps from a vented (open) hot-water heater or tank to supply hot water. The tank's water level fluctuates from about 150 mm above the heating element to a point 300 mm from the top of the tank; this fluctuation defines the working volume. The level drops for each machine fill, and makeup water runs continuously at the average flow rate and water service pressure during the complete washing cycle. The tank is sized to have full working volume at the beginning of each cycle. Lines and softeners may be sized for the average flow rate from the water service to the tank, not the peak machine fill rate as with a closed, pressurized system.

Waste heat exchangers have continuous flow across the heating surface at a low flow rate, with continuous heat reclamation from the wastewater and flash steam. Automatic flow-regulating valves on the inlet water manifold control this low flow rate. Rapid fill of machines increases production (i.e., more batches can be processed).

Heat Recovery. Commercial laundries are ideally suited for heat recovery because 58°C wastewater is discharged to the sewer. Fresh water can be conservatively preheated to within 8 K of the wastewater temperature for the next operation in the wash cycle. Regions with an annual average temperature of 13°C can increase to 50°C the initial temperature of fresh water going into the hot-water heater. For each litre or kilogram per hour of water preheated 37 K (13 to 50°C), heat reclamation and associated energy savings is 155 kW.

Flash steam from a condensate receiving tank is often wasted to the atmosphere. Heat in this flash steam can be reclaimed with a suitable heat exchanger, to preheat makeup water to the heater by 5 to 10 K above the existing makeup temperature.

Swimming Pools/Health Clubs. The desirable temperature for swimming pools is 27°C. Most manufacturers of water heaters and boilers offer specialized models for pool heating; these include a pool temperature controller and a water bypass to prevent condensation. The water-heating system is usually installed before the return of treated water to the pool. A circulation rate to generate a change of water every 8 h for residential pools and 6 h for commercial pools is acceptable. An indirect heater, in which piping is embedded in the walls or floor of the pool, has the advantage of reduced corrosion, scaling, and condensation because pool water does not flow through the pipes, but its disadvantage is the high initial installation cost.

The installation should have a pool temperature control and a water pressure or flow safety switch. The temperature control should be installed at the inlet to the heater; the pressure or flow switch can be installed at either the inlet or outlet, depending on the manufacturer's instructions. It affords protection against inadequate water flow.

Sizing should be based on four considerations:

- Conduction through the pool walls
- Convection from the pool surface
- Radiation from the pool surface
- Evaporation from the pool surface

Except in aboveground pools and in rare cases where cold groundwater flows past the pool walls, conduction losses are small and can be ignored. Because convection losses depend on temperature differentials and wind speed, these losses can be greatly reduced by installing windbreaks such as hedges, solid fences, or buildings.

Radiation losses occur when the pool surface is subjected to temperature differentials; these frequently occur at night, when the sky temperature may be as much as 45 K below ambient air temperature. This usually occurs on clear, cool nights. During the daytime, however, an unshaded pool receives a large amount of radiant energy, often as much as 30 kW. These losses and gains may offset each other. An easy method of controlling nighttime radiation losses is to use a floating pool cover; this also substantially reduces evaporative losses.

Evaporative losses constitute the greatest heat loss from the pool (50 to 60% in most cases). If it is possible to cut evaporative losses drastically, the pool's heating requirement may be cut by as much as 50%. A floating pool cover can accomplish this.

A pool heater with an input great enough to provide a heat-up time of 24 h would be the ideal solution. However, it may not be the most economical system for pools that are in continuous use during an extended swimming season. In this instance, a less expensive unit providing an extended heat-up period of as much as 48 h can be used. Pool water may be heated by several methods. Fuel-fired water heaters and boilers, electric boilers, tankless electric circulation water heaters, air-source heat pumps, and solar heaters have all been used successfully. Air-source heat pumps and solar heating systems are often used to extend a swimming season rather than to allow intermittent use with rapid pickup.

The following equations provide some assistance in determining the area and volume of pools.

Elliptical

Area = 3.14*AB*
A = Short radius
B = Long radius
Volume = Area × Average Depth

Kidney Shaped

Area = 0.45*L* (*A*+*B*) (approximately)
L = Length
A = Width at one end
B = Width at other end
Volume = Area × Average Depth

Oval (for circular, set *L* = 0)

Area = $3.14R^2 + LW$
L = Length of straight sides
W = Width or 2*R*
R = Radius of ends
Volume = Area × Average Depth

Rectangular

Area = *LW*
L = Length
W = Width
Volume = Area × Average Depth

The following is an effective method for heating outdoor pools. Additional equations can be found in Chapter 6.

1. Obtain pool water capacity, in cubic metres.
2. Determine the desired heat pickup time in hours.
3. Determine the desired pool temperature. If not known, use 27°C.
4. Determine the average temperature of the coldest month of use.

The required heater output q_t can now be determined by the following equations:

$$q_1 = \rho c_p V(t_f - t_i)/\theta \times 3600 \text{ s/h} \quad (14)$$

where

q_1 = pool heat-up rate, kW
ρ = density of water = 998 kg/m³
c_p = specific heat of water = 4.1868 kJ/(kg·K)
V = pool volume, m³
t_f = desired temperature (usually 27°C)
t_i = initial temperature of pool, °C
θ = pool heat-up time, h

$$q_2 = UA(t_p - t_a) \quad (15)$$

where

q_2 = heat loss from pool surface, kW
U = surface heat transfer coefficient = 0.060 kW/(m²·K)
A = pool surface area, m²
t_p = pool temperature, °C
t_a = ambient temperature, °C

$$q_t = q_1 + q_2 \quad (16)$$

Notes: These heat loss equations assume a wind velocity of 5 to 8 km/h. For pools sheltered by nearby fences, dense shrubbery, or buildings, an average wind velocity of less than 5.6 km/h can be assumed. In this case, use 75% of the values calculated by Equation (15). For a velocity of 8 km/h, multiply by 1.25; for 16 km/h, multiply by 2.0.

Because Equation (15) applies to the coldest monthly temperatures, results calculated may not be economical. Therefore, a value of one-half the surface loss plus the heat-up value yields a more viable heater output figure. Heater input then equals output divided by fuel source efficiency.

Whirlpools and Spas. Hot-water requirements for whirlpool baths and spas depend on temperature, fill rate, and total volume. Water may be stored separately at the desired temperature or, more commonly, regulated at the point of entry by blending. If rapid filling is desired, provide storage at least equal to the volume needed; fill rate can then be varied at will. An alternative is to establish a maximum fill rate and provide an instantaneous water heater that can handle the flow.

Industrial Plants. Hot water (potable) is used in industrial plants for cafeterias, showers, lavatories, gravity sprinkler tanks, and industrial processes. Employee cleanup load is usually heaviest and not concurrent with other uses. Other loads should be checked before sizing, however, to be certain that this is true.

Employee cleanup load includes (1) wash troughs or standard lavatories, (2) multiple wash sinks, and/or (3) showers. Hot-water requirements for employees using standard wash fixtures can be estimated at 3.8 L of hot water for each clerical and light-industrial employee per work shift and 7.6 L for each heavy-industrial worker.

For sizing purposes, the number of workers using multiple wash fountains is disregarded. Hot-water demand is based on full flow for the entire cleanup period. This usage over a 10 min period is indicated in Table 13. The shower load depends on the flow rate of the shower heads and their length of use. Table 13 may be used to estimate flow based on a 15 min period.

Water heaters used to prevent freezing in gravity sprinkler or water storage tanks should be part of a separate system. The load depends on tank heat loss, tank capacity, and winter design temperature.

Process hot-water load must be determined separately. Volume and temperature vary with the specific process. If the process load occurs at the same time as the shower or cafeteria load, the system must be sized to reflect this total demand. In some cases, it may be preferable to use separate systems, depending on the various load sizes and distance between them.

Table 13 Hot-Water Usage for Industrial Wash Fountains and Showers

Multiple Wash Fountains		Showers	
Type	L of 60°C Water Required for 10 min Period[a]	Flow Rate, mL/s	L of 60°C Water Required for 15 min Period[b]
910 mm Circular	150	190	110
Semicircular	83	250	150
1370 mm Circular	250	320	185
Semicircular	150	380	220

[a]Based on 43°C wash water and 5°C cold water at average flow rates.
[b]Based on 40°C shower water and 5°C cold water.

Table 14 Water Heater Sizing for Ready-Mix Concrete Plant
(Input and Storage Tank Capacity to Supply 65°C Water at 4°C Inlet Temperature)

Truck Capacity, m³	Water Heater Storage Tank Volume, L	Time Interval Between Trucks, min*					
		50	35	25	10	5	0
		Water Heater Capacity, kW					
4.6	1630	134	179	230	403	536	809

*This table assumes 10 min loading time for each truck. Thus, for a 50 min interval between trucks, it is assumed that 1 truck/h is served. For 0 min between trucks, it is assumed that one truck loads immediately after the truck ahead has pulled away. Thus, 6 trucks/h are served. It also assumes each truck carries a 450 L storage tank of hot water for washing down at the end of dumping the load. This hot water is drawn from the storage tank and must be added to the total hot water demands. This has been included in the table.

Ready-Mix Concrete. In cold weather, ready-mix concrete plants need hot water to mix the concrete so that it will not be ruined by freezing before it sets. Operators prefer to keep the mix at about 21°C by adding hot water to the cold aggregate. Usually, water at about 65°C is considered proper for cold weather. If the water temperature is too high, some of the concrete will flash set.

Generally, 150 L of hot water per cubic metre of concrete mix is used for sizing. To obtain the total hot-water load, this number is multiplied by the number of trucks loaded each hour and the capacity of the trucks. The hot water is dumped into the mix as quickly as possible at each loading, so ample hot-water storage or large heat exchangers must be used. Table 14 shows a method of sizing water heaters for concrete plants.

Sizing Boilers for Combined Space and Water Heating

When service water is heated indirectly by a space heating boiler, Figure 25 may be used to determine the additional boiler capacity required to meet the recovery demands of the domestic water-heating load. Indirect heaters include immersion coils in boilers as well as heat exchangers with space-heating media.

Because the boiler capacity must meet not only the water supply requirement but also the space heating loads, Figure 25 indicates the reduction of additional heat supply for water heating if the ratio of water-heating load to space-heating load is low. This reduction is possible because

- Maximum space-heating requirements do not occur at the time of day when the maximum peak hot-water demands occur.
- Space-heating requirements are based on the lowest outdoor design temperature, which may occur for only a few days of the total heating season.
- An additional heat supply or boiler capacity to compensate for pickup and radiation losses is usual. The pickup load cannot occur at the same time as the peak hot-water demand because the building must be brought to a comfortable temperature before the occupants use hot water.

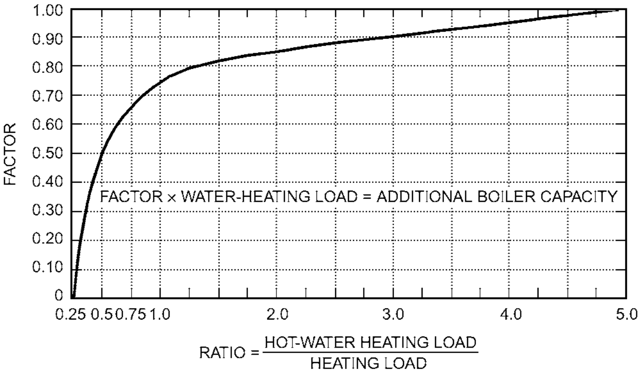

Fig. 25 Sizing Factor for Combination Heating and Water-Heating Boilers

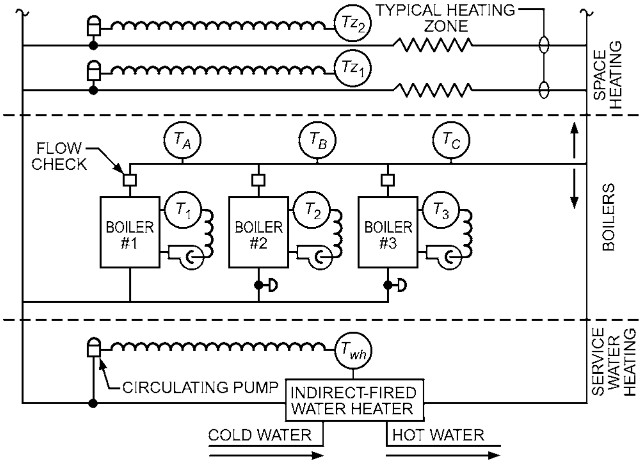

Fig. 26 Typical Modular Boiler for Combined Space and Water Heating

The factor obtained from Figure 25 is multiplied by the peak water-heating load to obtain the additional boiler output capacity required.

For reduced standby losses in summer and improved efficiency in winter, step-fired modular boilers may be used. Units not in operation cool down and reduce or eliminate jacket losses. Heated boiler water should not pass through an idle boiler. Figure 26 shows a typical modular boiler combination space- and water-heating arrangement.

Typical Control Sequence for Indirect Water Heaters

1. Any control zone or indirectly fired water heater thermostat (e.g., T_{z_1} or T_{wh} in Figure 26) starts its circulating pump and supplies power to boiler no. 1 control circuit.
2. If T_1 is not satisfied, burner is turned on, boiler cycles as long as any circulating pump is on.
3. If after 5 min T_A is not satisfied, V_1 opens and boiler no. 2 comes on line.
4. If after 5 min T_B is not satisfied, V_2 opens and boiler no. 3 comes on line.
5. If T_C is satisfied and two boilers or fewer are firing for a minimum of 10 min, V_2 closes.
6. If T_B is satisfied and only one boiler is firing for a minimum of 10 min, V_1 closes.
7. If all circulating pumps are off, boiler no. 1 shuts down.

Table 15 Needed Tankless Water Heater Output Heat Rates, kW*

*Divide table values by input efficiency to determine required heat input rate.

ASHRAE/IES *Standards* 90.1 and 90.2 discuss combination service water-heating/space-heating boilers and establish restrictions on their use. The ASHRAE/IES *Standard* 100 section on Service Water Heating also has information on this subject.

Sizing Tankless Water Heaters

Although tankless water heaters are sometimes also referred to as instantaneous water heaters, in this chapter the two types are distinct. Larger instantaneous water heaters for bigger commercial, institutional, and industrial applications may still have some water storage tank volume, even though their ratio of heating rate divided by storage volume is large. Smaller commercial and residential systems only contain a volume of water sufficient to fill the chambers or tubing where the heating is done; they do not incorporate storage tanks, and are truly tankless as the term is used here.

Tankless water heaters offer potential efficiency advantages over tank-type units for several reasons. Because they do not store heated water, they have low standby energy loss (typically, only a small amount of electricity to run controls). This energy savings potential can be significant for low-use applications. Another potential advantage is that the lack of a storage tank means they are much smaller than tank-type units and can more easily be located close to points of use (especially electric tankless units). Locating units close to points of use reduces energy losses in the hot-water distribution system, sometimes substantially. This ease of positioning may also make it easier to use more than one water heater, reducing hot-water distribution system heat losses still further by eliminating even more piping.

There are many good applications of both electric and fossil-fired tankless water heaters in residences, commercial, institutional, and industrial settings. Tankless water heaters are especially useful for providing more localized heating in point-of-use or near-point-of-use applications because they do not take up much space. In general, tankless water heaters are designed to completely heat cold water in one pass through the heater. There are exceptions, however, because some models with advanced controls can also heat prewarmed water by controllable amounts. See the discussion below about modulating heat input rates.

Tankless water heaters generally have some sort of flow detection method (e.g., a flow switch or method of differential temperature measurement that indicates flow is occurring). Water heating only begins once water flow is confirmed. Outlet temperature from tankless water heaters is determined by the flow rate, entering cold-water temperature, and applied heating rate. Simpler systems do not actively control outlet temperature, other than to turn off the heat input if exit temperature exceeds a set value. These systems are more likely to specify the use of water flow restrictors to restrict flow through the units to minimize undesirably cool water exiting the units.

Systems with more advanced controls continuously monitor the exit water temperature and modulate the heat input and/or water flow rate to maintain the specified outlet temperature. Advanced electric tankless water heaters modulate power to the heating elements, either in steps (multiple heating elements) or by varying the voltage and/or current supplied to the heating elements, or both. Advanced fossil-fired tankless water heaters, which are available in both natural-gas- and propane-fired versions, modulate the heating rate by either modulating heat input in steps (e.g. using multiple burners), or by modulating gas flow rate to the burner(s), or some combination of the two. These designs can be used as booster heaters or in recirculated heating systems (i.e., they can work well with prewarmed entering water temperatures) because they can better control exit temperature.

One of the most important tankless water heater sizing considerations is having adequate heat input rate to heat the desired flow rate of water by a temperature rise needed to make the water warm enough to use. Table 15 shows the necessary heat input rate (not considering heat input efficiency: divide table values by heat input efficiency in decimal form [e.g., 0.8 for some fossil-fired heaters]) to determine total energy input rate required for tankless water heaters versus flow rate and needed temperature rise. The heating rates shown are computed using Equation (1).

Note that 40°C is about the minimum acceptable temperature for human use at fixtures. Accounting for heat loss in piping and/or when atomizing droplets in a showerhead, 43°C is a more typical requirement. The needed temperature rise in a cold climate where the entering cold-water temperature may be 2°C would thus be 43°C – 2°C = 41 K; in a warm climate where the entering cold water temperature may be 29°C, the temperature rise would be 43°C – 29°C = 14 K. For comparison, the temperature rise specified in the U.S. federal water heater testing and rating procedure is 57°C – 14°C = 43°C. For reference, typical flow rate ranges are as follows:

- Hand-washing sinks: 0.01 to 0.6 L/sec
- Showers: 0.05 to 0.16 L/s
- Bathtub fill rates: 0.06 to 0.38 L/s
- Dishwasher fill rates: 0.06 to 0.19 L/s

Table 16 Hot-Water Demand in Fixture Units (60°C Water)

	Apartments	Club	Gymnasium	Hospital	Hotels and Dormitories	Industrial Plant	Office Building	School	YMCA
Basin, private lavatory	0.75	0.75	0.75	0.75	0.75	0.75	0.75	0.75	0.75
Basin, public lavatory	—	1	1	1	1	1	1	1	1
Bathtub	1.5	1.5	—	1.5	1.5	—	—	—	—
Dishwasher*	1.5	Five fixture units per 250 seating capacity							
Therapeutic bath	—	—	—	5	—	—	—	—	—
Kitchen sink	0.75	1.5	—	3	1.5	3	—	0.75	3
Pantry sink	—	2.5	—	2.5	2.5	—	—	2.5	2.5
Service sink	1.5	2.5	—	2.5	2.5	2.5	2.5	2.5	2.5
Shower	1.5	1.5	1.5	1.5	1.5	3.5	—	1.5	1.5
Circular wash fountain	—	2.5	2.5	2.5	—	4	—	2.5	2.5
Semicircular wash fountain	—	1.5	1.5	1.5	—	3	—	1.5	1.5

Note: Data predate modern low-flow fixtures and appliances. *See Water-Heating Terminology section for definition of fixture unit.

- Clothes-washing machine fill rates: 0.06 to 0.38 L/s
- Residential whole-house recurring peak rates: around 0.19 to 0.25 L/s
- Residential whole-house severe-peak flow rates: 0.38 to 0.5 L/s

As can be seen from Table 15, whole-house tankless water heaters need to be able to provide heating rates on the order of 22 to 44 kW in all but the warmest climates. Note, however, that in single-family residential applications, users have the opportunity to learn what works and what does not, and are likely to adjust their hot-water use habits somewhat to obtain adequately hot water from whatever water-heating system is used. They could do this for example, by avoiding hot-water use from multiple fixtures simultaneously, and reducing demanded flow rates.

An important issue in the sizing of tankless water heaters is thus what peak hot-water energy rate load to design for. It is generally acceptable to design the water-heating system to meet a peak hot-water load (in terms of energy rate needed, not just water flow rate needed) that is not exceeded by 97.5% of all draws. The difficulty in sizing whole-house tankless water heaters comes in predicting how draws will coincide to create the peak energy demand rate. This peak coincident energy demand rate must be estimated by the person sizing the system, because ASHRAE does not currently have a statistically valid amount of data on peak residential water/energy flow rates with which to make recommendations. However, research (Buchberger et.al. 2015) has for the first time provided hot-water draw information from a statistically large number of residential test sites, allowing estimation of probabilities of various types of draws occurring versus time of day, probabilities of how such draws may overlap in time within and between households, and normal ranges of flow rates and total volumes for the various types of draws. Sizing recommendations are easier with storage-type water heaters because their sizing is done more based on integrated total energy requirements, and is not highly dependent on knowledge of peak flow rates.

An issue related to proper sizing of tankless water heaters is the size of fuel piping and electrical service needed. Because gas-fired tankless water heaters must have significantly higher fuel burn rates than typical tank-types, larger gas piping may be required. The same is true for electric tankless water heaters, where a whole-house unit may require larger wiring and often additional (multiple) circuit breakers. Consequently, large tankless water heaters, both gas and electric, can in some cases require a service entrance upgrade. Notably, diversified electrical demand for large numbers of electric tankless water heaters is not much different (generally a little lower) than tank types, because of the lower number of tankless water heaters that are on at any point in time compared to tank types. However, as number of users on an electrical line decreases, demand diversity decreases, which can result in increased electrical demand compared to tank types as the number of users on the line decreases to fairly few. The number that "few" represents varies with size of the tankless units. Hiller (2017) found that diversified electrical demand of 28 kW tankless water heaters in residences was similar to that of 4.5 kW storage water heaters when number of households exceeded 2 to 15, depending on averaging time interval.

Sizing Instantaneous and Semi-Instantaneous Water Heaters

The methods for sizing storage water-heating equipment should not be used for instantaneous and semi-instantaneous heaters. The following is based on the Hunter (1941) method for sizing hot- and cold-water piping, with diversity factors applied for hot water and various building types.

Fixture units (Table 16) are assigned to each fixture using hot water and totalled. Maximum hot-water demand is obtained from Figures 27 or 28 by matching total fixture units to the curve for the type of building. Special consideration should be given to applications involving periodic use of shower banks, process equipment, laundry machines, etc., as may occur in field houses, gymnasiums, factories, hospitals, and other facilities. Because these applications could have all equipment on at the same time, total hot-water capacity should be determined and added to the maximum hot-water demand from the modified Hunter curves. Often, the temperature of hot water arriving at fixtures is higher than is needed, and hot and cold water are mixed together at the fixture to provide the desired temperature.

Equation (17), derived from a simple energy balance on mixing hot and cold water, shows the ratio of hot-water flow to desired end-use flow for any given hot, cold, and mixed end-use temperatures.

$$\text{Hot-water flow rate} = \frac{(\text{Mixed-temperature flow rate})(T_{mixed} - T_{cold})}{(T_{hot} - T_{cold})} \quad (17)$$

Once the actual hot-water flow rate is known, the heater can then be selected for the total demand and total temperature rise required. For critical applications such as hospitals, multiple heaters with 100% reserve capacity are recommended. Consider multiple heaters for buildings in which continuity of service is important. The minimum recommended size for semi-instantaneous heaters is 0.65 L/s, except for restaurants, for which it is 0.95 L/s. When system flow is not easily determined, the heater may be sized for full flow of the piping system at a maximum speed of 3 m/s. Heaters with low flows must be sized carefully, and care should be taken in the estimation of diversity factors. Unusual hot-water requirements should be analyzed to determine whether additional capacity is required. One example is a dormitory in a military school, where all showers and lavatories are used simultaneously when students return from a

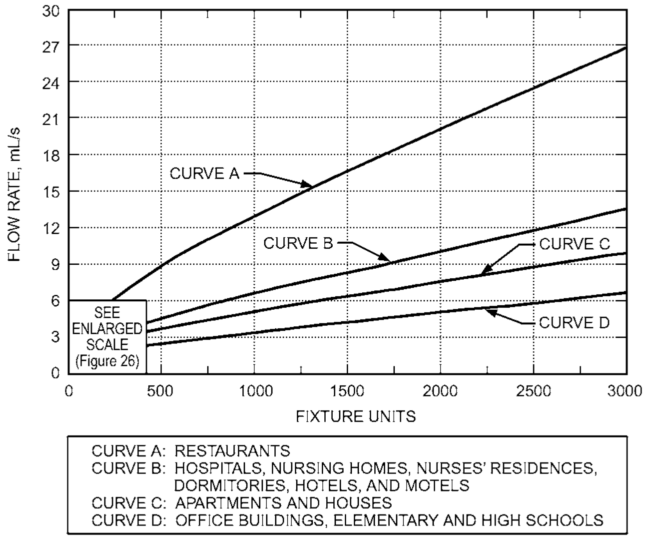

Fig. 27 Modified Hunter Curve for Calculating Hot-Water Flow Rate
(Data predate modern low-flow appliances.)

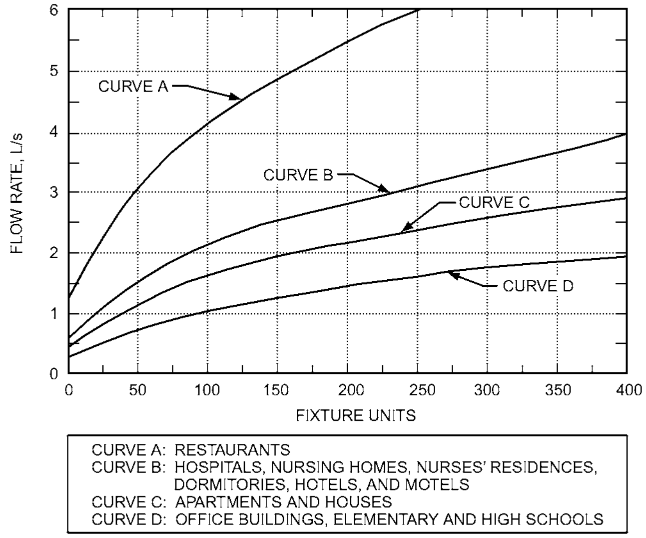

Fig. 28 Enlarged Section of Figure 27 (Modified Hunter Curve)
(Data predate modern low-flow appliances.)

drill. In this case, the heater and piping should be sized for full system flow.

Whereas the fixture count method bases heater size of the diversified system on hot-water flow, hot-water piping should be sized for full flow to the fixtures. Recirculating hot-water systems are adaptable to instantaneous heaters.

To make preliminary estimates of hot-water demand when the fixture count is not known, use Table 17 with Figure 27 or Figure 28. The result is usually higher than the demand determined from the actual fixture count. Actual heater size should be determined from Table 16. Hot-water consumption over time can be assumed to be the same as that in the section on Hot-Water Requirements and Storage Equipment Sizing.

Example 10. A 600-student elementary school has the following fixture count: 60 public lavatories, 6 service sinks, 4 kitchen sinks, 6 showers, and 1 dishwasher at 0.5 L/s. Determine the hot-water flow rate for sizing a semi-instantaneous heater based on the following:

a. Estimated number of fixture units

b. Actual fixture count

Solution:

a. Use Table 17 to find the estimated fixture count: 600 students × 0.3 fixture units per student = 180 fixture units. As showers are not included, Table 16 shows 1.5 fixture units per shower × 6 showers = 9 additional fixture units. The basic flow is determined from curve D of Figure 28, which shows that the total flow for 189 fixture units is 1.4 L/s.

b. To size the unit based on actual fixture count and Table 16, the calculation is as follows:

60 public lavatories	× 1.0 FU =	60 FU
6 service sinks	× 2.5 FU =	15 FU
4 kitchen sinks	× 0.75 FU =	3 FU
6 showers	× 1.5 FU =	9 FU
Subtotal		87 FU

At 87 fixture units, curve D of Figure 28 shows 1.0 L/s, to which must be added the dishwasher requirement of 0.54 L/s. Thus, the total flow is 1.54 L/s.

Table 17 Preliminary Hot-Water Demand Estimate

Type of Building	Fixture Units
Hospital or nursing home	2.50 per bed
Hotel or motel	2.50 per room
Office building	0.15 per person
Elementary school	0.30 per student*
Junior and senior high school	0.30 per student*
Apartment house	3.00 per apartment

*Plus shower load (in fixture units).

Comparing the flow based on actual fixture count to that obtained from the preliminary estimate shows the preliminary estimate to be slightly lower in this case. It is possible that the preliminary estimate could have been as much as twice the final fixture count. To prevent oversizing of equipment, use the actual fixture count method to select the unit.

Sizing Refrigerant-Based Water Heaters

Refrigerant-based heat pump water heaters (HPWHs) comprised of air-source, water-source, direct geoexchange, and sorption types of equipment are sized in a different manner than conventional systems because

- The variable nature of the heat source (air, water, and ground temperatures) depends on the geographic location of the application and the season of the year. HPWH manufacturers provide performance data and sizing information that take these factors into account.
- To reduce first costs, heat pump water heaters benefit from a greater ratio of storage tank capacity per unit of energy input than for conventional water heaters.

To achieve the lowest total system cost and the highest system efficiency, the HPWH system designer generally specifies the smallest-capacity HPWH consistent with an annual average of 12 to 18 h daily run time combined with the appropriately sized storage tank for the application. This means that part of the year the HPWH runs continuously. For air-source, water-loop, groundwater, and sorption-type HPWH systems, daily run times of up to 24 h are not uncommon. In many heat pump based systems, a conventional gas or electric commercial water heater is placed downstream in series to act as a reserve water heater. The conventional heater enables a continuous supply of hot water if the HPWHs need to be shut down for maintenance. Another strategy is to size the HPWH smaller for longer run times, thus saving on purchase and installation costs to meet a portion of the total daily load and use conventional heaters to meet the rest of the load and peak loads.

When sizing for redundancy, the HPWH portion of the system can have multiple HPWHs and storage tanks in flow parallel, but when additional conventional water heaters are also provided (normally to help serve peak hot water loads or provide back-up heating capacity) the cluster of conventional water heaters (which can be in flow parallel with each other) should be in flow series with but downstream of the cluster of HPWHs. Figure 29 shows an example HPWH system plumbing arrangement. Condensing fossil-fired water heaters can also operate more efficiently if configured in this manner, because they receive colder inlet water temperatures.

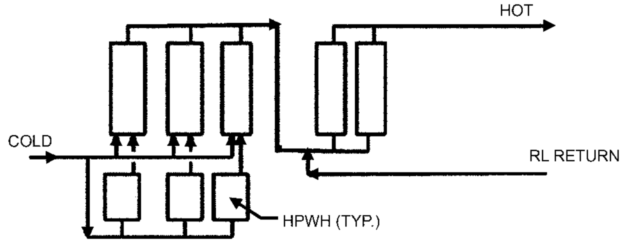

Fig. 29 Example Plumbing of HPWH and Conventional Water Heating System

10. WATER-HEATING ENERGY USE

Energy use in water-heating systems includes the following factors, not all of which apply in a given type of system (Hiller 2006c):

- Q_{water} is energy content in water actually used, relative to entering cold-water temperature.
- $Q_{tank\ loss}$ is standby heat loss from water heater storage tank; it is proportional to time and temperature difference between water in tank and surroundings.
- $Q_{cycling\ loss}$ is energy loss from on/off cycling of heat input device, where energy invested in mass of heating device (e.g., heat exchanger) and water in it is lost to surroundings after device turns off; loss is proportional to number of heating cycles (e.g., in a tankless instantaneous water heater). Some fossil-fuel-fired tankless water heaters have pre- and/or postfiring combustion air blower operation to purge combustion products from combustion chamber, which can cause very rapid loss of invested energy in heat exchanger.
- Q_{piping} is heat energy lost from piping while water is flowing; note that, on recirculation-loop systems, heat is lost from both supply and return piping.
- $Q_{cooldown}$ is heat energy lost from piping after flow ceases; note that $Q_{cooldown}$ exhibits a large step increase once water in a pipe cools to below a usable temperature, because remaining warm water in pipe must be dumped to drain before usable hot water can again be obtained at fixtures; time spacing between draws and pipe insulation levels thus strongly influence this energy loss.
- Q_{dump} is energy that must be provided to reheat an amount of water equal to that dumped down the drain while waiting for hot water to arrive at fixtures; knowing the time spacing between draws in nonrecirculated piping systems is very important.
- Input efficiency η_i (tank-type water heater) or thermal efficiency η_t (tankless water heater or heating device external to tank) of heating device must be considered when calculating total water-heating system energy use.
- $Q_{circulating\ pump}$ is energy used to move water within system, if done with pumps. There are often multiple circulating pumps in system (e.g., to circulate water from storage tanks to heating devices, recirculation-loop pumps).
- $Q_{parasitics}$ is energy to operate fans, blowers, controls, and other devices.
- Q_{supply} is energy used to deliver potable water to system and force it through system. Includes pumping energy for well pumps or city water supply pumps, and water treatment system energy.
- $Q_{disposal}$ is energy used to treat and dispose of waste water, including pumping energy and other treatment system energy.

Total piping system energy use is thus

$$Q_{total} = Q_{water}/\eta_i + Q_{tank\ loss}/\eta_i + Q_{cycling\ loss} + Q_{piping}/\eta_i + Q_{cooldown}/\eta_i + Q_{dump}/\eta_i + Q_{circulating\ pump} + Q_{parasitics} + Q_{supply} + Q_{disposal}$$

Additional energy use terms may apply in some water-heating systems.

The following simple examples demonstrate how to compute water-heating system energy use for different system types and draw patterns.

Assumptions for Examples 11 to 14 include the following:

- Two fixtures 30 m apart
- Six 5 min long draws per day of 0.065 L/s, 40°C water at each fixture, spaced 3 min apart compared to 4 h apart
- Water heater output temperature of 50°C
- Tank-type fossil-fuel-fired water heater with input efficiency η_i = 0.80 and a uniform energy factor (UEF) of 0.59, yielding UA_{tank} = 6 W/K, including energy input efficiency (note that tank heat loss rate is a function of UEF rating, not tank size. However, for equal amounts of insulation, smaller tanks have higher UEF rating)
- T_{air} = 20°C for both piping and tank
- T_{cold} = 14.5°C entering cold-water temperature
- Supply piping is 20 mm rigid copper with 13 mm thick foam insulation $(Mc_p)_{w,p,i}$ = 1.58 kJ/(m·K), (from Table 1) pipe volume = 0.3122 L/m
- Return piping is 13 mm rigid copper with 13 mm thick foam insulation (RL system only)
- For simplicity, neglect short lengths of piping between fixture branch piping and main recirculation-loop piping (or tank if at location of fixture)
- For simplicity, neglect supply and disposal energy, recirculating pump energy, and other parasitics.

Example 11. Assume a continuously running hot-water recirculation-loop system with an allowed loop temperature drop to the farthest fixture of 3 K, and assuming one fixture is near the water heater. Note that because this is a continuously running recirculation-loop system, time spacing between draws is unimportant because the supply and return piping are always hot.

Solution: First, compute the recirculation loop flow rate needed to prevent temperature dropping below 47°C, using Equations (1) to (4) and (9).

$$\Delta T_{lm} = \frac{(50 - 20°C) - (47 - 20°C)}{\ln[(50 - 20°C)/(47 - 20°C)]} = 28.47 \text{ K}$$

$UA_{flowing\ supply}$ = 0.433 W/(m·K) (from Table 1)

$$\begin{aligned} Q_{piping\ supply} &= [0.433 \text{ W/(m·K)}](30 \text{ m})(28.47 \text{ K})/0.8 = 462.28 \text{ W} \\ &= (462.28 \text{ J/s})(60 \text{ s/min})(60 \text{ min/h})(24 \text{ h/day}) \\ &= 39\,940 \text{ kJ/day} \end{aligned}$$

$$m_{circulating\ pump} = \frac{(462.28\ \text{W})(0.8)}{(1\ \text{kg/L})[4186.8\ \text{J/(kg·K)}](3\ \text{K})} = 0.029\ \text{L/s}$$

$$UA_{flowing\ return} = 0.346\ \text{W/(m·K)}\ \text{(from Table 1)}$$

$$T_{hot\ return\ out} = 20°\text{C} + (47 - 20°\text{C})e^{-\left[\frac{[0.346\ \text{W/(m·K)}](30\ \text{m})}{(0.029\ \text{L/s})(1\ \text{kg/L})[4186.8\ \text{J/(kg·K)}]}\right]} = 44.8°\text{C}$$

$$Q_{piping\ return} = (0.029\ \text{L/s})(1\ \text{kg/L})[4.1868\ \text{kJ/(kg·K)}] \times (47 - 44.8°\text{C})/0.8 = (336\ \text{J/s})(60\ \text{s/min})(60\ \text{min/h})(24\ \text{h/day}) = 28\ 858\ \text{kJ/day}$$

Next, determine the amount of hot water mixed with cold water to deliver the 40°C fixture delivery temperature, from Equation (24).

For the fixture at the water heater,

$$m_{hot\ near} = (0.065\ \text{L/s})(40 – 14.5°\text{C})/(50 – 14.5°\text{C}) = 0.047\ \text{L/s}$$

And for the far fixture,

$$m_{hot\ far} = (0.065\ \text{L/s})(40 – 14.5°\text{C})/(47 – 14.5°\text{C}) = 0.051\ \text{L/s}$$

Consequently,

$$Q_{water\ near} = (0.047\ \text{L/s})(1\ \text{kg/L})[4.1868\ \text{kJ/(kg·K)}](50 - 14.5°\text{C}) \times (60\ \text{s/min})(5\ \text{min/draw})(6\ \text{draws/day})/0.8 = 15\ 692\ \text{kJ/day}$$

$$Q_{water\ far} = (0.051\ \text{L/s})(1\ \text{kg/L})[4.1868\ \text{kJ/(kg·K)}](47 - 14.5°\text{C}) \times (60\ \text{s/min})(5\ \text{min/draw})(6\ \text{draws/day})/0.8 = 15\ 589\ \text{kJ/day}$$

This is the same as for the near fixture, as it should be, because piping heat loss is separately computed.

$$Q_{tank\ heat\ loss} = (6\ \text{W/K})(50 - 20°\text{C})(60\ \text{s/min})(60\ \text{min/h}) \times (24\ \text{h/day}) = 15\ 552\ \text{kJ/day}$$

Thus,

$$Q_{total\ RL\ system} = 39\ 940 + 28\ 858 + 15\ 692 + 15\ 589 + 15\ 552 = 115\ 631\ \text{kJ/day}$$

With the recirculation system, energy use is the same regardless of draw spacing.

Example 12. Assume a nonrecirculated piping system, one fixture at water heater, draws 3 min and 4 h apart.

Solution: First, determine the steady-state delivery temperature at the far fixture, and the actual hot-water flow rate to that fixture. This requires iteration: guessing an initial piping outlet temperature, calculating an estimated hot-water flow rate using Equation (17), and then calculating a new piping outlet temperature based on the calculated flow rate.

Guess $T_{hot\ out\ 1} = 50°\text{C}$. Then,

$$m_{hot\ 1} = \frac{(0.065\ \text{L/s})(40 - 14.5°\text{C})}{(50 - 14.5°\text{C})} = 0.047\ \text{L/s [from Equation (17)]}$$

$$T_{hot\ out\ 2} = 47°\text{C [from Equation (2), where}$$

$$UA_{flowing} = 0.433\ \text{W/(m·K)},\ L = 30\ \text{m]}$$

$$m_{hot\ 2} = \frac{(0.065\ \text{L/s})(40 - 14.5°\text{C})}{(47 - 14.5°\text{C})} = 0.051\ \text{L/s}$$

$$T_{hot\ out\ 3} = 47.1°\text{C}$$

$$m_{hot\ 3} = \frac{(0.065\ \text{L/s})(40 - 14.5°\text{C})}{(47.1 - 14.5°\text{C})} = 0.0508\ \text{L/s}$$

$$T_{hot\ out\ 4} = 47.11°\text{C}$$

Thus,

$$Q_{water\ far} + Q_{piping} = (0.0508\ \text{L/s})(1\ \text{kg/L})[4186.8\ \text{J/(kg·K)}] \times (50 - 14.5°\text{C})(60\ \text{s/min})(5\ \text{min/draw}) \times (6\ \text{draws/day})/0.8 = 16\ 989\ \text{kJ/day}$$

Note that, in this computation, water energy and piping flowing heat loss energy are calculated together for simplicity.

$$Q_{water\ near} = \text{same as in Example 11} = 15\ 692\ \text{kJ/day}$$

Next, compute the pipe temperature at the end of both the 3 min and 4 h cooldown (cd) periods, accounting for the different draw spacing scenarios. For simplicity, base the heat loss calculations on an average pipe temperature of (50 + 47.11°C)/2 = 48.6°C.

Using $UA_{zero\ flow}$ = 0.26 W/(m·K) from Table 1, and Equation (8),

$$T_{pipe\ 3\ min} = 20°\text{C} + (48.6 - 20°\text{C})e^{-\left[\frac{[0.26\ \text{W/(m·K)}](3\ \text{min})(60\ \text{s/min})}{[1.584\ \text{kJ/(m·K)}](1000\ \text{J/kJ})}\right]} = 47.76°\text{C}$$

and

$$T_{pipe\ 4\ h} = 22.67°\text{C}$$

The pipe does not cool below a usable temperature with the 3 min draw spacing, but it does with the 4 h draw spacing. This means that, for the 3 min draw spacing, there are five draws with small amounts of piping cooldown between draws plus one complete cooldown for the last draw of the day, whereas for the 4 h draw spacing, there are six complete cooldowns that result in dumping water in the pipe to drain at the next draw. Because pipe length to the fixture at the water heater is essentially zero under the assumptions here, only draws at the far fixture result in piping energy loses.

From Equation (5),

$$Q_{cd\ 3\ min} = [1584\ \text{J/(m·K)}](30\ \text{m})(48.6 - 47.76°\text{C}) \times 5\ \text{cd/day}/0.8 + 1\ \text{cd (lumped into}\ Q_{dump}) = 249.48\ \text{kJ/day}$$

To estimate Q_{dump} and the amount of water waste, assume an AF/PV ratio of 1.5. Thus, each time the pipe cools below a usable temperature, (1.5)(0.3122 L/m)(30 m) = 14.0 L of water must be dumped to drain.

$$Q_{dump\ 3\ min} = (1\ \text{dump/day})(14.0\ \text{L/dump})(1\ \text{kg/L}) \times [4.1868\ \text{kJ/(kg·K)}](50 - 14.5°\text{C})/0.8 = 2601\ \text{kJ/day}$$

$$Q_{dump\ 4\ h} = (6\ \text{dumps/day})(2601\ \text{kJ/dump}) = 15\ 606\ \text{kJ/day}$$

and

$$Q_{cd\ 4\ h} = 0$$

because all cooldown energy is lumped into Q_{dump}.

$$Q_{tank\ heat\ loss} = 18\ 400\ \text{kJ/day, as in Example 11}$$

To simplify calculation of total water-heating system energy use, it is convenient to add the cooldown energy term computed as shown to the Q_{water} term calculated as if all hot water were delivered to the fixture at a constant flow rate and the steady-state temperature. In reality, the hot-water flow rate to the fixture varies during the initial part of a draw as the cooled but still usable water temperature increases to the

Table 18 Results Comparisons for Examples 11 to 14

	3 min Draw Spacing			4 h Draw Spacing		
System Type	Energy Use, kJ/day	Energy Use Compared to One Tank, %	Water Waste, L/day	Energy Use, kJ/day	Energy Use Compared to One Tank, %	Water Waste, L/day
Recirculation loop	118 479	231	0	118 479	184	0
One-tank	53 930	100	14	66 687	100	85.6
Two-tank (large)	68 184	123	0	68 184	98	0
Two-tank (small)	58 341	115	0	58 341	92	0

steady-state value as flow progresses. The energy use thus computed will be mathematically correct either way.

$$Q_{total\ non\text{-}RL,\ 3\ min\ spacing} = 16\ 989 + 15\ 692 + 248 + 2601 + 18\ 400 = 53\ 930\ \text{kJ/day}$$

$$Q_{total\ non\text{-}RL,\ 4\ h\ spacing} = 16\ 989 + 15\ 692 + 0 + 15\ 606 + 18\ 400 = 66\ 687\ \text{kJ/day}$$

Note the large increase in energy use when draws are spaced far enough apart for the pipe to cool to below a usable temperature between draws. Also, the time spent waiting for hot water to arrive at the far fixture is

$$t_{wait} = (14\ \text{L})/(0.065\ \text{L/s}) = 215\ \text{s} = 3.59\ \text{min}$$

Example 13. Assume two full-sized water heaters, one at each fixture; no piping.

Solution: In this case, tank heat loss is doubled, but piping heat loss is eliminated.

$$Q_{water} = (2)(15\ 692\ \text{kJ/day}) = 31\ 384\ \text{kJ/day}$$

$$Q_{tank\ heat\ loss} = (2)(18\ 400\ \text{kJ/day}) = 36\ 800\ \text{kJ/day}$$

$$Q_{total\ 2\text{-}tank} = 31\ 384 + 36\ 800 = 68\ 184\ \text{kJ/day}$$

Draw spacing is irrelevant to the two-tank system because there is no piping.

Example 14. Assume two smaller water heaters, one at each fixture; no piping.

Solution: When two separate water heaters are used, each can be smaller than if one water heater were used. Assuming a smaller tank-type fossil-fuel-fired water heater with input efficiency $\eta_i = 0.80$ and a UEF of 0.61, yielding $UA_{tank} = 5.2$ W/K, including energy input efficiency,

$$Q_{water} = (2)(15\ 692\ \text{kJ/day}) = 31\ 384\ \text{kJ/day}$$

$$Q_{tank\ heat\ loss} = (2)(5.2\ \text{W/K})(50 - 20°\text{C})(60\ \text{s/min}) \times (60\ \text{min/h})(24\ \text{h/day}) = 26\ 957\ \text{kJ/day}$$

$$Q_{total\ 2\text{-}tank} = 31\ 384 + 26\ 957 = 58\ 341\ \text{kJ/day}$$

Again, draw spacing is irrelevant to the two-tank system because there is no piping.

Table 18 compares water and energy use of Examples 11 to 14, and shows that the continuously running recirculation-loop system uses substantially more energy than the other approaches (on the order of twice as much). This is not uncommon. Also note that, in these examples, the two-tank approach saves both water waste and energy. The multiple-water-heater approach has at worst only a small negative energy effect if done properly, and under real water draw scenarios usually uses less energy than other options. This is why multiple-water-heater design options should always be considered. In some cases, multiple-water-heater systems can have lower first costs than alternatives. Note that multiple-water-heater systems can use different types of water heaters for different parts of the system: fossil-fuel-fired or heat pump water heaters can be used to serve larger loads, whereas electric resistance water heaters may be preferred for serving smaller loads. In some cases, space limitations, life and maintenance issues, and other factors may make multiple-water-heater systems unattractive.

Both simplified and detailed computer models (Hiller 1992, 2000) are available to help calculate water heater energy use. These are especially useful for analyzing the energy used by heat pump water heaters, where efficiency and heating capacity vary strongly with both source (e.g., air, water) and sink (water) temperature. Computer models are also under development to compute water and energy waste associated with hot-water distribution systems.

11. HEALTH AND SAFETY

Legionellosis (Legionnaires' Disease)

Legionnaires' disease (a form of severe pneumonia) is caused by inhaling aerosolized water droplets containing the bacteria *Legionella pneumophila*. Susceptibility to Legionnaire's disease varies among individuals. People with compromised immune systems (e.g., organ transplant patients or others on immunosuppressant drugs, AIDS patients, smokers, elderly, those with other chronic health conditions or injuries) are at greater risk of contracting the disease at lower exposure levels.

Most water supplied to buildings contains some *Legionella* bacteria (and/or other microorganisms), often at levels too low to detect. The concern is that organism colonies can grow (amplify) within the building hot- and cold-water systems under certain conditions. At high *Legionella* concentrations, a hazard may exist. Some examples of conditions potentially conducive to *Legionella* growth are temperatures within a certain range (warm, not too hot or cold), locations of flow stagnation (e.g., pipe dead legs, low flow velocities, other flow stagnation points, intermittent or seasonal use), and inadequate oxidant residual levels. For more specific water system design guidance, refer to ASHRAE *Standard* 188-2018 and ASHRAE *Guideline* 12-2000.

Scalding

Scalding is an important concern in design and operation of potable hot-water systems. Figure 30 (Moritz 1947) shows plots of exposure time versus water temperature that results in both first-degree (pain, redness, swelling, minor tissue damage) and full-thickness third-degree (permanent damage, scarring) skin burns in adults. Children burn even more rapidly. Note that, at the high temperatures required for some commercial and institutional operations (e.g., 60°C and above), burns can occur almost instantaneously (3 s or less exposure). Even at lower temperatures such as 51°C, found commonly in multifamily housing, hospitality, and light commercial facilities, burns can occur in 2 min. Safety dictates some trade-offs to limit scalding injuries (e.g., during pressure transients that may inhibit proper operation of temperature regulating valves) while minimizing risk of Legionnaire's disease.

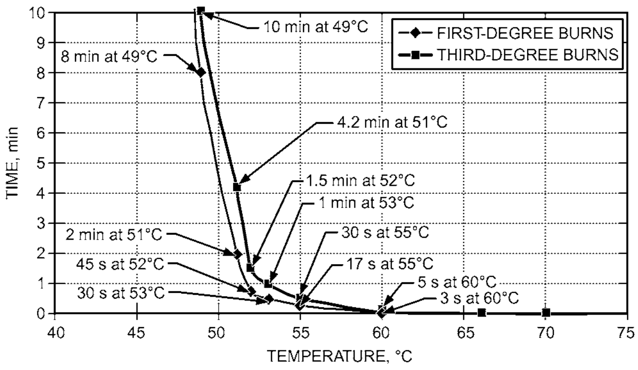

Fig. 30 Time for Adult Skin Burns in Hot Water

Temperature Requirement

Typical temperature guidelines for some services are shown in Table 19. A 60°C water temperature minimizes flue gas condensation in the equipment.

Other Safety Concerns

Regulatory agencies differ as to the selection of protective devices and methods of installation. It is therefore essential to check and comply with the manufacturer's instructions and the applicable local codes. In the absence of such instructions and codes, the following recommendations may be used as a guide:

- Water expands when it is heated. Although the water-heating system is initially under service pressure, the pressure rises rapidly if backflow is prevented by devices such as a check valve, pressure-reducing valve, or backflow preventer in the cold-water line or by temporarily shutting off the cold-water valve. When backflow is prevented, the pressure rise during heating may cause the safety relief valve to weep to relieve the pressure. However, if the safety relief valve is inadequate, inoperative, or missing, pressure rise may rupture the tank or cause other damage. Systems having this potential problem must be protected by a properly sized expansion tank located on the cold-water line downstream of and as close as practical to the device preventing backflow.
- Temperature-limiting devices (energy cutoff/high limit) prevent water temperatures from exceeding 99°C by stopping the flow of fuel or energy. These devices should be listed and labeled by a recognized certifying agency.
- Safety relief valves open when pressure exceeds the valve setting. These valves are typically applied to water-heating and hot-water supply boilers. The set pressure should not exceed the maximum allowable working pressure of the boiler. The heat input pressure steam rating (in kW) should equal or exceed the maximum out-put rating for the boiler. The valves should comply with current applicable standards or the ASME *Boiler and Pressure Vessel Code.*
- Temperature and pressure safety relief valves also open if the water temperature reaches 99°C. These valves are typically applied to water heaters and hot-water storage tanks. The heat input temperature/steam rating (in kW) should equal or exceed the heat input rating of the water heater. Combination temperature- and pressure-relief valves should be installed with the temperature-sensitive element located in the top 150 mm of the tank (i.e., where the water is hottest).
- To reduce scald hazards, discharge temperature at fixtures accessible to the occupant should not exceed 50°C. Thermostatically controlled mixing valves can be used to blend hot and cold water to maintain safe service hot-water temperatures.

Table 19 Representative Hot-Water Temperatures

Use	Temperature, °C
Lavatory	
Hand washing	40
Shaving	45

[a]As required by NSF.
[b]See manufacturer for actual temperature required.

- A relief valve should be installed in any part of the system containing a heat input device that can be isolated by valves. The heat input device may be solar water-heating panels, desuperheater water heaters, heat recovery devices, or similar equipment.

12. WATER QUALITY, SCALE, AND CORROSION

A complete water analysis and an understanding of system requirements are needed to protect water-heating systems from scale and corrosion. Analysis shows whether water is hard or soft. Hard water, unless treated, causes scaling or liming of heat transfer and water storage surfaces; soft water may aggravate corrosion problems and sacrificial anode consumption (Talbert et al. 1986).

Scale formation is also affected by system requirements and equipment. As shown in Figure 31, the rate of scaling increases with temperature and use because calcium carbonate and other scaling compounds lose solubility at higher temperatures. In water tube-type equipment, scaling problems can be offset by increasing water velocity over the heat transfer surfaces, which reduces the tube surface temperature. Also, flow turbulence, if high enough, works to keep any scale that does precipitate off the surface. When water hardness is over 140 mg/L, water softening or other water treatment is often recommended.

Corrosion problems increase with temperature because corrosive oxygen and carbon dioxide gases are released from the water. Electrical conductivity also increases with temperature, enhancing electrochemical reactions such as rusting (Taborek et al. 1972). A deposit of scale provides some protection from corrosion; however, this deposit also reduces the heat transfer rate, and it is not under the control of the system designer (Talbert et al. 1986).

Steel vessels can be protected to varying degrees by galvanizing or by lining with copper, glass, cement, electroless nickel-phosphorus,

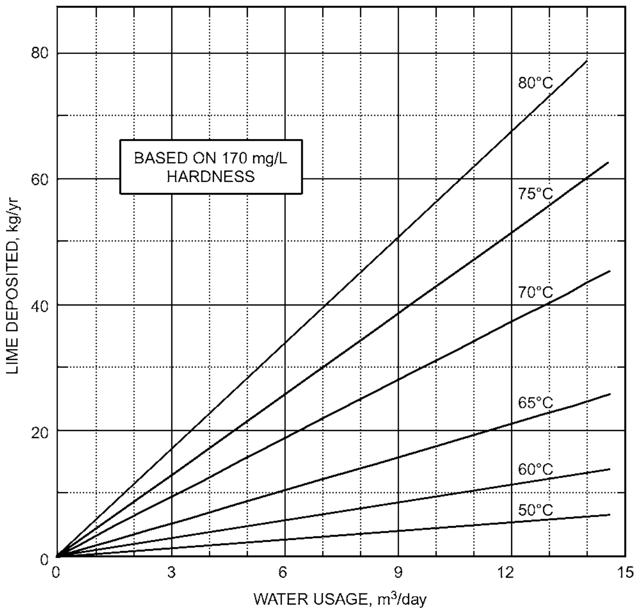

Fig. 31 Lime Deposited Versus Temperature and Water Use
(Based on data from Purdue University *Bulletin* No. 74)

or other corrosion-resistant material. Glass-lined vessels are almost always supplied with electrochemical protection. Typically, one or more anode rods of magnesium, aluminum, or zinc alloy are installed in the vessel by the manufacturer. This electrochemically active material sacrifices itself to reduce or prevent corrosion of the tank (the cathode). Higher temperature, softened water, and high water use may lead to rapid anode consumption. Manufacturers recommend periodic replacement of the anode rod(s) to prolong the life of the vessel. Some waters have very little electrochemical activity. In this instance, a standard anode shows little or no activity, and the vessel is not adequately protected. If this condition is suspected, consult the equipment manufacturer on the possible need for a high-potential anode, or consider using vessels made of nonferrous material.

Water heaters and hot-water storage tanks constructed of stainless steel, copper, or other nonferrous alloys are protected against oxygen corrosion. However, care must still be taken, as some stainless steel may be adversely affected by chlorides, and copper may be attacked by ammonia or carbon dioxide.

13. SPECIAL CONCERNS

Cross Flow at End-Use Fixtures

Cross flow occurs when there is a connection between the hot- and cold-water lines. Cross flow is problematic because moving hot water into the cold line or, alternatively, moving cold water into the hot line, can affect the performance of end-use equipment, reduce hot-water outlet temperatures or mix hot water into the cold line used for drinking water or ice making. If not resolved, cross flow in facilities can cause energy and water waste, poor water system performance, and facilitate growth of *Legionella*.

One way to determine whether cross flow is occurring from the cold-water side is to turn off the valve on the water heater cold-water inlet and let only hot water flow at a faucet. If pressure drops and water ceases to flow, then there is no cross flow, but if water continues to flow, this indicates cross flow between the hot and cold lines in the system.

Cross flow can occur in the commercial setting at various locations on the water distribution system, including at mop or utility sink faucets and at prerinse spray valve faucets. These are locations where both the hot- and cold-water valves are commonly kept in the open position for downstream tempering of water for "on-demand" sanitation tasks. Assemblies such as in-line chemical dispensers, hoses with attached spray nozzles, or downstream shutoff valves installed for filling mop buckets may promote cross flow if check valves are not installed. Similarly, in commercial kitchens, prerinse spray valve operation typically requires leaving the hot- and cold-water valves open at the faucet in advance of spray valve operation. Another place where cross flow can occur is with single-handle faucets at hand sinks and showers, where a worn seal in the faucet can cause a direct connection of the cold and hot line.

Installing a check valve on both the hot-water and cold-water connections at end-use fixtures ensures that water only flows in a single direction, eliminating cross flow. To ensure that cross flow at the faucet is prevented, specify faucets with check valves included. Otherwise, check valves should be installed ahead of these faucets on both the hot and cold lines.

Hot Water from Tanks and Storage Systems

With storage systems, 60 to 80% of the hot water in a tank is assumed to be usable before dilution by cold water lowers the temperature below an acceptable level. However, better designs can exceed 90%. Thus, the maximum hot water available from a self-contained storage heater is usually

$$V_t = Rd + MS_t \tag{18}$$

where

V_t = available hot water, L
R = recovery rate at required temperature, L/s
d = duration of peak hot-water demand, s
M = ratio of usable water to storage tank capacity
S_t = storage capacity of heater tank, L

However, Equation (11) only applies if the water draw rate is less than the available reheat rate. Otherwise, the tank cannot heat the flowing water to a usable temperature during the draw, and V_t drops to the same as an unfired tank. For example, a fossil-fuel-fired heater with a fuel input rate of 13 kW and an input efficiency of 80% can raise the temperature of water being drawn through a storage tank at a rate of 200 mL/s by approximately 13 K. If the entering cold-water temperature is 16°C, the water will be heated to only 28°C, too cold to be useful, so the heating rate cannot contribute to effective storage tank capacity under a prolonged draw at this flow rate. In reality, draw rates are rarely constant during peak draw or other times. Computer simulation models allow equipment sizing under these more realistic conditions (Hiller 1992).

Maximum usable hot water from an unfired tank is

$$V_a = MS_a \tag{19}$$

where

V_a = usable water available from unfired tank, L
S_a = capacity of unfired tank, L

Note: Assumes tank water at required temperature.

Hot water obtained from a water heater using a storage heater with an auxiliary storage tank is

$$V_z = V_t + V_a \tag{20}$$

where V_z is total hot water available during one peak, in litres.

Placement of Water Heaters

Many types of water heaters may be expected to leak at the end of their useful life. They should be placed where leakage will not cause damage. Alternatively, suitable drain pans piped to drains must be provided.

Water heaters not requiring combustion air may generally be placed in any suitable location, as long as relief valve discharge pipes open to a safe location.

Water heaters requiring ambient combustion air must be located in areas with air openings large enough to admit the required combustion/dilution air (see NFPA *Standard* 54/ANSI Z223.1).

For water heaters located in areas where flammable vapors are likely to be present, precautions should be taken against ignition. For water heaters installed in residential garages, additional precautions should be taken. Consult local codes for additional requirements or see sections 5.1.9 through 5.1.12 of NFPA *Standard* 54/ ANSI Z223.1.

Outdoor models with a weather-proofed jacket are available. Direct-vent gas- and oil-fired models are also available; they are to be installed inside, but are not vented through a conventional chimney or gas vent. They use outdoor air for combustion. They must be installed with the means specified by the manufacturer for venting (typically horizontal) and for supplying air for combustion from outside the building.

Air-source heat pump water heaters require access to an adequate air supply from which heat can be extracted. For residential units, a room of at least 27 m^3 or ducted air is recommended. See manufacturer's literature for more information.

CHAPTER 52

SNOW MELTING AND FREEZE PROTECTION

Snow-Melting Heat Flux Requirement 52.1
Slab Design 52.10
Hydronic System Design 52.10
Electric System Design 52.14
Control 52.19
Freeze Protection Systems 52.19

THE practicality of melting snow or ice by supplying heat to the exposed surface has been demonstrated in many installations, including sidewalks, roadways, ramps, bridges, access ramps, and parking spaces for the handicapped, and runways. Melting eliminates the need for snow removal by chemical means, provides greater safety for pedestrians and vehicles, and reduces the labor and cost of slush removal. Other advantages include eliminating piled snow, reducing liability, and reducing health risks of manual and mechanized shoveling.

This chapter covers three types of snow-melting and freeze protection systems:

1. Hot fluid circulated in slab-embedded pipes (**hydronic**)
2. Embedded **electric** heater cables or wire
3. Overhead high-intensity **infrared** radiant heating

Detailed information about slab heating can be found in Chapter 6 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. More information about infrared heating can be found in Chapter 16 of the same volume.

Components of the system design include (1) heat requirement, (2) slab design, (3) control, and (4) hydronic or electric system design.

1. SNOW-MELTING HEAT FLUX REQUIREMENT

The heat required for snow melting depends on five atmospheric factors: (1) rate of snowfall, (2) snowfall-coincident air dry-bulb temperature, (3) humidity, (4) wind speed near the heated surface, and (5) apparent sky temperature. The dimensions of the snow-melting slab affect heat and mass transfer rates at the surface. Other factors such as back and edge heat losses must be considered in the complete design.

Heat Balance

The processes that establish the heat requirement at the snow-melting surface can be described by terms in the following equation, which is the steady-state energy balance for required total heat flux (heat flow rate per unit surface area) q_o at the upper surface of a snow-melting slab during snowfall.

$$q_o = q_s + q_m + A_r(q_h + q_e) \tag{1}$$

where

q_o = heat flux required at snow-melting surface, W/m²
q_s = sensible heat flux, W/m²
q_m = latent heat flux, W/m²
A_r = snow-free area ratio, dimensionless
q_h = convective and radiative heat flux from snow-free surface, W/m²
q_e = heat flux of evaporation, W/m²

The preparation of this chapter is assigned to TC 6.5, Radiant Heating and Cooling.

Sensible and Latent Heat Fluxes. The sensible heat flux q_s is the heat flux required to raise the temperature of snow falling on the slab to the melting temperature plus, after the snow has melted, to raise the temperature of the liquid to the assigned temperature t_f of the liquid film. The snow is assumed to fall at air temperature t_a. The latent heat flux q_m is the heat flux required to melt the snow. Under steady-state conditions, both q_s and q_m are directly proportional to the snowfall rate s.

Snow-Free Area Ratio. Sensible and latent (melting) heat fluxes occur on the entire slab during snowfall. On the other hand, heat and mass transfer at the slab surface depend on whether there is a snow layer on the surface. Any snow accumulation on the slab acts to partially insulate the surface from heat losses and evaporation. The insulating effect of partial snow cover can be large. Because snow may cover a portion of the slab area, it is convenient to think of the insulating effect in terms of an effective or equivalent snow-covered area A_s, which is perfectly insulated and from which no evaporation and heat transfer occurs. The balance is then considered to be the equivalent snow-free area A_f. This area is assumed to be completely covered with a thin liquid film; therefore, both heat and mass transfer occur at the maximum rates for the existing environmental conditions. It is convenient to define a dimensionless **snow-free area ratio** A_r:

$$A_r = \frac{A_f}{A_t} \tag{2}$$

where

A_f = equivalent snow-free area, m²
A_s = equivalent snow-covered area, m²
A_t = $A_f + A_s$ = total area, m²

Therefore,

$$0 \le A_r \le 1$$

To satisfy $A_r = 1$, the system must melt snow rapidly enough that no accumulation occurs. For $A_r = 0$, the surface is covered with snow of sufficient thickness to prevent heat and evaporation losses. Practical snow-melting systems operate between these limits. Earlier studies indicate that sufficient snow-melting system design information is obtained by considering three values of the free area ratio: 0, 0.5, and 1.0 (Chapman 1952).

Heat Flux because of Surface Convection, Radiation, and Evaporation. Using the snow-free area ratio, appropriate heat and mass transfer relations can be written for the snow-free fraction of the slab A_r. These appear as the third and fourth terms on the right-hand side of Equation (1). On the snow-free surface, maintained at film temperature t_f, heat is transferred to the surroundings and mass is transferred from the evaporating liquid film. Heat flux q_h includes convective losses to the ambient air at temperature t_a and radiative losses to the surroundings, which are at mean radiant temperature T_{MR}. The convection heat transfer coefficient is a function of wind speed and a characteristic dimension of the snow-melting surface. This heat transfer coefficient is also a function of the thermodynamic properties of the air, which vary slightly over the temperature range for various snowfall events. The mean radiant temperature depends on air temperature, relative humidity, cloudiness, cloud altitude, and whether snow is falling.

The heat flux q_e from surface film evaporation is equal to the evaporation rate multiplied by the heat of vaporization. The evaporation rate is driven by the difference in vapor pressure between the wet surface of the snow-melting slab and the ambient air; it is a function of wind speed, a characteristic dimension of the slab, and the thermodynamic properties of the ambient air.

Heat Flux Equations

Sensible Heat Flux. The sensible heat flux q_s is given by the following equation:

$$q_s = \rho_{water} s[c_{p,ice}(t_s - t_a) + c_{p,water}(t_f - t_s)]/c_1 \tag{3}$$

where

$c_{p,ice}$ = specific heat of ice, J/(kg·K)
$c_{p,water}$ = specific heat of water, J/(kg·K)
s = snowfall rate water equivalent, typically assumed to be snowfall rate divided by 10, mm/h
t_a = ambient temperature coincident with snowfall, °C
t_f = liquid film temperature, °C
t_s = melting temperature, °C
ρ_{water} = density of water, kg/m^3
c_1 = 1000 mm/m × 3600 s/h = 3.6 × 10^6

The density of water, specific heat of ice, and specific heat of water are approximately constant over the temperature range of interest and are evaluated at 0°C. The ambient temperature and snowfall rate are available from weather data. The liquid film temperature is usually taken as 0.56°C.

Melting Heat Flux. The heat flux q_m required to melt the snow is given by the following equation:

$$q_m = \rho_{water} s h_{if}/c_1 \tag{4}$$

where h_{if} = heat of fusion of snow, J/kg.

Convective and Radiative Heat Flux from a Snow-Free Surface. The corresponding heat flux q_h is given by the following equation:

$$q_h = h_c(t_s - t_a) + \sigma\varepsilon_s(T_f^4 - T_{MR}^4) \tag{5}$$

where

h_c = convection heat transfer coefficient for turbulent flow, W/(m^2·K)
T_f = liquid film temperature, K
T_{MR} = mean radiant temperature of surroundings, K
σ = Stefan-Boltzmann constant = 5.670 × 10^{-8} W/(m^2·K^4)
ε_s = emittance of surface, dimensionless

The convection heat transfer coefficient over the slab on a plane horizontal surface is given by the following equations (Incropera and DeWitt 1996):

$$h_c = 0.037\left(\frac{k_{air}}{L}\right)\mathrm{Re}_L^{0.8}\mathrm{Pr}^{1/3} \tag{6}$$

where

k_{air} = thermal conductivity of air at t_a, W/(m·K)
L = characteristic length of slab in direction of wind, m
Pr = Prandtl number for air, taken as Pr = 0.7
Re_L = Reynolds number based on characteristic length L

and

$$\mathrm{Re}_L = \frac{VL}{\nu_{air}}c_2 \tag{7}$$

where

V = design wind speed near slab surface, km/h
ν_{air} = kinematic viscosity of air, m^2/s
c_2 = 1000 m/km × 1 h/3600 s = 0.278

Without specific wind data for winter, the extreme wind data in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* may be used; note, however, that these wind speeds may not correspond to actual measured data. Furthermore, oversizing systems based on weather extremes should be avoided. If the snow-melting surface is not horizontal, the convection heat transfer coefficient might be different, but in many applications, this difference is negligible.

From Equations (6) and (7), the turbulent convection heat transfer coefficient is a function of $L^{-0.2}$. Because of this relationship, shorter snow-melting slabs have higher convective heat transfer coefficients than longer slabs. For design, the shortest dimension should be used (e.g., for a long, narrow driveway or sidewalk, use the width). A snow-melting slab characteristic length L = 6.1 m is used in the heat transfer calculations that resulted in Tables 1, 2, and 3.

It is not practical or even sometimes possible to size systems to a snow-free ratio of A_r = 1 at a confidence ratio of 100%. Designers should evaluate the critical nature of the area to be treated and size the system for the lowest acceptable heat flux. See Table 3 for guidance on appropriate snow-free area ratios and confidence frequencies, typically used based on application. Under normal atmospheric conditions and given minimum thermal mass coverage (thermal resistance), an upper limit to heat flux is typically bounded by the maximum allowable flow temperature for a pipe embedded in a thermal mass. This is particularly important for concrete, where entering fluid temperatures should not exceed 66°C.

The **mean radiant temperature** T_{MR} in Equation (5) is the equivalent blackbody temperature of the surroundings of the snow-melting slab. Under snowfall conditions, the entire surroundings are approximately at the ambient air temperature (i.e., $T_{MR} = T_a$). When there is no snow precipitation (e.g., during idling and after snowfall operations for $A_r < 1$), the mean radiant temperature is approximated by the following equation:

$$T_{MR} = [T_{cloud}^4 F_{sc} + T_{sky\ clear}^4 (1 - F_{sc})]^{1/4} \tag{8}$$

where

F_{sc} = fraction of radiation exchange that occurs between slab and clouds
T_{cloud} = temperature of clouds, K
$T_{sky\ clear}$ = temperature of clear sky, K

The equivalent blackbody temperature of a clear sky is primarily a function of the ambient air temperature and the water content of the atmosphere. An approximation for the clear sky temperature is given by the following equation, which is a curve fit of data in Ramsey et al. (1982):

$$T_{sky\ clear} = T_a - (1.1058 \times 10^3 - 7.562T_a + 1.333 \times 10^{-2}T_a^2 - 31.292\phi + 14.58\phi^2) \tag{9}$$

where

T_a = ambient temperature, K
ϕ = relative humidity of air at elevation for which typical weather measurements are made, decimal; see energyplus.net/weather for typical meteorological year data by location

The cloud-covered portion of the sky is assumed to be at T_{cloud}. The height of the clouds may be assumed to be 3000 m. The temperature of the clouds at 3000 m is calculated by subtracting the product of the average lapse rate (rate of decrease of atmospheric temperature with height) and the altitude from the atmospheric temperature T_{atm}. The average lapse rate, determined from the tables of U.S. Standard Atmospheres (COESA 1976), is 6.4 K per 1000 m of elevation (Ramsey et al. 1982). Therefore, for clouds at 3000 m,

*Heat fluxes are at the snow-melting surface only. See text for calculation of back and edge heat loss fluxes.

Table 2 Mean Sensitivity of Snow-Melting Surface Heat Fluxes to Wind Speed and Slab Length

For loads not exceeded during 99% of snowfall hours, 1982 through 1993

Snow-Free Area Ratio, A_r	Ratio of Flux at Stated Condition to Flux at L = 6.1 m and $V = V_{met}$: L = 6.1 m		L = 1.5 m		
	$V = 0.5V_{met}$	$V = 2V_{met}$	$V = V_{met}$	$V = 0.5V_{met}$	$V = 2V_{met}$
1	0.7	1.6	1.2	0.8	2.0
0.5	0.8	1.4	1.2	0.9	1.7
0	1.0	1.0	1.0	1.0	1.0

Note: Based on data from U.S. locations.
L = characteristic length
V_{met} = meteorological wind speed from NCDC

$$T_{cloud} = T_{atm} - 19.2 \quad (10)$$

Under most conditions, this method of approximating the temperature of the clouds provides an acceptable estimate. However, when the atmosphere contains a very high water content, the temperature calculated for a clear sky using Equation (9) may be warmer than the cloud temperature estimated using Equation (10). When that condition exists, T_{cloud} is set equal to the calculated clear sky temperature $T_{sky\ clear}$.

Evaporation Heat Flux. The heat flux q_e required to evaporate water from a wet surface is given by

$$q_e = \rho_{dry\ air} h_m (W_f - W_a) h_{fg} \quad (11)$$

where

h_m = mass transfer coefficient, m/s
W_a = humidity ratio of ambient air, kg_{vapor}/kg_{air}
W_f = humidity ratio of saturated air at film surface temperature, kg_{vapor}/kg_{air}
h_{fg} = heat of vaporization (enthalpy difference between saturated water vapor and saturated liquid water), J/kg
$\rho_{dry\ air}$ = density of dry air, kg/m³

Determining the mass transfer coefficient is based on the analogy between heat transfer and mass transfer. Details of the analogy are given in Chapter 5 of the 2017 *ASHRAE Handbook—Fundamentals*. For external flow where mass transfer occurs at the convective surface and the water vapor component is dilute, the following equation relates the mass transfer coefficient h_m to the heat transfer coefficient h_c [Equation (6)]:

$$h_m = \left(\frac{\text{Pr}}{\text{Sc}}\right)^{2/3} \frac{h_c}{\rho_{dry\ air} c_{p,air}} \quad (12)$$

where Sc = Schmidt number. In applying Equation (11), the values Pr = 0.7 and Sc = 0.6 were used to generate the values in Tables 1 to 4.

The humidity ratios both in the atmosphere and at the surface of the water film are calculated using the standard psychrometric relation given in the following equation (from Chapter 1 of the 2017 *ASHRAE Handbook—Fundamentals*):

$$W = 0.622\left(\frac{p_v}{p - p_v}\right) \quad (13)$$

where

p = atmospheric pressure, kPa
p_v = partial pressure of water vapor, kPa

The vapor pressure p_v for calculating W_a is equal to the saturation vapor pressure p_s at the dew-point temperature of the air. Saturated conditions exist at the water film surface. Therefore, the vapor pressure used in calculating W_f is the saturation pressure at the film temperature t_f. The saturation partial pressures of water vapor for temperatures above and below freezing are found in tables of the thermodynamic properties of water at saturation, or can be calculated using appropriate equations. Both are presented in Chapter 1 of the 2017 *ASHRAE Handbook—Fundamentals*. The atmospheric pressure in Equation (13) is corrected for altitude using the following equation (Kuehn et al. 1998):

The atmospheric pressure in Equation (13) is corrected for altitude using the following equation (Kuehn et al. 1998):

$$p = p_{std}\left(1 - \frac{Az}{T_o}\right)^{5.265} \quad (14)$$

where

p_{std} = standard atmospheric pressure, kPa
A = 0.0065 K/m
z = altitude of the location above sea level, m
T_o = 288.2 K

Altitudes of specific locations are found in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*.

Heat Flux Calculations. Equations (1) to (14) can be used to determine the required heat fluxes of a snow-melting system. However, calculations must be made for coincident values of snowfall rate, wind speed, ambient temperature, and dew-point temperature (or another measure of humidity). By computing the heat flux for each snowfall hour over a period of several years, a frequency distribution of hourly heat fluxes can be developed. Annual averages or maximums for climatic factors should never be used in sizing a system because they are unlikely to coexist. Finally, it is critical to note that the preceding analysis only describes what is happening at the upper surface of the snow-melting surface. Edge losses and back losses have not been taken into account.

Example 1. During the snowfall that occurred during the 8 PM hour on December 26, 1985, in the Detroit metropolitan area, the following simultaneous conditions existed: air dry-bulb temperature = –8.3°C, dew-point temperature = –10°C, wind speed = 31.7 km/h, and snowfall

Table 3 Annual Operating Data at 99% Satisfaction Level of Heat Flux Requirement

Source: Ramsey et al. 1999.

*Does not include back and edge heat losses rate = 2.54 mm of liquid water equivalent per hour. Assuming L = 6.1 m, Pr = 0.7, and Sc = 0.6, calculate the surface heat flux q_o for a snow-free area ratio of A_r = 1.0. The thermodynamic and transport properties used in the calculation are taken from Chapters 1 and 33 of the 2017 *ASHRAE Handbook—Fundamentals*. The emittance of the wet surface of the heated slab is 0.9.

Solution:

By Equation (3),

$$q_s = 1000 \times \frac{2.54}{3.6 \times 10^6}[2100(0 + 8.3) + 4290(0.56 - 0)] = 14.0 \text{ W/m}^2$$

By Equation (4),

$$q_m = 1000 \times \frac{2.54}{3.6 \times 10^6} \times 334\,000 = 235.6 \text{ W/m}^2$$

By Equation (7),

$$\text{Re}_L = \frac{31.7 \times 6.1 \times 0.278}{1.3 \times 10^{-5}} = 4.13 \times 10^6$$

By Equation (6),

$$h_c = 0.037\left(\frac{0.0235}{6.1}\right)(4.13 \times 10^6)^{0.8}(0.7)^{1/3} = 24.8 \text{ W/(m}^2\cdot\text{K)}$$

By Equation (5),

$$q_h = 24.8(0.56 + 8.3) + (5.670 \times 10^{-8})(0.9)(273.7^4 - 264.9^4)$$
$$= 258.8 \text{ W/m}^2$$

By Equation (12),

$$h_m = \left(\frac{0.7}{0.6}\right)^{2/3}\frac{24.8}{1.33 \times 1005} = 0.0206 \text{ m/s}$$

Obtain the values of the saturation vapor pressures at dew-point temperature –10°C and film temperature 0.56°C from Table 3 in Chapter 1 of the 2017 *ASHRAE Handbook—Fundamentals*. Then, use Equation (13) to obtain $W_a = 0.00160$ kg$_{vapor}$/kg$_{air}$ and $W_f = 0.00393$ kg$_{vapor}$/kg$_{air}$. By Equation (11),

$$q_e = 1.33 \times 0.0206(0.00393 - 0.00160) \times 2499 \times 10^3 = 159.5 \text{ W/m}^2$$

By Equation (1),

$$q_o = 14.0 + 235.6 + 1.0(258.8 + 159.5) = 664 \text{ W/m}^2$$

Note that this is the heat flux needed at the snow-melting surface of the slab. Back and edge losses must be added as discussed in the section on Back and Edge Heat Losses.

Weather Data and Heat Flux Calculation Results

Table 1 shows frequencies of snow-melting loads for 46 cities in the United States (Ramsey et al. 1999).For the calculations, the temperature of the surface of the snow-melting slab was taken to be 0.56°C. Any time the ambient temperature was below 0°C and it was not snowing, it was assumed that the system was idling (i.e., that heat was supplied to the slab so that melting would start immediately when snow began to fall).

Weather data were taken for the years 1982 through 1993. These years were selected because of their completeness of data. The weather data included hourly values of the precipitation amount in equivalent depth of liquid water, precipitation type, ambient dry-bulb and dew-point temperatures, wind speed, and sky cover. All weather elements for 1982 to 1990 were obtained from the *Solar and Meteorological Surface Observation Network 1961 to 1990* (*SAMSON*), *Version 1.0* (NCDC 1993). For 1991 to 1993, all weather elements except precipitation were taken from *DATSAV2* data obtained from the National Climatic Data Center as described in Colliver et al. (1998). The precipitation data for these years were taken from NCDC's *Hourly Cooperative Dataset* (NCDC 1990).

All wind speeds used were taken directly from the weather data. Wind speed V_{met} is usually measured at height of approximately 10 m. As indicated in the section on Heat Balance, the heat and mass transfer coefficients are functions of a characteristic dimension of the snow-melting slab. The dimension used in generating the values of Table 1 was 6.1 m. Sensitivity of the load to both wind speed and the characteristic dimension is included in Table 2. During snowfall, the sky temperature was taken as equal to the ambient temperature.

The first data column in Table 1 presents the average number of snowfall hours per year for each location. All surface heat fluxes were computed for snow-free area ratios of 1, 0.5, and 0, and the frequencies of snow-melting loads are presented. The frequency indicates the percentage of time that the required snow-melting surface heat flux does not exceed the value in the table for that ratio.

This table is used to design a snow-melting system for a given level of customer satisfaction depending on criticality of function. For example, although a heliport at the rooftop of a hospital may require almost 100% satisfactory operation at a snow-free ratio of 1, a residential driveway may be considered satisfactory at 90% and A_r = 0.5 design conditions. To optimize cost, different percentiles may be applied to different sections of the slab. For example, train station slab embark/disembark areas may be designed for a higher percentile and A_r than other sections.

Figure 1 shows the distribution in the United States of snow-melting surface heat fluxes for a snow-free area ratio of 0.5. The values presented satisfy the loads 90% of the snowfall hours for each location (as listed in the 90% column of Table 1). Local values can be approximated by interpolating between values given on the figure; however, extreme care must be taken because special local climatological conditions exist for many areas (e.g., lake effect snow). Both altitude and geography should be considered in making interpolations. Generally, locations in the northern plains of the United States require the maximum snow-melting heat flux (Chapman 1999).

To help avoid excessive sizing of snow-melting systems, Table 4 outlines typical free area ratios and frequency distributions based on application. However, these ratios should be considered general guidance only: each design should be considered on a case-by-case basis to meet the needs of that specific application.

Example for Surface Heat Flux Calculation Using Table 1

Example 2. Consider the design of a system for Albany, New York, which has an installed heat flux capacity at the top surface of approximately 471 W/m². Based on data in Table 1, this system will keep the surface completely free of snow 95% of the time. Because there are 156 snowfall hours in an average year, this design would have some accumulation of snow approximately 8 h per year (the remaining 5% of the 156 h). This design will also meet the load for more than 98% of the time (i.e., more than 153 of the 156 snowfall hours) at an area ratio of 0.5 and more than 99% of the time for an area ratio of 0. A_r = 0.5 means that there is a thin snow layer on part of the slab such that it acts as though half the slab is insulated by a snow layer; A_r = 0 means that the snow layer is sufficient to insulate the surface from heat and evaporation losses, but that snow is melting at the base of this layer at the same rate that it is falling on the top of the layer.

Therefore, the results for this system can be interpreted to mean the following (all times are rounded to the nearest hour):

(a) For all but 8 h of the year, the slab will be snow free.
(b) For the less than 5 h between the 95% and 98% nonexceedance values, there will be a thin build-up of snow on part of the slab.
(c) For the less than 2 h between the 98% and 99% nonexceedance values, snow will accumulate on the slab to a thickness at which the snow blanket insulates the slab, but the thickness will not increase beyond that level.
(d) For less than 2 h, the system cannot keep up with the snowfall.

An examination of the 100% column shows that to keep up with the snowfall the last 1% of the time, in this case less than 2 h for an average

Table 4 General Guidance for Snow-Free Area Ratio and Frequency Distributions by Application Type

Application Type	Free Area Ratio, A_r	Frequency Distribution, %

Private landing pad/runway	1.0	90
Car wash aprons	1.0	90

year, would require a system capacity of approximately 870 W/m^2; to attempt to keep the slab completely snow free the entire season requires a capacity of 1011 W/m^2. Based on this interpretation, the designer and customer must decide the acceptable operating conditions. Note that the heat flux values in this example do not include back or edge losses, which must be added in sizing energy source and heat delivery systems.

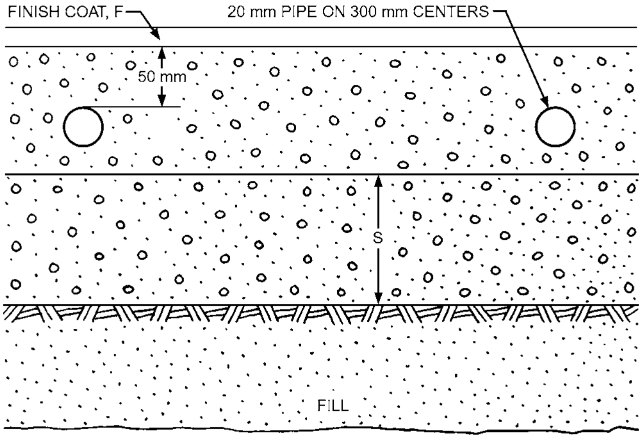
Sensitivity of Design Surface Heat Flux to Wind Speed and Surface Size

Some snow-melting systems are in sheltered areas, whereas others may be in locations where surroundings create a wind tunnel effect. Similarly, systems vary in size from the baseline characteristic length of 6.1 m. For example, sidewalks exposed to a crosswind may have a characteristic length on the order of 1.5 m. In such cases, the wind speed will be either less than or greater than the meteorological value V_{met} used in Table 1. To establish the sensitivity of the surface heat flux to wind speed and characteristic length, calculations were performed at combinations of wind speeds $0.5V_{met}$, V_{met}, and $2V_{met}$ and L values of 1.5 m and 6.1 m for area ratios A_r of 1.0 and 0.5. Wind speed and system size do not affect the load values for $A_r = 0$ because the calculations assume that no heat or mass transfer from the surface occurs at this condition. Table 2 presents a set of mean values of multipliers that can be applied to the loads presented in Table 1; these multipliers were established by examining the effect on the 99% nonexceedance values. The ratio of V to V_{met} in a given design problem may be determined from information given in Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*. The closest ratio in Table 2 can then be selected. The designer is cautioned that these are to be used only as guidelines on the effect of wind speed and size variations.

Back and Edge Heat Losses

The surface heat fluxes in Table 1 do not account for heat losses from the back and edges of the slab. Adlam (1950) demonstrated

Fig. 1 Snow-Melting Surface Heat Fluxes Required to Provide Snow-Free Area Ratio of 0.5 for 90% of Snowfall Hours at That Location



F = depth of finish coat—assumed to be 12 mm of concrete. Finish coat may be asphalt, but then cover slab should be reduced from 75 mm. Depth of slab should always keep thermal resistance equal to 75 mm of concrete.
S = depth required by structural design (should be at least 50 mm of concrete).

Fig. 2 Detail of Typical Hydronic Snow-Melting System

that these back and edge losses may vary from 4 to 50%, depending on factors such as slab construction, operating temperature, ground temperature, and back and edge insulation and exposure. With the construction shown in Figure 2 or Figure 5 and ground temperature of 4.5°C at a depth of 600 mm, back losses in steady state are approximately 20%. Higher losses occur with (1) colder ground, (2) more cover over the slab, or (3) exposed back, such as on bridges or parking decks. Spitler et al. (2002) estimated back losses in transient operation to range between approximately 12 and 29%, depending on storm conditions. Adding a 50 mm insulation layer reduces back losses to approximately 1 to 3% for the same storm conditions. Spitler et al. (2001) include a more detailed report, and provide the source code needed to repeat an analysis for other specific cases.

Transient Analysis of System Performance

Determination of snow-melting surface heat fluxes as described in Equations (1) to (14) is based on steady-state analysis. Snow-melting systems generally have heating elements embedded in material of significant thermal mass. Transient effects, such as occur when the system is started, may be significant. A transient analysis method was developed by Spitler et al. (2002) and showed that particular storm conditions could change the snow-melting surface heat flux requirement significantly, depending on the precipitation rate at a particular time in the storm. It is therefore difficult to find simple general design rules that account for transient effects. To keep slab surfaces clear from snow during the first hour of the snowstorm, when the system is just starting to operate, heat fluxes up to five times greater than those indicated by steady-state analysis could be required. In general, greater heat input is required for greater spacing and greater depth of the heating elements in the slab; however, because of transient effects, this is not always true.

Transient analysis (Spitler et al. 2002) has also been used to examine back and edge losses. Heat fluxes because of back losses in systems without insulation ranged from 10 to 30% of the surface heat flux, depending primarily on the particular storm data, though higher losses occurred where heating elements were embedded deeper in the slab. In cases where 50 mm of insulation was applied below the slab, back losses were significantly reduced, to 1 to 4%. Although peak losses were reduced, the surface heat fluxes required to melt the snow were not significantly affected by the presence of insulation, because transient effects at the start of system operation drive the peak design surface heat fluxes. Edge losses ranged from 15 to 35% of the heat delivered by the heating element nearest the edge. This may be converted to an approximately equivalent surface heat flux percentage by reducing the snow-melting surface length and width by an amount equal to two-thirds of the heating element spacing in the slab. Then the design surface heat flux may be adjusted by the ratio of the actual snow-melting surface area to the reduced surface area as described here. The effect of edge insulation was found to be similar to that at the back of the slab. Although edge insulation does not reduce the surface heat flux requirement significantly, increased snow accumulation at the edges should be expected.

Annual Operating Data

Annual operating data for the cities in Table 1 are presented in Table 3. Melting and idling hours are summarized in this table along with the energy per unit area needed to operate the system during an average year based on calculations for the years 1982 to 1993. Back and edge heat losses are not included in the energy values in Table 3. Data are presented for snow-free area ratios of 1.0, 0.5, and 0.

The energy per unit area values are based on systems designed to satisfy the loads 99% of the time (i.e., at the levels indicated in the 99% column in Table 1) for each A_r value. The energy use for each melting hour is taken as either (1) the actual energy required to maintain the surface at 0.56°C or (2) the design output, whichever is less. The design snow-melting energy differs, of course, depending on whether the design is for A_r = 1.0, 0.5, or 0; therefore, the annual melting energy differs as well.

The idling hours include all non-snowfall hours when the ambient temperature is below 0°C. The energy consumption for each idling hour is based on either (1) the actual energy required to maintain the surface at 0°C or (2) the design snow-melting energy, whichever is less.

In Table 3, the column labeled "2% Min. Snow Temp." is the temperature below which only 2% of the snowfall hours occur. This table should only be used to predict annual operating costs. Use Table 1 for system sizing.

Annual Operating Cost Example

Example 3. A snow-melting system of 200 m² is to be installed in Chicago. The application is considered critical enough that the system is designed to remain snow free 99% of the time. Table 3 shows that the annual energy requirement to melt the snow is 26.8 kWh/m². Assuming a fossil fuel cost of $9 per GJ, an electric cost of $0.07 per kWh, and back loss at 30%, find and compare the annual cost to melt snow with hydronic and electric systems. For the hydronic system, boiler combustion efficiency is 0.85 and energy distribution efficiency is 0.90.

Solution: Operating cost O may be expressed as follows:

$$O = \frac{A_t Q_a F}{[1-(B/100)](\eta_b \eta_d)} \tag{15}$$

where

O = annual operating cost $/yr
A_t = total snow-melting area, m²
Q_a = annual snow-melting or idling energy requirement, kWh/m²
F = primary energy cost $/kWh
B = back heat loss percentage, %
η_b = combustion efficiency of boiler (or COP of a heat pump in heating mode), dimensionless. If a waste energy source is directly used for snow-melting or idling purposes, the combustion efficiency term is neglected.
η_d = energy distribution efficiency, dimensionless (in an electric system, efficiencies may be taken to be 1)

Operating cost for a hydronic system is

Table 5 Thermal Conductivity of Concrete Based on Concrete Density

Thermal Conductivity k_c, W/(m·K)	Density, kg/m³
0.638	1600
0.782	1760
0.953	1920
1.17	2080
1.42	2240
1.75	2400

Source: ACI (2014).

$$O = \frac{(200)(26.8)(0.0324)}{\left[1-\left(\frac{30}{100}\right)\right][(0.85)(0.90)]} = \$324/\text{yr}$$

Operating cost for an electric system is

$$O = \frac{200(26.8)(0.07)}{1-(30/100)} = \$536/\text{yr}$$

It is desirable to use waste or alternative energy resources to minimize operating costs. If available in large quantities, low-temperature energy resources may replace primary energy resources, because the temperature requirement is generally moderate (Kilkis 1995). Heat pipes may also be used to exploit ground heat (Shirakawa et al. 1985).

2. SLAB DESIGN

Either concrete or asphalt slabs may be used for snow-melting systems. The thermal conductivity of asphalt is less than that of concrete; pipe or electric cable spacing and required fluid temperatures are thus different. Hot asphalt may damage plastic or electric (except mineral-insulated cable) snow-melting systems unless adequate precautions are taken. Typically, hydronic pipes are embedded in a sand layer below the asphalt before it is laid. For specific recommendations, see the sections on Hydronic System Design and Electric System Design.

Concrete slabs containing hydronic or electric snow-melting apparatus must have a subbase, expansion-contraction joints, reinforcement, and drainage to prevent slab cracking; otherwise, crack-induced shearing or tensile forces could damage the pipe or cable. The pipe or cable must not run through expansion-contraction joints, keyed construction joints, or control joints (dummy grooves); however, the pipe or cable may be run under 3 mm score marks or saw cuts (block and other patterns). Sleeved pipe is allowed to cross expansion joints (see Figure 3). Control joints must be placed wherever the slab changes size or incline. The maximum distance between control joints for ground-supported slabs should be less than 4.6 m, and the length should be no greater than twice the width, except for ribbon driveways or sidewalks. In ground-supported slabs, most cracking occurs during the early cure. Depending on the amount of water used in the concrete mix, shrinkage during cure may be up to 60 mm per 100 m. If the slab is more than 4.6 m long, the concrete does not have sufficient strength to overcome friction between it and the ground while shrinking during the cure period.

Analysis requiring the thermal conductivity of a concrete slab can be approximated based on the values in Table 5 or from Equation (16). This equation is based on the American Concrete Institute's *Guide to Thermal Properties of Concrete and Masonry Systems* (ACI 2014).

$$k_c = 0.0865\, e^{0.00125d} \tag{16}$$

Design of the concrete slab is ultimately the responsibility of the civil engineer. For general information purposes,

- The concrete mix of the top layer should give maximum weatherability
- Compressive strength should be 28 to 34 MPa
- Recommended slump is 75 mm maximum, 50 mm minimum

The pipe or cable may be placed in contact with an existing sound slab (either concrete or asphalt) and then covered as described in the sections on Hydronic System Design and Electric System Design. If there are signs of cracking or heaving, the slab should be replaced. Pipe or cable should not be placed over existing expansion-contraction, control, or construction joints. The finest grade of asphalt is best for the top course; stone diameter should not exceed 10 mm.

A moisture barrier should be placed between any insulation and the fill. If insulation is used, it should be nonhygroscopic. The joints in the barrier should be sealed and the fill made smooth enough to eliminate holes or gaps for moisture transfer. Also, the edges of the barrier should be flashed to the surface of the slab to seal the ends.

Snow-melting systems should have good surface drainage. When the ambient air temperature is 0°C or below, runoff from melting snow freezes immediately after leaving the heated area. Any water that gets under the slab also freezes when the system is shutdown, causing extreme frost heaving. Runoff should be piped away in drains that are heated or below the frost line. If the snow-melting surface is inclined (e.g., a ramp), surface runoff may collect at the lowest point. In addition to effective drainage down the ramp, the adjacent area may require heating to prevent freezing the accumulated runoff.

The area to be protected by the snow-melting system must first be measured and planned. For total snow removal, hydronic or electric heat must cover the entire area. In larger installations, it may be desirable to melt snow and ice from only the most frequently used areas, such as walkways and wheel tracks for trucks and autos. Planning for separate circuits should be considered so that areas within the system can be heated individually, as required.

Where snow-melting apparatus must be run around obstacles (e.g., a storm sewer grate), the pipe or cable spacing should be uniformly reduced. Because some drifting will occur adjacent to walls or vertical surfaces, extra heating capacity should be provided in these areas, and if possible also in the vertical surface. Drainage flowing through the area expected to be drifted tends to wash away some snow.

3. HYDRONIC SYSTEM DESIGN

Hydronic system design includes selection of the following components: (1) heat transfer fluid, (2) piping, (3) fluid heater, (4) pump(s) to circulate the fluid, and (5) controls. With concrete slabs, thermal stress is also a design consideration.

Heat Transfer Fluid

Various fluids, including brines, oils, and glycol/water solutions, are suitable for transferring heat from the fluid heater to the slab. Freeze protection is essential because most systems will not be operated continuously in subfreezing weather. Without freeze protection, power loss or pump failure could cause freeze damage to the piping and slab.

Brine is the least costly heat transfer fluid, but it has a lower specific heat than glycol. Using brine may be discouraged because of the cost of heating equipment that resists its corrosive potential. Although **heat transfer oils** are not corrosive, they are more expensive than brine or glycol, have a lower specific heat and higher viscosity, and are potentially flammable, and as such are no longer used in common practice.

Glycols (ethylene glycol and propylene glycol) are the most popular in snow-melting systems because of their moderate cost, high specific heat, and low viscosity; ease of corrosion control is another

Note: Table based on a characteristic pavement length of 6.1 m, standard air pressure, a water film temperature of 0.56°C, and relative humidity of 80%. Heat flux and temperature values in bold underline are not achievable based on material temperature limits of concrete.

A_r = snow-free area ratio
q_o = slab heating flux, W/m²
t_a = atmospheric dry-bulb temperature, °C
t_m = mean fluid temperature based on construction shown in Figure 2, °C

advantage. Automotive glycols containing silicates are not recommended because they can cause fouling, pump seal wear, fluid gelation, and reduced heat transfer. The piping should be designed for periodic addition of an inhibitor. Glycols should be tested annually to determine any change in reserve alkalinity and freeze protection. Only inhibitors obtained from the manufacturer of the glycol should be added. Heat exchanger surfaces should be kept below 140°C, which corresponds to about 280 kPa (gage) steam. Temperatures above 150°C accelerate deterioration of the inhibitors.

Because ethylene glycol and petroleum distillates are toxic, no permanent connection should be installed between the snow-melting system and the drinking water supply. Gordon (1950) discusses precautions concerning internal corrosion, flammability, toxicity, cleaning, joints, and hook-up that should be taken during installation of hydronic piping. The properties of brine and glycol are discussed in Chapter 31 of the 2017 *ASHRAE Handbook—Fundamentals*. The effect of glycol on system performance is detailed in Chapter 13 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Piping

Historically, piping may have been metal or ethylene-propylene terpolymer (EPDM), though cross-linked polyethylene (PEX) is typically used today.

Chapman (1952) derived the equation for the fluid temperature required to provide an output q_o. For construction as shown in Figure 2, the equation is

$$t_m = 0.089 q_o + t_f \tag{17}$$

where t_m = average fluid (antifreeze solution) temperature, °C. Equation (16) applies to {25 mm as well as 20 mm IPS pipe (Figure 2).

Design information about heated slabs given in Chapter 6 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* may be used for all other types of slab construction, pipe spacing, and pipe material. In using these design equations, snow cover or water film on the slab may be treated as surface covers.

For specific conditions or for cities other than those given in Table 1, Equations (1) and (16) are used. Table 6 gives solutions to these equations at a relative humidity of 80%. Splitting the surface heat flux among four components as in Equation (1) also affects the

Table 7 Typical Dependency of Maximum Heat Flux Deliverable by Plastic Pipes on Pipe Spacing and Concrete Overpour

(Mean fluid temperature = 55°C)

Heat Flux, W/m²	Pipe Spacing on Centers,* mm

555	230
665	150

*Space pipes 25 mm closer for each 25 mm of concrete cover over 50 mm. Space pipes 50 mm closer for each 25 mm of brick paver and mortar.

required water temperature; therefore, Equation (16) and Table 5 should be used with caution. Table 5 may also be used to determine successful systems operation conditions. For example, if a system as shown in Figure 2 is designed for 790 W/m², it will satisfy eight severe snow conditions such as –12°C, 4 mm/h, and 16 km/h wind speed (Chapman 1999).

Satisfactory standard practice is to use 20 mm pipe or tube on 230 mm centers, unless the snow-melting surface heat flux is too high. If pumping loads require reduced friction, circuit lengths can be reduced. Piping should be supported by a minimum of 50 mm of concrete above. This requires a 130 mm slab for 20 mm pipe.

Plastic Pipe. Plastic (polyethylene [PE], cross-linked polyethylene [PEX]), or multilayer pipe such as PEX-AL-PEX (a PEX inner and outer layer with a middle layer of aluminum) is popular because of lower material cost, lower installation cost, and corrosion resistance. Typical PEX pipe diameters for snow-melting applications are 16, 19, and 25 mm nominal diameter (CTS) as per ASTM *Standard* F876. Considerations when using plastic pipe include stress crack resistance, temperature limitations, and thermal conductivity. Heat transfer oils should not be used with plastic pipe.

Plastic pipe is furnished in coils. Smaller pipe can be bent to form a variety of heating panel designs without elbows or joints. Mechanical compression connections can be used to connect heating panel pipe to the larger supply and return piping leading to the pump and fluid heater, typically supplied by a distribution manifold where circuits can be balanced according to differences in length and associated pressure drop. PE pipe may be fused using appropriate fittings and fusion equipment. Fusion joining eliminates

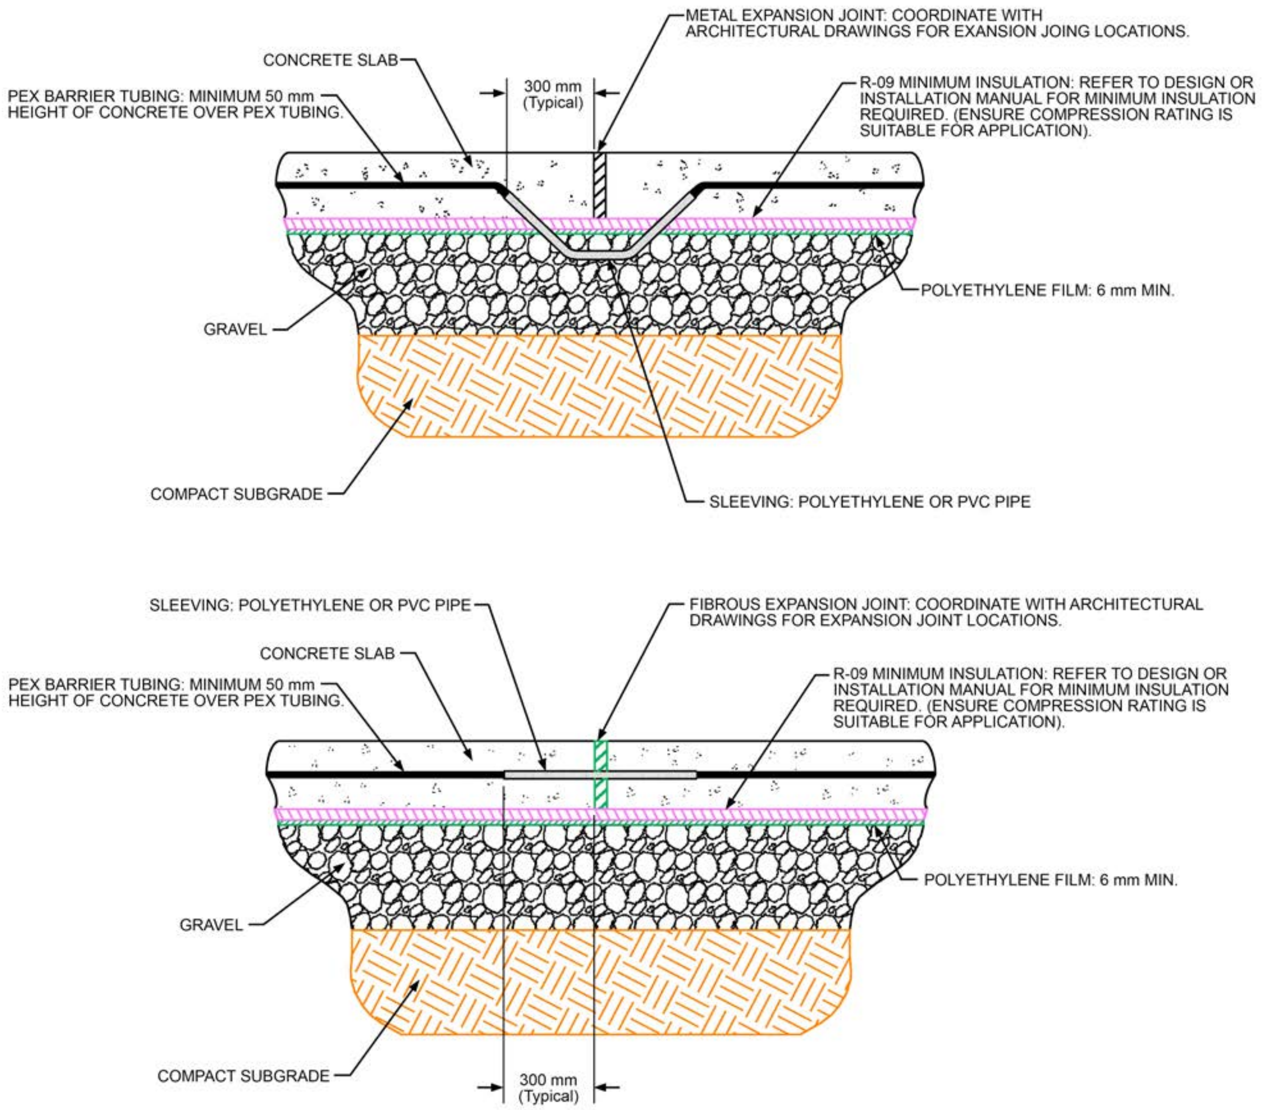

Fig. 3 Piping Details for Concrete Construction for Metal and Fibrous Expansion Joints

metallic components and thus the possibility of corrosion in the piping; however, it requires considerable installation training.

When plastic pipe is used, the system must be designed so that the fluid temperature required will not damage the pipe. If a design requires a temperature above the tolerance of plastic pipe, the delivered heat flux will never meet design requirements. The PE temperature limit is typically 60°C. For PEX, the temperature is 93°C (up to 550 kPa) sustained fluid temperature, or 82°C (up to 690 kPa). However, the entering water temperature for the concrete is typically the constraint: it usually must be less than 65°C, or the value specified in the relevant standard (e.g., CSA *Standard* A23). A potential solution to temperature limitations is to decrease the pipe spacing or depth. Closer pipe spacing also helps eliminate striping of snow (unmelted portions between adjacent pipe projections on the surface). Adlam (1950) addresses the parameter of pipe size and the effect of pipe spacing on heat output. A typical solution is summarized in Table 7, which shows a way of designing pipe spacing according to flux requirements.

Oxygen permeation (see DIN *Standard* 4726 for typical permeation values) through plastic pipes may lead to corrosion on metal surfaces in the entire system unless plastic pipes are equipped with an oxygen barrier layer. Otherwise, either a heat exchanger must separate the plastic pipe circuitry from the rest of the system or corrosion-inhibiting additives must be used in the entire hydronic system.

Pipe Installation. It is good design practice to avoid passing any embedded piping through a concrete expansion joint; otherwise, the pipe may be stressed and possibly ruptured. Figure 3 shows a method of protecting piping that must pass through a concrete expansion joint from stress under normal conditions.

After pipe installation, but before slab installation, all piping should be air-tested to about 700 kPa (gage). This pressure should be maintained until all welds and connections have been checked for leaks. Isolate the air pressure test to manifold and piping, because boilers or other energy-converting, accumulating, or conditioning equipment may have lower pressure test limits. For example, boilers normally have an air test capability of 235 kPa. Testing should not be done with water because (1) small leaks may not be observed during slab installation; (2) water leaks may damage the concrete during installation; (3) the system may freeze before antifreeze is added; and (4) it is difficult to add antifreeze when the system is filled with water.

Air Control. Because introducing air causes deterioration of the antifreeze, the piping should not be vented to the atmosphere. It should be divided into smaller zones to facilitate filling and allow isolation when service is necessary.

Air can be eliminated from piping during initial filling by pumping the antifreeze from an open container into isolated zones of the piping. A properly sized pump and piping system that maintains adequate fluid velocity, together with an air separator and expansion tank, will keep air from entering the system during operation.

A strainer, sediment trap, or other means for cleaning the piping system may be provided. It should be placed in the return line ahead of the heat exchanger and must be cleaned frequently during initial system operation to remove scale and sludge. A strainer should be checked and cleaned, if necessary, at the start of and periodically during each snow-melting season.

An ASME safety relief valve of adequate capacity should be installed on a closed system.

Fluid Heater

The heat transfer fluid can be heated using any of a variety of energy sources, depending on availability. A fluid heater can use steam, hot water, gas, oil, or electricity. In some applications, heat may be available from secondary sources, such as engine generators, condensate, and other waste heat sources. Other low-temperature waste, or alternative energy resources may also be used with or without heat pumps or heat pipes. In a district heating system, the snow-melting system may be tied to the return piping of the district, which increases the overall temperature drop in the district heating system (Brown 1999).

Design of the fluid heater should follow standard practice, with adjustments for the film coefficient. Consideration should be given to flue gas condensation and thermal shock in boilers because of low fluid temperatures. Bypass flow and temperature controls may be necessary to maintain recommended boiler temperatures. Boilers should be derated for high-altitude applications.

Thermal Stress

Chapman (1955) and Kilkis (1994) discuss the problems of thermal stress in a concrete slab. In general, thermal stress will cause no problems if the following installation and operation rules are observed:

- Minimize the temperature difference between the fluid and the slab surface by maintaining (1) close pipe spacing (see Figure 2), (2) a low temperature differential in the fluid (less than 17 K), and (3) continuous operation (if economically feasible). According to Shirakawa et al. (1985), the temperature difference between the slab surface and the heating element skin should not exceed 39 K during operation.
- Install pipe within about 50 mm of the surface.
- Use reinforcing steel designed for thermal stress if high structural loads are expected (e.g., on highways).

Thermal shock to the slab may occur if heated fluid is introduced from a large source of residual heat such as a storage tank, a large piping system, or another snow-melting area. The slab should be brought up to temperature by maintaining the fluid temperature differential at less than 20 K.

Heated concrete slab creates temperature gradients, which in turn causes tensile stress. When tensile stress exceeds the concrete's tensile strength, thermal cracking results. Figure 4 shows the maximum allowable temperature difference based on properties of concrete calculated per ACI (2014) guidelines.

In a heated slab, the largest temperature difference occurs between the heating element skin t_d and slab surface t_{max}. The temperature difference $(t_d - t_{max})$ must be less than the maximum allowable temperature difference to prevent concrete damage. The designer should

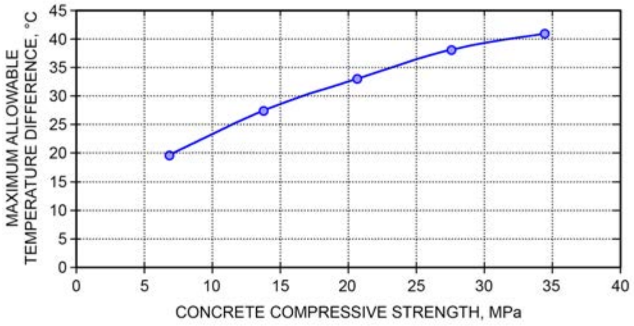

Fig. 4 Relationship Between Concrete Compressive Strength and Maximum Allowable Temperature Difference

apply a safety factor to further ensure the integrity of the concrete slab and system design. Ultimately, the design of the concrete slab should be the responsibility of the civil engineer of record.

$$(t_{max} - t_d) < \nabla T(\text{MATD}) \tag{18}$$

$$(k_e \cdot t_{total}) = 2 \cdot \left[\sum_{i=1}^{n_i} (k_i \cdot s_i) + k \cdot L \right] \tag{19}$$

$$(t_p - t_a) = \frac{q_f}{h_f} \tag{20}$$

$$m = \left(\frac{h_f}{k_e \cdot t_{total}} \right)^{1/2} \tag{21}$$

$$\eta = \frac{\tanh(m \cdot W)}{(m \cdot W)} \qquad \{A_r > 0\} \tag{22}$$

$$R_{co} = \sum_{i=1}^{n_i} (k_i \cdot s_i) \tag{23}$$

$$t_{max} = t_a + \frac{q_f / h_f \cdot M}{2 \cdot W \cdot \eta + D_o} \tag{24}$$

$$t_d = t_{max} + q_o \left(R_{co} + \frac{L - D_o/2}{k} \right) \tag{25}$$

where

A_r = snow-free ratio, dimensionless
D_o = outside diameter of heating element, m
h_f = coefficient of surface heat loss intensity, W/(m^2·K)
k = thermal conductivity of material in which heating element is embedded, W/(m^2·K)
k_e = equivalent thermal conductivity of composite slab for lateral heat diffusion, W/(m^2·K)
k_{film} = thermal conductivity of film of melted snow, W/(m^2·K)
k_h = thermal conductivity of heating element, W/(m^2·K)
k_i = thermal conductivity of each material layer on top of slab, W/(m^2·K)
L = distance from center of heating element to surface of slab, m
M = embedded heating element spacing on centers, mm
m = fin coefficient, m^{-1}
n_i = number of layers above heated slab, dimensionless
q_e = evaporative heat loss intensity during snowfall, W/m^2
q_f = total surface heat loss intensity, W/m^2

q_h = radiation and convention heat loss intensity during snowfall, W/m²
q_o = design heat load intensity, W/m²
R_{co} = total thermal resistance of layers above slab, (m²·K)/W
S_i = thickness of each material layer on top of slab, m
t_a = air temperature at snowfall, °C
t_d = heating element surface temperature, °C
t_{max} = maximum slab surface temperature, °C
∇T = temperature gradient, dimensionless
t_{total} = distance from center of heating element to surface, including thickness of water film, m
W = half of net spacing between adjacent heating elements $(M - D_o)/2$, m
η = fin efficiency of composite fin, dimensionless

Example 4. Determine the maximum temperature difference for a 200 mm concrete slab with the following properties: compressive strength ~34 500 kPa; density: ~2400 kg/m³; conductivity k_c ~ ~ 175 W/(m·K). Pipe outside diameter is 19 mm, pipe spacing 305 mm on center; pipe depth 50 mm below slab.

Parameters from Example 1:

t_a = –8.3°C
t_p = 0.56°C
k_{film} = 0.54 W/(m·K)
q_h = 258.8 W/m²
q_e = 162 W/m²
q_f = 425 W/m²
q_o = 675 W/m²
D_o = 0.019 m
L = 0.06 m
M = 0.3048 m
W = (0.3048 – 0.019)/2 = 0.1429 m
$(k_e T_{total})$ = 0.257 W/K, by Equation (19)
h_f = 47.7 W/(m²·K), by Equation (20)
m = 13.65 m⁻¹, by Equation (21)
η = 0.49, by Equation (22)
R_{co} = [0.019 m/k_{film} + (0.0127 m/k_c)] = 0.0102 (K·m²)/W; by Equation (23)
t_{max} = 8.7°C, by Equation (24)
t_d = 35.2°C, by Equation (25)
$(t_d - t_{max})$= (35.2 – 8.7) = 26.5 K

The maximum allowable temperature difference for concrete with a 34 500 kPa compressive strength is about 40 K; therefore, $(t_d - t_{max})$ is well within concrete's strength.

4. ELECTRIC SYSTEM DESIGN

Snow-melting systems using electricity as an energy source have heating elements in the form of (1) mineral-insulated (MI) cable, (2) self-regulating cable, (3) constant-wattage cable, or (4) high-intensity infrared heaters.

Heat Flux

The basic load calculations for electric systems are the same as presented in the section on Snow-Melting Heat Flux Requirement. However, because electric system output is determined by the resistance installed and the voltage impressed, it cannot be altered by fluid flow rates or temperatures. Consequently, neither safety factors nor marginal capacity systems are design considerations.

Heat flux within a slab can be varied by altering the heating cable spacing to compensate for anticipated drift areas or other high-heat-loss areas. Power density should not exceed 1300 W/m² (NFPA *Standard* 70).

Electrical Equipment

Installation and design of electric snow-melting systems is governed by Article 426 of the *National Electrical Code*® (NEC, or NFPA *Standard* 70), which requires that each electric snow-melting circuit (except mineral-insulated, metal-sheathed cable embedded in a noncombustible medium) be provided with a ground fault protection device. An equipment protection device (EPD) with a trip level of 30 mA should be used to reduce the likelihood of nuisance tripping.

Double-pole, single-throw switches or tandem circuit breakers should be used to open both sides of the line. The switchgear may be in any protected, convenient location. It is also advisable to include a pilot lamp on the load side of each switch so that there is a visual indication when the system is energized.

Junction boxes located at grade level are susceptible to water ingress. Weatherproof junction boxes installed above grade should be used for terminations.

The power supply conduit is run underground, outside the slab, or in a prepared base. With concrete slab, this conduit should be installed before the reinforcing mesh.

Mineral-Insulated Cable

Mineral-insulated (MI) heating cable is a magnesium oxide (MgO)-filled, die-drawn cable with one or two copper or copper alloy conductors and a seamless copper or stainless steel alloy sheath. Copper sheath versions are usually protected from salts and other chemicals by a polyvinyl chloride (PVC) or high-density polyethylene jacket.

Cable Layout. To determine the characteristics of the MI heating cable needed for a specific area, the following must be known:

- Heated area size
- Power density required
- Voltage(s) available
- Approximate cable length needed

To find the approximate MI cable length, estimate 6 m of cable per square metre of concrete. This corresponds to 150 mm on-center spacing. Actual cable spacing will vary between 75 and 230 mm for proper power density.

Cable spacing is dictated primarily by the heat-conducting ability of the material in which the cable is embedded. Concrete has a higher heat transmission coefficient than asphalt, permitting wider cable spacing. The following is a procedure to select the proper MI heating cable:

1. Determine total power required for each heated slab.

$$W = Aw \tag{26}$$

2. Determine total resistance.

$$R = E^2/W \tag{27}$$

3. Calculate cable resistance per metre.

$$r_1 = R/L_1 \tag{28}$$

where

W = total power needed, W
A = heated area of each heated slab, m²
w = required power density input, W/m²
R = total resistance of cable, Ω
E = voltage available, V
r_1 = calculated cable resistance, Ω per metre of cable
L_1 = estimated cable length, m
L = actual cable length needed, m
r = actual cable resistance, Ω/m
M = cable on-center spacing, mm
I = total current per MI cable, A

Commercially available mineral-insulated heating cables have actual resistance values (if there are two conductors, the value is the total of the two resistances) ranging from 0.005 to 2 Ω/m. Manufacturing tolerances are ±10% on these values. MI cables are die-drawn, with the internal conductor drawn to size indirectly by pressures transmitted through the mineral insulation.

4. From manufacturers' literature, choose a cable with a resistance r closest to the calculated r_1. Note that r is generally listed at ambient room temperature. At the specific temperature, r may drift from the listed value. It may be necessary to make a correction as described in Chapter 6 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.
5. Determine the actual cable length needed to give the wattage desired.

$$L = R/r \tag{29}$$

6. Determine cable spacing within the heated area.

$$M = 1000A/L \tag{30}$$

For optimum performance, heating cable spacing should be within the following limits: in concrete, 75 mm to 230 mm; in asphalt, 75 mm to 150 mm.

Because the manufacturing tolerance on cable length is ±1%, and installation tolerances on cable spacing must be compatible with field conditions, it is usually necessary to adjust the installed cable as the end of the heating cable is rolled out. Cable spacing in the last several passes may have to be altered to give uniform heat distribution.

The installed cable within the heated areas follows a serpentine path originating from a corner of the heated area (Figure 5). As heat is conducted evenly from all sides of the heating cable, cables in a concrete slab can be run within half the spacing dimension of the perimeter of the heated area.

7. Determine the current required for the cable.

$$I = E/R, \text{ or } I = W/E \tag{31}$$

Table 8 Mineral-Insulated Cold-Lead Cables (Maximum 600 V)

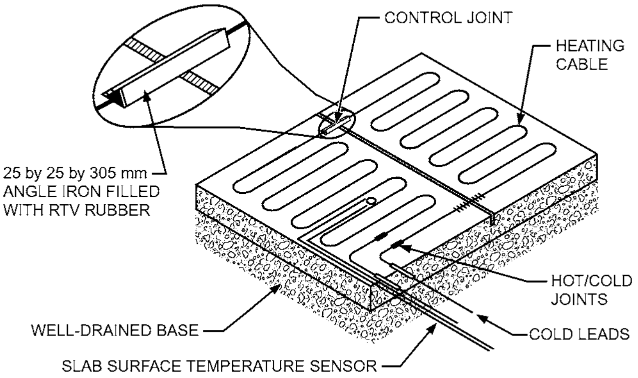

Fig. 5 Typical Mineral Insulated Heating Cable Installation in Concrete Slab

8. Choose cold-lead cable as dictated by typical design guidelines and local electrical codes (see Table 8).

Cold-Lead Cable. Every MI heating cable is factory-fabricated with a non-heat-generating cold-lead cable attached. The cold-lead cable must be long enough to reach a dry location for termination and of sufficient wire gage to comply with local and *NEC* standards. The *NEC* requires a minimum cold-lead length of 180 mm within the junction box. MI cable junction boxes must be located such that the box remains dry and at least 0.9 m of cold-lead cable is available at the end for any future service (Figure 5). Preferred junction box locations are indoors; on the side of a building, utility pole, or wall; or inside a manhole on the wall. Boxes should have a hole in the bottom to drain condensation. Outdoor boxes should be completely watertight except for the condensation drain hole. Where junction boxes are mounted below grade, the cable end seals must be coated with an epoxy to prevent moisture entry. Cable end seals should extend into the junction box far enough to allow the end seal to be removed if necessary.

Although MgO, the insulation in MI cable, is hygroscopic, the only vulnerable part of the cable is the end seal. However, should moisture penetrate the seal, it can easily be detected with a megohmmeter and driven out by applying a torch 0.6 to 0.9 m from the end and working the flame toward the end.

Installation. When MI electric heating cable is installed in a concrete slab, the slab may be poured in one or two layers. In single-pour application, the cable is hooked on top of the reinforcing mesh before the pour is started. In two-layer application, the cable is laid on top of the bottom structural slab and embedded in the finish layer. For a proper bond between layers, the finish slab should be poured within 24 h of the bottom slab, and a bonding grout should be applied. The finish slab should be at least 50 mm thick. Cable should not run through expansion, control, or dummy joints (score or groove). If the cable must cross such a joint, it should cross the joint as few times as possible and be protected at the point of crossing with RTV rubber and a 25 by 25 by 300 mm angle iron as shown in Figure 5.

The cable is uncoiled from reels and laid as described in the section on Cable Layout. Prepunched copper or stainless steel spacing strips are often nailed to the lower slab for uniform spacing.

A high-density polyethylene (HDPE) or polyvinyl chloride (PVC) jacket is extruded by the manufacturer over the cable to protect from chemical damage and to protect the cable from physical damage without adding excessive thermal insulation.

If unjacketed MI cables are used, calcium chloride or other chloride additives should not be added to a concrete mix in winter because chlorides are destructive to copper. Cinder or slag fill under snow-melting slabs should also be avoided. The cold-lead cable should exit the slab underground in suitable conduits to prevent physical and chemical damage.

In asphalt slabs, the MI cable is fixed in place on top of the base pour with prepunched stainless steel strips or 150 mm by 150 mm wire mesh. A coat of bituminous binder is applied over the base and the cable to prevent them from floating when the top layer is applied. The layer of asphalt over the cable should be 40 mm to 75 mm thick (Figure 6).

Testing. Mineral-insulated heating cables should be thoroughly tested before, during, and after installation to ensure they have not been damaged either in transit or during installation.

Because MgO insulation is hygroscopic, damage to the cable sheath is easily detectable with a 500 V field megohmmeter. Cable insulation resistance should be measured on arrival of the cable. Cable with insulation resistance of less than 20 MΩ should not be used. Cable that shows a marked loss of insulation resistance after installation should be investigated for damage. Cable should also be checked for electrical continuity.

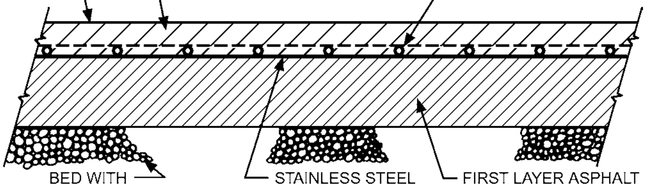

Fig. 6 Typical Section, Mineral-Insulated Heating Cable in Asphalt
(Potter 1967—*ASHRAE Journal*)

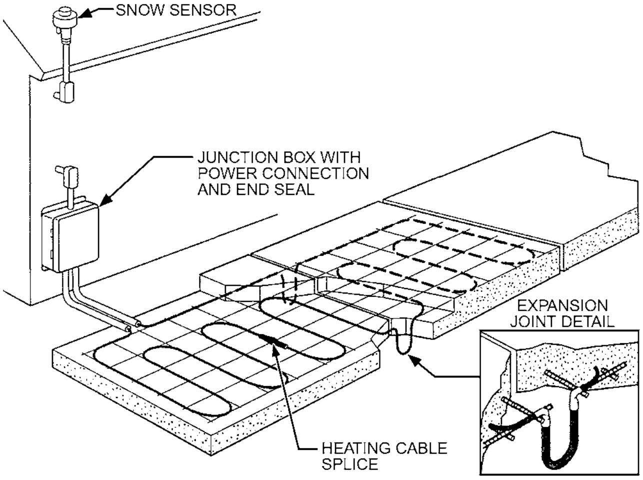

Fig. 7 Typical Self-Regulating Cable Installation

Self-Regulating Cable

Self-regulating heating cables consist of two parallel conductors embedded in a heating core made of conductive polymer. These cables automatically adjust their power output to compensate for local temperature changes. Heat is generated as electric current passes through the core between the conductors. As the slab temperature drops, the number of electrical paths increases, and more heat is produced. Conversely, as the slab temperature rises, the core has fewer electrical paths, and less heat is produced.

Power output of self-regulating cables may be specified as watts per unit length at a particular temperature or in terms of snow-melting performance at a given cable spacing. In typical slab-on-grade applications, adequate performance may be achieved with cables spaced up to 300 mm apart. Narrower cable spacings may be required to achieve the desired snow-melting performance. The parallel construction of the self-regulating cable allows it to be cut to length in the field without affecting the rated power output.

Layout. For uniform heating, the heating cable should be arranged in a serpentine pattern that covers the area with 300 mm on-center spacing (or alternative spacing determined for the design). The heating cable should not be routed closer than 100 mm to the edge of the slab, drains, anchors, or other material in the concrete.

Crossing expansion, control, or other slab joints should be avoided. Self-regulating heating cables may be crossed or overlapped as necessary. Because the cables limit power output locally, they will not burn out.

Both ends of the cable should terminate in an aboveground weatherproof junction box. Junction boxes installed at grade level are susceptible to water ingress. An allowance of heating cable should be provided at each end for termination.

The maximum circuit length published by the manufacturer for the cable type should be respected to prevent tripping of circuit breakers. Use ground fault circuit protection as required by national and local electrical codes.

Installation. Figure 7 shows a typical self-regulating cable installation. The procedure for installing a self-regulating system is as follows:

1. Hold a project coordination meeting to discuss the role of each trade and contractor. Good coordination helps ensure a successful installation.
2. Attach the heating cable to the concrete reinforcing steel or wire mesh using plastic cable ties at approximately 300 mm intervals. Reinforcing steel or wire mesh is necessary to ensure that the slab is structurally sound and that the heating cable is installed at the design depth.
3. Test the insulation resistance of the heating cable using a 2500 V dc megohmmeter connected between the braid and the two bus wires. Readings of less than 20 MΩ indicate cable jacket damage. Replace or repair damaged cable sections before the slab is poured.
4. Pour the concrete, typically in one layer. Take precautions to protect the cable during the pour. Do not strike the heating cable with sharp tools or walk on it during the pour.
5. Terminate one end of the heating cable to the power wires, and seal the other end using connection components provided by the manufacturer.

Constant-Wattage Systems

In a constant-wattage system, the resistance elements may consist of a length of copper wire or alloy with a given amount of resistance. When energized, these elements produce the required amount of heat. Witsken (1965) describes this system in further detail.

Elements are either solid-strand conductors or conductors wrapped in a spiral around a nonconducting fibrous material. Both types are covered with a layer of insulation such as PVC or silicone rubber.

The heat-generating portion of an element is the conductive core. The resistance is specified in ohms per linear metre of core. Alternately, a manufacturer may specify the wire in terms of watts per metre of core, where the power is a function of the resistance of the core, the applied voltage, and the total length of core. As with MI cable, the power output of constant-wattage cable does not change with temperature.

Considerations in the selection of insulating materials for heating elements are power density, chemical inertness, application, and end use. Polyvinyl chloride is the least expensive insulation and is widely used because it is inert to oils, hydrocarbons, and alkalies. An outer covering of nylon is often added to increase its physical strength and to protect it from abrasion. The linear power density of embedded PVC is limited to 16 W/m. Silicone rubber is not inert to oils or hydrocarbons. It requires an additional covering (metal braid, conduit, or fiberglass braid) for protection. This material can dissipate heat of up to 30 W/m.

Lead can be used to encase resistance elements insulated with glass fiber. The lead sheath is then covered with a vinyl material. Output is limited to approximately 30 W/m by the PVC jacket.

Polytetrafluoroethylene (PTFE) has good physical and electrical properties and can be used at temperatures up to 260°C.

Low-power-density (less than 30 W/m) resistance wires may be attached to plastic or fiber mesh to form a mat unit. Prefabricated factory-assembled mats are available in a variety of watt densities

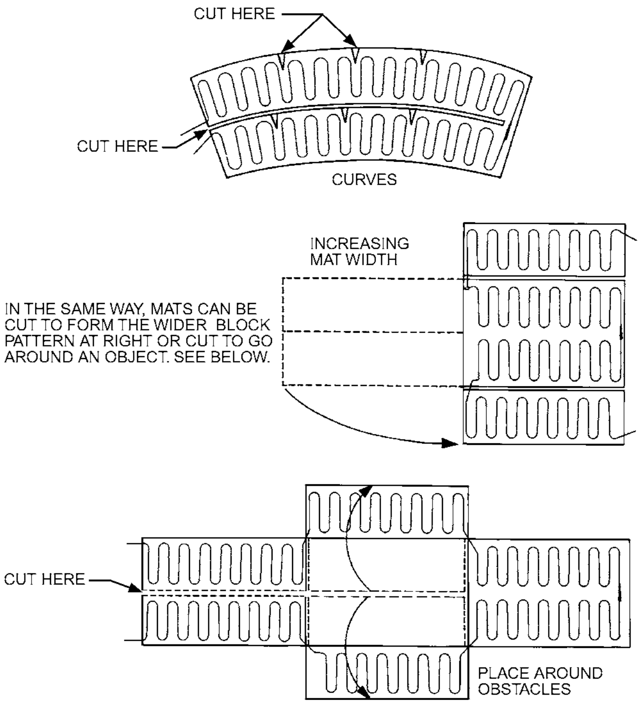

Fig. 8 Shaping Heating Mats Around Curves and Obstacles

for embedding in specified paving materials to match desired snow-melting capacities. Mats of lengths up to 18 m are available for installation in asphalt sidewalks and driveways.

Preassembled heating mats of appropriate widths are also available for **stair steps**. Heating mats are seldom made larger than 5.6 m^2, because larger ones are more difficult to install, both mechanically and electrically. With a series of cuts, in the plastic or fiber mesh heating mats can be tailored to follow contours of curves and fit around objects, as shown in Figure 8. Extreme care should be exercised to prevent damage to the heater wire (or lead) insulation during this operation.

Mats should be installed 40 to 75 mm below the finished surface of asphalt or concrete. Installing mats deeper decreases the snow-melting efficiency. Only mats that can withstand hot-asphalt compaction should be used for asphalt paving.

Layout. Heating wires should be long enough to fit between the concrete slab dummy groove control or construction joints. Because concrete forms may be inaccurate, 50 to 100 mm of clearance should be allowed between the edge of the concrete and the heating wire. Approximately 100 mm should be allowed between adjacent heating wires at the control or construction joints.

For asphalt, the longest wire or largest heating mat that can be used on straight runs should be selected. The mats must be placed at least 300 mm in from the slab edge. Adjacent mats must not overlap. Junction boxes should be located so that each accommodates the maximum number of mats. Wiring must conform to requirements of the *NEC* (NFPA *Standard* 70). It is best to position junction boxes adjacent to or above the slab.

Installation

General

1. Check the wire or heating mats with an ohmmeter before, during, and after installation.
2. Temporarily lay the mats in position and install conduit feeders and junction boxes. Leave enough slack in the lead wires to permit temporary removal of the mats during the first pour. Carefully ground all leads using the grounding braids provided.
3. Secure all splices with approved crimped connectors or set screw clamps. Tape all of the power splices with plastic tape to make them waterproof. All junction boxes, fittings, and snug bushings must be approved for this class of application. The entire installation must be completely waterproof to ensure trouble-free operation.

In Concrete

1. Pour and finish each slab area between the expansion joints individually. Pour the base slab and rough level to within 40 to 50 mm of the desired finish level. Place the mats in position and check for damage.
2. Pour the top slab over the mats while the rough slab is still wet, and cover the mats to a depth of at least 40 mm, but not more than 50 mm.
3. Do not walk on the mats or strike them with shovels or other tools.
4. Except for brief testing, do not energize the mats until the concrete is completely cured.

In Asphalt

1. Pour and level the base course. If units are to be installed on an existing asphalt surface, clean it thoroughly.
2. Apply a bituminous binder course to the lower base, install the mats, and apply a second binder coating over the mats. The finish topping over the mats should be applied in a continuous pour to a depth of 30 to 40 mm. *Note*: Do not dump a large mass of hot asphalt on the mats because the heat could damage the insulation.
3. Check all circuits with an ohmmeter to be sure that no damage occurred during the installation.
4. Do not energize the system until the asphalt has completely hardened.

Infrared Snow-Melting Systems

Although overhead infrared systems can be designed specifically for snow-melting and freeze protection, they are usually installed for additional features they offer. Infrared systems provide comfort heating, which is particularly useful at entrances of plants, office buildings, and hospitals or on loading docks. Infrared lamps can improve a facility's security, safety, and appearance. These additional benefits may justify the somewhat higher cost of infrared systems.

Infrared fixtures can be installed under entrance canopies, along building facades, and on freestanding poles. Approved equipment is available for recessed, surface, and pendant mounting.

Infrared Fixture Layout. The same infrared fixtures used for comfort heating installations (as described in Chapter 16 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*) can be used for snow-melting systems. The major differences are in the orientation of the target area: whereas in comfort applications, the *vertical* surfaces of the human body constitute the target of irradiation, in snow-melting applications, a *horizontal* surface is targeted. When snow melting is the primary design concern, fixtures with narrow beam patterns confine the radiant energy within the target area for more efficient operation. Asymmetric reflector fixtures, which aim the thermal radiation primarily to one side of the fixture centerline, are often used near the periphery of the target area.

Infrared fixtures usually have a longer energy pattern parallel to the long dimension of the fixture than at right angles to it (Frier 1965). Therefore, fixtures should be mounted in a row parallel to the longest dimension of the area. If the target area is 2.4 m or more in width, it is best to locate the fixtures in two or more parallel rows. This arrangement also provides better comfort heating because

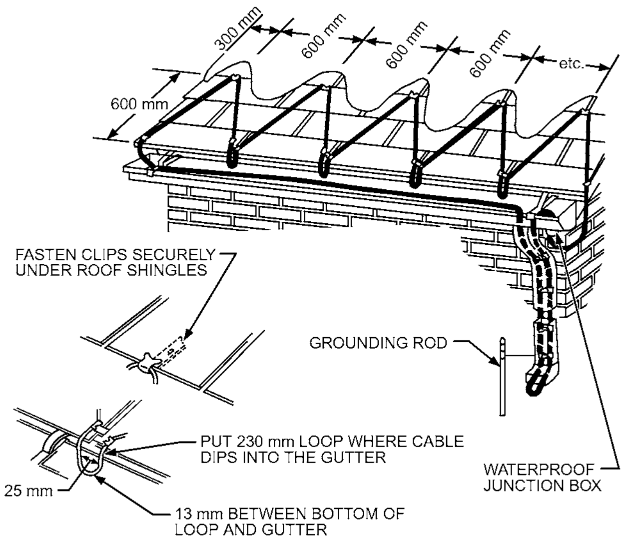

Fig. 10 Typical Insulated Wire Layout to Protect Roof Edge and Downspout

radiation is directed across the target area from both sides at a more favorable incident angle.

Radiation Spill. An ideal energy distribution is uniform throughout the snow-melting target area at a density equal to the design requirement. The design of heating fixture reflectors determines the percentage of the total fixture radiant output scattered outside the target area design pattern.

Even the best-controlled beam fixtures do not produce a completely sharp cutoff at the beam edges. Therefore, if uniform distribution is maintained for the full width of the area, a considerable amount of radiant energy falls outside the target area. For this reason, infrared snow-melting systems are designed so that the power density on the slab begins to decrease near the edge of the area (Frier 1964). This design procedure minimizes stray radiant energy losses.

Figure 9 shows the power densities obtained in a sample snow-melting problem (Frier 1965). The sample design average is 480 W/m^2. It is apparent that the incident power density is above the design average value at the center of the target area and below average at the periphery. Figure 9 shows how the power density and distribution in the snow-melting area depend on the number, wattage, beam pattern, and mounting height of the heaters, and on their position relative to the slab (Frier 1964).

With distributions similar to the one in Figure 9, snow begins to collect at the edges of the area as the energy requirements for snow melting approach or exceed system capacity. As snowfall lessens, the snow at the edges of the area and possibly beyond is then melted if the system continues to operate.

Target Area Power Density. Theoretical target area power densities for snow melting with infrared systems are the same as those for commercial applications of constant-wattage systems except that back and edge heat losses are smaller. However, note that theoretical density values are for radiation incident on the slab surface, not that emitted from the lamps. Merely multiplying the recommended snow-melting power density by the slab area to obtain the total power input for the system does not result in good performance. Experience has shown that multiplying this product by a correction factor of 1.6 gives a more realistic figure for the total required power input. The resulting wattage compensates not only for the radiant inefficiency involved, but also for the radiation falling outside the target area. For small areas, or when the fixture mounting height exceeds 5 m, the multiplier can be as large as 2.0; large areas with sides of approximately equal length can have a multiplier of about 1.4.

The point-by-point method is the best way to calculate the fixture requirements for an installation. This method involves dividing the target area into 1 m squares and adding the radiant energy from each infrared fixture incident on each square (Figure 9). The radiant energy distribution of a given infrared fixture can be obtained from the equipment manufacturer and should be followed for that fixture size and placement.

With infrared energy, the target area can be preheated to snow-melting temperatures in 20 to 30 min, unless the air temperature is well below –7°C or wind velocity is high (Frier 1965). This short warm-up time makes it unnecessary to turn on the system before snow begins to fall. The equipment can be turned on either manually or with a snow detector. A timer is sometimes used to turn the system off 4 to 6 h after snow stops falling, allowing time for the slab to dry completely.

If snow is allowed to accumulate before the infrared system is turned on, there will be a delay in clearing the slab, as with embedded hydronic or electric systems. Because infrared energy is absorbed in the top layer of snow rather than by the slab surface, the time needed depends on snow depth and on atmospheric conditions. Generally, a system that maintains a clear slab by melting 25 mm of snow per hour as it falls requires 1 h to clear 25 mm of accumulated snow under the same conditions.

To ensure maximum efficiency, fixtures should be cleaned at least once a year, preferably at the beginning of the winter season. Other maintenance requirements are minimal.

Snow Melting in Gutters and Downspouts

Electrical heating cables are used to prevent heavy snow and ice accumulation on roof overhangs and to prevent ice dams from forming in gutters and downspouts (Lawrie 1966). Figure 10 shows a typical cable layout for protecting a roof edge and downspout. Cable for this purpose is generally rated at approximately 20 to 50 W/m, and about 2.5 m of wire is installed per linear metre of roof edge. One metre of heated wire per linear metre of gutter or downspout is usually adequate.

If the roof edge or gutters (or both) are heated, downspouts that carry away melted snow and ice must also be heated. A heated length of cable (weighted, if necessary) is dropped inside the downspout to the bottom, even if it is underground.

Lead wires should be spliced or plugged into the main power line in a waterproof junction box, and a ground wire should be installed from the downspout or gutter. Ground fault circuit protection is required per the *NEC* (NFPA *Standard* 70).

The system can be controlled with a moisture/temperature controller, ambient thermostat, or manual control. The moisture/temperature controller is the most energy efficient. If manual control is used, a protective thermostat should also be used to prevent system operation at ambient temperatures above 5°C.

5. CONTROL

Automated Controls

Manual operation, where an operator must activate and deactivate the system when snow falls, does not comply with current energy standards such as ASHRAE *Standard* 90.1 and is not recommended. ASHRAE *Standard* 90.1-2016 requires that snow and ice melting systems include automatic controls that can shut off the systems when the pavement temperature is above 10°C and no precipitation is falling, and an automatic or manual control that allows shutoff when the outdoor temperature is above 4.4°C so that the potential for snow or ice accumulation is negligible.

In addition, hydronic systems require fluid temperature control for safety and for component longevity. Slab stress and temperature limits of the heat transfer fluid, pipe components, and fluid heater need to be considered. Some nonmetallic pipe materials should not be subjected to temperatures above 60°C. If the primary control fails, a secondary fluid temperature sensor should deactivate the snow-melting system and possibly activate an alarm.

Control Selection

Automatic controls provide satisfactory operation by activating the system when light snow starts, allowing adequate warm-up before heavy snowfall develops. Automatic deactivation reduces operating costs.

Snow Detectors. Snow detectors monitor precipitation and temperature. They allow operation only when snow is present and may incorporate a delay-off timer. Snow detectors located in the heated area activate the snow-melting system when precipitation (snow) occurs at a temperature below the preset slab temperature (usually 4°C). Another type of snow detector is mounted above ground, adjacent to the heated area, without cutting into the existing system; however, it does not detect tracked or drifting snow. Both types of sensors should be located so that they are not affected by overhangs, trees, blown snow, or other local conditions.

Slab Temperature Sensor. To limit energy waste during normal and light snow conditions, a remote temperature sensor is commonly installed midway between two pipes or cables in the slab; the set point is adjusted between 5 and 15°C. Thus, during mild-weather snow conditions, the system is automatically modulated or cycled on and off to keep the slab temperature (at the sensor) at set point.

Outdoor Thermostat. The control system may include an outdoor thermostat that deactivates the system when the outdoor ambient temperature rises above 2 to 5°C as automatic protection against accidental operation in summer or mild weather.

For optimum operating convenience and minimum operating cost, all of the preceding controls should be incorporated in the snow-melting system.

Operating Cost

To evaluate operating cost during idling or melting, use the annual output data from Table 3. Idling and melting data are based on slab surface temperature control at 0°C during idling, which requires a slab temperature sensor. Without a slab temperature sensor, operating costs will be substantially higher.

6. FREEZE PROTECTION SYSTEMS

If the slab surface temperature is below 0°C, any water film present on that surface freezes. Water may be present because of accidental spillage, runoff from a nearby source, or premature shutoff of snow-melting operation after precipitation ends but before the surface dries (temperature usually drops rapidly after snow). Therefore, for cases with $A_r < 1$, if the system is shut off too soon, the remaining snow and fluid film on the surface may freeze (Adlam 1950). As previously discussed, idling keeps the slab surface from freezing by maintaining a surface temperature of at least 0.5°C and also reduces the required start-up surface heat flux for snow-melting.

To calculate surface heat flux during idling, the surface may be assumed to be free of snow, covered with a film of water. Unless there is a constant influx of water from the vicinity, the evaporation heat flux of that film may be ignored and the surface may be assumed to be uncovered because the insulation effect of the water film is negligible. In this case, surface heat flux can be calculated by Equation (5).

The surface is free of snow; therefore, Equation (5) approximates the surface heat flux. The mean radiant temperature that appears in Equation (5) is evaluated using Equations (8), (9), and (10). The fraction F_{sc} of radiation between the surface and the clouds is equal to the cloud cover fraction in the meteorological data.

Chapman (1952) also proposed the following equation to determine the required surface heat flux for idling q_i in W/m^2, if the mean ambient air temperature t_m during freezing is known:

$$q_i = (0.953V + 18.74)(0°\text{C} - t_m) \quad (32)$$

A slab surface temperature monitor may control the freeze protection system. Whenever the slab surface temperature drops below 0.56°C, the system activates. However, idling the slab during the entire winter, as given in Table 3, may be too costly, and unnecessary if the main purpose is to reduce high snow-melting surface heat flux at start-up. For example, the annual energy requirement for idling is 45 times more than that for snow-melting in Chicago, $A_r = 0.5$. Therefore, a cost-effective operation may require starting the system to idle only before an anticipated snow. The lead time may be determined by the thermal mass of the slab, local meteorological conditions, idling and start-up snow-melting heat fluxes, and energy cost. Depending on local weather conditions, idling may also be started automatically when prevailing atmospheric conditions make snowfall likely.

Freeze protection systems may also be used in a variety of applications. For example, the foundation of a cold-storage warehouse may be protected from heaving by using a heated floor slab similar to a snow-melting system. The slab must be insulated at the top as well as the back and edges. Top insulation prevents the heated slab from interfering with the space-cooling process in the warehouse. Edge insulation must penetrate below the freezing line. Generally, design heat flux is taken to be between 16 and 32 W/m^2 and the system is operated year-round.

Another freeze protection application is pipe tracing, where a pipe or conduit exposed to the atmosphere is protected against freezing of the fluid within. If a highly viscous fluid is transported, the desired pipe (fluid) temperature may need to be higher than the fluid-freezing temperature to maintain the viscosity required for fluid flow. Figure 11 shows a typical application in which small "tracer" pipes or electrical heating cables are banded along the lower surface of the pipe (Kenny 1999). In a hydronic tracing system, hot fluid or steam may be used. In electric systems, heating cable or mats may be used. Pipe and the tracing elements are covered with thermal insulating material such as fiberglass, polyurethane, calcium silicate, or cellular glass. Sometimes multiple insulation layers may be used. Insulating material must be protected from rain and other external conditions by a weather barrier. Pipe-tracing heat load per unit pipe length q_k is given by the following formula (IEEE 1983):

$$q_k = \frac{(t_p - t_a)}{\frac{1}{\pi D_i h_i} + \frac{\ln(D_o/D_i)}{2\pi k_1} + \frac{\ln(D_3/D_o)}{2\pi k_2} + \frac{1}{\pi D_3 h_{co}} + \frac{1}{\pi D_3 h_o}} \quad (33)$$

where

q_k = pipe tracing heat load per unit pipe length, W/m
t_p = desired pipe temperature, °C
t_a = design ambient temperature, °C
D_i = inside diameter of inner insulation layer (and outer diameter of pipe), m
D_o = outside diameter of inner insulation layer (and inside diameter of outer insulation layer, if present), m
D_3 = outside diameter of outer insulation layer (if present), m. Otherwise, the expression $\ln(D_3/D_o)/2\pi k_2$ in Equation (24) is dropped and D_3 in the last two terms in the denominator of the same equation is replaced by D_o.
k_1 = thermal conductance of inner insulation layer, W/(m · K) (evaluated at its average operating temperature)
k_2 = thermal conductance of outer insulation layer, if present, W/(m · K) (evaluated at its average operating temperature)
h_i = thermal convection coefficient of air film between pipe and inner insulation surface, W/(m · K).
h_{co} = thermal convection coefficient of air between outer insulation surface and weather barrier (if present), W/(m · K).
h_o = combined surface heat transfer coefficient for radiation and convection between weather barrier, if present (otherwise, the outer insulation layer), to ambient, W/(m · K). Values for h_o may be calculated from information in Chapter 4 of the 2017 *ASHRAE Handbook—Fundamentals* and Chapter 16 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

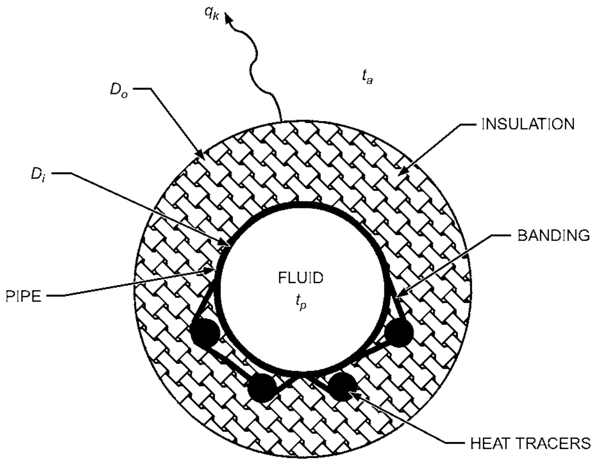

Fig. 11 Typical Heat Tracing Arrangement (Hydronic or Electric)

An appropriate pipe-tracing system is selected to satisfy q_k. For ease of product selection, some manufacturers offer design software or simple charts and graphs of heat losses for various pipe temperatures and insulation configurations. Safety factors are usually added by explicitly increasing the calculated heat load, by decreasing the design ambient temperature, or by conservative selection of k and h values. Pipe- or conduit-tracing heat loads can be more complex because of the heat sinks that penetrate the insulation surface(s); they often require a complex analysis to determine total heat loss, so a heat trace supplier should be consulted.

Steam Pipe-Tracing Systems

Steam tracing involves circulating steam in a pipe or tube that runs parallel to the pipe being traced. As the steam recondenses, it releases its latent heat and transfers it into the traced pipe. A typical steam pipe-tracing system is shown in Figure 12.

Steam systems have relatively high installed costs, particularly if an appropriately sized boiler and header system is not already in place. Steam is widely used for industrial applications, and the design is familiar to pipe installers. Steam is well suited for applications that require a high heat flux, but often is not as efficient for lower-heat-flux applications such as pipe freeze protection.

Electric Pipe-Tracing Systems

Electric pipe-tracing systems involve placing (tracing) an electrical resistance wire parallel to the pipe or tube being traced. This electric heater provides heat to the pipe to balance heat loss to the lower-ambient surrounding. A typical electric system is shown in Figure 13.

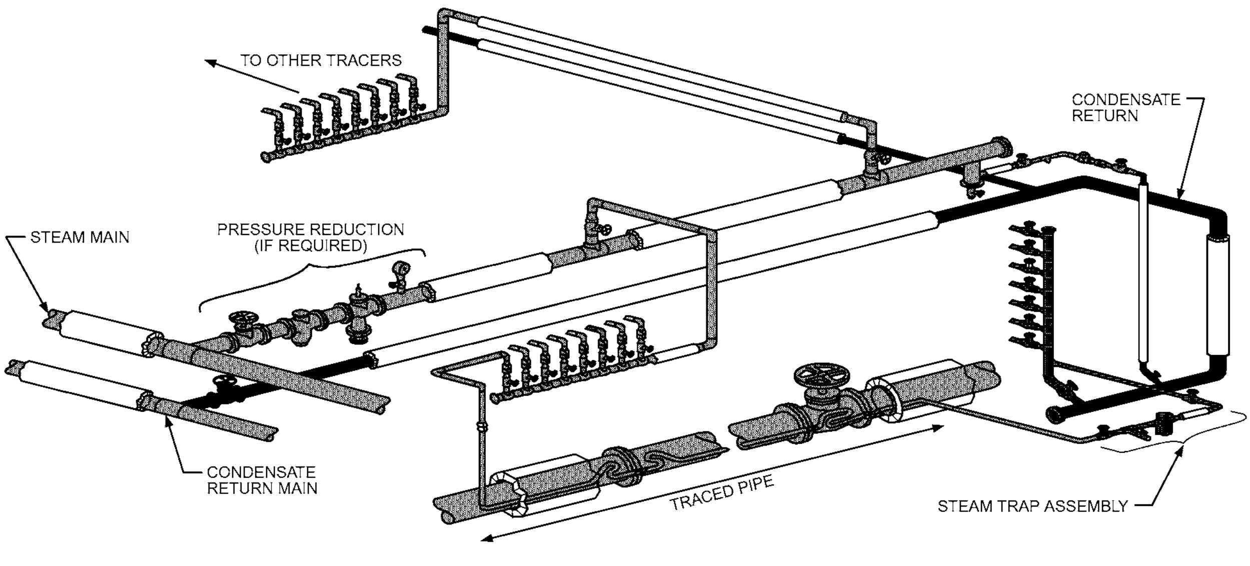

Fig. 12 Typical Pipe-Tracing System with Steam System

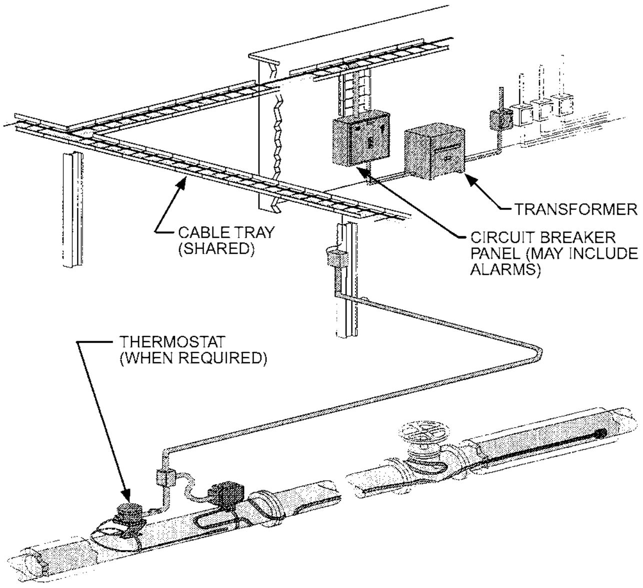

Fig. 13 Typical Pipe Tracing with Electric System

Types of electric heating cables include the following:

- **Self-regulating heating cables** consist of two parallel conductors embedded in a heating core made of conductive polymers. These cables automatically adjust their power output to compensate for local temperature changes. Heat is generated as electric current passes through the conductive core between the conductors. As the pipe temperature drops, the number of electrical paths increases, and more heat is produced. Power output of self-regulating heating cables is specified as watts per unit length at a particular temperature. The self-regulating feature makes the heating cables more energy efficient, because they change their power output based on the need at that point in the pipe. Because they are parallel, they can be cut to length and spliced in the field. Disadvantages are that they are often more expensive and have shorter maximum run lengths because of inrush current.
- **Series heating cables** are one or two copper, copper alloy, or nichrome elements surrounded by a polymer insulating jacket. Power outputs of series cables are specified in watts per unit length. These heating cables are usually inexpensive. Their main disadvantage is that the length cannot be adjusted without changing the power output.
- **Mineral-insulated (MI) heating cables** are series heating cables composed of a magnesium oxide (MgO)-filled, die-drawn cable with one or two copper or copper alloy conductors and a seamless copper or stainless steel alloy sheath. Power output of an MI heating cable is specified in watts per unit length. MI heating cables are rugged and can withstand high temperatures, but are not very flexible. They generally must be ordered in the size needed; splicing in the field is craft-sensitive.
- **Zone heaters** consist of two insulated copper bus wires wrapped with a small-gage (38 to 41 AWG) nichrome heating wire, covered with polymer insulation. The heating wire is connected to alternate bus wires at nodes spaced 0.3 to 1.2 m apart. Current flowing between the bus wires on the heating element generates heat. Power output of a zone heating cable is specified in watts per unit length. Zone heaters are parallel heaters, and thus can be cut to length and spliced in the field. Care must be used to prevent the thin heating wire from being damaged.

Control

The pipe-tracing system is designed to replace pipe heat loss in the worst case (at the lowest ambient temperature). Most of the time, when the temperature is above the lowest ambient temperature, the heat trace system will produce more heat than is required. To conserve energy, or to prevent the pipe from getting too warm, a control system is usually added.

Approaches to basic control include the following:

- **None.** Sometimes heat trace can be allowed to remain energized, most commonly with short lengths of self-regulating electric heat trace or in cases where the ambient temperature does not change (such as a pipe inside a cold-storage area). This is the least efficient control method from an energy usage standpoint, but the easiest to design. A slight variation on this is a manual switch to disconnect power when not needed, using a switch or circuit breaker.
- **Ambient thermostat.** This involves reading the air temperature and activating the system when the air temperature approaches freezing (often at 4°C). This ensures that the system is energized when the pipe could freeze and de-energized when it is warm. This system is often the best compromise between energy efficiency and ease of design.
- **Pipe-sensing thermostat.** This involves reading the pipe temperature and activating the heat trace system when the pipe temperature approaches freezing (often at 4°C). This is the most energy-efficient system, but is more complex to design so that the sensor reading is representative of all areas of the pipe. Always put the control sensor on the smallest pipe and at the coldest anticipated location.

Economic Factors 53.18
Psychrometrics 53.19
Entering Air Considerations 53.19

EVAPORATIVE cooling is energy-efficient, environmentally friendly, and cost-effective in many applications and all climates. Applications range from comfort cooling in residential, agricultural, commercial, and institutional buildings, to industrial applications for spot cooling in mills, foundries, power plants, and other hot indoor environments. Several types of apparatus cool by evaporating water directly in the airstream, including (1) direct evaporative coolers, (2) spray-filled and wetted-surface air washers, (3) sprayed-coil units, and (4) humidifiers. Indirect evaporative cooling equipment combines the evaporative cooling effect in a secondary airstream with a heat exchanger to produce cooling without adding moisture to the primary airstream.

Direct evaporative cooling reduces the dry-bulb (db) temperature and increases the relative humidity of the air. It is most commonly applied to dry climates or to applications requiring high air exchange rates. Innovative schemes combining evaporative cooling with refrigeration equipment have resulted in energy-efficient designs with improved indoor air quality (IAQ) (Scofield and Sterling 1992).

When temperature and/or humidity must be controlled within narrow limits, heat and mechanical refrigeration can be combined with evaporative cooling in stages. Evaporative cooling equipment, including unitary equipment and air washers, is covered in Chapter 41 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. GENERAL APPLICATIONS

Cooling

Evaporative cooling is used in almost all climates. The wet-bulb temperature of the entering airstream limits direct evaporative cooling. The wet-bulb temperature of the secondary airstream limits indirect evaporative cooling.

Design wet-bulb temperatures are rarely higher than 25.6°C, making direct evaporative cooling economical for spot cooling in kitchens, laundries, agricultural, and industrial applications. In regions with lower wet-bulb temperatures, evaporative cooling can be effectively used for comfort cooling, although some climates may require mechanical refrigeration for part of the year.

Indirect applications lower the air wet-bulb temperature and can produce leaving dry-bulb temperatures that approach the wet-bulb temperature of the secondary airstream. Using building return air as the secondary airstream can further enhance performance of the indirect cooler, especially if the building has a high capacitance for moisture absorption. Incorporating sensible precooled air in the secondary airstream further enhances the indirect evaporative cooler's cooling capability.

Direct evaporative cooling is an adiabatic exchange of energy. Heat must be added to evaporate water in the supply airstream. The air into which water is evaporated supplies the heat; thus, the dry-bulb temperature is lowered and the moisture content increases. The amount of heat removed from the air equals the amount of heat absorbed by the water evaporated as heat of vaporization. If the direct evaporative cooler sump water is recirculated in the direct evaporative cooling apparatus, the water temperature in the reservoir approaches the wet-bulb (wb) temperature of the air entering the process. By definition, no heat is added to, or extracted from, an adiabatic process; the initial and final conditions of the process air fall on a line of constant wet-bulb temperature, which nearly coincides with a line of constant enthalpy on the psychrometric chart (Figure 1).

The maximum reduction in dry-bulb temperature is the difference between the entering air dry- and wet-bulb temperatures. If air is cooled to the entering air wet-bulb temperature in a direct evaporative cooling process, it becomes saturated and the process would have 100% **wet bulb depression effectiveness (WBDE).** WBDE is the depression of the dry-bulb temperature in the process divided by the difference between the entering air dry- and wet-bulb conditions.

When a direct evaporative cooling unit alone cannot provide desired conditions, several alternatives can satisfy application requirements and still be energy-effective and economical to operate. The recirculating water supplying the direct evaporative cooling unit can be increased in volume and chilled by mechanical refrigeration to provide lower leaving wet- and dry-bulb temperatures and lower humidity. Compared to the cost of using mechanical refrigeration only, this arrangement reduces operating costs by as much as 25 to 40%. Indirect evaporative cooling applied as a first stage, upstream from a second, direct evaporative stage, reduces both the entering dry- and wet-bulb temperatures before the air enters the direct evaporative cooler. Indirect evaporative cooling may save as much as 60 to 75% or more of the total cost of operating mechanical refrigeration to produce the same cooling effect for 100% outdoor air (OA) systems. Systems may combine indirect evaporative cooling, direct evaporative cooling, heaters, and mechanical refrigeration, in any combination.

The psychrometric chart in Figure 1 shows what happens when air is passed through a direct evaporative cooler. In the example shown, assume an entering condition of 35°C db and 24°C wb. The initial difference is 35 – 24 = 11 K. If the effectiveness is 80%, the depression is 0.80 × 11 = 8.8 K db. The dry-bulb temperature leaving the direct evaporative cooler is 35 – 8.8 = 26.2°C. In the adiabatic evaporative cooler, only part of the water recirculated is assumed to evaporate and the water supply is recirculated. The recirculated water reaches an equilibrium temperature approximately the same as the wet-bulb temperature of the entering air.

The performance of an indirect evaporative cooler can also be shown on a psychrometric chart (Figure 1). Many manufacturers define effectiveness similarly for both direct and indirect evaporative cooling equipment. With indirect evaporative cooling, the cooling process in the primary airstream follows a line of constant moisture

The preparation of this chapter is assigned to TC 5.7, Evaporative Cooling.

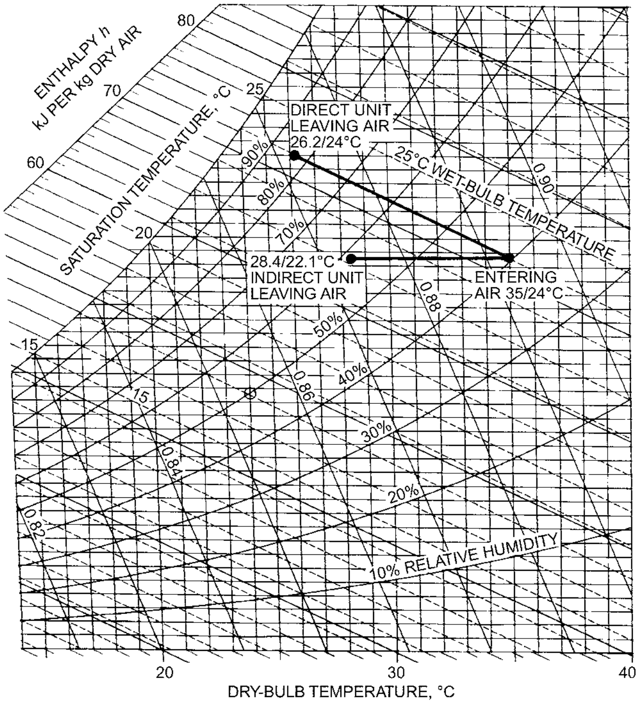

Fig. 1 Psychrometrics of Evaporative Cooling

content (constant dew point). Indirect evaporative cooling effectiveness is the dry-bulb depression in the primary airstream divided by the difference between the entering dry-bulb temperature of the primary airstream and the entering wet-bulb temperature of the secondary air. Depending on heat exchanger design and relative quantities of primary and secondary air, effectiveness ratings may be as high as 85%.

Assuming 60% effectiveness, and assuming both primary and secondary air enter the apparatus at the outdoor condition of 35°C db and 24°C wb, the dry-bulb depression is (35 – 24) = 6.6 K. The dry-bulb temperature leaving the indirect evaporative cooling process is 35 – 6.6 = 28.4°C. Because the process cools without adding moisture, the wet-bulb temperature is also reduced. Plotting on the psychrometric chart shows that the final wet-bulb temperature is 22.1°C. Because both wet- and dry-bulb temperatures in the indirect evaporative cooling process are reduced, indirect evaporative cooling can substitute for part of the refrigeration load in 100% OA systems. This sensible cooling process can make a second-stage direct evaporative cooler more effective in arid climates, because the sensible cooling it contributes allows reduction of mechanical cooling.

Adiabatic Humidification

The benefit of humidification by the adiabatic direct evaporative cooling component is often overlooked in evaporative cooling design. During cold winter conditions, the outdoor air required to meet building code ventilation requirements quickly drives indoor relative humidity below acceptable levels.

Figure 2 shows a schematic of an air-handling unit design that provides hydration to the dry outdoor air in winter without greatly affecting building heating energy costs. The variable-air-volume (VAV) design concept (Scofield et al. 2016) uses a heat pipe air-to-air heat exchanger, selected for indirect evaporative cooling (IEC) in summer, to recover heat from the building return air to (1) increase the fresh air fraction introduced to the building and (2) provide the heat necessary for evaporation of water for humidification furnished by the direct evaporative cooler/humidifier (DEC/H). In mild winter climates, such as Sacramento, California, this design can provide 100% outdoor air to a VAV cooling-only air-handling unit with free hydration of the building supply air sufficient to hold indoor relative humidity above 32% at 22°C indoor temperature when ambient conditions are –5.6°C in winter.

Combining an all-air VAV cooling design with an air-to-air heat exchanger provides significant heating and humidification energy savings, compared to a more conventional air-side economizer design without heat recovery. When ambient temperatures drop in winter and air mass flow decreases through the heat exchanger, the heat pipe becomes more effective. The percentage of heat recovery increases as air-side parasitic losses (caused by static pressure) decline. When dwell time in the heat exchanger increases, effectiveness increases. The same is true for the DEC/H heat exchanger. In the Sacramento application, the heat pipe dry-to-dry effectiveness increases from 65.7% at cooler ambient bin weather conditions, when the VAV system is at 70% of full flow, up to 68.3% effective, at the winter design ambient of –5.6°C and a flow of 50%. The IEC cooling sprays in Figure 2 would be off at all ambient bin conditions below 16.7°C db. Heat recovery is achieved using the 22°C room return air condition in winter.

Recent studies (Karim et al. 1985; Tang 2014; Taylor 2014) identify low room relative humidity as a factor contributing to the buoyancy, viability and spread of some airborne pathogens, such as the flu virus, within the human breathing zone. Maintaining indoor humidity between 40 and 60% at a comfortable room temperature can reduce the risk of human exposure to a number of respiratory infections (Sterling et al. 1985).

Another factor in the spread of pathogens within the human breathing zone indoors is air turbulence. Artificially high room air change rates will push airborne contaminants farther away from a human host thereby exposing healthy humans farther away from a cough or sneeze (Pantelic and Tham 2013). Reducing a VAV supply air temperature set point in cold weather reduces not only air change rates, but also fan energy for both the supply and return fans in Figure 2 (English et al. 2015).

Dilution of indoor-generated contaminants and airborne pathogens with a filtered supply of outdoor air is just one advantage of an all-outdoor-air design. Human productivity has been shown to increase 3 to 4% when outdoor air is increased from the code minimum of 7.1 L/sec per person up to 50 L/s per person (Seppanen et al. 2005). Absentee rates for business employees were shown to decrease by 33% when fresh air rates went from 11.3 to 22.6 L/s per person (Milton et al. 2000).

The installed cost of a DEC/H component in an air-handling unit, such as the one shown in Figure 2, adds about $3.18 to $3.71 per supply air litre per second to the first cost. This added cost has a very short payback because of the payroll savings from increased productivity and reduced absenteeism. If summer sensible cooling and winter hydration of outdoor air are not a design option, the outdoor air increase shown in Table 1 would still make the heat recovery economizer (HRE) a viable option, at a first cost of approximately $4.24 to $5.30 per supply air litre per second installed. In cold climates, the air-to-air heat exchanger offers additional protection against winter freeze-up of water coils downstream in the air-handling unit. Blending preheated OA with building return air becomes a much simpler process. Cold-climate blending devices may often be eliminated without concern for hot- and cold-air stratification causing water freezing problems. An HRE alone offers outdoor ventilation rates well above code minimums in even the coldest climates without preheating costs, unlike a conventional air-side economizer without heat recovery. Outdoor air dampers with OA preheating through heat recovery admit more outdoor air than they would without preheating. Thereby, the fresh air fraction to the building is increased above code minimums prescribed by ASHRAE *Standard* 62.1 (Scofield and Bergman 1997).

Fig. 2 Schematic of VAV Heat Recovery Economizer Unit to Provide Free Adiabatic Humidification during Cold Ambient Conditions
(Scofield et al. 2016)

Recirculated Water. Except for the small amount of energy added by shaft work from the recirculating pump and the small amount of heat leakage through the unit enclosure, evaporative humidification is strictly adiabatic. As the recirculated liquid evaporates, its temperature approaches the thermodynamic wet-bulb temperature of the entering air.

The airstream cannot be brought to complete saturation, but its state point changes adiabatically along a line of constant wet-bulb temperature. Typical saturation or humidifying effectiveness of various air washer spray arrangements is between 50 an 98%. The degree of saturation depends on the extent of contact between air and water. Other conditions being equal, low-velocity airflow is conducive to higher humidifying effectiveness.

Preheated Air. Preheating air increases both the dry- and wet-bulb temperatures and lowers the relative humidity; it does not, however, alter the humidity ratio (i.e., mass ratio of water vapor to dry air) or dew-point temperature of the air. At a higher wet-bulb temperature but with the same humidity ratio, more water can be absorbed per unit mass of dry air in passing through the direct evaporative humidifier. Analysis of the process that occurs in the direct evaporative humidifier is the same as that for recirculated water. The desired conditions are achieved by heating to the desired wet-bulb temperature and evaporatively cooling at constant wet-bulb temperature to the desired dry-bulb temperature and relative humidity. Relative humidity of the leaving air may be controlled by (1) bypassing air around the direct evaporative humidifier or (2) reducing the number of operating spray nozzles or the area of media wetted.

Heated Recirculated Water. Heating humidifier water increases direct evaporative humidifier effectiveness. When heat is added to the recirculated water, mixing in the direct evaporative humidifier may still be modeled adiabatically. The state point of the mixture should move toward the specific enthalpy of the heated water. By raising the water temperature, the air temperature (both dry- and wet-bulb) may be raised above the dry-bulb temperature of entering air. The relative humidity of leaving air may be controlled by methods similar to those used with preheated air.

Dehumidification and Cooling

Direct evaporative coolers may also be used to cool and dehumidify air. If the entering water temperature is cooled below the entering wet-bulb temperature, both the dry- and wet-bulb temperatures of the leaving air are lowered. Dehumidification results if the leaving water temperature is maintained below the entering air dew point. Moreover, the final water temperature is determined by the sensible and latent heat absorbed from the air and the amount of circulated water, and it is 0.5 to 1 K below the final required dew-point temperature.

The air leaving a direct evaporative cooler being used as a dehumidifier is substantially saturated. Usually, the spread between dry-and wet-bulb temperatures is less than 0.5 K. The temperature difference between leaving air and leaving water depends on the difference between entering dry- and wet-bulb temperatures and on certain design features, such as the cross-sectional area and depth of the media or spray chamber, quantity and velocity of air, quantity of water, and the water distribution.

*Economizer using a 70% effectiveness air-to-air heat exchanger to preheat incoming outdoor air using heat from building return air at 22°C. Room conditions held between 22 and 24°C with relative humidity above 40% without requiring additional preheating.

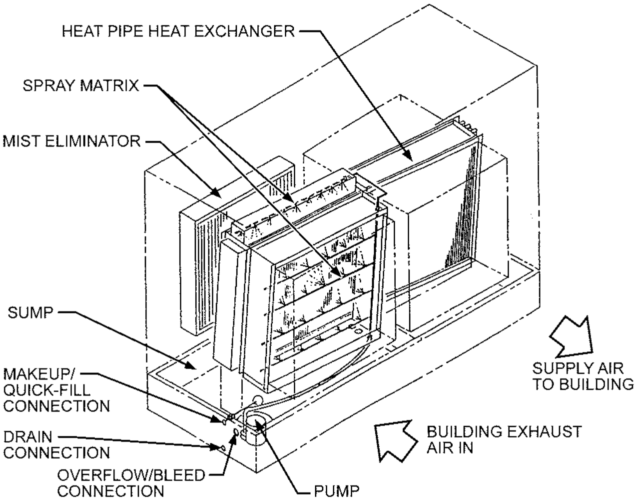

Fig. 3 Heat Pipe Air-to-Air Heat Exchanger with Sump Base

Air Cleaning

Direct evaporative coolers of all types perform some air cleaning. See the section on Air Cleaning and Sound Attenuation for detailed information.

2. INDIRECT EVAPORATIVE COOLING SYSTEMS FOR COMFORT COOLING

Several types of indirect evaporative cooling systems are used for commercial, institutional, and industrial cooling applications. Figures 3 to 7 show schematics of the five most common dry evaporative cooling systems.

Indirect evaporative cooling efficiency is measured by the approach of the outdoor air dry-bulb condition to either the room return air or scavenger outdoor air wet-bulb condition on the wet side

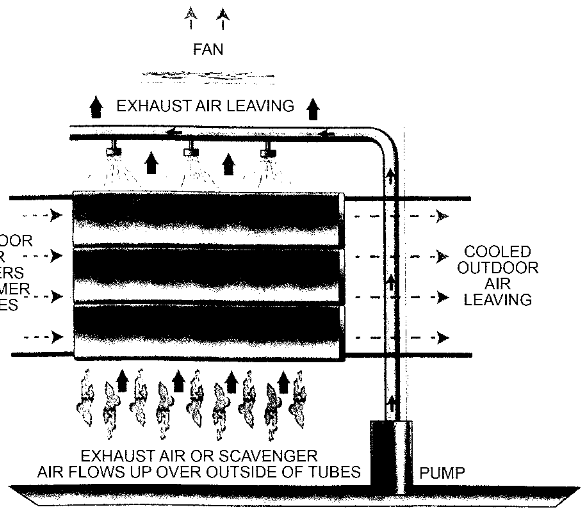

Fig. 4 Cross-Flow Plate Air-to-Air Indirect Evaporative Cooling Heat Exchanger
(Munters)

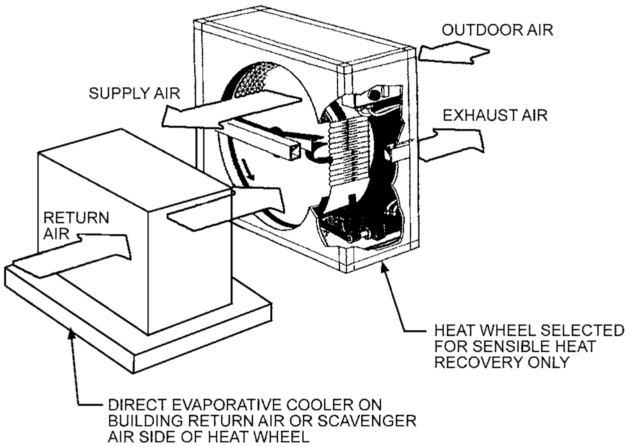

Fig. 5 Rotary Heat Exchanger with Direct Evaporative Cooling

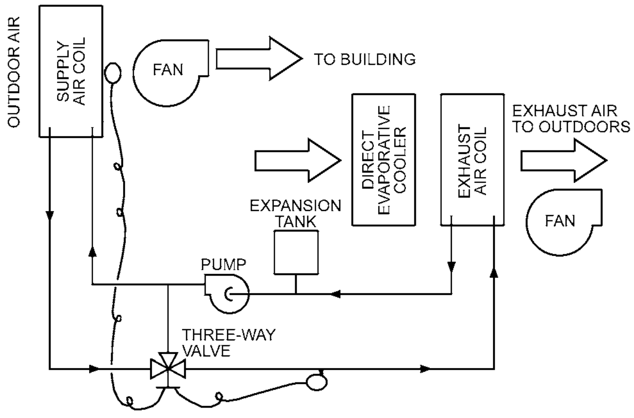

Fig. 6 Coil Energy Recovery Loop with Direct Evaporative Cooling

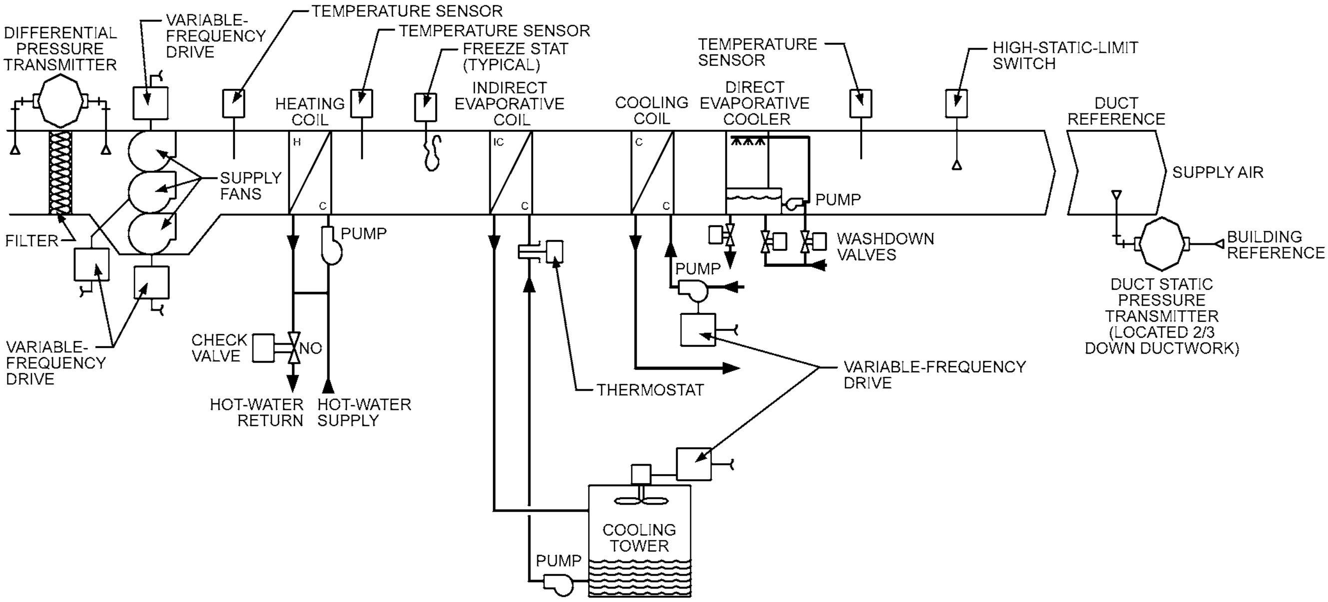

Fig. 7 Cooling-Tower-to-Coil Indirect Evaporative Cooling

of the air-to-air heat exchanger. The **wet-bulb depression efficiency (WBDE)** is expressed as follows:

$$\text{WBDE} = \frac{t_1 - t_2}{t_1 - t_3} \times 100$$

where

t_1 = supply air inlet dry-bulb temperature, °C
t_2 = supply air outlet dry-bulb temperature, °C
t_3 = wet-side air inlet wet-bulb temperature, °C

The heat pipe air-to-air heat exchanger in Figure 3 uses a direct water spray from a recirculation sump on the wet side of the heat pipe tubes (Scofield and Taylor 1986). When either room return or scavenger outdoor air passes over the wet surface, outdoor air entering the building is dry-cooled and produces an approach to the wet-side wet-bulb temperature in the range of 60 to 80% WBDE for equal mass flow rates on both sides of the heat exchanger. The WBDE is a function of heat exchanger surface area, face velocity, and completeness of wetting achieved for the wet-side heat exchanger surface. Face velocities on the wet side are usually selected in the range of 2 to 2.3 m/s.

Figure 4 shows an indirect evaporative cooling (IEC) heat exchanger. This cross-flow, polymer tube air-to-air heat exchanger uses a sump pump to circulate water to wet the outside of the horizontal heat exchanger tubes. A secondary air fan draws either building return or outdoor air vertically upward over the outside of the wetted tubes, causing evaporative cooling to occur. Outdoor air entering the building passes horizontally through the inside of the polymer tube bundle and is sensibly (dry) cooled. Latent and sensible cooling may occur in the outdoor makeup airstream if the secondary air's wet-bulb temperature is lower than the outdoor air's dew-point temperature.

The heat wheel (Figure 5) and the run-around coil (Figure 6) both use a direct evaporative cooling component on the cold side to enhance the dry-cooling effect on the makeup air side. The heat wheel (sensible transfer), when sized for 2.5 m/s face velocity with equal mass flows on both sides, has a WBDE around 60 to 70%. The run-around coil system at the same conditions produces a WBDE of 35 to 50%. The adiabatic cooling component is usually selected for an effectiveness of 85 to 95%. Water coil freeze protection is required in cold climates for the run-around coil loop.

Air-to-air heat exchangers that are directly wetted produce a closer approach to the cold-side wet-bulb temperature, all things being equal. First cost, physical size, and parasitic losses are also reduced by direct wetting of the heat exchanger. In applications having extremely hard makeup water conditions, using a direct evaporative cooling device in lieu of directly wetting the air-to-air heat exchanger may reduce maintenance costs and extend the useful life of the system.

All of the air-to-air heat exchangers shown in Figures 3 to 6 produce beneficial winter heat recovery when using building return air with the sprays or adiabatic cooling component turned off.

Figure 7 shows a cooling-tower-to-coil indirect evaporative cooling system with WBDE in the range of 50 to 75% (Colvin 1995). This system is sometimes called a water-side economizer. The cooling tower is selected for a close approach to the ambient wet-bulb temperature, with sump water from the tower then pumped to precooling coils in an air-handling unit. A plate-and-frame heat exchanger or water filtration to remove solids from sump water is needed, and water coils may need to be cleanable. Freeze protection of the water coil loop is required in cold climates. No winter heat recovery is available with this design.

Table 2 gives the designer some performance predictions and application limits that may be helpful in determining the indirect evaporative cooling system that best solves the design problem at hand. If winter heat recovery is a priority, the heat wheel system may provide the quickest payback. Runaround coil systems are applied where supply air and exhaust air ducts are remote from each other. The heat pipe adapts well to high-volume air-handling systems where cooling energy reduction is the priority. The plate heat exchanger fits smaller-volume systems with high cooling requirements but with lower winter heat recovery potential. Des Champs and Dunnavant (2014) give additional information on air-side economizers using direct and indirect evaporative cooling in data centers.

Indirect Evaporative Cooling Controls

Where the heat exchanger is directly wetted, a water hardness monitor for the recirculation water sump is recommended. Water

Table 2 Indirect Evaporative Cooling Systems Comparison

System Type[a]	WBDE,[b] %	Heat Recovery Efficiency, %	Wet-Side Air Δ*P*, Pa	Dry-Side Air Δ*P*, Pa	Pump power, W per 4720 L/s	Parasitic Loss Range,[e] W/3517 W of Cooling	Equipment Cost Range,[f] US $ per L/s	Notes
Cooling tower to coil	40 to 60	NA	NA	99.5 to 174.1	Varies	Varies	1.06 to 2.12	Best for serving multiple AHUs from a single cooling tower. No winter heat recovery.
Cross-flow plate	60 to 85	40 to 50	174.2 to 248.8	99.5 to 174.1	74.6 to 149.2	120 to 200	2.54 to 3.60	Most cost-effective for lower airflows. Some cross contamination possible. Low winter heat recovery.
Heat pipe[c]	65 to 75	50 to 60	174.2 to 248.8	124.4 to 174.1	149.2 to 298.4	150 to 259	3.18 to 5.30	Most cost-effective for large airflows. Some cross contamination possible. Medium winter heat recovery.
Heat wheel[d]	60 to 70	70 to 80	149.3 to 223.9	99.5 to 161.7	74.6 to 149.2	200 to 300	3.18 to 5.30	Best for high airflows. Some cross contamination. Highest winter heat recovery rates.
Runaround coil[d]	35 to 50	40 to 60	149.3 to 199.0	99.5 to 161.7	Varies	> 350	2.12 to 4.24	Best for applications where supply and return air ducts are separated. Lowest summer WBDE.

WBDE = wet-bulb depression efficiency
Notes:
[a]All air-to-air heat exchangers have equal mass flow on supply and exhaust sides.
[b]Plate and heat pipe are direct spray on exhaust side. Heat wheel and runaround coil systems use 90% WBDE direct evaporative cooling media on exhaust air side.
[c]Assumes six-row heat pipe, 2.3 mm fin spacing, with 2.54 m/s face velocity on both sides.
[d]Assumes 2.54 m/s face velocity. Parasitic loss includes wheel rotational power.
[e]Includes air-side static pressure and pumping penalty.
[f]Excludes cooling tower cost and assumes less than 60 m piping between components.

hardness should be kept within 200 to 500 parts per million (ppm) to minimize plating out of dissolved solids from the sump water. To maintain its set point, the hardness monitor may initiate a sump dump cycle when it detects increased water hardness. In addition, the sump should have provisions for a fixed bleed so that extra makeup water is continuously introduced to dilute dissolved solids left behind when water evaporates from the wetted heat exchanger surface. Sumps should always be drained at the end of a duty cycle and refilled the next day when the system is turned on. For rooftop applications, sumps should be drained for freeze protection during low ambient temperatures.

Air-side control for a cooling system with a 13°C supply air set point may be set up as follows. The heat exchanger's wet-side sprays or indirect evaporative cooling component should be activated whenever ambient dry-bulb temperatures exceed 18°C, if room return air is used on the wet side of the air-to-air heat exchanger. Air-conditioned buildings have a stable return air wet-bulb condition in the range of 15.5 to 18°C. Outdoor air may be usefully precooled when ambient dry-bulb temperatures exceed the return air wet-bulb condition.

Where outdoor air is used on the cold-air side of the heat exchanger, cooling may begin at ambient temperatures above 13°C, because the wet-bulb condition of outdoor air is always lower than its dry-bulb condition.

Parasitic losses generated by the heat exchanger static pressure penalty to supply and return air fans and by the water pump need to be evaluated. These losses may be mitigated by opening bypass dampers around the heat exchanger for pressure relief and shutting off the pump in the ambient temperature range of 13 to 18°C db. Where outdoor air is used on the wet side (scavenger air) of an air-to-air heat exchanger, this temperature range may be reduced somewhat. Comparing the energy penalty to the precooling energy avoided determines the optimum range of ambient conditions for this control strategy.

For variable-air-volume (VAV) supply and return fan systems, the static penalty reduces by the square of the airflow reduction from full design flow at summer peak design condition. As airflow rates decrease across an air-to-air heat exchanger, the WBDE increases, thereby providing better precooling. Where scavenger outdoor air is used for indirect evaporative cooling, the wet-side airflow rate is usually constant volume.

Winter heat recovery may be initiated at ambient temperatures below the 13°C supply air set point. Where building return air is used with an air-to-air heat exchanger, the 21 to 24°C return air condition

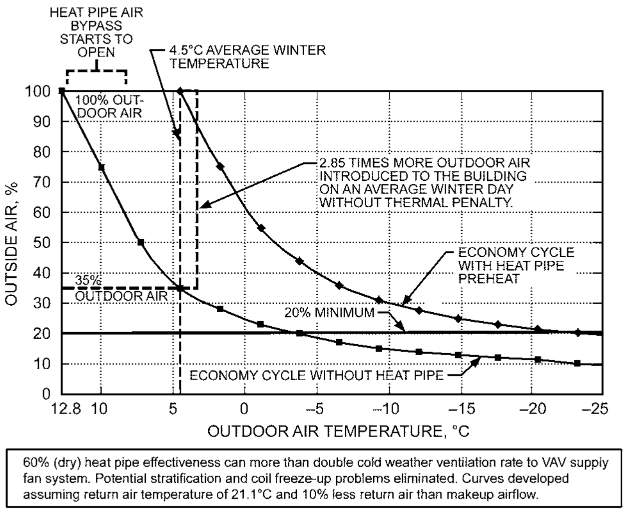

Fig. 8 Increased Winter Ventilation

is used to preheat makeup air for the building. For a VAV supply air system, Figure 8 shows the increased ventilation potential of a heat pipe air-to-air heat exchanger that uses face and bypass dampers on the supply air side to mix unheated outdoor air with preheated outdoor air to maintain the 13°C building supply air set point (Scofield and Bergman 1997). The heat pipe leaving air temperature may also be controlled with a tilt control (see Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*). With a heat pipe economizer, a minimum outdoor air ventilation rate of 20% would not be breached until ambient temperatures dropped below –26°C.

Runaround coils control leaving supply air temperature with a three-way valve (see Figure 6). Because of their higher parasitic losses, these systems may require a wider range of ambient conditions where pressure-relief bypass dampers are open and the pump system shut down. Some projects limit activation of these recovery systems to ambient temperatures above 29°C or below 4°C.

Indirect/Direct Evaporative Cooling with VAV Delivery

Coupling indirect and direct evaporative cooling to a variable-air-volume (VAV) delivery system in arid climates can effectively

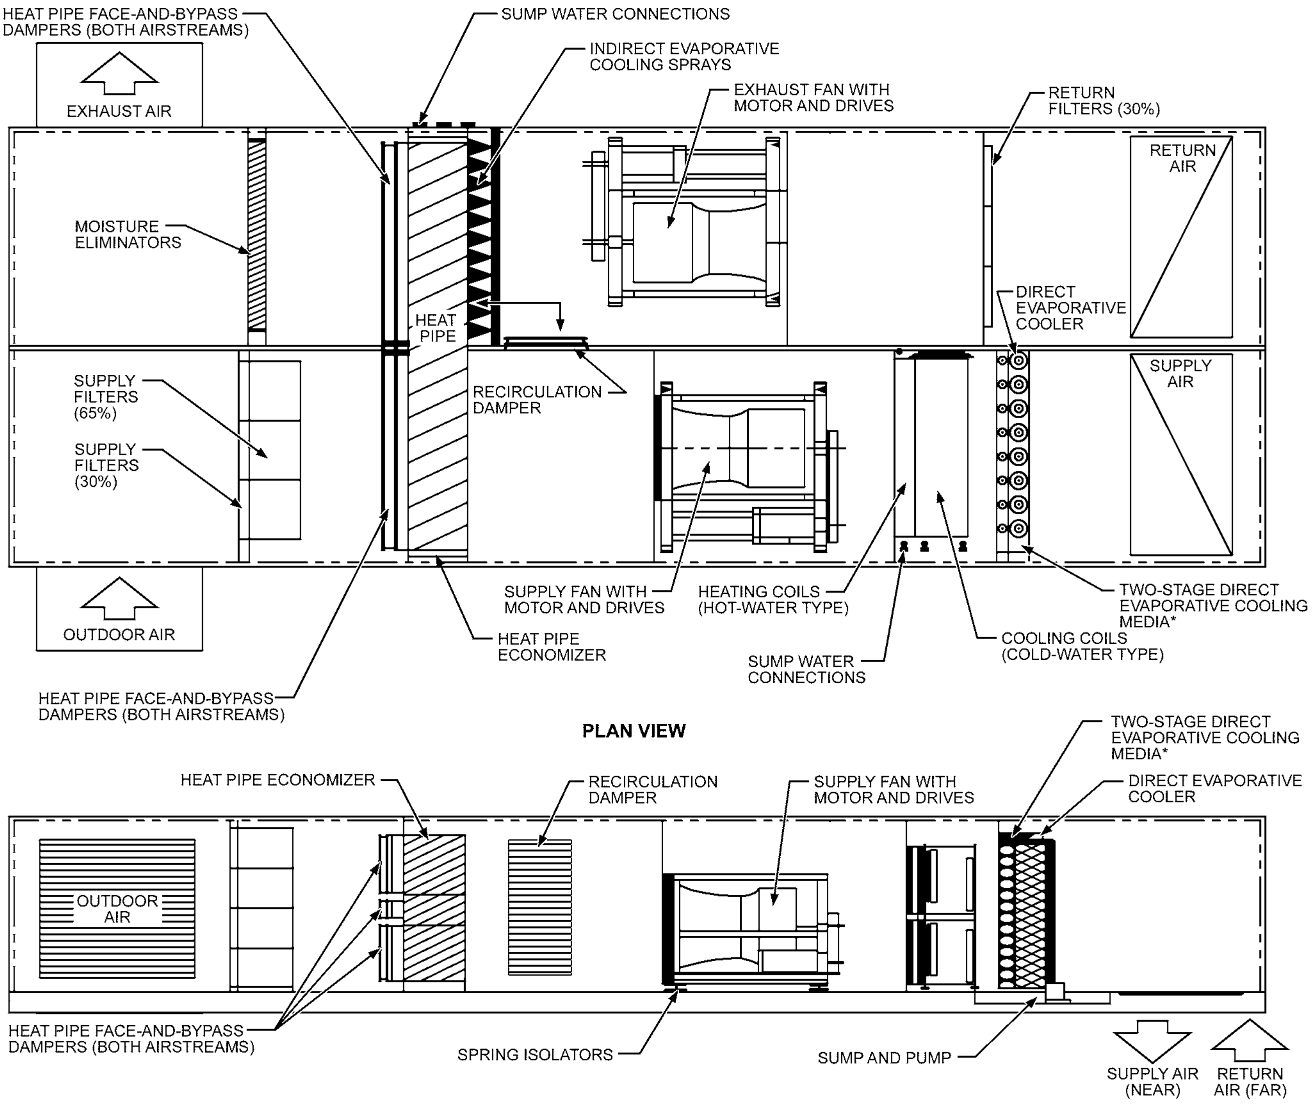

Fig. 9 Heat Pipe Air-Handling Unit

eliminate requirements for mechanical refrigeration in many applications. Many cities in the western United States have summer design conditions suitable to deliver 13°C or lower supply air to a building using a 70% WBDE indirect and a 90% effective direct evaporative cooling system.

Figure 9 shows plan and elevation views of an air-handling unit using a sprayed heat pipe air-to-air heat exchanger and a wetted-media direct evaporative cooling section augmented by a final-stage chilled-water cooling coil (Scofield and Bergman 1997). The 70% indirect WBDE is achieved with a direct-sprayed heat pipe using a sump and a recirculation water system on the building return air side of the heat exchanger. The 90% effective direct evaporative cooling medium is split into two sections for two-stage cooling capacity control of the 13°C leaving air temperature. The direct evaporative cooling system also uses a sump and water recirculation. Supply-side heat pipe face and bypass dampers control the final supply air temperature (13°C) in both summer (when indirect sprays are on) and winter, to control the heat pipe's heat recovery capacity. Heat pipe dampers on both sides of the heat exchanger are powered to full open to mitigate system parasitic losses during ambient temperature conditions when the value of energy recovered is exceeded by the fan energy penalty. The recirculation damper is used for morning warm-up of the building and for blending building return air with preheated outdoor air during extreme cold ambient conditions (see Figure 8).

Table 3 uses ASHRAE bin weather data for the semi-arid climate of Sacramento, California, to illustrate potential cooling energy savings for a 4.7 m^3/s VAV design that turns down to 2.4 m^3/s at winter design (Scofield and Bergman 1997). Compared to a conventional-refrigeration cooling VAV design with a 25% minimum outdoor air economizer, the two-stage evaporative cooling system reduces peak cooling load by 49% while introducing 100% outdoor air. For a building duty cycle of 8760 h per year, the savings is 119 712 kWh, or a 60% reduction compared to the conventional air-side economizer system with mechanical cooling only. For ambient bin conditions of

[b]Bin hours at each condition based on 24 h/day, 365 days/year duty cycle.

[c]Heat pipe overheats outdoor air to allow direct evaporative humidifier to add moisture.

[d]Recirculated building heat used for preheating 100% outdoor air and increasing humidity levels.

[e]Additional heat is required or recirculation damper must open during these bin conditions, to maintain both acceptable 30% indoor relative humidity and reach the 12.79°C supply air set point.

17°C db/12°C wb to 14°C db/11°C wb, there are 2376 cooling hours per year (27% of the annual cooling hours) where a 90% wet-bulb depression efficiency (WBDE) direct evaporative cooling system may be used for the 13°C supply air requirement without refrigeration.

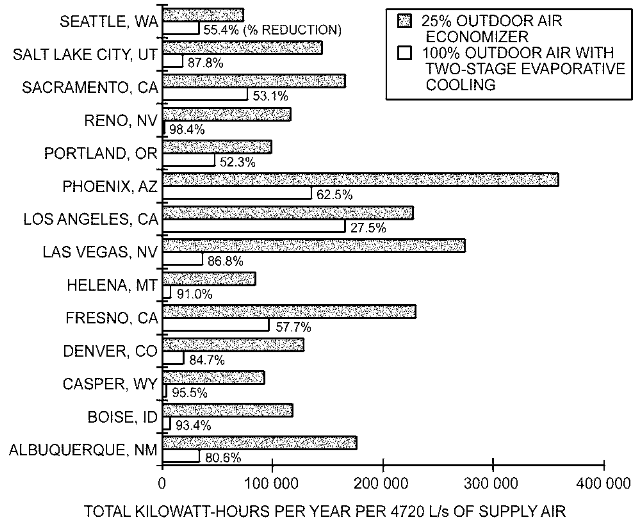
Figure 10 uses typical meteorological year (TMY) data for 14 cities in the western United States to illustrate the evaporative cooling annual refrigeration avoidance per 4.7 m/s of VAV supply air, compared to a 25% minimum outdoor air economizer (Scofield and Bergman 1997). For thermal energy storage (TES) applications, the two-stage evaporative cooling design may significantly reduce chiller plant storage capacity and refrigeration equipment first cost.

Benefits of this design in dry climates include the following:

- Indoor air quality is improved by using all-outdoor air during cooling, and increased ventilation in winter through the heat pipe economizer (see Figure 8).
- Energy demand is in the range of 0.04 to 0.07 kW/kW of cooling, versus air-cooled refrigeration at 0.3 to 0.4 kW/kW.
- Peak building electrical cooling and gas heating demand requirements are reduced, especially for applications that require higher amounts of outdoor air.
- Because VAV pinchdown terminals may reduce their minimum airflow settings and comply with ASHRAE *Standard* 62.1, supply and return fan energy savings are possible in cooler weather when using an all-outdoor-air design.
- VAV turndown of fans during cooler ambient conditions decreases fan parasitic energy losses because of the evaporative cooling system components.
- VAV turndown increases the WBDE of both the air-to-air heat exchanger and direct evaporative cooling system.
- In semi-arid climates where a chilled-water final cooling stage is required, two-stage evaporative cooling allows central chilled-water plants to be turned off earlier in the fall and reactivated later in the spring. This results in significant maintenance and cooling energy cost savings.
- In cooler weather, resetting supply air down to 10°C and using only the direct evaporative cooler extends free cooling hours and reduces fan energy.
- When using building return air, winter heat recovery provides increased outdoor air quantities during the period when fan turndown can result in loss of proper ventilation rates for VAV systems (see Figure 8).
- During mild winter daytime ambient conditions, the 100 mm deep wetted media section may be used for beneficial building humidification (see Table 4).

Beneficial Humidification

Areas with mild winter climates (e.g., the western U.S. coast) may use the heat available in building return air, through the air-to-air heat exchanger, to overheat supply air and add building humidification during the driest season of the year. The 100 mm section of direct evaporative cooling media (see Figure 8) is used in cool



Note: Fourteen Western cities where indirect/direct evaporative cooling systems, using heat pipe (wet) indirect evaporative effectiveness of 70% and direct evaporative cooler saturation efficiency of 90%, can be used to introduce 100% outdoor air, with substantial reductions in kilowatt-hour cooling requirements compared to conventional 25% outdoor air economizer damper design. Kilowatt-hour totals for each system based on 24 h/day, 365 day/year duty cycle and 4720 L/s VAV supply air. NREL hour-by-hour TMY data used to develop kilowatt-hours listed. Fan heat not included.

Fig. 10 Refrigeration Reduction with Two-Stage Evaporative Cooling Design

ambient conditions as a humidifier. Table 4 (Scofield and Bergman 1997) extends the Table 3 bin weather data for the Sacramento, California, site into winter ambient conditions. The table shows that 100% outdoor air may be introduced and humidity controlled between 54 and 32% for ambient conditions down to 2.8°C with a 60% heat pipe recovery effectiveness. There are only 146 bin hours below the 2.8°C ambient threshold during which the building recirculation air damper (see Figure 8) would have to open or additional heat be added with the hot-water coil to maintain the 12.8°C air delivery set point. The average winter temperature in Sacramento is 11.5°C.

Indirect Evaporative Cooling With Heat Recovery

In indirect evaporative cooling, outdoor supply air passes through an air-to-air heat exchanger and is cooled by evaporatively cooled air exhausted from the building or application. The two airstreams never mix or come into contact, so no moisture is added to the supply airstream. Cooling the building's exhaust air results in a larger overall temperature difference across the heat exchanger and a greater cooling of the supply air. Indirect evaporative cooling requires only fan and water pumping power, so the coefficient of performance tends to be high. The principle of indirect evaporative cooling is effective in most air-conditioned buildings, because evaporative cooling is applied to exhaust air rather than to outdoor air.

Indirect evaporative cooling has been applied in a number of heat recovery applications (Mathur et al. 1993), such as plate heat exchangers (Scofield and DesChamps 1984; Wu and Yellot 1987), heat pipe exchangers (Mathur 1998; Scofield 1986), rotary regenerative heat exchangers, and two-phase thermosiphon loop heat exchangers (Mathur 1990). In residential air conditioning, the outdoor condensing unit can be evaporatively cooled to enhance performance (Mathur 1997; Mathur and Goswami 1995; Mathur et al. 1993). Indirect evaporative cooling with heat recovery is covered in detail in Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

3. BOOSTER REFRIGERATION

Staged evaporative coolers can completely cool office buildings, schools, gymnasiums, sports facilities, department stores, restaurants, factory space, and other buildings. These coolers can control room dry-bulb temperature and relative humidity, even though one stage is a direct evaporative cooling stage. In many cases, booster refrigeration is not required. Supple (1982) showed that even in higher-humidity areas with a 1% mean wet-bulb design temperature of 24°C, 42% of the annual cooling load can be satisfied by two-stage evaporative cooling. Refrigerated cooling need supply only 58% of the load.

Figure 11 shows indirect/direct two-stage performance for 16 cities in the United States. Performance is based on 60% WBDE of the indirect stage and 90% for the direct stage. Supply air temperatures (leaving the direct stage) at the 0.4% design dry-bulb mean coincident wet-bulb condition range from 13.4 to 22.4°C. Energy use ranges from 16.4 to 51.8%, compared to conventional refrigerated equipment.

Booster mechanical refrigeration provides indoor design comfort conditions regardless of the outdoor wet-bulb temperature without having to size the mechanical refrigeration equipment for the total cooling load. If the indoor humidity level becomes uncomfortable, the quantity of moisture introduced into the airstream must be limited to control room humidity. Where the upper relative humidity design level is critical, a life-cycle cost analysis favors a design with an indirect cooling stage and a mechanical refrigeration stage.

Figure 12 shows an air-handling unit design that uses building return air instead of outdoor air to develop the indirect (dry) evaporative cooling effect with a direct-sprayed, heat pipe, air-to-air, heat exchanger (Felver et al. 2001). The humid, cool air off the heat pipe is then used to reject the heat of refrigeration at a condenser coil downstream of the exhaust fan. The direct expansion (DX) cooling coil, the last component in the supply air, develops the final building supply air temperature when the two-stage evaporative cooling components cannot meet the design cooling requirements. Figure 13 shows the process points for both supply and exhaust airstreams, using the Stockton, California, ASHRAE 0.4% summer dry-bulb design ambient condition. Several benefits accrue from this evaporative cooling design:

- Building return air has a more predictable and stable wet-bulb condition (15.5 to 18°C) than ambient air for use in generating the first stage of indirect (dry) evaporative cooling. Daytime absorption of moisture inside most buildings further enhances the first-stage cooling effect.
- Locating a DX condenser coil in sprayed exhaust off the heat pipe results in a more efficient rejection of refrigeration heat than a condenser coil located outdoors in the ambient air.
- Lower refrigeration condensing temperatures increase compressor capacity and compressor life, and reduce energy consumption.
- Central chilled-water plant or remote chiller installation and piping costs are eliminated.
- Evaporative cooling components provide back-up cooling capability in case of compressor failure. Figure 13 shows equilibrium conditions in the occupied area with indirect/direct evaporative cooling only at the design dry-bulb ambient condition.
- Peak refrigeration demand can be reduced 14 to 40% in California's semi-arid climate (Scofield 1994).
- Blow-through supply fan and draw-through exhaust fans provide
  - Reduced supply fan heat addition for DX cooling system
  - Reduced risk of cross contamination of supply air with exhaust air for hospital or laboratory applications
  - Reduced fan noise breakout into building duct system

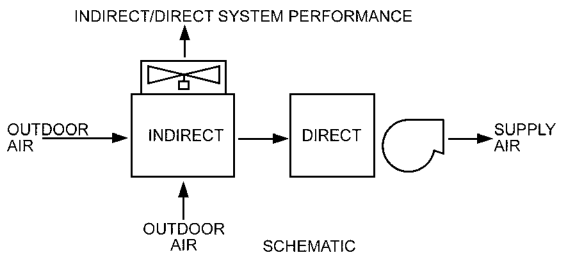
*At 20°C and 101.325 kPa



Notes:
I/D effectiveness: Indirect = 60% or 0.6 (dry bulb – wet bulb); Direct = 90% or 0.9 (dry bulb – wet bulb).
Outdoor air design condition: 0.4% dry bulb/mean coincident wet bulb (2017 *ASHRAE Handbook—Fundamentals*, Chapter 14).
Fan heat is added to two-stage supply air dry bulb (0.5 K)
Assume 0.6 W per L/s for the direct and 0.4 W per L/s* for the indirect section (200 W total). AC is 1000 W in all cases.
Sensible capacity = 1.08 × L/s* × Δt. For AC, this is 2530 W in all cases, based on 11 K Δt.
EER = energy efficiency ratio = watts cooling output per watt of electrical input. Comparison base to conventional refrigeration with 15.5°C supply air and 11 K temperature drop.
Sensible EER = Sensible cooling capacity ÷ wattage.
EUC = Energy use comparison to conventional refrigeration with EER = 8.6 (watt cooling per watt input).
Psychrometric routines are calculated using site atmospheric pressure.

Fig. 11 Indirect/Direct Two-Stage System Performance

There are several design considerations for the successful integration of DX refrigeration with two-stage evaporative cooling air-handling units, as shown in Figure 12.

For both constant-volume (CV) and variable-air-volume (VAV) units, the return air must closely match the supply airflow to ensure adequate heat rejection at the condenser coil. Buildings with large fixed-exhaust systems may not provide sufficient building return airflow for absorption of refrigeration heat at acceptable refrigerant condensing temperatures.

Secondary face-and-bypass dampers are required around the condenser coil for control of the refrigerant condensing pressure and temperature.

Note that peak refrigeration requirements always occur during the highest ambient humidity (dew-point design) conditions. In semi-arid climates, this design condition occurs during reduced summer ambient dry-bulb temperatures (Ecodyne Corp. 1980). Review of site ASHRAE dew-point design conditions (Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*) is required to determine the peak refrigeration cooling capacity needed to maintain the specified supply air temperature set point to the building.

4. RESIDENTIAL OR COMMERCIAL COOLING

In dry climates, evaporative cooling is effective at lower air velocities than those required in humid climates. Packaged direct evaporative coolers are used for residential and commercial application. Cooler capacity may be determined from standard heat gain calculations (see Chapters 17 and 18 of the 2017 *ASHRAE Handbook—Fundamentals*).

Detailed calculation of heat load, however, is usually not economically justified. Instead, one of several estimates gives satisfactory results. In one method, the difference between dry-bulb design temperature and coincident wet-bulb temperature multiplied by 10 is equal to the number of seconds needed for each air change. This or any other arbitrary method for equating cooling capacity with airflow depends on a direct evaporative cooler effectiveness of 70 to 80%. Obviously, the method must be modified for unusual conditions such as large unshaded glass areas, uninsulated roof exposure, or high internal heat gain. Also, such empirical methods make no attempt to predict air temperature at specific points; they merely establish an air quantity for use in sizing equipment.

Example 1. An indirect evaporative cooler is to be installed in a 15 by 24.4 m one-story office building with a 3 m ceiling and a flat roof. Outdoor design conditions are assumed to be 35°C db and 18.3°C wb. The following heat gains are to be used in the design:

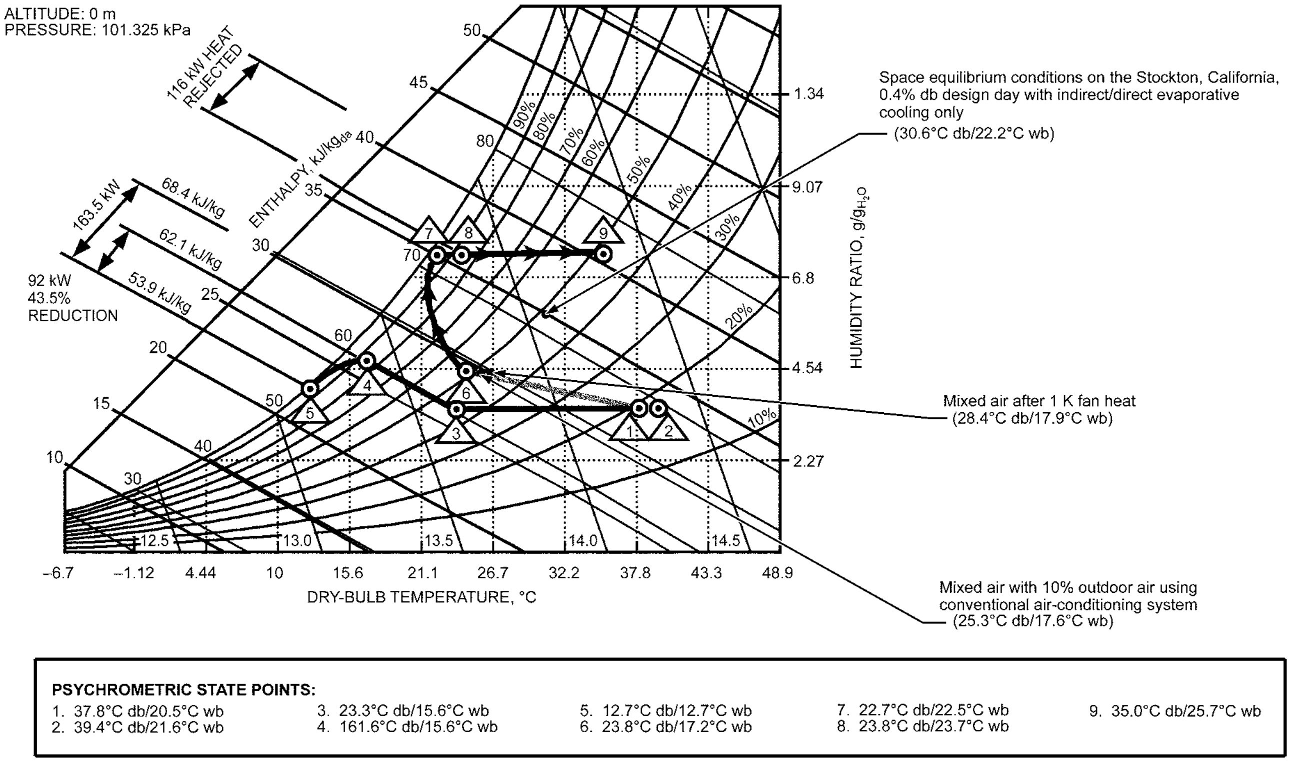

Fig. 13 Psychrometrics of 100% OA, Two-Stage Evaporative Cooling Design (9440 L/s Supply, 8496 L/s Return) Compared with 10% OA Conventional System Operating at Stockton, California, ASHRAE 0.4% db Design Condition

	Heat Gains, kW
All walls, doors, and roof	23.0
Glass area	1.7
Occupants (sensible load)	5.0
Lighting	18.4
Total sensible heat load	48.1
Total latent load (occupants)	6.2
Total heat load	54.3

Find the required air quantity, the temperature and humidity ratio of the air leaving the cooler (entering the office), and the temperature and humidity ratio of the air leaving the office.

Solution: A temperature rise of 5 K in the cooling air is assumed. The airflow rate that must be supplied by the indirect evaporative cooler may be found from the following equation:

$$Q_{ra} = \frac{q_s}{\rho c_p(t_1 - t_s)} = \frac{48.1}{1.2 \times 5} = 8.0\ \text{m}^3/\text{s} \tag{1}$$

where

Q_{ra} = required airflow, m³/s
q_s = instantaneous sensible heat load, kW
t_1 = indoor air dry-bulb temperature, °C
t_s = room supply air dry-bulb temperature, °C
ρc_p = density times specific heat of air ≈ 1.2 kJ/(m³·K)

This air volume represents a 137 s (15 × 24.4 × 3/8.0) air change for a building of this size. The indirect evaporative air cooler is assumed to have a saturation effectiveness of 80%. This is the ratio of the reduction of the dry-bulb temperature to the wet-bulb depression of the entering air. The dry-bulb temperature of the air leaving the indirect evaporative cooler is found from the following equation:

$$t_2 = t_1 - \frac{e_h}{100}(t_1 - t') = 35 - \frac{80}{100}(35 - 18.3) = 21.6°\text{C} \tag{2}$$

where

t_2 = dry-bulb temperature of leaving air, °C
t_1 = dry-bulb temperature of entering air, °C
e_h = humidifying or saturating effectiveness, %
t' = thermodynamic wet-bulb temperature of entering air, °C

From the psychrometric chart, the humidity ratio W_2 of the cooler discharge air is 11.85 g/kg$_{da}$. The humidity ratio W_3 of the air leaving the space being cooled is found from the following equation:

$$W_3 = \frac{q_e}{3.010 Q_{ra}} + W_2 \tag{3}$$

$$W_3 = \frac{6.2}{3.010 \times 8.0} + 11.85 = 12.11\ \text{g/kg (dry air)}$$

where q_e = latent heat load in kW.

The remaining values of wet-bulb temperature and relative humidity for the problem may be found from the psychrometric chart. Figure 14 shows the various relationships of outdoor air, supply air to the space, and discharge air.

The wet-bulb depression (WBD) method to estimate airflow gives the following result:

$$\text{WBD} \times 10 = (35 - 18.3) \times 10 = 167\ \text{s per air change}$$

$$Q_{ra} = \frac{\text{Volume}}{\text{Air change rate}} = \frac{15 \times 24.4 \times 3}{167} = 6.6\ \text{m}^3/\text{s}$$

Although not exactly alike, these two air volume calculations are close enough to select cooler equipment of the same size.

5. EXHAUST REQUIRED

If air is not exhausted freely, the increased static pressure will reduce airflow through the evaporative cooler. The result is a marked increase in the moisture and heat absorbed per unit mass of

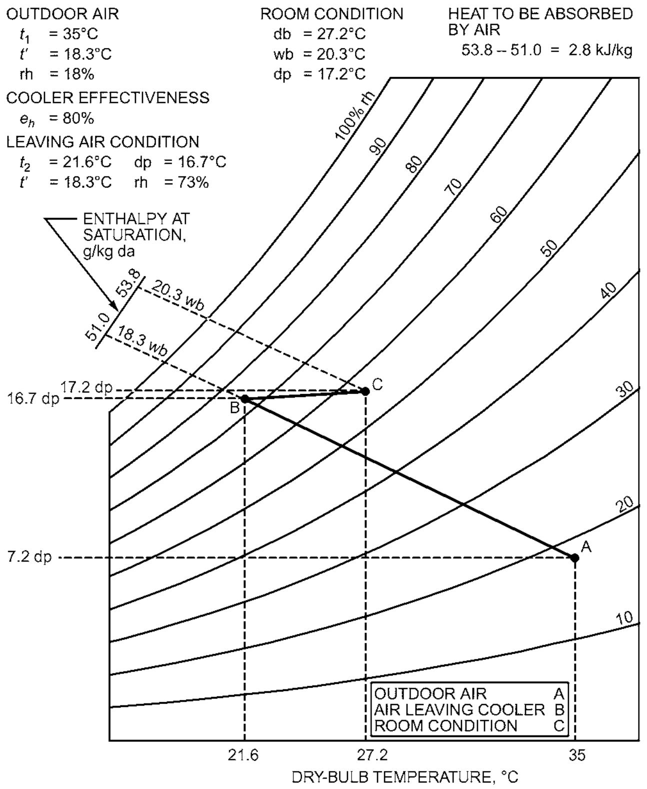

Fig. 14 Psychrometric Diagram for Example 1

air leaving the evaporative cooler. Reduced airflow also reduces the air velocity in the room. The combination of these effects reduces the comfort level. Properly designed systems should have a maximum air velocity of 2.5 m/s through the exhaust. If the exhaust area is not sufficient, a powered exhaust should be used. The amount of power depends on the total airflow and the amount of free or gravity exhaust. Some applications require that the powered exhaust capacity equal the cooler output.

6. TWO-STAGE COOLING

Two-stage coolers for commercial applications can extend the range of atmospheric conditions under which comfort requirements can be met, as well as reduce the energy cost. For the same design conditions, two-stage cooling provides lower cool-air temperatures, which reduces required airflow.

7. INDUSTRIAL APPLICATIONS

In factories with large internal heat loads, it is difficult to approach outdoor conditions during the summer simply by ventilating without using extremely large quantities of outdoor air. Both direct and indirect evaporative cooling may be used to reduce heat stress with less outdoor air. Evaporative cooling normally results in lower effective temperatures than ventilation alone, regardless of the ambient relative humidity.

Effective Temperature. Comfort cooling in air-conditioned spaces is usually based on providing space temperature and relative humidity conditions for human comfort without a draft. The effective temperature relates the cooling effects of air motion and relative humidity to the effect of conditioned (cooled) air. Figure 15 shows an effective temperature chart for air velocities from 0.1 to 3.5 m/s. Although the maximum velocity shown on the chart is 3.5 m/s, workers exposed to high-heat-producing operations may prefer air movement up to 20 m/s to offset the radiant heat effect of equipment. Because the normal working range of the chart is approximately midway between the vertical dry- and wet-bulb scales, changes in either dry- or wet-bulb temperatures have similar effects on worker comfort. A reduction in either one decreases the effective temperature by about one-half of the reduction. Lines ED and CD on the chart show this.

A condition of 35°C db and 24°C wb was chosen as the original state, because this condition is usually considered the summer design criterion in most areas. Reducing the temperature 8 K by evaporating water adiabatically provides an effective temperature reduction of 3 K for air moving at 0.1 m/s and a reduction of 5 K for air moving at 3.5 m/s, an improvement of 2 K.

The reduction in dry-bulb temperature through water evaporation increases the effectiveness of the cooling power of moving air in this example by 137%. On line ED, the effective temperature varies from 28.5°C at 0.1 m/s to 26.5°C at 3.5 m/s with unconditioned air, whereas line CD indicates an effective temperature of 25.5°C at 0.1 m/s and 21.5°C at 3.5 m/s with air cooled by a simple direct evaporative process. In the unconditioned case, increasing the air velocity from 0.1 to 3.5 m/s resulted in only a 2 K decrease in effective temperature. This contrasts with a 4 K decrease in effective temperature for the same range of air movement when the dry-bulb temperature was lowered by water evaporation. This demonstrates that direct evaporative cooling can provide a more comfortable environment regardless of geographical location.

Two methods are demonstrated to illustrate the environmental improvement that may be achieved with evaporative coolers. In one method, shown in Figure 16, temperature is plotted against time of day to show effective temperature depression over time. Curve A shows ambient maximum dry-bulb temperature recordings. Curve B shows the corresponding wet-bulb temperatures. Curve C depicts the effective temperature when unconditioned air is moved over a person at 1.5 m/s. Curve D shows air conditioned in an 80% effective direct evaporative cooler before being projected over the person at 1.5 m/s. Curve E shows the additional decrease in effective temperature with air velocities of 3.5 m/s. Although a maximum suggested effective temperature of 27°C is briefly exceeded with unconditioned air at 1.5 m/s (curve C), both the differential and total hours are substantially reduced from still-air conditions. Curves D and E illustrate that, despite the high wet-bulb temperatures, the in-plant environment can be continuously maintained below the suggested upper limit of 27°C effective temperature. This demonstration assumes that the combination of air velocity, duct length, and insulation between evaporative cooler and duct outlet is such that there is little heat transfer between air in ducts and warmer air under the roof.

Figure 17 shows another method of demonstrating the effect of using direct evaporative coolers by plotting effective comfort zones using ambient wet- and dry-bulb temperatures on a psychrometric chart (Crow 1972). The dashed lines show the expected improvement when using an 80% effective direct evaporative cooler.

Area Cooling

Both direct and indirect evaporative cooling may be used for area or spot cooling of industrial buildings. Both can be controlled either automatically or manually. In addition, evaporative coolers can supply tempered air during fall, winter, and spring. Gravity or power ventilators exhaust the air. Area cooling works well in buildings where personnel move about and workers are not subjected to concentrated, radiant heat sources. Area cooling may be used in either high- or low-bay industrial buildings, but may provide significant advantages in high-bay construction where cooling loads associated with roofs, lighting, and heat from equipment may be effectively eliminated by taking advantage of stratification. When cooling an area, ductwork should be designed to distribute air to the lower 3 m of the space to ensure that cooler air is supplied to the workers.

Cooling requirements change from day to day and season to season, so if discharge grilles are used, they should be adjustable to prevent drafts. The horizontal blades of an adjustable grille can be adjusted so that air is discharged above workers' heads rather than directly on them. In some cases, the air volume can be adjusted, either at each outlet or for the entire system, in which case the exhaust volume may need to be varied accordingly.

Spot Cooling

Spot cooling is a more efficient use of equipment when personnel work in one area. Cool air is brought to the spot at levels below 3 m, and may even be delivered from floor outlets. Duct height may depend on the location of other equipment in the area. For best results, air velocity should be kept low. Controls may be automatic or manual, with the fan often operating throughout the year. Workers are especially appreciative of spot cooling in hot environments, such as in chemical plants and die casting shops, and near glass-forming machines, billet furnaces, and pig and ingot casting.

When spot-cooling a worker, the air volume depends on the throw of the air jet, worker activity, and amount of heat that must be overcome. Air volumes can vary from 90 to 2400 L/s per worker, with target velocities ranging between 1 to 20 m/s. Outlets should be between 1.2 to 3 m from workstations to avoid entrainment of warm air and to effectively blanket workers with cooler air. Workers should be able to control the direction of air discharge, because air motion that is appropriate for hot weather may be too great for cool weather or even cool mornings. Volume controls may be required to prevent overcooling the building and to minimize excessive grille blade adjustment.

Spot cooling is useful in rooms with elevated temperatures, regardless of climatic or geographical location. When the dry-bulb temperature of the air is below skin temperature, convection rather than evaporation cools workers. In these conditions, a 27°C airstream can provide comfort regardless of its relative humidity.

Cooling Large Motors

Electrical generators and motors are generally rated for a maximum ambient temperature of 40°C. When this temperature is exceeded, excessive temperatures develop in the electrical windings unless the load on the motor or generator is reduced. By providing evaporatively cooled air to the windings, this equipment may be safely operated without reducing the load. Likewise, transformer capacity can be increased using evaporative cooling.

Heat emitted by high-capacity electrical equipment may also be sufficient to raise the ambient condition to an uncomfortable level. With mill drive motors, an additional problem is often encountered with the commutator. If the air used to ventilate the motor is dry, the temperature rise through the motor results in a still lower relative humidity, at which the brush film can be destroyed, with unusual brush and commutator wear as well as the occurrence of dusting.

As a rule, a motor with a temperature rise of 14 K requires approximately 60 L/s of ventilating air per kilowatt-hour of loss. If inlet air to the motor is 35°C, air leaving the motor would be 49°C. This average motor temperature of over 42°C is 2 K higher than it should be for the normal 40°C ambient. The same quantity of 35°C db inlet air at 24°C wb can be cooled by a direct evaporative cooler with a 97% saturation effectiveness. The resulting 31°C average motor temperature eliminates the need for special high-temperature insulation and improves the motor's ability to absorb temporary overloads. By comparison, an air quantity of 90 L/s is required if supplied by a cooler with 80% saturation effectiveness.

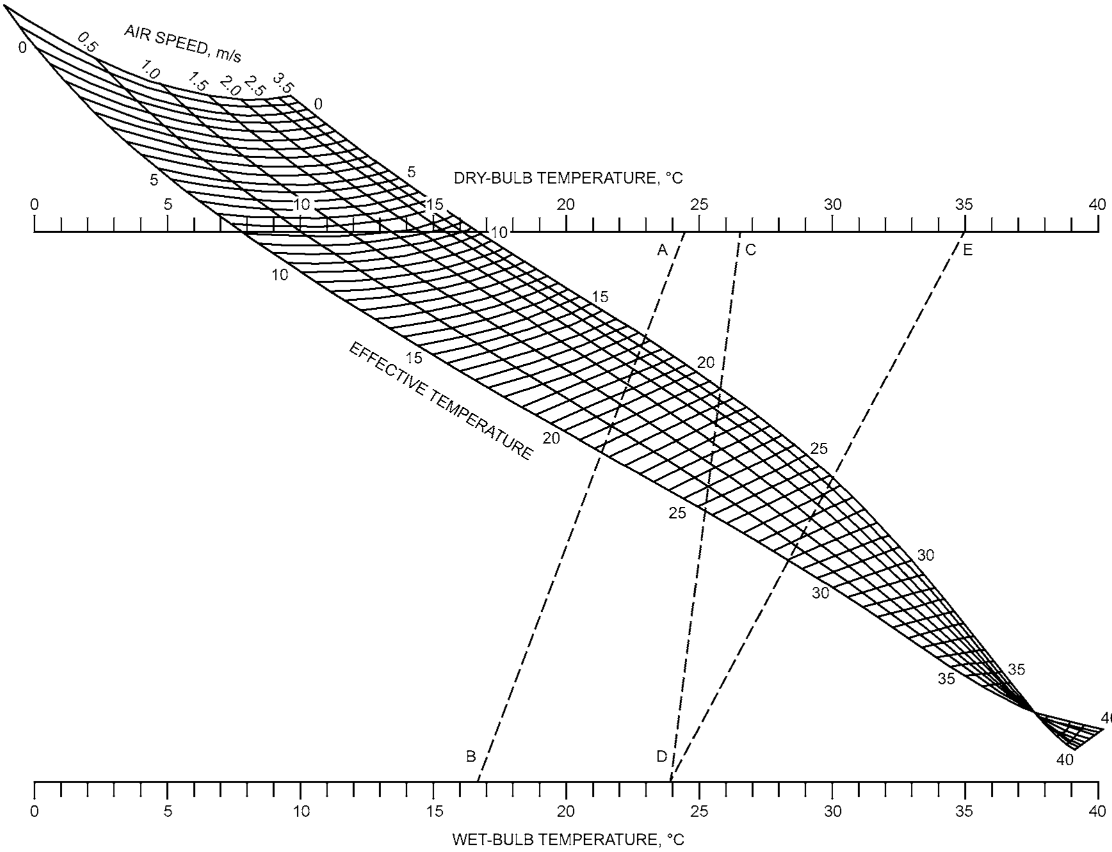

Fig. 15 Effective Temperature Chart

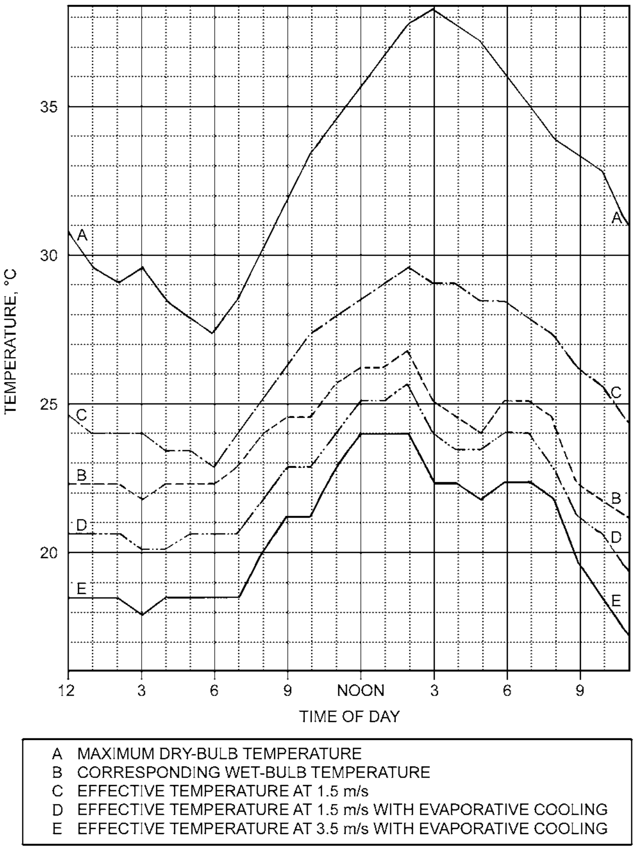

Fig. 16 Effective Temperature for Summer Day in Kansas City, Missouri (Worst-Case Basis)

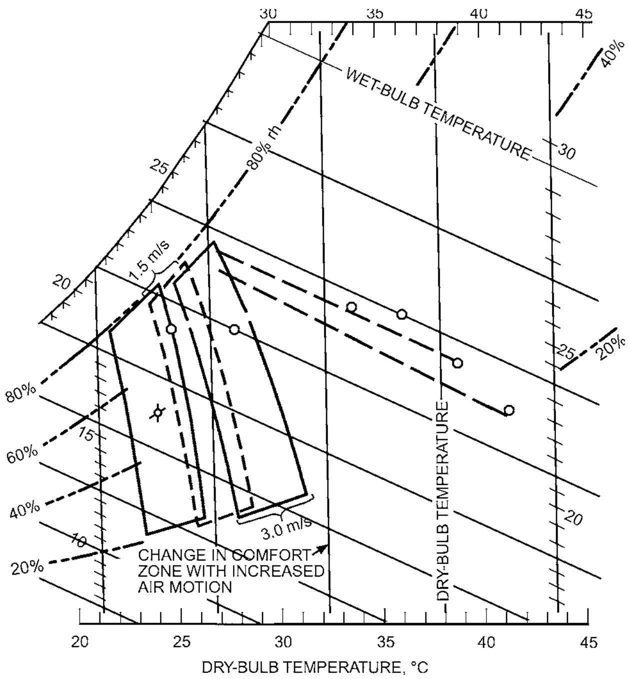

Fig. 17 Change in Human Comfort Zone as Air Movement Increases

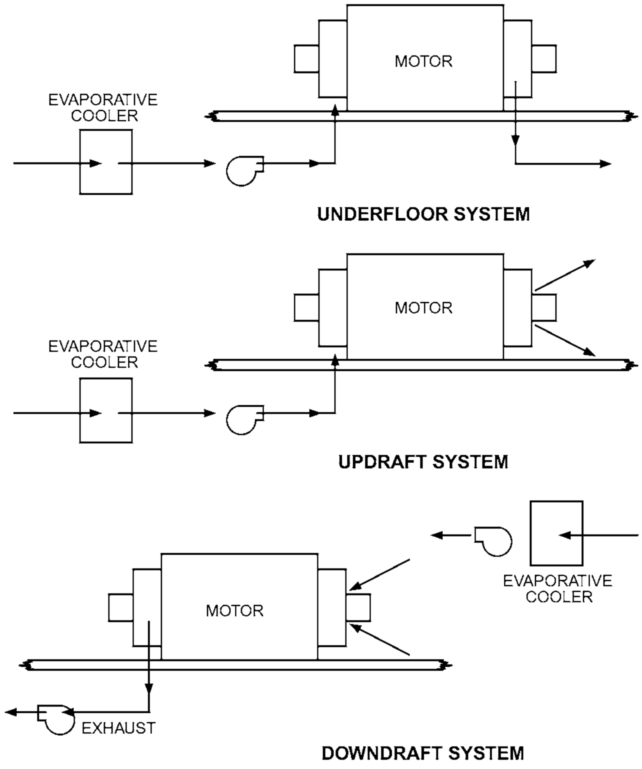

Fig. 18 Arrangements for Cooling Large Motors

Figure 18 shows three basic arrangements for motor cooling. Air from the evaporative cooler may be directed on the motor windings, or into the room; the latter requires greater air volume to compensate for the building heat load. Direct evaporative cooler operation should be keyed to motor operation to ensure that (1) saturated or nearly saturated air is never introduced into a motor until it has had time to warm up, and (2) if more than one motor is served by a single system, air circulation through idle motors should be prevented.

Cooling Gas Turbine Engines and Generators

Combustion turbines used for electric power production are normally rated at 15°C. Their performance is greatly influenced by the compressor inlet air temperature because temperature affects air density and therefore mass flow. As ambient temperature increases, demand on electric utilities increases and combustion turbine capacity decreases. Capacity recovery due to inlet air cooling is approximately 0.2%/K (cooling). Direct and indirect evaporative cooling is beneficial to gas turbine performance in almost all climates because when the air is the hottest, it generally has the lowest relative humidity. Expected increases in output using direct evaporative cooling range from 5.8% in Albany, New York, to 14% in Yuma, Arizona. In addition to increasing gas turbine output, direct evaporative cooling also improves heat rate and reduces NO_x emissions.

For an installation of this type, the following precautions must be taken: (1) mist eliminators must be provided to stop entrainment of free moisture droplets, (2) coolers must be turned off at a temperature below 7°C to prevent icing, and (3) water quality must be monitored closely (Stewart 1999).

Process Cooling

In the manufacture of textiles and tobacco and in processes such as spray coating, the required accurate relative humidity control can be provided by direct evaporative coolers. For example, textile manufacturing requires relatively high humidity and the machinery load is heavy, so a split system is customarily used to introduce free moisture directly into the room. The air handled is reduced to approximately 60% of that normally required by an all-outdoor-air, direct evaporative cooler.

Cooling Laundries

Laundries have one of the most severe environments in which direct evaporative air cooling is applied, because heat is produced not only by the processing equipment, but by steam and water vapor as well. A properly designed direct evaporative cooler reduces the temperature in a laundry 3 to 6 K below the outdoor temperature. With only fan ventilation, laundries usually exceed the outdoor temperature by at least 5 K. Air distribution should be designed for a maximum throw of not more than 9 m. A minimum circulated velocity of 0.5 to 1 m/s should prevail in the occupied space. Ducts can be located to discharge the air directly onto workers in exceptionally hot areas, such as pressing and ironing departments. For these outlets, manual control should be provided to direct the air where it is desired, with at least 250 to 500 L/s at a target velocity of 3 to 4.5 m/s for each workstation.

Cooling Wood and Paper Products Facilities

Wood-processing plants and paper mills are good applications for evaporative cooling because of the high temperatures and gases associated with wood-processing equipment. Wood dust should be kept out of the recirculation sumps of evaporative coolers, because the dust contains microorganisms and worm larvae that will grow in sumps.

Because of the types of gases and particulates present in most paper plants, water-cooled systems are preferred over air-cooled systems. The most prevalent contaminant is wood dust. Chlorine gas, caustic soda, sulfur, hydrogen sulfide, and other compounds are also serious problems, because they accelerate the corrosion of steel and yellow metals. With more efficient air scrubbing, ambient air quality in and about paper mills has become less corrosive, allowing use of equipment with well-analyzed and properly applied coatings on coils and housings. Phosphor-free brazed coil joints should be used in areas where sulfur compounds are present.

Heat is readily available from processing operations and should be used whenever possible. Most plants have good-quality hot water and steam, which can be readily geared to unit heater, central station, or reheat use. Newer plant air-conditioning methods, including evaporative cooling, that use energy-conservation techniques (such as temperature stratification) lend themselves to this type of large structure. Chapter 26 has further information on air-conditioning of paper facilities.

8. OTHER APPLICATIONS

Cooling Power-Generating Facilities

An appropriate air-cooling system can be selected once preliminary heating and cooling loads are determined and criteria are established for temperature, humidity, pressure, and airflow control. The same considerations for selection apply to power-generating facilities and industrial facilities.

Cooling Mines

Chapter 29 describes evaporative cooling methods for mines.

Cooling Animals

The design criteria for farm animal environments and the need for cooling animal shelters are discussed in Chapter 24. Direct evaporative cooling is ideally suited to farm animal shelters because 100% outdoor air is used. Fresh air removes odors and reduces the harmful effects of ammonia fumes. At night and in the spring and fall, direct evaporative cooling can also be used for ventilation.

Equipment should be sized to change the air in the shelter in 1 to 2 min, assuming the ceiling height does not exceed 3 m. This flow rate usually keeps the shelter at or below 27°C. In addition, conditions can be improved with portable or packaged spot coolers.

For poultry housing, most applications require an air change every 0.75 to 1.5 min, with the majority at 1 min. Placing the fans at the ends or the center of the house, with the direct evaporative cooler located at the opposite end, creates a tunnel ventilation system with an air velocity of 1.5 to 2.5 m/s. Fans are generally selected for a total pressure drop of 30 Pa, which means that the direct evaporative cooling media cannot have a pressure drop in excess of 20 Pa. Thus, to prevent an inadequate volume of air being pulled through the poultry house, the designer must carefully size the media selected.

Using direct evaporative cooling for poultry broiler houses decreases bird mortality, improves feed conversion ratio, and increases the growth rate. Poultry breeder houses are evaporatively cooled to improve egg production and fertility during warm weather. Evaporative cooling of egg layers improves feed conversion, shell quality, and egg size. When the ambient outdoor temperature exceeds 38°C, evaporative cooling is often the only way to keep a flock alive. Direct evaporative cooling is also used to cool swine farrowing and gestation houses to improve production.

Produce Storage Cooling

Potatoes. Direct evaporative cooling for bulk potato storage should pass air directly through the pile. The ventilation and cooling system should provide 10 to 15 mL/s per kilogram of potatoes. Average potato density is 720 kg/m^3 in the pile. Pile depths range from 3.5 to 6 m, which creates a static pressure of 40 to 60 Pa. Ventilation consists of fresh air inlets, return air openings, exhaust air openings, main air ducts, and lateral ducts with holes or slots to distribute air uniformly through the pile. Distribution ducts should be placed no farther apart than 80% of the potato pile depth, and should extend to within 450 mm of the storage walls. Ducts, the direct evaporative cooling media, and any refrigeration coils cause a static pressure ranging from 120 to 250 Pa. Typically the total static pressure ranges from 200 to 300 Pa, depending on the equipment. Air speed through each of the openings in the ventilation/cooling system should be as listed in Table 5.

Direct evaporative cooling media should be 90 to 95% effective, depending on the climate. In arid regions, 95% effective media are recommended. In more humid climates, such as in the midwestern and eastern United States, 90% effective media are commonly used. Air speed through the media should be 2.5 to 2.8 m/s to ensure high pad efficiency with low static-pressure penalty.

For more information, see Chapter 37 of the 2018 *ASHRAE Handbook—Refrigeration*.

Apples. Direct evaporative cooling for apple storage without refrigeration should distribute cool air to all parts of the storage. The evaporative cooler may be floor-mounted or located near the

Table 5 Air Speed for Potato Storage Evaporative Cooler

Opening	Minimum Speed, m/s	Maximum Speed, m/s	Desired Speed, m/s
Fresh air inlet	5	7	6
Return air opening	5	7	6
Exhaust opening	5	6	5.5
Main duct	2.5	4.5	3.5
Lateral duct	3.8	5.5	4.5
Slot	4.5	6.5	5.3

ceiling in a fan room. Air should be discharged horizontally at ceiling level. Because the prevailing wet-bulb temperature limits the degree of cooling, a cooler with maximum reasonable size should be installed to reduce the storage temperature rapidly and as close to the wet-bulb temperature as possible. Generally, a cooler designed to exchange air every 3 min (20 air changes per hour) is the largest that can be installed. This capacity provides a complete air change every 1 to 1.5 min (40 to 60 air changes per hour) when the storage is loaded.

For further information on apple storage, see Chapter 35 of the 2018 *ASHRAE Handbook—Refrigeration*.

Citrus. The chief purpose of evaporative-cooling fruits and vegetables is to provide an effective, inexpensive means of improving storage. However, it also serves a special function in the case of oranges, grapefruit, and lemons. Although mature and ready for harvest, citrus fruits are often still green. Color change (degreening) is achieved through a sweating process in rooms equipped with direct evaporative cooling. Air with a high relative humidity and a moderate temperature is circulated continuously during the operation. Ethylene gas, the concentration depending on the variety and intensity of green pigment in the rind, is discharged into the rooms. Ethylene destroys chlorophyll in the rind, allowing the yellow or orange color to become evident. During degreening, a temperature of 21°C and a relative humidity of 88 to 90% are maintained in the sweat room. (In the Gulf States, 28 to 30°C with 90 to 92% rh is used.) The evaporative cooler is designed to deliver 1.1 L/s per kilogram of fruit.

Direct and indirect evaporative cooling is also used as a supplement to refrigeration in the storage of citrus fruit. Citrus storage requires refrigeration in the summer, but the required conditions can often be obtained using evaporative cooling during the fall, winter, and spring when the outdoor wet-bulb temperature is low. For further information, see Chapter 36 of the 2018 *ASHRAE Handbook—Refrigeration*.

Cooling Greenhouses

Proper regulation of greenhouse temperatures during the summer is essential for developing high-quality crops. The principal load on a greenhouse is solar radiation, which at sea level at about noon in the temperate zone is approximately 630 W/m². Smoke, dust, or heavy clouds reduce the radiation load. Table 6 gives solar radiation loads for representative cities in the United States. Note that the values cited are average solar heat gains, not peak loads. Temporary rises in temperature inside a greenhouse can be tolerated; an occasional rise above design conditions is not likely to cause damage.

Not all solar radiation that reaches the inside of the greenhouse becomes a cooling load. About 2% of the total solar radiation is used in photosynthesis. Transpiration of moisture varies by crop, but typically uses about 48% of the solar radiation. This leaves 50% to be removed by the cooler. Example 2 shows a method for calculating the size of a greenhouse evaporative cooling system.

Example 2. A direct evaporative cooler is to be installed in a 15 by 30 m greenhouse. Design conditions are 34°C db and 23°C wb, and average solar radiation is 435 W/m². An indoor temperature of 32°C db must not be exceeded at design conditions.

Solution: The direct evaporative air cooler is assumed to have a saturation effectiveness of 80%. Equation (2) may be used to determine the dry-bulb temperature of the air leaving the direct evaporative cooler:

$$t_2 = 34 - \frac{80}{100}(34 - 23) = 25.2°\text{C}$$

The following equation, a modification of Equation (1), may be used to calculate the airflow rate that must be supplied by the direct evaporative cooler:

$$Q_{ra} = \frac{0.5 A I_t}{\rho c_p (t_1 - t_2)} \tag{4}$$

where

A = greenhouse floor area, m²
I_t = total incident solar radiation, W/m² of receiving surface
ρc_p = density times specific heat of air ≈ 1150 J/(m³·K) at design conditions

For this problem

$$Q_{ra} = \frac{0.5 \times 15 \times 30 \times 435}{1150(32 - 25.2)} = 12.5 \text{ m}^3/\text{s}$$

Horizontal illumination from the direct rays of noonday summer sun with clear sky can be as much as 100 klx; under clear glass, this is approximately 90 klx. Crops such as chrysanthemums and carnations grow best in full sun, but many foliage plants, such as gloxinias and orchids, do not need more than 16 to 22 klx. Solar radiation is nearly proportional to light intensity. Thus, the greater the amount of shade, the smaller the cooling capacity required. A value of 1 klx is approximately equivalent to 9 W/m². Although atmospheric conditions such as clouds and haze affect the relationship, this is a safe conversion factor. This relationship should be used instead of Table 5 when illumination can be determined by design or measurement.

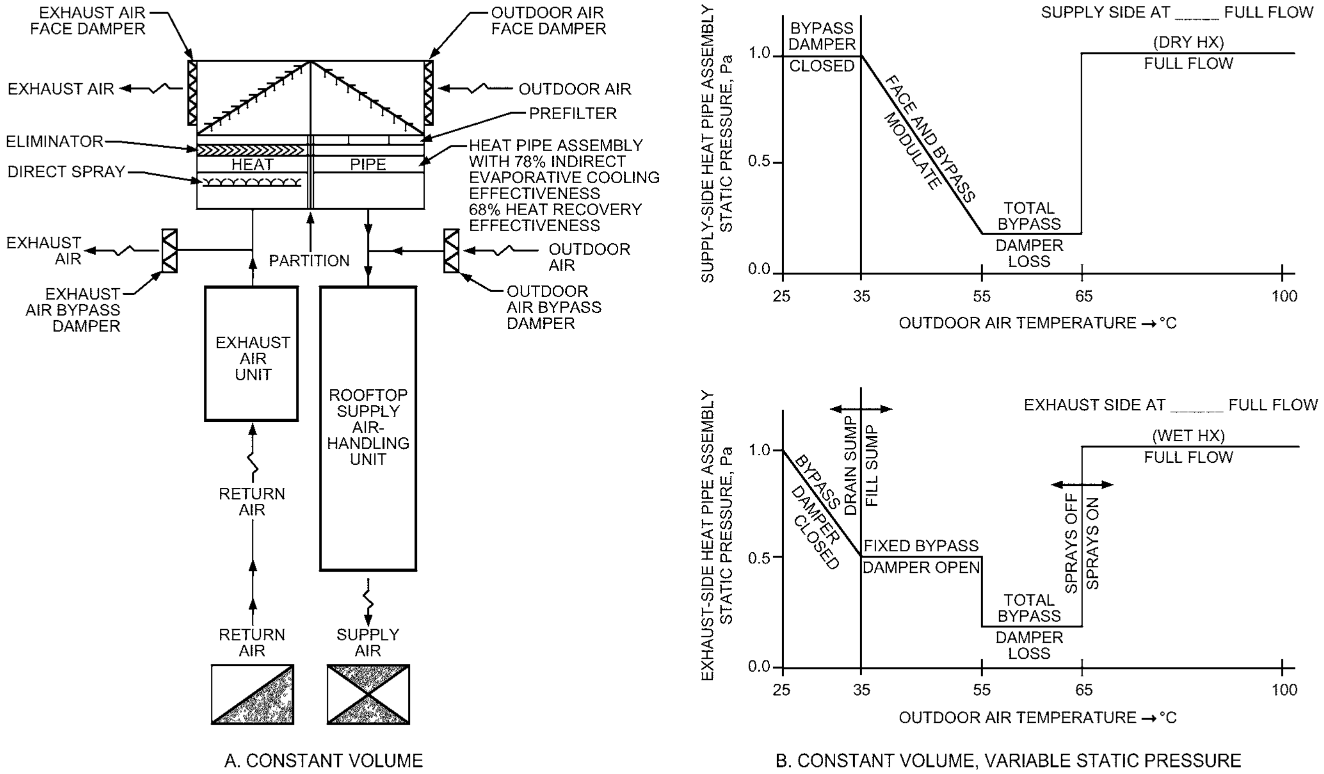

Fig. 19 Schematics for 100% Outdoor Air Used in Hospital

Direct evaporative cooling for greenhouses may be under either positive or negative pressure. Regardless of the type of system used, the length of air travel should not exceed 50 m. The temperature rise of the cool air limits the throw to this value. Air movement must be kept low because of possible mechanical damage to the plants, but it should generally not be less than 0.5 m/s in areas occupied by workers.

9. CONTROL STRATEGY TO OPTIMIZE ENERGY RECOVERY

Figures 19A and 19B show a heat pipe air-to-air heat exchanger used in a hospital for winter heat recovery and summer indirect (dry) evaporative cooling. The heat pipe has a double-walled partition between the clean outdoor air (OA) flow and the contaminated building exhaust air (EA). With this partition, leakage from the EA side of the heat exchanger to the supply air (SA) side is eliminated and fans may be positioned as shown for blow-through exhaust and draw-through supply. The heat pipe has a direct spray manifold on the building return air side of the heat exchanger for indirect evaporative cooling. The spray pump is located in a water sump below the wet side of the heat pipe and uses recirculated water from the sump to wet the heat pipe. Potable makeup water is supplied to replace the water evaporated in the indirect cooling process along with wasted water required to maintain dissolved solids in the sump at acceptable levels. Using the building return air wet-bulb condition of 15.5 to 18°C, the summer cooling effect is greatly increased over dry-to-dry heat recovery.

The operation of both outdoor (OA) and exhaust air (EA) face and bypass dampers, working in concert with supply and return fan variable-frequency drives (VFD), allow parasitic fan static pressure losses to be minimized during favorable climatic conditions. Figure 19B shows a total bypass of the heat exchanger in the range of ambient temperatures of 13 to 18°C. The value of energy recovered is exceeded by the fan energy penalty during these outdoor air temperatures.

Table 7 Particulate Removal Efficiency of Rigid Media at 2.54 m/s Air Velocity

Media Depth, mm	Particle Sizes, µm

10. AIR CLEANING AND SOUND ATTENUATION

Evaporative coolers can effectively improve IAQ in many ways. Their similarity to wet scrubbers means they can remove particulates and soluble gases. Direct evaporative coolers of all types perform some air cleaning. Rigid-media direct evaporative coolers are effective at removing particles down to about 1 µm. Air washers are effective down to about 10 µm.

The dust removal efficiency of direct evaporative coolers depends largely on the size, density, wettability, and solubility of the dust particles. Larger, more wettable particles are the easiest to remove. Separation is largely a result of the impingement of particles on the wetted surface of the eliminator plates or on the surface of the media. Because the force of impact increases with the size of the solid, the impact (together with the adhesive quality of the wetted surface) determines the cooler's usefulness as a dust remover. Table 7 gives an overview of particle removal efficiency for different filtration media depths.

The standard low-pressure spray is relatively ineffective in removing most atmospheric dusts. Direct evaporative coolers are of little use in removing soot particles because their greasy surface will not adhere to the wet plates or media. Direct evaporative coolers are also ineffective in removing smoke, because the small particles (less than 1 µm) do not impinge with sufficient impact to pierce the water film and be held on the media. Instead, the particles follow the air path between the media surfaces.

Table 8 Insertion Loss for 300 mm Depth of Rigid Media at 2.8 m/s Air Velocity, dB

Media Orientation	Octave Band Center Frequency, Hz							
	63	125	250	500	1000	2000	4000	8000
Dry, forward flow	2	1	2	5	4	5	10	14
Reverse flow	4	1	2	4	5	4	9	13
Wet, forward flow	1	0	3	3	3	4	6	9
Reverse flow	3	1	3	3	3	3	4	8

Source: Data courtesy of Munters Corporation.

In the case of cross-corrugated media, the particles are removed from the media by the recirculated water. In locations with high particulate contamination, the sump and water distribution system should be flushed at least quarterly. If the particulate contains organic matter, it can contribute to biological growth on the media.

Control of Gaseous Contaminants

When used in a makeup air system comprised of a mixture of outdoor air and recirculated air, direct evaporative coolers function as scrubbers and reduce some gaseous contaminants found in outdoor air. These contaminants may concentrate in the recirculating water, so some water must be bled off. For more information regarding control of gaseous contaminants, see Chapter 46.

Evaporative coolers near sources of airborne nitric acid, chlorine, or ammonia absorb these chemicals, which can damage the cooler. The amount of soluble gases cleaned from the air depends on the air/water mixing, retention time, the water's pH, and the bleed rate. When exposed to soluble gases, evaporative coolers should be operated with a high bleed rate.

Ozone levels of the airstream can be reduced using evaporative coolers and air washers. Ozone is fairly unstable in a watery solution, decaying to ordinary diatomic oxygen. The stability of ozone absorbed in water depends on water temperature, ozone concentration, and length of holding time. Higher room humidity can vastly improve the rate at which it decays back to oxygen (Sterling et al. 1985).

Legionnaires' Disease. There have been no known cases of Legionnaires' disease with air washers or wetted-media evaporative air coolers. This is can be attributed to the low temperature of the recirculated water, which is not conducive to *Legionella* bacteria growth, as well as the absence of aerosolized water carryover that could transmit the bacteria to a host (ASHRAE *Guideline* 12-2000).

Evaporative cooler media can attenuate sound attenuation somewhat. This insertion loss varies, depending on whether the media is wet or dry and whether the sound is traveling counter to (reverse flow) or with (forward flow) the airstream. Sound attenuation for 300 mm depth of rigid media can be found in Table 8. Components in the path of airflow in an air-handler plenum or duct provide some sound attenuation; one of the more effective at reducing sound pressure levels is the rigid-media direct evaporative cooler (DEC). Periannan (2013) performed tests in accordance with ASTM *Standard* E477-90 to measure insertion losses (1) with airflow in the direction of sound and (2) with reverse airflow. Measurements were also made at different velocities and for different media depths. As Table 8 shows, a rigid-media DEC is quite effective in reducing low-frequency noise levels, which are usually the most difficult to reduce. Rigid media should likely not be used purely as a sound attenuator, but noise reduction can be an additional benefit when these types are selected.

11. ECONOMIC FACTORS

Design of direct and indirect evaporative cooling systems and sizing of equipment are based on the application's load requirements and on the local dry- and wet-bulb design conditions, which may be found in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* (with extended data and locations on the CD accompanying that volume, and in the Handbook Online version of that chapter). Total energy use for a specific application during a set period may be forecasted by using annual weather data. Dry-bulb and mean coincident wet-bulb temperatures, with the hours of occurrence, can be summarized and used in a modified bin procedure. The calculations must reflect the hours of use, conditions of load, and occupancy. Because of annual variations in dry- and wet-bulb temperatures and the effect of increasing cooling capacity with decreasing wet-bulb temperatures, bin calculations using mean coincident wet-bulb temperatures generally produce conservative results. When comparing various cooling systems, cost analysis should include annual energy reduction at the applicable electrical rate, plus anticipated energy cost escalation over the expected life.

Many areas have time-of-day electrical metering as an incentive to use energy during off-peak hours when rates are lowest. Reducing air-conditioning kilowatt demand is especially important in areas with ratcheted demand rates (Scofield and DesChamps 1980). Thermal storage using ice banks or chilled-water storage may be used as part of a multistage evaporatively refrigerated cooler to combine the energy-saving advantages of evaporative cooling and off-peak savings of thermal storage (Eskra 1980).

Direct Evaporation Energy Saving

Direct evaporative cooling may be used in all climates to save cooling and humidification energy. In humid climates, the benefits of direct evaporation are realized during periods when outdoor air is warm and dry, but cooling savings are unlikely to be realized during peak design conditions. In more arid areas, direct evaporative cooling may partially or fully offset mechanical cooling at peak load conditions. Humidification energy savings may be realized during the heating season when outdoor air is used to provide cooling and humidification. If properly controlled, direct evaporative cooling can use waste heat otherwise rejected from buildings when outdoor air is used for cooling.

Indirect Evaporation Energy Saving

Indirect evaporative cooling may be used in all climates to save cooling and, in some applications, heating energy. In humid climates, indirect evaporative cooling may be used throughout the cooling cycle to precool outdoor air. Indirect evaporative cooling can be used to extend the range of 100% outdoor air ventilation to both higher and lower temperatures, and to increase the percentage of outdoor air a system can support at any given temperature through heat recovery. In high-humidity areas, indirect evaporative cooling may be used to (1) partially offset mechanical cooling requirements at peak load conditions and (2) provide better control over low-load humidity conditions by allowing use of smaller refrigeration equipment to provide ventilation over a wider range of outdoor air conditions. The cost of heating may be reduced when operating below temperatures at which minimum outdoor air quantities exceed the rates of ventilation required for free cooling by using heat recovered from building exhausts.

Water Cost for Evaporative Cooling

Typically, domestic service water is used for evaporative cooling to avoid excessive scaling and associated problems with poor water quality. In designing evaporative coolers, the cost of water treatment is included in the overall project cost. However, water cost is typically ignored for evaporative coolers because it is usually an insignificant part of the operational cost. Depending on the ambient dry-bulb temperature and wet-bulb depression for a specific location, the cost of water could become a significant part of the operational cost, because the greater the differential between dry- and wet-bulb temperatures, the greater the amount of water evaporated (Mathur 1997, 1998).

12. PSYCHROMETRICS

Figure 20 shows the two-stage (indirect/direct) process applied to nine cities in the western United States. The examples indicated are primarily shown for arid areas, but the principles also apply to moderately humid and humid areas when weather conditions allow. For each city indicated, the entering conditions to the first-stage indirect unit are at or near the 0.4% design dry- and wet-bulb temperatures in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*. Although higher effectiveness can be achieved for both the indirect and direct evaporative processes modeled, the effectiveness ratings are 60% for the first (indirect) stage and 90% for the second (direct) stage. Leaving air temperatures range from 11 to 21°C, with leaving conditions approaching saturation.

Figure 21 projects space conditions in each city at 25.5°C db for these second-stage supply temperatures based on a 95% room sensible heat factor (i.e., room sensible heat/room total heat). Except in Wichita, Los Angeles, and Seattle, room conditions can be maintained in the comfort zone without a refrigerated third stage. But even in these cities, third-stage refrigeration requirements are sharply reduced as compared to conventional mechanical cooling. However, Figures 20 and 21 indicate the need to consider the following factors when deciding whether to include a third cooling stage:

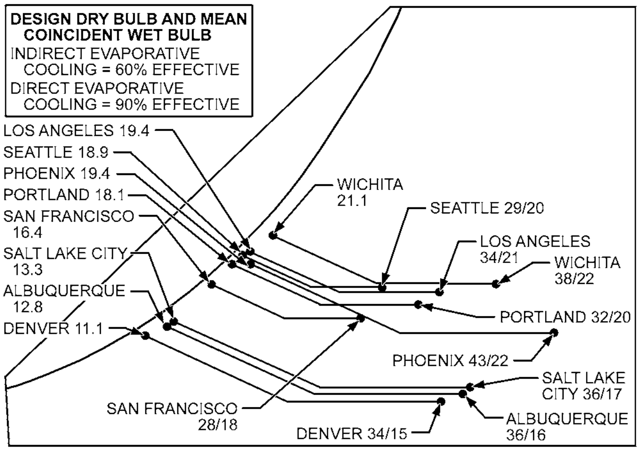

Fig. 20 Two-Stage Evaporative Cooling at 0.4% Design Condition in Various Cities in Western United States

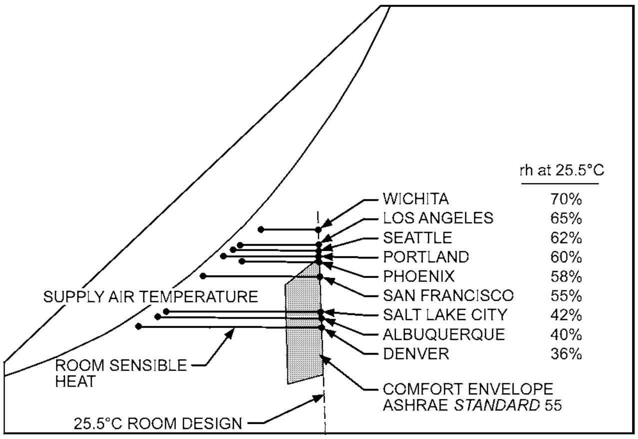

Fig. 21 Final Room Design Conditions After Two-Stage Evaporative Cooling

- As the room sensible heat factor decreases, the supply air temperature required to maintain a given room condition decreases.
- As supply air temperature increases, the supply air quantity must increase to maintain space temperature, which results in higher air-side initial cost and increased supply air fan power.
- A decrease in the required room dry-bulb temperature requires an increase in the supply air quantity. For a given room sensible heat factor, a decrease in room dry-bulb temperature may cause the relative humidity to exceed the comfort zone.
- The suggested 0.4% entering design (dry-bulb/mean wet-bulb) conditions are only one concern. Partial-load conditions must also be considered, along with the effect (extent and duration) of spike wet-bulb temperatures. Mean wet-bulb temperatures can be used to determine energy use of the indirect/direct system. However, the higher wet-bulb temperature spikes should be considered to determine their effect on room temperatures.

An ideal condition for maximum use with minimum energy consumption of a two- and three-stage indirect/direct system is a room sensible heat factor of 90% and higher, a supply air temperature of 16°C, and a dry-bulb room design temperature of 25.5°C. In many cases, third-stage refrigeration is required to ensure satisfactory dry-bulb temperature and relative humidity. Example 3 shows a method for determining the refrigeration capacity for three-stage cooling. Figure 22 is a psychrometric diagram of the process.

Example 3. Assume the following:

- Supply air quantity = 11.3 m^3/s; supply air temperature = 16°C
- Design condition = 37°C db and 20°C wb
- Effectiveness of indirect unit = 60%;
- Effectiveness of direct unit = 90%

Using Equation (2), the leaving air state from the indirect unit (first stage) is

$$37 - 0.60(37 - 20) = 26.8\text{°C db (16.6°C wb)}$$

Using Equation (2), the leaving air state from the direct unit (second stage) is

$$26.8 - 0.90(26.8 - 16.6) = 17.6\text{°C db (16.6°C wb)}$$

Calculate booster refrigeration capacity to drop the supply air temperature from 17.6°C to the required 16°C.

If the refrigerating coil is located ahead of the direct unit,

$$\text{kW cooling} = \frac{(h_1 - h_2)(\text{supply air, L/s})}{\text{Specific volume dry air at leaving air condition}}$$

With numeric values of enthalpies h_1 and h_2 (in kJ/kg) and the specific volume of air (in m^3/kg_{da}) taken from ASHRAE psychrometric chart no. 1, the cooling load is calculated as follows:

$$(46.5 - 42.8)11.3/0.860 = 48.6 \text{ kW}$$

The load for a coil located in the leaving air of the direct unit is

$$(46.6 - 42.9)11.3/0.838 = 49.9 \text{ kW}$$

Depending on the booster coil's location, the preceding calculations can be used to determine third-stage refrigeration capacity and to select a cooling coil.

Using this example, refrigeration sizing can be compared to conventional refrigeration without staged evaporative cooling. Assuming mixed air conditions to the coil of 27°C db and 19.1°C wb, and the same 16°C db supply air as shown in Figure 21, the refrigerated capacity is

$$(54.1 - 42.9)11.3/0.833 = 152 \text{ kW}$$

This represents an increase of 103 kW. The staged evaporative effect reduces the required refrigeration by 68%.

13. ENTERING AIR CONSIDERATIONS

The effectiveness of direct and indirect evaporative cooling depends on the entering air condition. Where outdoor air is used in

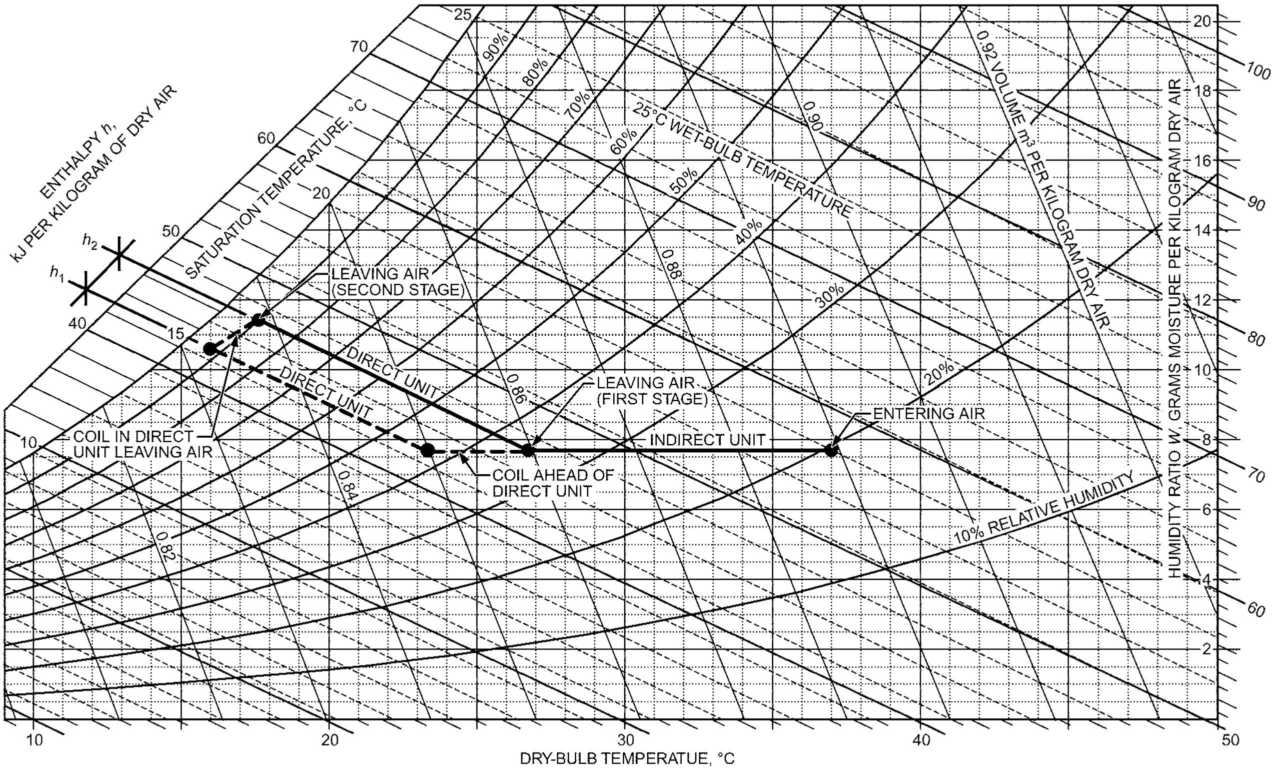

Fig. 22 Psychrometric Diagram of Three-Stage Evaporative Cooling Example 3

a direct evaporative cooler, the design is affected by the prevailing outdoor dry- and wet-bulb temperatures as well as by the application. Where conditioned exhaust air is used as secondary air for indirect evaporative cooling, the design is less affected by local weather conditions, which makes evaporative cooling viable in hot and humid environments.

For example, in arid areas like Reno, Nevada, a simple, direct evaporative cooler with an effectiveness of 80% provides a leaving air temperature of 19.8°C when dry- and wet-bulb temperatures of the entering air are 35 and 16°C, respectively. In the same location, adding an indirect evaporative precooling stage with an effectiveness of 80% produces a leaving air condition of 12°C.

In a location such as Atlanta, Georgia, with design temperatures of 34 and 23.5°C, the same direct evaporative cooler could supply only 25.6°C. This could be reduced to 22.1°C by adding an 80% effective indirect evaporative precooling stage (Supple 1982). If exhaust air from the building served is provided at a stable 24°C db and 17°C wb, an indirect evaporative precooler could deliver air at 20.5°C, substantially reducing outdoor air cooling loads. Under these conditions, indirect evaporative precoolers can provide limited dehumidification capabilities.

Long-term benefits to owners of direct evaporative cooling systems include a 20 to 40% reduction of utility costs compared to mechanical refrigeration (Watt 1988). When used to control humidity, the reduction in cooling and humidification energy use ranges from 35 to 90% (Lentz 1991). Although direct evaporative cooling does not reduce peak cooling loads except in arid areas, it can reduce both total cooling energy and humidification energy requirements in a wide range of environments, including hot and humid ones.

Indirect evaporative cooling lowers the temperature (both dry- and wet-bulb) of the air entering a direct evaporative cooling stage and, consequently, lowers the supply air temperature. When used with mechanical cooling on 100% outdoor air systems, with the secondary air taken from the conditioned space, the precooling effect may reduce peak cooling loads between 50 and 70%. Total cooling requirements may be reduced between 40 and 85% annually, depending on location, system configuration, and load characteristics. Indirect evaporative coolers may also function as heat recovery systems, which expands the range of conditions over which the process is used. Indirect evaporative cooling, when used with building exhaust air, is especially effective in hot and humid climates.

Extraordinary Incidents 54.24
Symbols 54.25

SMOKE, which causes the most deaths in fires, consists of airborne solid and liquid particles and gases produced when a material undergoes pyrolysis or combustion, together with air that is entrained or otherwise mixed into the mass. In building fires, smoke often flows to locations remote from the fire, threatening life and damaging property. Stairwells and elevators frequently fill with smoke, thereby blocking or inhibiting evacuation.

The idea of using pressurization to prevent smoke infiltration of stairwells began to attract attention in the late 1960s. This concept was followed by the idea of the pressure sandwich (i.e., venting or exhausting the fire floor and pressurizing the surrounding floors). Frequently, a building's HVAC system is used for this purpose. This chapter focuses on smoke control systems in buildings, including the relationship between smoke control and HVAC. A **smoke control system** is an engineered system that modifies smoke movement for the protection of building occupants, firefighters and property. The focus of code-mandated smoke control is life safety.

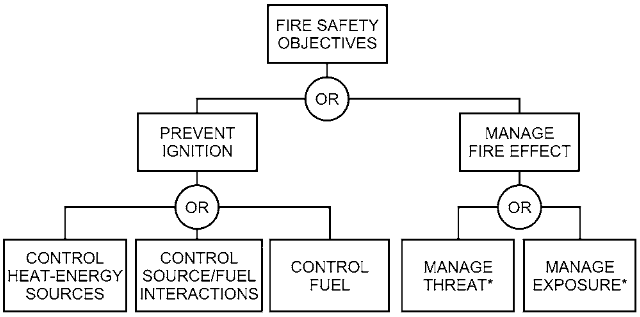
For an extensive technical treatment of smoke control and related topics, see the *Handbook of Smoke Control Engineering* (Klote et al. 2012), referred to in this chapter as the *Smoke Control Handbook*. For those interested in the theoretical foundations of smoke control, the *Smoke Control Handbook* includes an appendix of derivations of equations.

National Fire Protection Association (NFPA) *Standard* 92 provides information about smoke control systems for buildings. For further information about heat and smoke venting for large industrial and storage buildings, see NFPA *Standard* 204.

The objective of fire safety is to provide some degree of protection for a building's occupants, the building and property inside it, and neighboring buildings. Various forms of analysis have been used to quantify protection. Specific life safety objectives differ with occupancy; for example, nursing homes have different requirements than office buildings do.

Two basic approaches to fire protection are (1) to prevent fire ignition and (2) to manage fire effects. Figure 1 shows a decision tree for fire protection. Building occupants and managers have the primary role in preventing fire ignition, though the building design team may incorporate features into the building to support this effort. Because it is impossible to prevent fire ignition completely, managing fire's effects is significant in fire protection design. Examples include compartmentalization, suppression, control of construction materials, exit systems, and smoke control. The *SFPE Handbook of Fire Protection Engineering* (SFPE 2016) contains detailed fire safety information.

The preparation of this chapter is assigned to TC 5.6, Control of Fire and Smoke.



**Note*: Smoke control is one of many fire protection tools that can be used to help manage the threat and exposure of fire.

Fig. 1 Simplified Fire Protection Decision Tree

Historically, fire safety professionals have considered the HVAC system a potentially dangerous penetration of natural building membranes (walls, floors, etc.) that can readily transport smoke and fire. For this reason, HVAC has traditionally been shut down when fire is discovered; this prevents fans from forcing smoke flow, but does not prevent ducted smoke movement caused by buoyancy, stack effect, or wind. Smoke control methods have been developed to address smoke movement; however, smoke control should be viewed as only one part of the overall building fire protection system.

1. BALANCED APPROACH TO FIRE PROTECTION

Many codes and standards seek a balanced approach to fire protection consisting of detection, suppression, and occupant protection. This approach results in highly reliable protection from the threat of fire. A NFPA study (Ahrens 2017) based on data from the National Fire Incident Reporting System provides reliability information for automatic sprinkler protection. The report states "In fires considered large enough to activate the sprinkler, sprinklers operated 92% of the time. Sprinklers were effective in controlling the fire in 96% of the fires in which they operated. Taken together, sprinklers both operated and were effective in 88% of the fires large enough to operate them." This means that sprinklers have an overall reliability of 88% (or, put another way, an overall failure rate of 12%).

In general, such reliability data are not available for other fire safety features such as detectors, fire alarms, fire-resistant construction, fire stopping, or smoke control. Smoke control is particularly important because it provides protection for occupants from the threat of smoke. It is generally recognized that fires that have resulted in loss of life have had failures of one or more fire safety features. With the balanced approach, if one or more fire safety feature fails, other features will continue to provide a level of protection, thereby providing greater reliability of fire protection than any single system.

2. FIRE STOPPING AT HVAC PENETRATIONS

Although most of this chapter discusses smoke control, fire management at HVAC penetrations is also a concern. Fire-rated assemblies (e.g., floor or walls) keep the fire in a given area for a specific period. However, fire can easily pass through openings for plumbing, HVAC ductwork, communication cables, or other services. Therefore, fire stop systems are installed to maintain the rating of the fire-rated assembly. The rating of a fire stop system depends on the number, size, and type of penetrations, and the construction assembly in which it is installed.

Performance of the entire fire stop system, which includes the construction assembly with its penetrations, is tested under fire conditions by recognized independent testing laboratories. ASTM *Standard* E814 and UL *Standard* 1479 describe ways to determine performance of **through-penetration fire stopping (TPFS)**.

TPFS is required by building codes under certain circumstances for specific construction types and occupancies. In the United States, the model building codes require that most penetrations pass ASTM *Standard* E814 testing. TPFS classifications are published by testing laboratories. Each classification is proprietary, and each applies to use with a specific set of conditions, so numerous types are usually required on any given project.

The construction manager and general contractor, not the architects and engineers, make work assignments. Sometimes they assign fire stopping to the discipline making the penetration; other times, they assign it to a specialty fire-stopping subcontractor. The Construction Specifications Institute (CSI 2018) assigns fire-stopping specifications to Division 7, Thermal and Moisture Protection, which

- Encourages continuity of fire-stopping products on the project by consolidating their requirements (e.g., TPFS, expansion joint fire stopping, floor-to-wall fire stopping, etc.)
- Maintains flexibility of work assignments for the general contractor and construction engineer
- Encourages prebid discussions between the contractor and subcontractors regarding appropriate work assignments

3. FIRE AND SMOKE DAMPERS

Dampers are used for one or more of the following purposes: (1) balancing flow by adjusting airflow in HVAC system ducts, (2) controlling flow (for HVAC purposes), (3) resisting passage of fire (**fire dampers**), (4) resisting heat transfer (**ceiling radiation dampers**), and (5) resisting passage of smoke (**smoke dampers**). Dampers that are intended to resist the passage of both fire and smoke are called **combination fire and smoke dampers**. All dampers should be installed in accordance with manufacturer's recommendations. For more detailed information about dampers, including pressure losses, flow characteristics, actuators, installation, and balancing, see Felker and Felker (2009).

The UL *Standard* 555 series (555, 555S, and 555C) includes reliability testing provisions for each type of damper, the heat-responsive device, and the actuator (if used). Among the tests are cycling (20 000 full cycles for two-position dampers and 100 000 cycles for modulating dampers), structural integrity, salt spray for accelerated lifespan testing, hose stream spray, elevated temperatures, and leakage.

Fire Dampers

Fire dampers are intended to prevent the spread of flames from one part of the building to another through the ductwork. They are not expected to prevent airflow between building spaces, because gaps of up to 9.5 mm are allowed for operating clearances. Fire dampers are rated to indicate the time they can be exposed to flames and still maintain their integrity, with typical ratings of 3 h, 1.5 h, 1 h, and less than 1 h. Fire dampers are two-position devices (open or closed), and are usually of either the multiblade (Figure 2) or curtain design (Figure 3). Most multiblade fire dampers are held open by a fusible link and are spring loaded. In a fire, hot gases cause this link to come apart so that the spring makes the blades slam shut. Some applications use other heat-responsive devices in place of fusible links. Typically, curtain dampers are also held open by a fusible link that comes apart when heated. Vertical static curtain dampers often rely on gravity to make the blades close off the opening, but horizontal (ceiling) and all dynamic curtain dampers must have spring closure. Dynamic dampers are for applications where the damper may be required to close against airflow, such as an HVAC system that remains operational for smoke control purposes. In the United States, fire dampers are usually made and labeled in accordance with UL *Standard* 555. This standard addresses fire dampers intended for use (1) where air ducts penetrate or terminate at openings in walls or partitions, (2) in air transfer openings, and (3) where air ducts extend through floors.

Ceiling Radiation Dampers

Ceiling radiation dampers are designed and tested to UL *Standard* 555C. These dampers prevent heat transfer; they have some resistance to fire and smoke, but are not tested for fire and smoke passage.

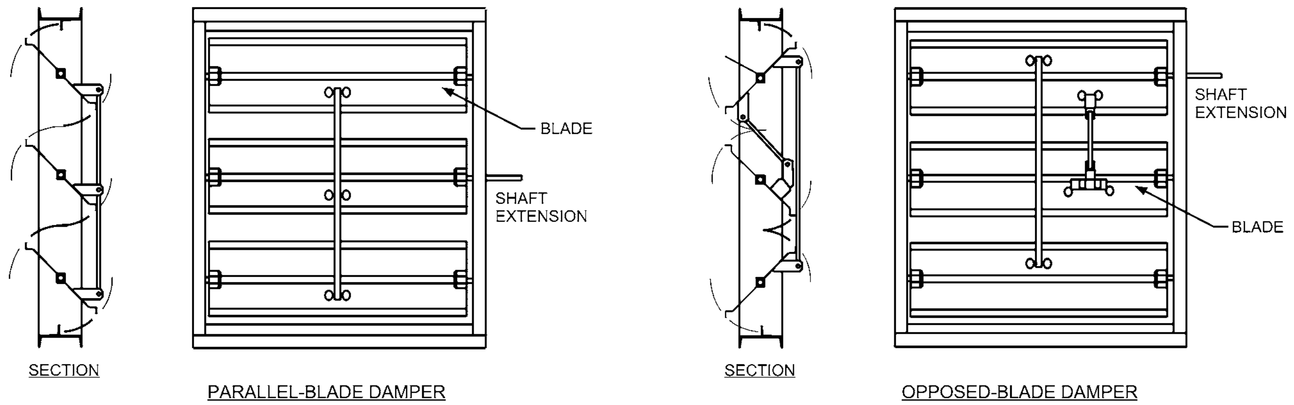


Fig. 2 Multiblade Dampers

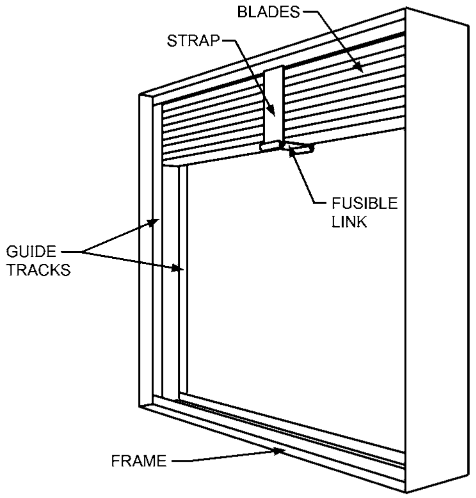

Fig. 3 Curtain Fire Damper

Smoke Dampers

Smoke dampers are intended to seal tightly to prevent the spread of smoke from one part of the building to another through the ductwork, and to allow an engineered smoke control system to build up pressures across zone boundaries. A smoke damper is not required to withstand high temperature and will not prevent a fire from spreading. Smoke dampers are of the multiblade design (Figure 2), and may be listed for either two-position (open and closed) or modulating service. Smoke dampers listed for modulating service can be used as combination smoke and HVAC dampers.In the United States, smoke dampers are usually made and classified for leakage in accordance with UL *Standard* 555S. This standard includes construction requirements; air leakage tests; and endurance tests of cycling, temperature degradation, salt-spray exposure, and operation under airflow. Combination fire and smoke dampers comply with the dynamic fire damper requirements of UL *Standard* 555 and with the smoke damper requirements of UL *Standard* 555S.

Corridor Dampers

Corridor dampers are combination fire and smoke dampers that are tested for horizontal installation in ceilings. They have sleeves designed for this application and allow use of front grilles for access to the damper and actuator. Corridor dampers need to be tested to UL *Standards* 555 and 555S for 1 h at 0.76 m/s.

4. SMOKE EXHAUST FANS

Typically, smoke control systems for buildings are designed to avoid the need for operation at elevated temperatures. For zoned smoke control systems, usually the zone being exhausted is much larger than the fire space, and this limits the gas temperature at the exhaust fan. For atrium smoke control systems, air is entrained in the smoke plume that rises above the fire, and this entrained air reduces the temperature of the smoke exhaust.

ASHRAE *Standard* 149 establishes uniform methods of laboratory testing and test documentation for fans used to exhaust smoke in smoke control systems.

5. DESIGN WEATHER DATA

The performance of smoke control systems can depend on outdoor temperature and wind. Chapter 2 of the *Smoke Control Handbook* lists design climatological data (winter and summer temperatures, wind speed, standard barometric pressure) for design of smoke control systems for many locations in the United States, Canada, and other countries.

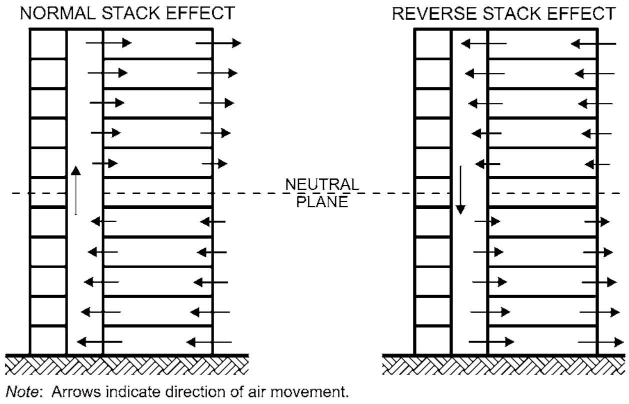

Fig. 4 Air Movement Caused by Normal and Reverse Stack Effect

Wind is measured at weather stations, which are often at airports. Because local terrain has a significant effect on wind, wind speeds at project sites are usually very different from those measured at neighboring weather stations. For information about adjusting design wind speed to a project site, see Chapter 3 of the *Smoke Control Handbook* and Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*.

6. SMOKE MOVEMENT

A smoke control system needs to be designed so that it is not overpowered by the driving forces that cause smoke movement: stack effect, buoyancy, expansion, wind, forced ventilation, and elevator piston effect. In a building fire, smoke is usually moved by a combination of these forces.

Stack Effect

It is common to have an upward flow of air in building shafts during winter. These shafts include stairwells, elevator shafts, dumbwaiters, and mechanical shafts. The upward flow is caused by the buoyancy of warm air relative to the cold outdoor air. This upward flow is similar to the upward flow in smoke stacks, and it is from this analogy that the upward flow in shafts got the name stack effect. In summer, flow in shafts is downward. Upward flow in shafts is called **normal stack effect**, and downward flow is called **reverse stack effect**.

Figure 4 shows both kinds of stack effect. In normal stack effect, air flows into the building below the neutral plane, flows up building shafts, and out of the building above the neutral plane. The neutral plane is a horizontal plane where pressure inside the shaft equals outdoor pressure, and is often near the midheight of a building.

At standard atmospheric pressure, the pressure difference caused by either normal or reverse stack effect is expressed as

$$\Delta p_{SO} = 3460\left(\frac{1}{T_O} - \frac{1}{T_S}\right)z \qquad (1)$$

where

Δp_{SO} = pressure difference from shaft to outdoors, Pa
T_S = absolute temperature of shaft, K
T_O = absolute temperature of outdoors K
z = distance above neutral plane, m

Figure 5 diagrams the pressure difference between a building shaft and the outdoors. A positive pressure difference indicates that shaft pressure is higher than the outdoor pressure, and a negative pressure difference indicates the opposite. For a building 60 m tall

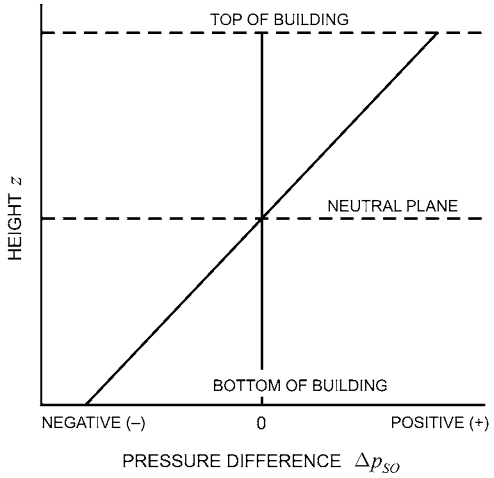

Fig. 5 Pressure Difference Between Building Shaft and Outdoors Caused by Normal Stack Effect

with a neutral plane at midheight, an outdoor temperature of –18°C (255 K), and an indoor temperature of 21°C (294 K), the maximum pressure difference from stack effect is 54 Pa. This means that, at the top of the building, pressure inside a shaft is 54 Pa greater than the outdoor pressure. At the base of the building, pressure inside a shaft is 54 Pa lower than the outdoor pressure.

Smoke movement from a building fire can be dominated by stack effect. In a building with normal stack effect, the existing air currents (as shown in Figure 4) can move smoke considerable distances from the fire origin. If the fire is below the neutral plane, smoke moves with building air into and up the shafts. This upward smoke flow is enhanced by buoyancy forces from the smoke temperature. Once above the neutral plane, smoke flows from the shafts into the upper floors of the building. If leakage between floors is negligible, floors below the neutral plane (except the fire floor) remain relatively smoke free until more smoke is produced than can be handled by stack effect flows.

Smoke from a fire located above the neutral plane is carried by building airflow to the outdoors through exterior openings in the building. If leakage between floors is negligible, all floors other than the fire floor remain relatively smoke free until more smoke is produced than can be handled by stack effect flows. When leakage between floors is considerable, smoke flows to the floor above the fire floor.

Air currents caused by reverse stack effect (see Figure 4) tend to move relatively cool smoke down. In the case of hot smoke, buoyancy forces can cause smoke to flow upward, even during reverse stack effect conditions.

Caution: It is a myth that the pressure difference caused by stack effect is nearly proportional to the temperature difference between the *building* and the outdoors. Instead, this pressure difference is nearly proportional to the temperature difference between a *shaft* and the outdoors. Looking at Figure 4, it is easy to see how the shaft and building temperatures might be considered identical. Often, they are the same. However, shafts that have one or more walls on the outside of the building tend to be relatively cold in winter and warm in summer, and this can have a major influence on stack effect.

For a building with shafts of various heights and different shaft temperatures, the flows become very complicated and would not resemble those in Figure 4. Each shaft could have its own neutral plane with respect to the outdoors, and may have more than one neutral plane. Equation (1) is not applicable for such complicated buildings, but the flows and pressures in such buildings can be analyzed by a network flow model such as CONTAM (see the section on Computer Analysis).

Buoyancy

High-temperature smoke has buoyancy because of its reduced density. At sea level, the pressure difference between a fire compartment and its surroundings can be expressed as follows:

$$\Delta p_{FS} = 3460z\left(\frac{1}{T_S} - \frac{1}{T_F}\right) \tag{2}$$

where

Δp_{FS} = pressure difference from fire compartment to surroundings, Pa
z = distance above neutral plane, m
T_S = absolute temperature of surroundings, K
T_F = average absolute temperature of fire compartment, K

The neutral plane is the plane of equal hydrostatic pressure between the fire compartment and its surroundings. For a fire with a fire compartment temperature at 800°C (1073 K), the pressure difference 1.5 m above the neutral plane is 13 Pa. Fang (1980) studied pressures caused by room fires during a series of full-scale fire tests and found a maximum pressure difference of 16 Pa across the burn room wall at the ceiling. Much larger pressure differences are possible for tall fire compartments, where the distance z from the neutral plane can be larger.

In sprinkler-controlled fires, the temperature in the fire room remains at that of the surroundings except for a short time before sprinkler activation. Sprinklers are activated by the **ceiling jet**, which is a layer of hot gas under the ceiling. The ceiling jet's maximum temperature depends on the fire's location, activation temperature of the sprinkler, and thermal lag of the sprinkler's heat-responsive element. For most residential and commercial applications, the ceiling jet is between 80 and 150°C. In Equation (2), TF is the average temperature of the fire compartment.

For a sprinkler-controlled fire,

$$T_F = \frac{T_S(H - H_J) + T_J H_J}{H} \tag{3}$$

where

T_F = average absolute temperature of fire compartment, K
T_S = absolute temperature of surroundings, K
H = floor-to-ceiling height, m
H_J = thickness of ceiling jet, m
T_J = absolute temperature of ceiling jet, K

Example 1. For $H = 2.5$ m, $H_J = 0.1$ m, $T_S = 20 + 273 = 293$ K, and $T_J = 150 + 273 = 423$ K, the average absolute temperature of the fire compartment is

$$T_F = [293(2.5 - 0.1) + 423 \times 0.1]/2.5 = 298 \text{ K or } 25°\text{C}$$

In Equation (2), this value of T_F and z of 1.5 m results in a pressure difference of 0.5 Pa, which is insignificant for smoke control applications.

Expansion

Energy released by a fire can also move smoke by expansion. In a fire compartment with only one opening to the building, building air flows in, and hot smoke flows out. Neglecting the added mass of the fuel, which is small compared to airflow, the ratio of volumetric flows can be expressed as a ratio of absolute temperatures:

$$\frac{V_{out}}{V_{in}} = \frac{T_{out}}{T_{in}} \tag{4}$$

where

V_{out} = volumetric flow rate of smoke out of fire compartment, m^3/s
V_{in} = volumetric flow rate of air into fire compartment, m^3/s

T_{out} = absolute temperature of smoke leaving fire compartment, K
T_{in} = absolute temperature of air entering fire compartment, K

For smoke at 700°C (973 K) and entering air at 20°C (293 K), the ratio of volumetric flows is 3.32. Note that absolute temperatures are used in the calculation. In such a case, if air enters the compartment at 1.5 m^3/s, then smoke flows out at 5.0 m^3/s, with the gas expanding to more than three times its original volume.

For a fire compartment with open doors or windows, the pressure difference across these openings caused by expansion is negligible. However, for a tightly sealed fire compartment, the pressure differences from expansion may be important.

Wind

In many instances, wind can have a pronounced effect on smoke movement within a building. The pressure that wind exerts on a wall is

$$p_w = \frac{1}{2} C_w \rho_o U_H^2 \qquad (5)$$

where

p_w = wind pressure, Pa
C_w = pressure coefficient
ρ_o = outdoor air density, kg/m^3
U_H = velocity at wall height H, m/s

The pressure coefficient C_w depends on wind direction, building geometry, and local obstructions to the wind. The pressure coefficients are in the range of –0.8 to 0.8, with positive values for windward walls and negative for leeward walls.

Frequently, a window breaks in the fire compartment. If the window is on the leeward side of the building, the negative pressure caused by the wind vents the smoke from the fire compartment. This reduces smoke movement throughout the building. However, if the broken window is on the windward side, wind forces the smoke throughout the fire floor and to other floors, which endangers the lives of building occupants and hampers firefighting. Wind-induced pressure in this situation can be large and can dominate air movement throughout the building. For more detailed information about wind and smoke control, see Chapter 3 of the *Smoke Control Handbook*.

Forced Ventilation

Modern HVAC systems are built of materials intended to withstand fires, and either shut down in the event of a fire or go into a smoke control mode of operation. For details on the latter approach, see the section on Zoned Smoke Control.

Elevator Piston Effect

The transient pressures and flows produced when an elevator car moves in a shaft are called **piston effect**, and can pull smoke into a normally pressurized elevator lobby or elevator shaft. For a validated analysis of piston effect, see Klote (1988) and Klote and Tamura (1986, 1987).

In the absence of stack effect or other driving forces, pressure above a rising elevator car is higher than that below the car. For this upward-moving car, there is airflow into the shaft below the car, and airflow out of the shaft above the car. When the car passes a floor, the pressure difference across the elevator door on that floor suddenly drops and then increases. For elevators with lobbies that have closed doors (enclosed lobbies), the pressure difference across the closed lobby doors reacts in a similar way to elevator car motion.

For a car traveling from the bottom to the top of the shaft, the largest value of pressure difference from piston effect is at the top of the shaft; for a car traveling from the top to the bottom, the largest value is at the bottom of the shaft. This largest value of pressure difference (called the piston effect) for an elevator with enclosed lobbies is

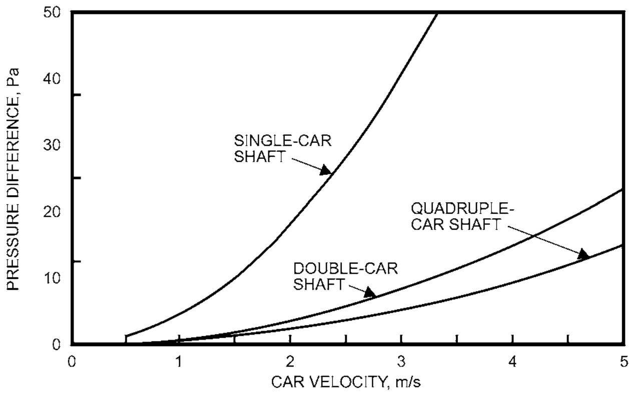

Fig. 6 Calculated Upper Limit of Piston Effect Across Elevator Lobby Doors.

$$\Delta p_{u,si} = \frac{\rho}{2}\left(\frac{A_s A_e U}{A_a A_{ir} C_c}\right)^2 \qquad (6)$$

where

$\Delta p_{u,si}$ = upper limit pressure difference from shaft to building, Pa
ρ = air density in hoistway, kg/m^3
A_s = cross-sectional area of shaft, m^2
A_e = effective area, m^2
U = elevator car velocity, m/s
A_a = free area around elevator car, m^2
A_{ir} = leakage area between building and lobby, m^2
C_c = flow coefficient for flow around car

The flow coefficient C_c was determined experimentally at about 0.94 for a multiple-car hoistway and 0.83 for a single-car hoistway. The free area around the elevator car is the cross-sectional area of the shaft less the cross-sectional area of the car. Effective areas are discussed in the section on Height Limit.

Figure 6 shows the upper limit of piston effect from the lobby to the building for normal elevator car velocities from 1 to 5 m/s. All elevator velocities are in this range except for those in extremely tall buildings. Figure 6 shows that piston effect is greatest for single-car shafts, and elevators that travel at relatively high velocities in single-car shafts have the potential for piston effect that may adversely affect smoke control performance.

7. METHODS USED TO CONTROL SMOKE

In this chapter, smoke control includes all methods that can be used singly or in combination to modify smoke movement to protect occupants or firefighters or reduce property damage. These methods are (1) compartmentation, (2) dilution, (3) pressurization, (4) airflow, and (5) buoyancy. These mechanisms are discussed in the following sections.

Compartmentation

Barriers that can remain effective throughout a fire exposure have long been used to protect against fire spread. In this approach, walls, partitions, floors, doors, and other barriers provide some level of smoke protection to spaces remote from the fire. Passive smoke control consists of using barriers alone (or without pressurization). Using compartmentation with pressurization is discussed in the section on Pressurization (Smoke Control). Passive smoke control systems can be analyzed with the goal of providing a tenable environment at specific locations during a fire. For more information, see the section on Tenability Systems. Many codes, such as the *Life Safety Code*® (NFPA 2012) and the *International Building Code*® (ICC 2012), provide specific criteria for construction of passive smoke barriers (including doors) and their smoke dampers. The extent to which smoke leaks through such barriers depends on the size and shape of the leakage paths in the barriers and the pressure difference across the paths.

Dilution Remote from Fire

Smoke dilution is sometimes referred to as **smoke purging**, **smoke removal**, **smoke exhaust**, or **smoke extraction**. Dilution can be used to maintain acceptable gas and particulate concentrations in a compartment subject to smoke infiltration from an adjacent space. It can be effective if the rate of smoke leakage is small compared to either the total volume of the safeguarded space or the rate of purging air supplied to and removed from the space. Also, dilution can be beneficial to the fire service for removing smoke after a fire has been extinguished. Sometimes, when doors are opened, smoke flows into areas intended to be protected. Ideally, the doors are only open for short periods during evacuation. Smoke that has entered spaces remote from the fire can be purged by supplying outdoor air to dilute the smoke.

The following is a simple analysis of smoke dilution for spaces in which there is no fire. At time zero ($t = 0$), a compartment is considered contaminated with some concentration of smoke and no more smoke flows into the compartment or is generated in it. Further, the contaminant is considered to be uniformly distributed throughout the space. The concentration of contaminant in the space can be expressed as

$$\frac{C}{C_O} = e^{-at} \tag{7}$$

and the dilution rate can be calculated from

$$a = \frac{1}{t}\ln\left(\frac{C_O}{C}\right) \tag{8}$$

where

C = concentration of contaminant at time t
C_O = initial concentration of contaminant
e = base of natural logarithm (approximately 2.718)
a = dilution rate, air changes per minute
t = time after smoke stops entering space or smoke production has stopped, min

Concentrations C_O and C need to be expressed in the same units, but can be any units appropriate for the particular contaminant being considered.

In reality, it is impossible to ensure that the concentration of the contaminant is uniform throughout the compartment. Because of buoyancy, it is likely that concentrations are higher near the ceiling. Therefore, exhausting smoke near the ceiling and supplying air near the floor probably dilutes smoke even more quickly than indicated by Equation (8). Supply air should be free or nearly free of smoke, as discussed in the Smoke Feedback section.

Example 2. A space is isolated from a fire by smoke barriers and self-closing doors, so that no smoke enters the compartment when the doors are closed. When a door is opened, smoke flows through the open doorway into the space. If the door is closed when the contaminant in the space is 20% of the burn room concentration, what dilution rate is required to reduce the concentration to 1% of that in the burn room in 6 min?

Solution. Time t = 6 min and $C_O/C = 20$. From Equation (8), the dilution rate is about 0.5 air changes per minute, or 30 air changes per hour.

Caution About Dilution near Fire: Some people have unrealistic expectations about what dilution can accomplish in the fire space. Neither theoretical nor experimental evidence indicates that using a building's HVAC system for smoke dilution significantly improves tenable conditions in a fire space. The exception is an unusual space where the fuel is such that fire size cannot grow above a specific limit, such as in some tunnels and underground transit situations. Because HVAC systems promote a considerable degree of air mixing in the spaces they serve and because very large quantities of smoke can be produced by building fires, it is generally believed that smoke dilution by an HVAC system in the fire space does not improve tenable conditions in that space. Thus, any attempt to improve hazard conditions in the fire space, or in spaces connected to the fire space by large openings, with smoke purging will be ineffective.

Pressurization

Many smoke control systems use mechanical fans to control smoke by pressurization. Pressure difference across a barrier can control smoke movement by preventing smoke on the low-pressure side of the barrier from migrating to the high-pressure side. Pressurization can control smoke from a fire remote from a barrier, or from a very large fire located next to a barrier (Figure 7).

Frequently, in field tests of smoke control systems, pressure differences across partitions or closed doors fluctuate by 5 Pa. These fluctuations are generally attributed to wind, although they could have been caused by the HVAC system or some other source. To control smoke movement, the pressure difference produced by a smoke control system needs to be large enough to overcome pressure fluctuations, stack effect, smoke buoyancy, and wind pressure, but not so large that the door is difficult to open. Pressurization of smoke control systems is discussed in the section on Pressurization System Design.

Opposed Airflow

Airflow can be used to control smoke flow in many applications, including buildings, rail tunnels, and highway tunnels, if the air velocity equals or exceeds the limiting velocity (Figure 8). For information about rail and highway tunnels, see Chapter 16. For control of smoke between an atrium and a communicating space, see NFPA *Standard* 92 and the limiting velocity equations in Chapter 15 of the *Smoke Control Handbook*.

Airflow smoke control is not used much in buildings because of the very large amounts of airflow needed, and (more importantly) because airflow can supply oxygen to the fire, which can result in catastrophic failure. Even full sprinkler protection does not completely eliminate this risk. For any application that uses the airflow approach, this failure mode needs to be addressed in the design analysis.

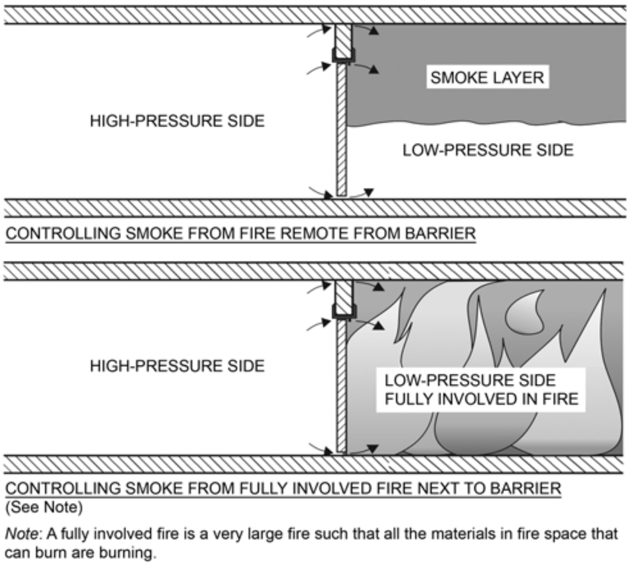

Fig. 7 Smoke Flow Controlled by Pressurization

Buoyancy

Buoyancy of hot combustion gases is used for smoke control in large-volume spaces such as atriums. A smoke plume rises above the fire to form a smoke layer under the ceiling of the large volume space. The smoke plume entrains air from the surroundings. The mass flow of the plume increases with height, and the plume temperature decreases with height. Plume flow is the basis of atrium smoke control (see the section on Atrium Smoke Control).

8. SMOKE FEEDBACK

Smoke feedback occurs when smoke from an indoor fire flows outdoors and then either (1) is pulled into a smoke control supply fan or (2) flows into an atrium makeup air vent. To minimize the potential for smoke feedback, supply air intakes should be located away from the major openings from which smoke could leave a building, such as smoke control exhausts, heat and smoke vents, and open vents of elevator shafts. Smoke entering a building at a loading dock because of a large fire inside a truck should be evaluated. Considering the enormous number of possible fire scenarios and building designs, it is not possible to anticipate all the possible openings where smoke could leave a building.

Outdoor air intakes of smoke control systems should be located such that forces of wind and buoyancy minimize the potential for smoke feedback into supply air. An understanding of airflow around buildings can be helpful in minimizing the potential for smoke feedback. See Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals* for information about airflow around buildings.

Caution: using smoke detectors to automatically shut down smoke control supply fans is not recommended, because smoke detectors are extremely sensitive to small amounts of smoke that would not result in an untenable environment. This high sensitivity is important to provide early warning of fires, but it could shut down a smoke control system from a puff of smoke that would not be life threatening.

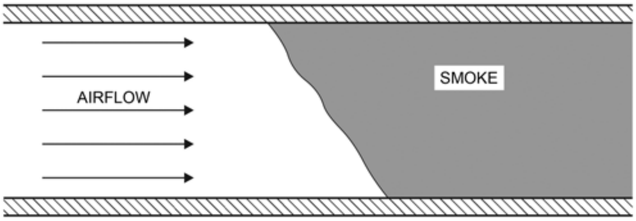
9. PRESSURIZATION SYSTEM DESIGN

The section has general information applicable to all pressurization smoke control systems. The common pressurization smoke control systems are pressurized stairwells, pressurized elevators, and zoned smoke control, which are discussed later. Supply air for pressurization smoke control systems should be free or nearly free of smoke as discussed in the section on smoke feedback.

Door-Opening Forces

The pressure difference across a barrier must not result in door-opening forces that exceed the maximum values stipulated in codes. For example, in the NFPA *Life Safety Code*® (NFPA *Standard* 101), this maximum force is 133 N.

The force required to open a side-hinged swinging door is the sum of the forces to overcome the pressure difference across the door and to overcome the door closer. This can be expressed as



Note: Airflow can control smoke flow if air velocity is large enough.

Fig. 8 Opposed Airflow Controlling Smoke Flow

$$F = F_{dc} + \frac{WA\Delta p}{2(W-d)} \quad (9)$$

where

F = total door-opening force, N
F_{dc} = force to overcome door closer and other friction, N
W = door width, m
A = door area, m^2
Δp = pressure difference, Pa
d = offset, m

The offset d is the distance between where the door-opening force is applied and the side of the door opposite the hinges (i.e., the latch side). For a lever handle, the door-opening force can be applied where the hand grasps the lever handle. For panic hardware, the door-opening force can be applied somewhere along the panic bar. For doors that do not stick to the door frame and have properly lubricated hinges, F_{dc} is the force to overcome the door closer. For more detailed information about door-opening forces, see Klote (2018).

Example 3. For a side-hinged swinging door 0.914 m wide by 2.13 m high with a door closer that requires 40 N of force, and a pressure difference across it of 87 Pa. The door-opening force is applied at a lever handle such that the offset is 76 mm. The door-opening force calculated from Equation (9) is 132 N.

Flow and Pressure Difference

The primary equation used for analysis of pressurization smoke control systems is the orifice equation:

$$m = CA\sqrt{2\rho\Delta p} \quad (10)$$

Alternatively, Equation (10) can be expressed in terms of volumetric flow:

$$V = CA\sqrt{\frac{2\Delta p}{\rho}} \quad (11)$$

where

m = mass flow through the path, kg/s
C = flow coefficient
A = flow area (or leakage area), m^2
Δp = pressure difference across path, Pa
V = volumetric flow, m^3/s
ρ = gas density in path, kg/m^3

Equations (10) and (11) are equivalent forms of the same orifice equation. Airflow paths need to be identified and evaluated in smoke control system design. Some leakage paths are obvious, such as cracks around closed doors, open doors, elevator doors, windows, and air transfer grilles. Construction cracks in building walls are less obvious but no less important.

The flow area of most large openings, such as open windows, can be calculated easily. However, flow areas of cracks are more difficult to evaluate. The area of these leakage paths depends on quality of work (e.g., how well a door is fitted or how weatherstripping is installed).

For many flow paths in buildings, a flow coefficient of 0.65 is used. The open doors of pressurized stairwells commonly have stationary vortices that reduce flow significantly (Cresci 1973; Klote and Bodart 1985). These vortices are thought to be caused by asymmetric flow from the stairs, and stationary vortices can be expected at many open doors in other locations of smoke control systems. For open doors in stairwells, the geometric area of the opening should be used for the flow area, with a flow coefficient of 0.35.

Typical leakage areas for walls and floors of commercial buildings are tabulated as area ratios in Table 1. These data are based from field tests performed by the National Research Council of Canada (Shaw et al. 1993; Tamura and Shaw 1976a, 1976b, 1978;

Table 1 Typical Flow Areas of Walls and Floors of Commercial Buildings

Construction Element	Wall Tightness	Area Ratio A/A_W*
Exterior building walls (includes construction cracks and cracks around windows and doors)	Tight	5.0×10^{-5}
	Average	1.7×10^{-4}
	Loose	3.5×10^{-4}
	Very Loose	1.2×10^{-3}
Stairwell walls (includes construction cracks but not cracks around windows or doors)	Tight	1.4×10^{-5}
	Average	1.1×10^{-4}
	Loose	3.5×10^{-4}
Elevator shaft walls (includes construction cracks but not cracks around doors)	Tight	1.8×10^{-4}
	Average	8.4×10^{-4}
	Loose	1.8×10^{-3}
		A/A_F*
Floors (includes construction cracks and gaps around penetrations)	Tight	6.6×10^{-6}
	Average	5.2×10^{-5}
	Loose	1.7×10^{-4}

*A = leakage area; A_W = wall area; A_F = floor area.

Tamura and Wilson 1966). Considerable leakage data through building components are also provided in Chapter 3 of the *Smoke Control Handbook*.

Both the maximum and minimum allowable pressure differences across the boundaries of smoke control should be considered. The term *acceptable pressurization* applies to a system that operates within the range of minimum to maximum allowable pressure differences. The maximum allowable pressure difference should not cause excessive door-opening forces.

The minimum allowable pressure difference intended to prevent smoke migration across a barrier of a smoke control system is generally stipulated by code. The smoke control system needs to be designed to maintain this minimum design pressure difference under likely conditions of wind, stack effect, or buoyancy of hot smoke. Pressure differences caused by wind and stack effect can be large in the event of a broken window or an open window or door in the fire compartment. (Windows exposed to the heat of a fire often break.) Evaluation of these pressure differences depends on evacuation time, rate of fire growth, building configuration, and the presence of a fire suppression system. The code-required minimum and maximum design pressure differences need to be used. For locations with no such code requirements, the values of NFPA *Standard* 92 are suggested.

Computer Analysis by Network Modeling

CONTAM (Dols and Polidoro 2016) is the de facto standard computer program for analyzing pressurization smoke control systems. It is a network model that simulates airflow and contaminant flow in buildings. Network modeling for smoke control dates back to the 1960s, but these early models were subject to numerical difficulties and data input was extremely cumbersome and time consuming. CONTAM has superior numerical routines and sophisticated data input, and can be downloaded from the NIST website (www.nist.gov/el/energy-and-environment-division-73200/nist-multizone-modeling/download-contam) at no cost. Because CONTAM does not solve the energy equation, the user needs to input the temperatures of the spaces in the network.

Note that, when CONTAM is discussed in this chapter, other network models could be used instead. Network models represent a building by a network of spaces or nodes, each at a specific pressure and temperature. The stairwells and other shafts can be modeled by a vertical series of spaces, one for each floor. Air flows through leakage paths (e.g., doors or windows that may be opened or closed, partitions, floors, exterior walls, roofs) from regions of high pressure to regions of low pressure. Airflow through a leakage path is a function of the pressure difference across the leakage path.

In network models, air from outside the building can be introduced by a pressurization system into any level of a shaft or into other building spaces. This allows simulating pressurization of a stairwell, elevator shaft, stairwell vestibule, and any other building space. In addition, any building space can be exhausted. This allows analysis of zoned smoke control systems where the fire zone is exhausted and other zones are pressurized. The pressures and flows throughout the building are obtained by solving conservation equations for the network. Analysis can include the driving forces of wind, the pressurization system, and indoor-to-outdoor temperature difference.

The primary purpose of network simulations is to determine whether a particular smoke control system in a particular building can be balanced such that it will perform as intended. Network models can simulate pressures and flows throughout very large and complicated building networks with high accuracy, although the results are approximations.

There are many flow paths in buildings, including gaps around closed doors, open doors, and construction cracks in walls, roof, and floors. These flow paths are approximated for a design analysis. However, the approximated results can be useful in identifying problems with specific smoke control systems, so the smoke control system or the building can be modified appropriately. These simulations can also provide information to help size system components such as supply fans, exhaust fans, and vents.

First-time users of CONTAM may be confused by its extensive capabilities, many of which are not usually used for smoke control analysis. Chapter 14 of the *Smoke Control Handbook* has CONTAM user information intended to help start using the software for analysis of smoke control systems that rely on pressurization. This information includes a section on speeding up data input.

10. SHAFT PRESSURIZATION

Stairwell pressurization and elevator pressurization are two kinds of shaft pressurization systems. Major factors that must be addressed in the design of these systems are building complexity and stack effect.

Building Complexity

Building complexity is a major factor in shaft pressurization, and successful shaft pressurization can be challenging in complicated buildings. A simple building has floor plans that are nearly the same from floor to floor, whereas a complicated building's floor plans differ considerably from floor to floor. Figure 9 shows examples of these buildings. Air leaving a pressurized shaft flows through the building to the outdoors, and flow paths to the outdoors differ by floor in complicated buildings. This results in varying pressure differences across pressurized shafts from floor to floor in complicated buildings, and can result in challenging shaft pressurization systems. Stairwell pressurization is usually straightforward for simple buildings, but elevator pressurization can be a challenge even in simple buildings. Systems that can be used to overcome these challenges are discussed in the sections on Pressurized Stairwells and Pressurized Elevators.

Stack Effect

Sometimes engineers will say that a pressurized stairwell or elevator must be designed to account for stack effect. If the space is properly pressurized, there is no neutral plane, and all the flows are from the stairwell. Strictly speaking, then, there is no stack effect in the pressurized stairwell or elevator: what is meant is that the space

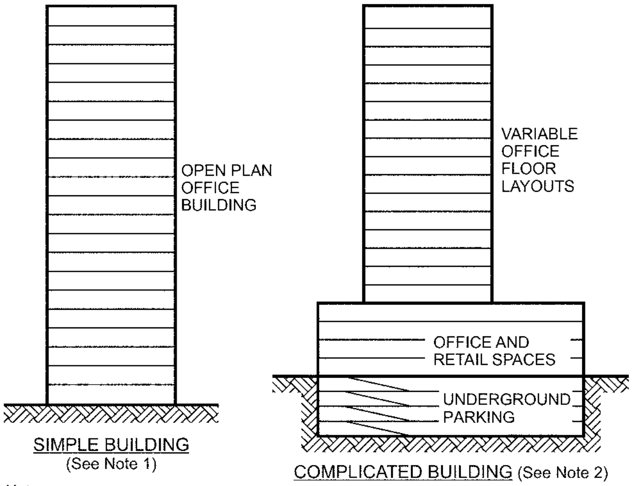


Fig. 9 Examples of Simple and Complicated Buildings

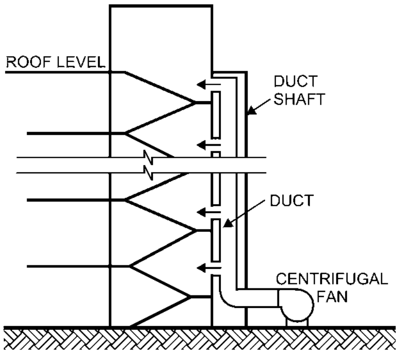

Fig. 10 Stairwell Pressurization by Multiple Injection with Fan Located at Ground Level

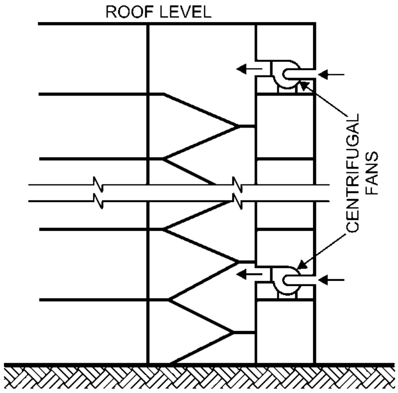

Fig. 11 Stairwell Pressurization by Multiple Injection with Multiple Fans

must be designed to account for the temperature differences that cause stack effect.

Caution: It is a myth that stack effect is the major factor affecting stairwell and elevator pressurization. Although stack effect can be the major factor, it often is a minor factor for pressurized stairwells and elevators. Pressurization air for many stairwells and elevators is untreated outdoor air that is not heated or cooled. The temperature of these shafts is often nearly the same as the outdoor temperature, and the consequence of stack effect is significantly reduced as compared to shafts pressurized with air treated to the building temperature.

Shaft Temperature. When pressurization air is untreated, the shaft temperature can be expressed as

$$T_S = T_O + \eta(T_B - T_O) \quad (12)$$

where

T_S = temperature in stairwell, °C
T_O = temperature outdoors, °C
η = heat transfer factor
T_B = temperature in building, °C

There has been little research on the heat transfer factor, but it is believed to be in the range of 0.05 to 0.15. Without better data for a specific application, a heat transfer factor of 0.15 is suggested as conservative for the consequence of stack effect.

For untreated supply air, it takes a few minutes for the temperature in the shaft to stabilize near that of the outdoors. During this stabilization, excessive pressure differences could be produced. To prevent this, supply air can gradually be increased so that, when the shaft temperature is near that of the building, there is insufficient flow to cause excessive pressurization. If needed, temperature stabilization can be evaluated by a heat transfer analysis.

Friction Losses in Shafts. Pressure losses from friction in stairwells and elevator shafts can be significant when flow rates are high. CONTAM uses data from Achakji and Tamura (1988) and Tamura and Shaw (1976b) to calculate pressure loss in stairwells.

11. PRESSURIZED STAIRWELLS

Many pressurized stairwells have been designed and built to provide a tenable environment inside the stairwell in the event of a building fire. They also provide a smoke-free staging area for firefighters. On the fire floor, a pressurized stairwell is intended to provide a positive pressure difference across a closed stairwell door to prevent smoke infiltration. For stairwells in cold climates, designers should consider treating supply air to minimize the potential of freezing water in standpipes. Supply air for pressurized stairwells should be free or nearly free of smoke, as discussed in the Smoke Feedback section.

Air can be supplied to a pressurized stairwell at one or several locations. A single-injection system supplies pressurized air to the stairwell at one location, usually at the top. For tall stairwells, single-injection systems can fail when a few doors are open near the air supply injection point, especially in bottom-injection systems when a ground-level stairwell door is open.

Air can be supplied at multiple locations over the height of a tall stairwell. Figures 10 and 11 show two examples of **multiple-injection systems** that can be used to overcome the limitations of single-injection systems. Multiple-injection systems can use one or multiple fans. When one fan is used, air is supplied through a duct that is usually in a separate duct shaft. However, some systems eliminate the expense of a separate duct shaft by locating the supply duct in the stairwell itself. In such a case, ensure that the duct does not obstruct orderly building evacuation.

Stairwell Compartmentation

Stairwell compartmentation, which is not often used, consists of dividing a stairwell into several sections consisting of five to ten stories each; each compartment has at least one supply air injection point. The compartments are separated by walls with normally closed doors. The main advantage of compartmentation is that it allows acceptable pressurization of stairwells that are otherwise too tall for acceptable pressurization. A disadvantage is the increase in floor area needed for the walls and doors separating the stairwell sections. When the doors between compartments are open, the effect of compartmentation is lost. For this reason, compartmentation is inappropriate for densely populated buildings, where total building evacuation by stairwell is planned in the event of a fire.

Vestibules

Pressurized stairwells with vestibules are occasionally used. The vestibules can be unpressurized, pressurized, ventilated, or both pressurized and ventilated. Vestibules provide an additional barrier around a stairwell, and can reduce the probability of an open-door connection existing between the stairwell and the building.

An evacuation analysis can determine the extent to which both vestibule doors are likely to be opened simultaneously. For densely populated buildings, it is expected that on many floors both vestibule doors would be opened simultaneously. Therefore, vestibules may provide little benefit of an extra barrier for densely populated buildings.

The algebraic equation method of analysis can be used to analyze a pressurized stairwell with an unpressurized vestibule. The pressure differences and flows of stairwell systems with any kind of vestibules, including those with openings to the outdoors and those with combinations of supply air and exhaust air, can be analyzed by CONTAM.

System with Fire Floor Exhaust

This system can achieve acceptable pressurization of tall stairwells in very complicated buildings. A relatively small amount of air is supplied to the stairs, and the fire floor is exhausted such that acceptable pressurization is maintained on the fire floor where it is needed. Floors above and below the fire floor also may be exhausted. These systems are discussed further in the section on Zoned Smoke Control. When a CONTAM analysis shows that the code-mandated systems cannot or are likely not to be able to achieve successful pressurization, stairwell pressurization with fire floor exhaust could be a solution. The design analysis of these systems should include CONTAM simulations.

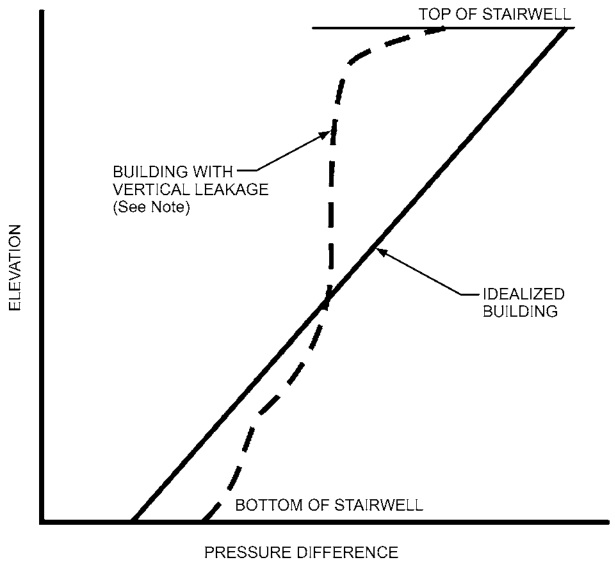
Analysis of Pressurized Stairwells

Pressure differences across a stairwell tend to vary over the height of the stairwell. Figure 12 shows pressure profiles for pressurized stairwells in an idealized building (i.e., no vertical leakage through the floors and shafts, and leakage is the same from floor to floor) and in a more realistic building with vertical leakage through floors and an elevator shaft. This figure is for winter. When it is cold outdoors, the pressure differences tend to be less at the bottom of the stairwell than at the top. When it is hot outdoors, the trend is the opposite. For both winter and summer conditions, the pressure profile for an idealized building is a straight line.

The pressure profiles of stairs in real buildings depend on many factors, including (1) leakage values of the building components, (2) building floor plans, (3) size of elevator shaft or shafts and number of elevator doors, (4) presence or absence of elevator lobbies and vents, and (5) leakage through other shafts. There are many possible shapes for such pressure profiles in real buildings, but the complexities of airflow in buildings are such that specific patterns for pressure profiles are unknown.

For a building with vertical leakage, flows through the floors and shafts to some extent even out the highest and lowest pressure differences across the stairwell. The profile for a building with vertical leakage is bounded by the extremes of the pressure profile of the idealized building. This means that, other things being equal, the smallest pressure difference of the idealized analysis is less than that of the realistic building, and that the largest pressure difference of the idealized analysis is more than that of the realistic building. This is why the algebraic equation method discussed in the section on Equations for Steady Smoke Exhaust is conservative.

An algebraic equation method of analysis pressurized stairwells is also presented in Chapter 10 of the *Smoke Control Handbook*. This algebraic equation method is based on (1) the idealized building, (2) flows calculated by the orifice equation, (3) effective areas, and (4) symmetry. It does not account for pressure losses in the stairwell from friction, but these losses tend to be small for stairwells when all stair doors are closed. CONTAM can analyze pressurized stairwells much more realistically than the algebraic equation method.



Notes:
1. The pressure difference is from the stairwell to the building across the stair door.
2. The shape of the curve for a building with vertical leakage depends on many factors, and the curve shown is only one of many possible shapes.

Fig. 12 Pressure Profile of a Pressurized Stairwell in Winter

Table 2 Stairwell Supply Air as Function of Leakage Classification

Stairwell Leakage Classification	Wall Leakage, m^2/m^2	Door Leakage, m^2	Supply Air, $m^3/(s \cdot floor)$
Low	1.4×10^{-5}	0.0075	0.04
Average	1.1×10^{-4}	0.015	0.11
High	3.5×10^{-4}	0.022	0.26

Note: The supply air listed was calculated by equation method to maintain a minimum pressure difference of 25 Pa.

Stairwell Fan Sizing

Some designers size fans for pressurized stairwells using their own rules of thumb, which are generally in the range of 0.14 to 0.26 m^3/s per floor. Such estimates can be appropriate for simple buildings such as those discussed previously. The primary factor regarding the amount of pressurization air needed is stairwell leakage. Table 2 lists the supply air needed to pressurize stairwells as a function of leakage classification. If the fan is oversized, the amount of supply air can be adjusted during commissioning to achieve successful pressurization. Because of the high cost of replacing undersized fans (including electrical wiring), rules of thumb chosen by designers usually incorporate an allowance for leakier construction than actually anticipated.

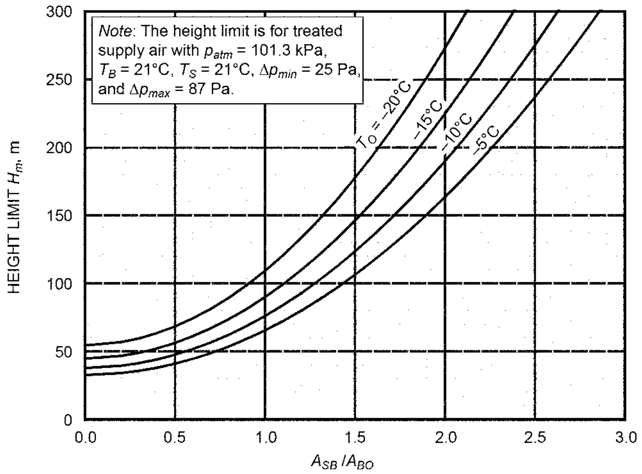


Fig. 13 Height Limit with Treated Supply Air in Winter

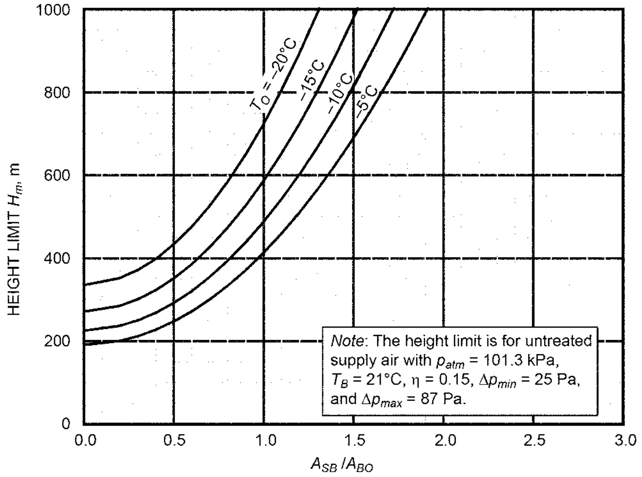

Fig. 14 Height Limit with Untreated Supply Air in Winter

Height Limit

For some tall stairwells, acceptable pressurization may not be possible because of indoor-to-outdoor temperature differences. Acceptable pressurization is more likely with systems using untreated supply air than those using treated supply air.

The **height limit** is the height above which acceptable pressurization is not possible for an idealized building. For the height limit to be applicable to a building, all the floors of the building must be the same or relatively similar. When using the height limit, shafts that are not pressurized are neglected. For standard atmospheric pressure at sea level, the height limit is

$$H_m = 2.89 \times 10^{-4} \frac{F_R(\Delta p_{max} - \Delta p_{min})}{\left|\frac{1}{T_O} - \frac{1}{T_S}\right|} \quad (13)$$

where

H_m = height limit, m
F_R = flow area factor
Δp_{max} = maximum design pressure difference, Pa
Δp_{min} = minimum design pressure difference, Pa
T_O = absolute temperature outdoors, K
T_S = absolute temperature in stairwell, K

The flow area factor is

$$F_R = 1 + \frac{A_{SB}^2(T_B)}{A_{BO}^2(T_S)} \quad (14)$$

where

A_{SB} = flow area between stairwell and building, m²
T_B = absolute temperature in building, K
A_{BO} = flow area per stairwell between building and outdoors, m²
T_S = absolute temperature in stairwell, K

Figures 13 and 14 show the height limit calculated from Equations (13) and (14) for winter with treated and untreated supply air, respectively. The areas A_{SB} and A_{BO} are calculated using effective areas. The effective area of a system of flow areas is the area that results in the same flow as the system when it is subjected to the same pressure difference over the total system of flow paths. The effective area of any number of flow paths in parallel is

$$A_e = \sum_{i=1}^{n} A_i \quad (15)$$

and the effective area of any number of paths in series is

$$A_e = \left(\sum_{i=1}^{n} \frac{1}{A_i^2}\right)^{-1/2} \quad (16)$$

where

A_e = effective area, m²
A_i = flow area of path i, m²

Two examples (Figures 15 and 16) demonstrate evaluation of A_{SB} and A_{BO}. The areas on these figures include wall leakage through construction cracks or other paths, including gaps around doors, as appropriate for each section of wall. Figure 15 is a floor plan of a simplified open-plan office building. Because the height limit is based on symmetry, the area A_{BO} is on a per-stairwell basis. Figure 15 shows the axis of symmetry, and flows and flow paths on one side of this axis are the mirror image of those on the other side. This figure is geometrically symmetric, but the height limit also can be used for buildings where the building is only symmetric with respect to flow. In this figure, the areas between the building and the outdoors are A_1, A_2, and A_3. These areas are in parallel, and based on Equation (15), $A_{BO} = A_1 + A_2 + A_3$. The areas between the stairwell and the building are A_4 and A_5, which are also in parallel. Based on Equation (15), $A_{SB} = A_4 + A_5$.

The stairwells of Figure 16 have unpressurized vestibules. As with Figure 15, $A_{BO} = A_1 + A_2 + A_3$. Calculating A_{SB} involves flow areas both in parallel and in series. Equation (16) can only be used when no air is supplied to or exhausted from the spaces in the system of series paths. The effective area approach can be used because the only space in this path is an unpressurized vestibule. In Figure 16, the areas A_5 and A_6 are in parallel, so $A_{56} = A_5 + A_6$. The path through the vestibule is series, so from Equation (16), $A_{456} = (1/A^2_4 + 1/A^2_{56})^{-1/2}$. The paths A_{456} and A_7 are in parallel, so $A_{SB} = A_{456} + A_7$.

Example 4. For the simple building of Figure 17, (1) evaluate wind effect, (2) evaluate stack effect, and (3) determine the design capacity of the supply fans. The height of the building and stairwells is 33.5 m. The minimum and maximum design pressure differences are 25 and 87 Pa.

Wind Effect. For this building, wind effect is not considered to be an issue because

- There are no windows or balcony doors that can be opened between the building and the outdoors.
- A centrifugal fan is used to minimize wind effect on the flow rate of pressurization air. (Wind effect can also be minimized by other kinds of fans, although this requires evaluation for the specific case.)

For designs where wind effect is not minimized, CONTAM is recommended for analyzing the stair pressurization system.

Stack Effect. Because the example building is only 11 stories tall, stack effect was not an issue. For larger buildings, the impact of stack effect should be analyzed.

The winter outdoor design temperature is T_O = –15°C, and the building temperature is T_B = 21°C. The atmospheric pressure is 101.3 kPa. Consider a heat transfer factor of η = 0.15. Because the building is simple, height limit can be used to evaluate stack effect. First, evaluate stack effect before stabilization; the first approach for this is to examine the height limit for the stairwell if pressurization air were treated. From Figure 14 with T_O = –15°C, the smallest value of height limit is about 45 m when A_{SB}/A_{BO} is near zero. The stairwell height is 33.5 m, which is less than the height limit. This means that stack effect is not an issue before temperature stabilization; consequently, it cannot be an issue after stabilization.

Size Supply Fans: Because this building is simple, the rule of thumb method can be used to size the fans. Generally, rules of thumb for pressurized stairwells are in the range of 0.14 to 0.26 m^3/s per floor. The most important factor to consider in choosing a rule of thumb is the stairwell leakage, which primarily consists of the leakage of stairwell walls and stairwell doors.

Construction of the stairwell is believed to be of average leakiness or higher. Table 2 lists supply air of 0.11 m^3/s per floor for average leakage, and 0.26 m^3/s per floor for high leakage. Because of the cost of replacing an undersized fan, the rule of thumb of 0.21 m^3/s per floor is chosen. The stairwell has 11 floors, and fan capacity is 11(0.21) = 2.31 m^3/s. Each stairwell is pressurized by one fan with capacity of 2.31 m^3/s.

Stairwells with Open Doors

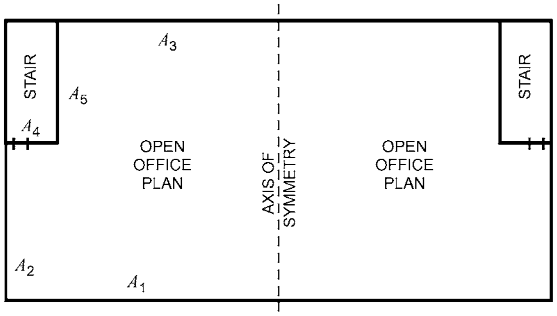
When any stair door is opened in a simple stairwell pressurization system, the pressure difference drops significantly. When all doors are closed suddenly in such a simple system, the pressure difference increases significantly. A **compensated stairwell pressurization system** adjusts for changing conditions either by modulating supply airflow or by relieving excess pressure. The intent is to maintain acceptable pressurization when doors are opening and closing.

In the United States, most codes do not require pressurized stairwells to be compensated, and such stairwells are designed to maintain pressurization only when all the stair doors are closed. Traditionally, some engineers felt that pressurized stairwells needed to be compensated, but research projects by Klote (2004) and Ko and Lougheed (2016) show that noncompensated stairwell pressurization systems can maintain a tenable environment in the stairwell as long as the door on the fire floor remains closed, even if doors on other floors are opened. In computer simulations by Klote and fire experiments by Ko and Lougheed, the small amount of smoke that leaked through the gaps around a closed stair door was diluted by pressurization air and a tenable environment was maintained in the stairwell.

When compensated stairwell pressurization systems are required, the systems described by Klote et al. (2017) can be used: barometric damper (BD), variable-air-volume (VAV), open exterior door (OED), and exterior vent (EV) systems. As with noncompensated stairwell pressurization systems, performance of compensated systems can be negatively affected by wind, and this needs to be taken into account during design. Compensated stairwell pressurization systems have the failure modes discussed in the following paragraphs.

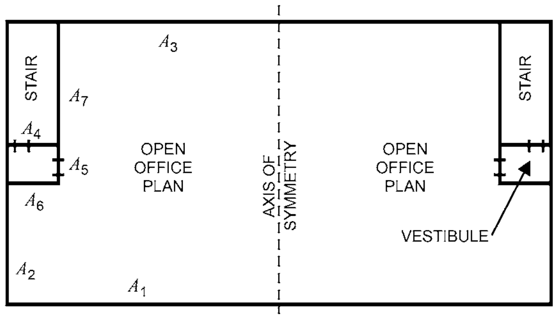
Barometric Damper (BD) System. This system has constant-supply airflow, which is designed to maintain acceptable pressurization with the required number of doors open. The supply air rate is not actually constant, but varies to some extent with pressure across the fan. For centrifugal fans, this flow variation is generally small. However, the term *constant supply* is used to differentiate this system from those where the supply air intentionally changes. When a stair door is closed, the excess supply air is relieved to the outdoors through one or more vents with barometric dampers.

Barometric dampers tend to chatter because of the wind. This chatter can be so annoying that building maintenance staff sometimes wire these dampers shut to stop the noise, which can lead to failure because of excessive stair pressurization. Because barometric dampers are usually located on walls, wind can affect system



Note: This figure is geometrically symmetric, but height limit can be used for buildings where building is only symmetric with respect to flow.

Fig. 15 Example for Effective Flow Areas of Building with Pressurized Stairwells



Note: This figure is geometrically symmetric, but height limit can be used for buildings where building is only symmetric with respect to flow.

Fig. 16 Example for Effective Flow Areas of Building with Pressurized Stairwells and Unpressurized Vestibules

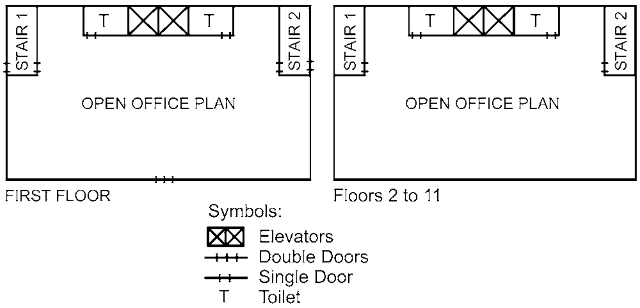


Fig. 17 Office Building of Stairwell Examples

performance more than with most other systems. If a BD compensated stairwell pressurization system is to be used, the design needs to mitigate damper chatter and any adverse wind effects.

Variable-Air-Volume (VAV) System. In a VAV compensated stairwell system, the flow rate of supply air to the stairwell is adjusted to account for opening and closing of doors. The flow of supply air to the stairwell is controlled by multiple static pressure sensors that sense the pressure difference between the stairwell and the building. When doors are opened, the stairwell pressure drops and the flow rate of supply air is increased to achieve at least the minimum design pressurization. When all the doors are closed, stair pressure increases, and supply air is reduced to prevent excessive pressure differences. When a door is opened in the VAV system, the pressure in the stairwell drops, and it takes about 3 to 7 s for the pressure to recover to the initial value (Tamura 1990).

When the last open door in a VAV system closes, there is a pressure spike that can be on the order of 250 Pa, which is extremely high compared to the usual pressure differences maintained by pressurized stairwells. A person encountering such a peak would probably not be able to open the stair door, but they could open it a minute or so later provided they knew to try. A person encountering such a peak may think the stair door was locked, and might not try to open it again.

Wind can have an unusual and serious impact on VAV systems. During design analysis, engineers have encountered very high pressure differences during some wind conditions. For example, when an exterior door is opened during the design wind speed, there can be so much supply air that the pressure difference across some stair doors can exceed the maximum design value by as much as 100%, making it impossible or extremely difficult for occupants to enter the stairwell.

A VAV compensated stairwell pressurization system design needs to deal with both the pressure spike and the effects of wind on the system. To address these potential failure modes, the design analysis needs to include simulations by network analysis computer program such as CONTAM.

Open Exterior Door (OED) System. The open exterior door (OED) system has constant-supply airflow, and an exterior stairwell door that opens automatically on system activation. This system is sometimes called the Canadian system, because it originated in Canada and has been used extensively there. By eliminating opening and closing of the exterior stairwell door during system operation, the OED system eliminates the major source of pressure fluctuations. However, there can be security concerns about exterior doors that open automatically, so OED systems are suggested only for applications where this security issue is not a concern or where the concerns can be resolved with other measures.

Exterior Vent (EV) System. The open exterior vent (EV) system is an alternative when security concerns prohibit using the OED system. An EV system has constant-supply airflow and an exterior vent that opens automatically upon system activation. The intent of this vent is to minimize the effect of opening and closing the exterior stair door. To minimize the effect of wind, it is suggested that the vent be near (and facing the same direction as) the exterior door. The size of the vent can be determined by CONTAM simulations.

12. PRESSURIZED ELEVATORS

The elevator pressurization systems discussed in this section are intended to prevent smoke from flowing from the fire floor through an elevator shaft and threatening life on floors away from the fire floor. This section does not address smoke control for elevator evacuation (see Chapter 12 of the *Smoke Control Handbook*). Usually, pressurized elevators are in buildings that have pressurized stairwells, and this section assumes that these pressurization systems operate together. In the rare situation where pressurized elevators are the only pressurization smoke control system in a building, the information in this section may still be useful. Supply air for pressurized elevators should be free or nearly free of smoke, as discussed in the Smoke Feedback section.

The information discussed in the section on Elevator Piston Effect can be used to evaluate the influence of piston effect on performance of pressurized elevator systems. The piston effect produces a pressure spike when a car passes a particular floor, and this happens for only a few seconds during the run of an elevator. For elevators in multiple-car shafts with car velocities less than 5 m/s, or for those in single-car shafts with car velocities less than 2.5 m/s, piston effect should not adversely affect performance of elevator pressurization.

Design of pressurized elevators is much more complicated than design of pressurized stairwells, because (1) the building envelope often cannot effectively handle the large airflow resulting from both elevator and stairwell pressurization, and (2) open exterior doors on the ground floor can cause high pressure differences across the elevator shaft at the ground floor. Several systems discussed in this section can deal with this complexity, however.

Usually, several exterior doors on the ground floor are open during a building fire: the fire service opens several exterior doors and keeps them open while fighting the fire. Occupants also open exterior doors during evacuation. The shaft pressurization system needs to operate as intended with these exterior doors open.

Generally, a CONTAM analysis is needed to determine whether pressurized elevators and pressurized stairwells in a particular building can be balanced to perform as intended. Though it is theoretically possible to use only a rule of thumb to design these systems, a CONTAM analysis is strongly recommended.

The following discussion is intended to provide an understanding about the elevator pressurization systems, and is based on 36 CONTAM simulations with a 14-story building (Figure 18). For a more detailed discussion of these simulations, see Chapter 11 of the *Smoke Control Handbook*. Elevator pressurization systems discussed here are for use in buildings with pressurized stairwells.

For these simulations, the pressure difference criteria are listed in Table 3. The leakage values and flow coefficients used for these simulations are listed in Tables 4 and 5. For the CONTAM simulations of the example building, supply air was injected only at the top of the elevator shafts, but for stairwells, about half the supply air was injected at the top of the stairs and the rest at the second floor.

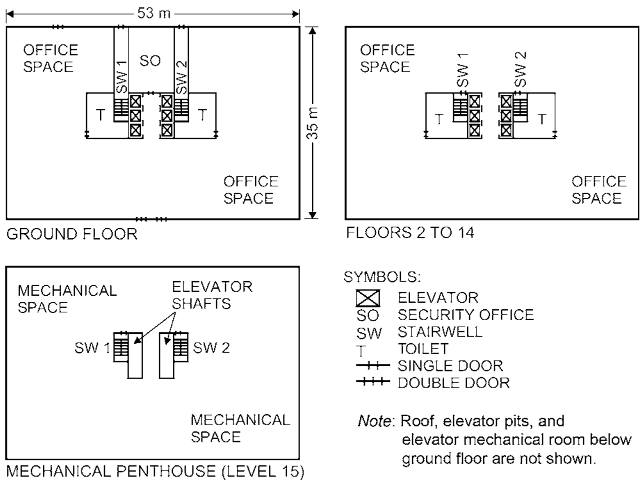

Fig. 18 Floor Plans of Example 14-Story Open Plan Office Building for Elevator Pressurization Study

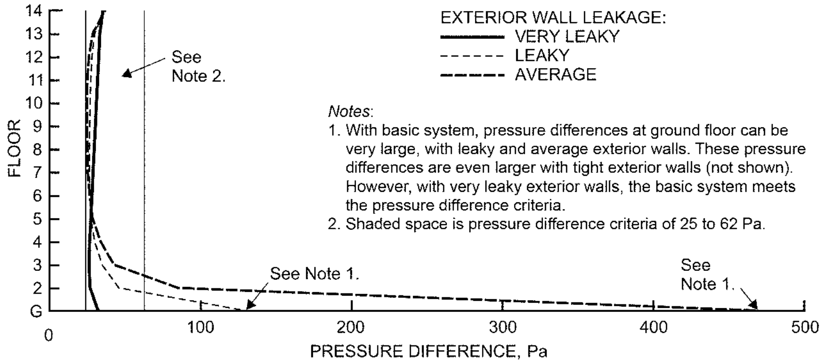

Fig. 19 Elevator Pressure Differences for Basic Elevator Pressurization System

Basic System

In the basic system, each stairwell and elevator shaft has one or more dedicated fans that supply pressurization air. For reasons mentioned previously, the basic system also includes stairwell pressurization, and the stair subsystems are not compensated. In most buildings, the basic system does not result in successful pressurization, so the systems discussed in this section add extra features to improve performance.

For the example building with very leaky exterior walls, the CONTAM simulations showed that the basic system would perform well, but this was not so for with less leaky exterior walls. In Figure 19, for leaky exterior walls, the pressure difference across the elevator doors on the ground floor is about 130 Pa. For exterior walls of average leakage, the pressure difference across the elevator doors on the second floor is about 87 Pa, and at the ground floor it is about 470 Pa. These values exceed the maximum criterion used for elevator doors, which is 62 Pa (see Table 4). For average and leaky exterior walls, there is insufficient leakage in the building envelope to accommodate the large amount of pressurization air supplied to the shafts.

With very leaky exteriors walls in the example building of Figure 18, Figure 19 shows that the basic system meets the pressure difference criteria (Table 4). Air was supplied to each elevator shaft at 13.1 m^3/s, and to each stairwell at 3.09 m^3/s. With very leaky exteriors walls, there is enough wall leakage area to accommodate this large amount of pressurization air. For the few buildings that have very leaky building envelopes, the basic system can be a simple way to pressurize elevators and stairwells. The basic system also might work well for less leaky walls in other buildings. When a CONTAM analysis shows that the basic system does not work for a building, consider the systems discussed in the following sections.

Exterior Vent (EV) System

This system uses vents in the exterior walls to increase the leakiness of the building envelope such that successful pressurization can be achieved. The vents are usually closed, but they open when the pressurization system is activated. These vents are relatively small and not intended to be a substitute for windows broken open by the fire service. Vents should be located to mitigate the potential for the wind to produce excessive pressures on the fire floor; one way to accomplish this is putting vents on each side of the floor, as shown in Figure 20. These vents may need fire dampers, depending on code requirements.

Figure 20 is a typical floor of the example building with vents in the exterior walls. Vents can be sized to ensure that design criteria are met. In the example building, the vents were sized such that the amount of pressurization used for the basic system produced acceptable pressurization with the EV system in the example building.

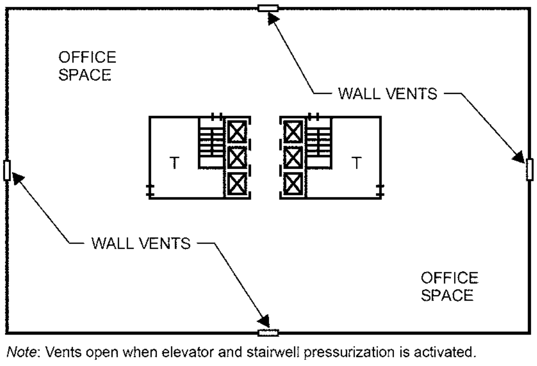

Fig. 20 Typical Floor Plan of Example Building with Exterior Vent (EV) System

In Figure 20, the vents are in all four exterior walls to minimize any adverse effects of wind. The vent area should be proportional to the area of the exterior walls. If fewer vents are used, wind effects should be incorporated in the CONTAM analysis.

With open exterior doors, it is not necessary to have exterior vents on the ground floor. Because the EV system may not be able to achieve acceptable pressurization with some or all the exterior doors closed, it may be necessary to have some of the exterior doors open automatically on system activation. The number of exterior doors that need to open automatically can be evaluated by CONTAM analysis.

The example building has an open office plan, but the EV system can be adapted to other buildings. Ducted flow paths can be installed from the vicinity of the unenclosed elevator lobbies to the outdoors. Such ducted paths can overcome the flow resistance of interior walls. The ducts can be located above suspended ceilings. Duct penetrations of a fire-rated wall may have fire resistance requirements, depending on code specifications.

Floor Exhaust (FE) System

The FE system is a kind of zoned smoke control that reduces the amount of supply air used. In the FE system, a relatively small amount of air is supplied to the elevator shafts and the stairwells, and the fire floor is exhausted such that acceptable pressurization is maintained on that floor where it is needed. It is common to also exhaust one or two floors above and below the fire floor.

As discussed in the section on Zoned Smoke Control, exhausting air from the fire floor and some floors above and below the fire floor benefits shaft pressurization. Often, this system can achieve successful pressurization in tall and very complicated buildings.

Table 3 Pressure Difference Criteria for Elevator Pressurization Simulations, Pa

System	Minimum	Maximum
Pressurized elevators	25	62
Pressurized stairwells	25	87

Note: Criteria are for elevator simulations discussed in this chapter, but some projects may have different criteria, depending on code requirements and requirements of specific applications.

Table 4 Flow Areas and Flow Coefficients of Doors Used for Elevator Pressurization Simulations

Flow Path		Flow Coefficient	Flow Area, m²
Single door,	closed	0.65	0.023
	opened	0.35	2.0
Double door,	closed	0.65	0.045
	opened	0.35	3.9
Elevator door,	closed	0.65	0.06
	opened	0.65	0.56

Note: Values were chosen for elevator simulations discussed in this chapter; flow areas and coefficients appropriate for design analysis of a specific building may be different.

Table 5 Flow Areas and Flow Coefficients of Leakages Used for Elevator Pressurization Simulations

Flow Path	Leakage Classification	Flow Coefficient	Flow Area, m² per m² of wall
Exterior walls	Tight	0.65	0.50×10^{-4}
	Average		0.17×10^{-3}
	Loose		0.35×10^{-3}
	Very loose		0.12×10^{-2}
Interior walls	Loose	0.65	0.35×10^{-3}
Floor or roof	Tight	0.65	0.66×10^{-5}
	Average		0.52×10^{-4}
	Loose		0.17×10^{-3}
			m² per m of wall
Curtain wall gap	Tight	0.65	0.00061
	Loose		0.0061

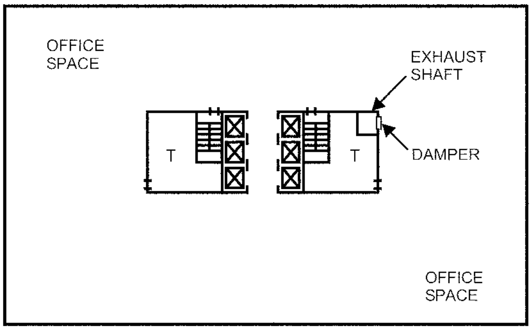
Note: Values were chosen for elevator simulations discussed in this chapter; flow areas and coefficients appropriate for design analysis of a specific building may be different.

Typically, exhaust is through a shaft with a fan located in a mechanical floor or on the roof, and dampers between the shaft and the floors are closed on all floors when the system is not operating. On system activation, the dampers open on the floors to be exhausted. Where the code requires zoned smoke control, it may be necessary to pressurize one or two floors above and below the fire floor. The exhaust rates should be balanced so that the pressure differences from the elevator shaft to the building and from the stairwell to the building are acceptable. This acceptable pressurization meets the intent of the code. At floors not exhausted, pressure differences would be below the minimum design pressure difference. Because the FE system only maintains acceptable pressure differences at the fire floor (and other floors that may be exhausted), use of a FE system needs to be approved by the local code authority.

As with the EV system, some of the exterior doors on the ground floor may need to open automatically upon system activation, and the number of such doors can be evaluated by the CONTAM analysis.

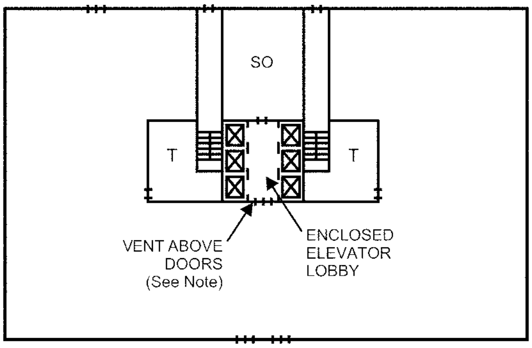
For the example building, an FE system is shown in Figure 21. Simulations showed that each elevator shaft needed 7.14 m³/s, and each stairwell needed 1.79 m³/s. The floor exhaust needed from the floors ranged from 2.28 to 2.55 m³/s.

As with the EV system, the FE system can be adapted to other buildings. This can be done by having the exhaust draw from a space onto which the elevators and stairwells open.



Note: Exhaust shaft has fan (not shown) located in mechanical penthouse, and dampers are closed on all floors when system is not operating. On system activation, dampers open on floors to be exhausted, and fan is activated.

Fig. 21 Typical Floor Plan of Example Building with Floor Exhaust (FE) System



Note: This vent needs fire damper and adjustable damper for balancing.

Fig. 22 Ground Floor of Building with Ground-Floor Lobby (GFL) System

Ground-Floor Lobby (GFL) System

This system has an enclosed elevator lobby on the ground floor to reduce the tendency of open exterior doors to cause high pressure differences across the elevator shaft at the ground floor. The GFL system often has a vent between the enclosed lobby and the building to prevent excessive pressure differences across the lobby doors (i.e., the doors between the enclosed lobby and the building).

The pressure difference across the lobby door and the elevator door depends on the area of the vent. There is no established criterion for the maximum pressure difference across the lobby doors, but the pressure should not be high enough to prevent the doors from remaining closed. This value depends on the specific doors and hardware. This discussion uses a maximum pressure difference for the lobby doors of 87 Pa, but this value can be much different for specific applications. The vent should have a fire damper and a control damper in series. The control damper can be used to adjust the flow area of the vent so it can be balanced during commissioning. Figure 22 shows the ground floor of the example building with a GFL system.

The intent of the elevator pressurization systems discussed in this chapter is to prevent smoke from flowing from the fire floor through an elevator shaft and threatening life on other floors. In the GFL system, the enclosed lobby on the ground floor protects the elevator from smoke from a fire on the ground floor. Thus, the minimum elevator pressure difference criterion of Table 3 does not apply to the ground floor for a GFL system. Table 6 lists the criteria used for the GFL system simulations. Successful pressurization consists of meeting these criteria.

Table 6 Pressure Difference Criteria for GFL Elevator Pressurization Simulations, Pa

Location	Minimum	Maximum
Pressurized elevators on ground floor	N/A	62
on other floors	25	62
Pressurized stairwells on all floors	25	87
Ground-floor elevator lobby door	N/A	87

Note: These pressure differences are with doors to stairwell, elevator, and ground-floor lobby closed. Criteria are for GFL simulations discussed in this chapter; some projects may have different criteria depending on code requirements and requirements of specific applications.

For fires in high-rise buildings, the fire service frequently uses the elevators for rescue and for mobilization of firefighting equipment. When ground-floor lobby doors are opened, the pressure difference may exceed the maximum pressure difference. If this can happen for a particular design, the fire service should be contacted to determine whether this is acceptable to them.

Floor-to-floor leakage can significantly affect a GFL system's performance. This leakage consists of the leakage of the floor and that of the curtain wall gap (Table 6).

13. ZONED SMOKE CONTROL

The traditional approach for HVAC systems is to shut them down during building fires, but HVAC systems can be operated in smoke control mode during building fires. Zoned smoke control consists of exhausting the zone of the fire and possibly pressurizing the surrounding zones. In addition to using the HVAC system, dedicated equipment can be used for zoned smoke control. Supply air for zoned smoke control systems should be free or nearly free of smoke, as discussed in the Smoke Feedback section.

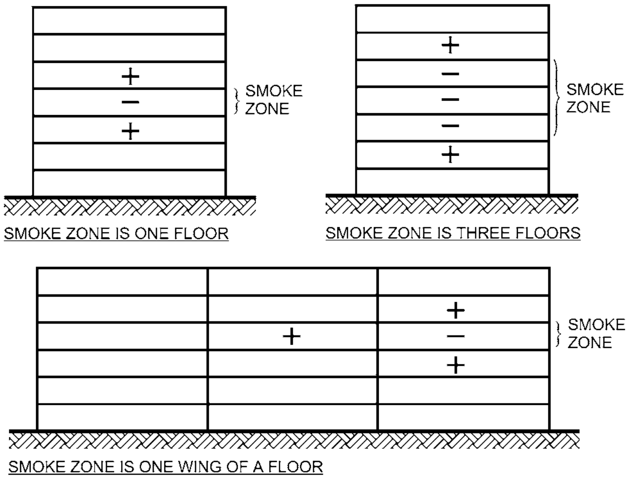
In zoned smoke control, a building is divided into several zones, each separated from the others by barriers. In the event of a fire, the zone with the fire is called the **smoke zone**, and the others are called the **nonsmoke zones**. Zones bordering on the smoke zone are called the **surrounding zones**. Either passive or pressurization smoke protection is used to limit smoke spread beyond the smoke zone. Smoke control cannot make conditions tenable in the smoke zone, and occupants should evacuate the smoke zone as soon as possible.

Some arrangements of smoke control zones are shown in Figure 23. In this figure, the smoke zone is indicated by a minus sign, and the surrounding zones are indicated by a plus sign. The smoke zone is often one floor of the building, but it can be the fire floor plus the floors directly above and below the fire floor. In a relatively low, sprawling building with several wings, the smoke zone can be part of a floor.

When separate HVAC systems serve each zone, systems distant from the smoke zone and surrounding zones should only remain operating if the building pressurization produced by these systems does not adversely impact zoned smoke control system performance. Otherwise, they should be shut down.

The traditional approach to zoned smoke control is to exhaust the smoke zone and to pressurize the surrounding zones, but other approaches have been used. Although fan-powered smoke exhaust is the most common method of treating the smoke zone, passive smoke control using smoke barriers may be satisfactory when fan-powered exhaust is not practical. Using exterior wall vents or smoke shafts to treat the smoke zone is not common, but these methods are discussed in Chapter 13 of the *Smoke Control Handbook*.

Fan-powered pressurization or passive smoke control using smoke barriers can be used for the zones surrounding the smoke zone. Fan-powered pressurization of the surrounding zones has a negative consequence on stairwell pressurization, as discussed in the following sections. In this section, fan-powered pressurization is called pressurization, and fan-powered exhaust is called exhaust.



Notes:
1. In these figures, smoke zone is indicated by minus sign (–), and surrounding zones are indicated by plus sign (+).
2. Smoke zone can be treated by fan-powered exhaust or passive smoke control using smoke barriers.
3. Surrounding zones can be treated by fan-powered pressurization or passive smoke control using smoke barriers.

Fig. 23 Some Arrangements of Smoke Control Zones

When the floors or wings of a building are divided into many rooms with normally closed doors, these floors do not lend themselves to the traditional concept of zoned smoke control. For such applications, a form of zoned smoke control can be used that relies on a combination of corridor exhaust and passive smoke control using smoke barriers. The passive protection tends to minimize smoke flow through the ceiling floor assembly during building fires. Some applications suitable for such an approach are hotel guest floors, apartment buildings, and some office buildings.

Interaction with Pressurized Stairs

The interaction of zoned smoke control with pressurized stairwells can have a significant effect on pressure differences across the stairwell doors. The following discussion is about smoke zones that are one floor and surrounding zones consisting of one floor above and one floor below. However, the same kind of interactions can happen with smoke zones and surrounding zones that are more than one floor.

The interaction between zoned smoke control and pressurized stairwells is shown in Figure 24. For zoned smoke control using both exhaust and pressurization, pressurization of the surrounding zones decreases the pressure difference Δp_{SB} across pressurized stairwell doors on these floors. This decreased pressure difference can result in failure of pressurized stairwells on the floors being pressurized. However, this failure mode is eliminated by using zoned smoke control that uses exhaust only.

Ideally, exhaust and pressurization zoned smoke control should prevent smoke from reaching the floor above the smoke zone, and negative stairwell pressurization should not compromise tenability of the stairwell. The effectiveness of this depends on proper identification of the fire floor. Properly maintained fire alarm systems are very good at identifying the location of a fire, but no system is perfect. In some fires, the first smoke detector to activate was a floor or so above the fire floor. This can be attributed to any of the following: (1) smoke flowing through a complex route to a floor above the fire, (2) smoke detectors not working properly on the fire floor, and (3) signals from smoke detectors being misidentified.

Regardless of the reason, when a fire floor is incorrectly identified, the smoke zone is incorrectly chosen. In this situation, the failure mode is that inadvertent pressurization of the fire floor can

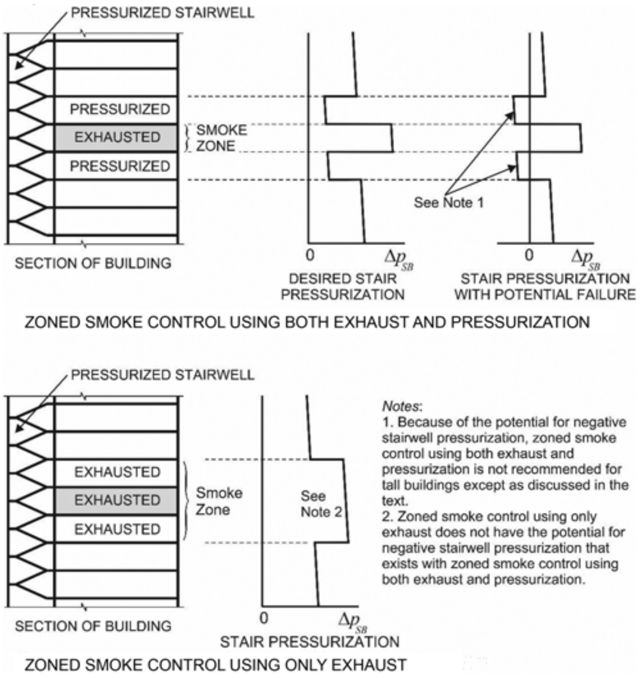


Fig. 24 Interaction Between Zoned Smoke Control and Pressurized Stairwells

push smoke into the stairwells (probably into all stairwells serving the fire floor). This failure mode is more of a concern for tall buildings, which are more difficult to pressurize acceptably, and for buildings with 10 or more stories, for which stairwell smoke protection is more critical. Occupant density is another factor affecting the importance of stairwell smoke protection. Because of this failure mode, it is recommended that zoned smoke control using systems using both exhaust and pressurization not be used for tall buildings where protection of the stairwells is especially important. Alternatively, analyze this failure mode, including factors such as evacuation time, emergency response time, and probability of using the firefighter's smoke control station (FSCS) for corrective action.

14. ATRIUM SMOKE CONTROL

Because of the lack of compartmentation in large-volume spaces, smoke protection for such spaces is important. This chapter considers a large-volume space to be at least two stories high, such as an atrium, exhibition center, enclosed shopping mall, arcade, sports arena, or airplane hangar.

For simplicity, the term **atrium** is used generically here to mean any of these large spaces.

Most atrium smoke control systems are designed to prevent exposure of occupants to smoke during evacuation; this is the approach described in this section. An alternative goal is to maintain tenable conditions even when occupants have some contact with smoke, as discussed in the section on Tenability Systems.

The following approaches can be used to manage smoke in atriums:

- **Smoke filling.** This approach allows smoke to fill the atrium space while occupants evacuate the atrium. It applies only to spaces where the smoke-filling time is sufficient for both decision making and evacuation. For information about people movement and evacuation time, see Chapter 4 of the *Smoke Control Handbook*. The filling time can be estimated either by zone fire models or by Equations (15.1) and (15.2) in the *Smoke Control Handbook*.

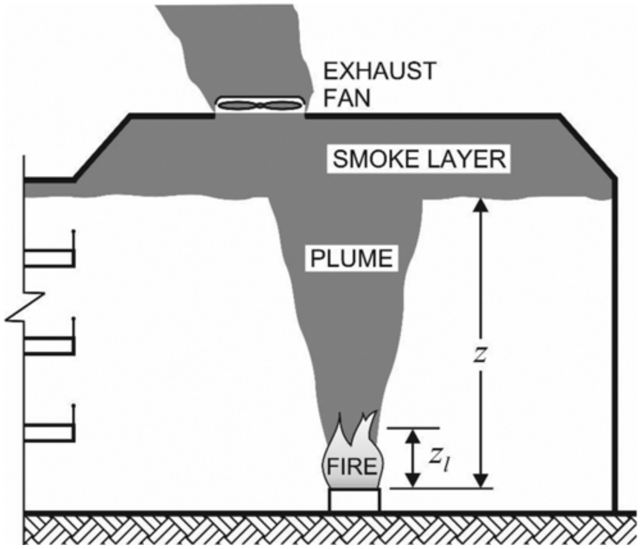

Fig. 25 Atrium Smoke Exhaust

- **Unsteady smoke exhaust.** This approach exhausts smoke from the top of the atrium at a rate such that occupants have sufficient time for decision making and evacuation. It requires analysis of people movement and fire model analysis of smoke filling.
- **Steady smoke exhaust.** This approach exhausts smoke from the top of the atrium to achieve a steady smoke layer height for a steady fire (Figure 25). A calculation method is given in the section on Equations for Steady Smoke Exhaust.

Design Fires

Analysis of the design fire is extremely important for atrium smoke control design, and an understanding of fire development is needed for such analysis. The intent of this section is to provide preliminary information of these topics. For more complete information, see Chapter 5 of the *Smoke Control Handbook*. By nature, fire is an unsteady process, but many design fires are steady fires. One of the most important aspects of a design fire is the **heat release rate (HRR)**. Other fuel properties (e.g., heat of combustion, soot yield) are not discussed here, because they are not used in the calculations in the Equation Method for Steady Smoke Exhaust section. However, such fuel properties are needed for CFD simulations that include tenability analysis.

When steady design fires are based on test data, it is accepted that the HRR of the steady fire is taken as the maximum HRR of the test data. For example, the HRR of upholstered furniture from test data is shown in Figure 26. For a sofa, the HRR grows to a maximum of about 3200 kW, then decreases as the fuel burns out. A sofa design fire could be unsteady based on the fire test data, or it could be a steady 3200 kW.

A design scenario is an outline of events and conditions that are critical to determining the outcome of alternative situations or designs. In addition to the fire location and HRR, it may include many other conditions such as materials being burned, outdoor temperature, wind, status of the HVAC system, and doors that are opened and closed.

A design analysis should include several design scenarios to ensure that the smoke control system will operate as intended. It is possible for an atrium project to have only one scenario, but most projects have two or three, and some complex projects require five or more.

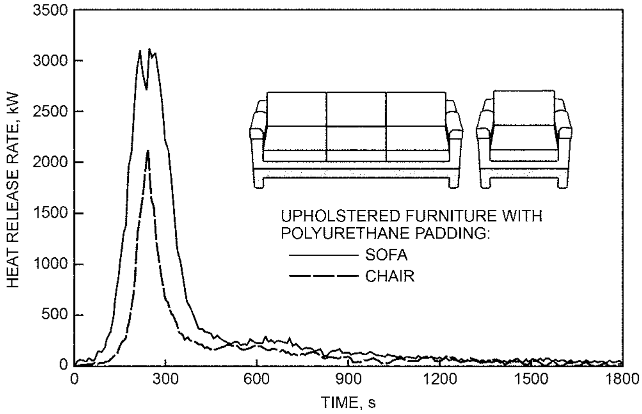

Fig. 26 HRR of Upholstered Sofa and Chair

Fire Development

The stages of fire development are useful when discussing fires. These stages are (1) growth, (2) flashover, (3) fully developed fire, and (4) decay. Not all fires go through all the stages, primarily because of fire suppression or a lack of fuel. The growth stage follows ignition, and the early part of the growth stage is characterized by an abundance of air for the fire. During the growth stage, the fire often spreads from one object to another. The growth stage of a sofa fire is from ignition to the peak HRR of about 3200 kW. The growth stage is often characterized by the following equation:

$$q = 1000\left(\frac{t}{t_g}\right)^2 \qquad (17)$$

where

q = heat release rate, kW
t = time, s
t_g = growth time, s

Such a growth stage is a called a ***t*-squared fire**, and typical growth times are listed in Table 7.

Development of a room fire in the growth stage may seem gradual. Smoke rises above the fire to form a smoke layer under the ceiling. Typically, the fire spreads from object to object, while the temperature of the smoke layer increases.

Flashover is a rapid change from a growth-stage fire to a fully developed fire, and primarily occurs by thermal radiation. This radiation is from the flames, the smoke plume, and the hot smoke layer below the ceiling. Thin, easy-to-ignite materials (newspapers, draperies, etc.) near the fire are the first to burst into flame, and this is followed by ignition of the rest of the flammable materials in the room.

In a room with a fully developed fire, everything that can burn is burning. A fully developed fire also is called a **ventilation-controlled fire**, because the HRR depends on the amount of air that reaches the fire. During a fully developed fire, flames generally extend from the doorways or open windows of the fire room. A fully developed fire is characterized by inefficient combustion resulting in high carbon monoxide production. For a fully developed fire in room with one opening, the HRR within the fire room can be expressed as

$$q = 1260 A_w H_w^{1/2} \qquad (18)$$

where

q = heat release rate of fully developed fire, kW
A_w = area of ventilation opening, m^2
H_w = height of ventilation opening, m

Table 7 Typical Fire Growth Times

t-Squared Fire	Growth Time t_g, s
Slow	600
Medium	300
Fast	150
Ultrafast	75

Note: Growth times from NFPA *Standards* 92 and 204.

For example, a fully developed fire in a room with a single door 1.07 by 2.13 m has an HRR of 4190 kW. The decay stage is a decrease in the HRR, which results from either fuel consumption or fire suppression. As the fuel is consumed, the fire may change from ventilation controlled to fuel controlled.

Sprinklers

Sprinklers are used extensively because they effectively suppress fires. The possible responses to sprinkler spray include (1) HRR decay, (2) constant HRR, or (3) an increase in HRR. The first two responses might be considered successful suppression, but in the third case, the sprinkler spray is overpowered by the fire.

Sprinkler actuation depends on the temperature and velocity of the gases flowing by the sprinkler and on the responsiveness of the sprinkler. The responsiveness of a sprinkler is characterized by the **response time index (RTI)**. In a fire, a ceiling jet of hot gases flows in a radial direction from where the smoke plume contacts the ceiling. The RTI of standard-response sprinklers is greater than or equal to 80 $m^{1/2} \cdot s^{1/2}$; fast-response sprinklers' RTIs are equal to or less than 50 $m^{1/2} \cdot s^{1/2}$. Computer programs can use the RTI and correlations for the ceiling jet to predict sprinkler actuation time, and some zone fire models (including CFAST, discussed in the section on Zone Fire Modeling) have this ability.

In spaces with high ceilings (greater than about 8 or 11 m), the temperature of the smoke plume can drop so much that sprinklers may not activate, or activation may be so delayed that the spray can evaporate before it reaches the fire. Sprinklers in an atrium could have some beneficial effect, but for design purposes they are considered not effective in an atrium. However, they are usually considered effective for fires in communicating spaces (i.e., a space with an open pathway to an atrium, such that smoke from a fire in either the atrium or the communicating space can move from one to the other without restriction). Fires in communicating spaces are often included in design scenarios.

Shielded Fires

A fire can be shielded from the sprinkler spray if an obstruction is between the sprinkler and the fire. Not only does the obstruction shield the fire from the water spray, but it also prevents the usual formation of a smoke plume. Because the smoke plume of a shielded fire can be very different from that of an unshielded fire, the sprinkler actuation time of shielded fires must not be calculated by the computer methods mentioned previously.

Two models have been developed for the HRR of shielded fires, based on test data. At NIST, fire tests were based on a few field observations of fuel loadings in office buildings (Madrzykowski and Vettori 1992), with a peak HRR of shielded fires of 500 kW. At the National Research Council of Canada (NRCC), fire tests were based on extensive field observations of fuel loadings in many buildings (Lougheed 1997), with a peak HRR of shielded fires of 1000 kW.

A peak HRR of 1000 kW is suggested for most shielded fires, and an HRR of 500 kW for locations where fuel is limited, such as in a showplace office of the president of a large corporation.

Transient Fuels

Transient fuels are materials that are in a space temporarily. Examples include seasonal decorations, paint and solvents in stairwells during redecorating, unpacked foam cups in cardboard boxes after delivery, cut-up cardboard boxes awaiting removal, upholstered furniture after delivery, stacked folding chairs, and materials from special events such as parties or dinners. Sometimes, transient fuels remain in place for long periods: for instance, polyurethane-filled mattresses delivered to a dormitory and waiting for distribution in the next school year, automobiles on display in a shopping mall, boats and campers on display in an arena, and a two-story wood frame house built for display inside a shopping mall.

Transient fuel is likely to accumulate at most locations in a building, except where it would block the usual paths of heavy traffic. It is unlikely that a commonly used building entrance or corridor would be blocked by transient fuel, but there could be accumulations next to a wall near the entrance or in the corridor.

Location can play a key role in transient fuels. Consider a sofa with polyurethane foam padding that is delivered for the office of the corporate president. Because the sofa is new and clean, it is decided to temporarily leave it in the nearby atrium until it can be moved to the president's office. In a corridor of an office building, the fuel could be trash consisting of any number of things such as an old upholstered chair or cardboard boxes with packing materials.

Suggested Fire Sizes

In many atriums, fuel loading is severely restricted with the intent of restricting fire size. Such atriums are characterized by interior finishes of metal, brick, stone, or gypsum board and furnished with objects made of similar materials, plus plants. In this chapter, a heat release rate per floor area of 225 kW/m^2 is used for a fuel-restricted atrium, and 500 kW/m^2 is used for atriums containing furniture, wood, or other combustible materials. These heat release rates per unit floor area are from Morgan (1979) and Morgan and Hansell (1987). In a fuel-restricted atrium, transient fuels must not be overlooked when selecting a design fire. The minimum fire is often considered as occupying 9.29 m^2 of floor area. The HRR of the minimum transient fire is (225 kW/m^2)(9.29 m^2) = 2100 kW. The HRR of the minimum fire with combustibles is (500 kW/m^2) (9.29 m^2) = 4600 kW. However, the area involved in fire can be much greater, and large fires can easily occupy 22 to 52 m^2 of floor area. This translates to large fires ranging from 11 000 to 26 000 kW. Table 8 lists some steady design fires, but an engineering analysis as discussed in Chapter 5 of the *Smoke Control Handbook* can result in different fire sizes. The large fires in Table 8 are not often used for design, but they represent an atrium with a large amount of fuel such as many upholstered sofas and chairs.

Atrium Smoke Filling

Atrium smoke filling is only applicable to very large atriums. Atrium smoke filling time can be calculated by empirical equations for steady fires and for *t*-squared fires in NFPA *Standard* 92 and Chapter 15 of the *Smoke Control Handbook*. These equations are based on the conventional approach of keeping smoke from coming into contact with occupants during evacuation. In very large atriums, smoke can often be diluted to the extent that a tenable environment is maintained for some time in the smoke layer at the top of the atrium. Design analysis of atrium filling is usually done with CFD modeling and tenability analysis (see the section on Tenability Systems).

Loss of Buoyancy in Atriums

For some applications, loss of buoyancy can cause the smoke layer to descend and threaten occupants. There is little research on this event, but the geometry of the large-volume space and the fire's heat release rate are major factors. Spaces that are unusually large or unusually long are of particular concern; for these cases, draft curtains can divide up the atrium into several smaller spaces. Theoretically, CFD modeling can predict loss of buoyancy in a large-volume space, but this has not been experimentally verified.

Table 8 Steady Design Fire Sizes for Atriums

	kW
Minimum fire for fuel-restricted atrium	2100
Minimum fire for atrium with combustibles	4600
Large fires	11 000 to 26 000

Note: These fire sizes apply to fire in the atrium space, but not to fires in communicating spaces in fully sprinklered buildings.

Minimum Smoke Layer Depth

The ceiling jet and smoke flow under the jet each have a depth of about 10% of the floor-to-ceiling height. Thus, the minimum smoke layer depth should be 20% of the floor-to-ceiling height, except when an engineering analysis using full-scale data, scale modeling, or computational fluid dynamic (CFD) modeling indicates otherwise (see the section on CFD Modeling). For information about scale modeling and full-scale fire testing, see Chapters 21 and 22 of the *Smoke Control Handbook*.

Makeup Air

Makeup air needs to be provided to ensure that exhaust fans can move the design air quantities and to ensure that door-opening force requirements are not exceeded. Makeup air can be provided using fans, openings to the outdoors, or both. Supply points for makeup air need to be below the smoke layer. Makeup air should be free or nearly free of smoke, as discussed in the section on Smoke Feedback.

Makeup air can be provided by mechanical fans or openings to the outdoors (e.g., opened doors or windows). When makeup air is supplied by fans, the makeup air system should be designed to provide 85 to 95% of the exhaust mass flow rate (not volumetric flow rate). The remaining 5 to 15% of makeup air enters as leakage through cracks in the construction, including gaps around closed doors and windows. Evaluation of this leakage needs to take energy standards into account. Makeup air fans can be activated concurrent with smoke exhaust fans, but the flow rate of makeup air fans should always be less that of the smoke exhaust fans.

When makeup air enters through openings to the outdoors, (1) the mass airflow through these openings should be considered the same as that of the smoke exhaust, and (2) the openings need to be opened automatically before the smoke exhaust fans are activated.

Hadjisophocleous and Zhou (2008) and Zhou and Hadjisophocleous (2008) show that, for makeup air velocities exceeding 1.02 m/s, the plume can be deflected, resulting in an increase in smoke production. For even higher velocities, the plume and smoke layer can be disrupted. The maximum air velocity must not exceed 1.02 m/s if the makeup air could come into contact with the smoke plume, unless a higher velocity is supported by engineering analysis. A secondary reason for the 1.02 m/s restriction is that it reduces the potential for fire growth and spread caused by airflow. For systems using fans, the exhaust fans should operate before the makeup air system does.

A CFD study of makeup air velocity conducted at the University of Maryland supports higher makeup air velocities higher than 1.02 m/s, provided that there is an appropriate increase in smoke exhaust flow rate and that the higher velocity does not increase fire spread or growth (ASHRAE research project RP-1600; Pongratz et al. 2016). The study examined 1, 2.5, and 5 MW fires. A method of determining the increase in smoke exhaust was developed, and one of the factors is the height of the makeup air supplied relative to the flame height.

When makeup air is supplied through openings, the wind can affect makeup air velocity. When makeup air openings are on walls facing different directions, wind can increase the makeup air velocity. A simple approach is to have all makeup air openings on walls facing the same direction. Although many code authorities do not require it, a wind analysis is suggested to mitigate the possibility of excessive makeup air velocity when makeup air openings are on walls facing different directions.

Stratification and Detection

A layer of hot air often forms under the ceiling of an atrium because of solar radiation on the atrium roof. Although no studies have been made of this stratification layer, building designers indicate that its temperature can exceed 50°C. Temperatures below this layer are controlled by the building's heating and cooling system.

When the average temperature of the plume is lower than that of the hot-air layer, a stratified smoke layer will form beneath the hot-air layer. In this situation, smoke cannot be expected to reach the atrium ceiling, and smoke detectors mounted on that ceiling cannot be expected to go into alarm.

Beam smoke detectors can overcome this detection difficulty. The following approaches can provide prompt detection regardless of air temperature under the ceiling when a fire begins:

- **Upward-Angled Beam to Detect Smoke Layer.** One or more beams are aimed upward to intersect the smoke layer regardless of the level of smoke stratification. For redundancy, more than one beam smoke detector is recommended. Advantages include not needing to locate several horizontal beams, and minimized risk of false activation by sunlight (a risk with some beam smoke detectors), because the receivers are angled downward. Review the manufacturer's recommendation when using beam smoke detectors for this application, because some beam detectors are not recommended for upward-angled installation.
- **Horizontal Beams at Various Levels to Detect Smoke Layer.** One or more beam detectors are located at roof level, with additional detectors at lower levels. Exact beam positioning depends on the specific design, but should include beams at the bottom of identified unconditioned spaces and at or near the design smoke level, with several beams at intermediate positions.
- **Horizontal Beams to Detect Smoke Plume.** Beams are arranged below the lowest expected stratification level. These beams must be close enough to each other to ensure intersection of the plume; spacing should be based on the width of the plume at the least elevation above a point of fire potential.

All components of a beam smoke detector must be accessible for maintenance, which may require maintenance openings in walls or the roof depending on the application.

Equation Method for Steady Smoke Exhaust

This section describes the algebraic equation method for analysis of atrium smoke control systems with a steady fire. A steady atrium smoke exhaust system has a steady smoke layer interface and a fire with a constant HRR. The smoke layer interface is an idealized concept described in the section on Zone Fire Modeling, and the equations used here are used in some zone fire models. There is some diluted smoke below the smoke layer interface, but this diluted smoke is considered insignificant. CFD modeling can calculate tenability of this diluted smoke.

For a case study of an engineering analysis for a three-story atrium that uses the algebraic equations of this section, see Chapter 16 of the *Smoke Control Handbook*. This case study addresses (1) the impact of wind, (2) determination of the minimum smoke layer depth, (3) system activation with a stratified hot-air layer, (4) analysis of design scenarios, (5) calculation of smoke exhaust for a fire in the atrium, (5) calculation of smoke exhaust for a fire with a balcony spill plume, (6) determination of makeup air, and (7) evaluation of the number of exhaust inlets and separation between them to prevent plugholing.

Readers who need to analyze atriums by the equation method may want to use AtriumCalc (Klote 2014), which uses common routines for designing atrium smoke control systems. For example, one routine calculates the smoke exhaust needed to maintain a steady smoke layer height when there is a steady design fire in the atrium with an axisymmetric plume. Each routine can be printed on a page suitable to be inserted in an engineering report. The page consists of a relevant figure, the equations used for calculation, input, and output. Other routines address balcony spill plumes, window plumes, preventing plugholing, and opposed airflow.

For an atrium fire, most of the heat flows upward in the smoke plume, and practically the rest of the heat leaves the fire by radiation. Heat transfer from fires by conduction is negligible. The convective heat release rate is expressed as

$$q_c = \chi_c q \tag{19}$$

where

χ_c = convective fraction
q_c = convective heat release rate, kW
q = heat release rate, kW

The convective fraction depends on the material being burned, heat conduction through the fuel, and the radiative heat transfer of the flames, but a value of 0.7 is usually used. For fire reconstruction, the specific value of the fuel being burned must be used.

Fire in Atrium

For a fire in an atrium, the mass flow rate of the plume is usually calculated by the empirical plume equations for axisymmetric plumes. Theoretically, an axisymmetric plume has a round cross section, but the plumes of many burning objects behave like an axisymmetric plume at some distance above the fire.

For a distance above the base of fire z equal to or greater than the **limiting elevation z_l**, the mass flow of the plume is

$$m = 0.071 q_c^{1/3} z^{5/3} + 0.0018 q_c \tag{20}$$

For $z < z_l$, the mass flow of the plume is

$$m = 0.032 q_c^{3/5} z \tag{21}$$

where

m = mass flow in axisymmetric plume at height z, kg/s
q_c = convective heat release rate of fire, kW
z = distance above base of fire to smoke layer interface, m
z_l = limiting elevation, m

The limiting elevation is approximately the average flame height, which is

$$z_l = 0.166 q_c^{2/5} \tag{22}$$

For a burning solid (e.g., chair, sofa, desk), the base of the fire is some distance above the floor (see Figure 25). When a flammable liquid has spilled and is burning, the base of the fire is at the floor.

Figures 27 and 28 show the smoke layer temperature and the smoke exhaust rate for fires in an atrium with an axisymmetric plume. The mass flow was calculated from the preceding equations, and the smoke layer temperature and volumetric flow were calculated by equations discussed in the following sections. As z increases, the smoke layer temperature decreases (Figure 27) as a consequence of air being entrained by the plume as it rises. The plume mass flow increases with height, and plume temperature decreases with height. Figure 28 shows that as z increases, the smoke exhaust rate increases.

Example 5. For a 2100 kW fire in an atrium with a distance from the base of the fire to the smoke layer interface of 11 m, what is the mass flow of the plume? The parameters are: $q = 2100$ kW, $z = 11$ m, and $\chi_c = 0.7$.

$$q_c = \chi_c\, q = 2100(0.7) = 1470 \text{ kW}$$

The limiting elevation is

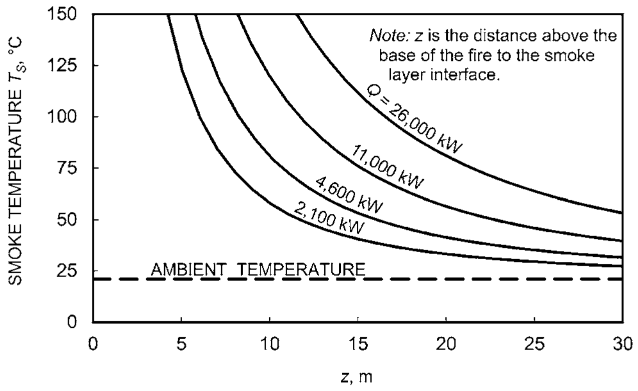

Fig. 27 Smoke Layer Temperature for Steady Smoke Exhaust Systems

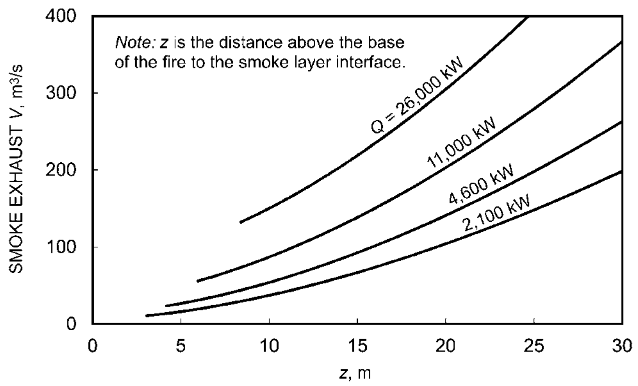

Fig. 28 Smoke Exhaust Rate for Steady Smoke Exhaust Systems

$$z_l = 0.166 q_c^{2/5} = 0.166(1470)^{2/5} = 3.1 \text{ m}$$

Because z is greater than z_l, the mass flow of the plume is calculated with the following equation:

$$m = 0.071 q_c^{1/3} z^{5/3} + 0.0018 q_c = 0.071(1470)^{1/3}(11)^{5/3} + 0.0018(1470)$$
$$m = 46.6 \text{ kg/s}$$

Fire in Communicating Space

For a fire in a communicating space, usually the mass flow rate of the plume is calculated by balcony spill plume equations. The following equations are based on extensive research, including scale model fire experiments, full-scale fire experiments, and analytical studies (Ko et al. 2008; Law 1986; Lougheed and McCartney 2008a, 2008b; Lougheed et al. 2007; McCartney et al. 2008; Morgan and Marshall 1979).

The equations were developed for fire room and balcony geometry similar to that of Figure 29. If the geometry is different, CFD modeling is recommended. For plume height z_b less than 15 m above the balcony edge, the mass flow of the plume is

$$m = 0.36(qW^2)^{1/3}(z_b + 0.25H) \tag{23}$$

Note: the mass flow equations and regions of applicability for the equations listed here have been corrected. NFPA issued errata correcting balcony spill plume equations in NFPA *Standard* 92-2012. There is an erratum for the bounds of one of these equations in the *Smoke Control Handbook*.

For $z_b \geq 15$ m and plume width of less than 10 m, mass flow of the plume is

$$m = 0.59 q_c^{1/3} W^{1/5}(z_b + 0.17 W^{7/15} H + 10.35 W^{7/15} - 15) \tag{24}$$

For $z_b \geq 15$ m and plume width between 10 and 14 m, the mass flow of the plume is

$$m = 0.2(q_c W^2)^{1/3}(z_b + 0.51H + 15.75) \tag{25}$$

where

- m = mass flow rate in plume, kg/s
- q = heat release rate, kW
- q_c = convective heat release rate of fire, kW
- W = width of the spill, m
- z_b = height of plume above balcony edge, m
- H = height of balcony above fuel, m

Physical barriers can be used to restrict the horizontal spread of smoke under the balcony. Draft curtains used for this application must extend at least 10% of the floor-to-ceiling height below the

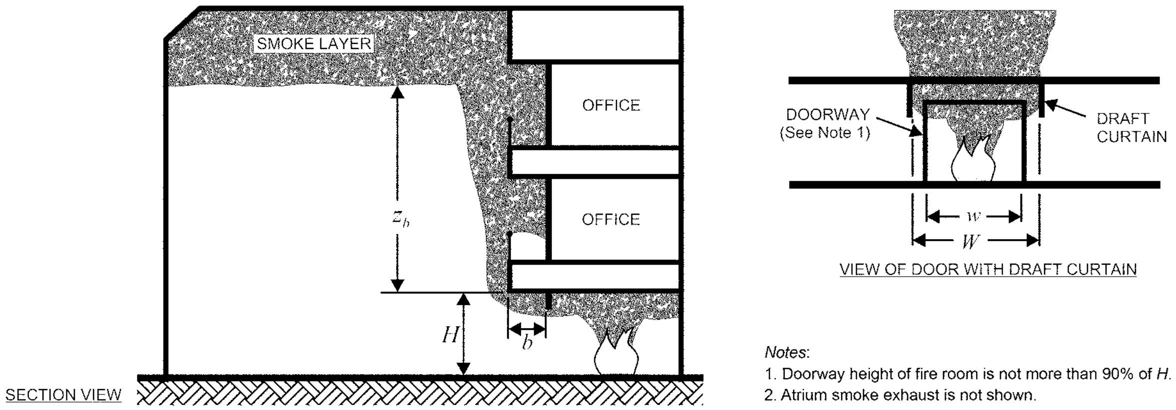

Fig. 29 Balcony Spill Plume

balcony. In almost all U.S. and Canadian applications, there are no draft curtains to restrict flow as shown in Figure 29. Without draft curtains, the spill width is estimated as

$$W = w + b \quad (26)$$

where

W = width of spill, m
w = width of opening from area of origin, m
b = distance from opening to balcony edge, m

Example 6. For a 1000 kW shielded fire in a communicating space as shown in Figure 29, calculate the mass flow of the balcony spill plume. There are no draft curtains to restrict the smoke flow under the balcony. The parameters are q = 1000 kW, z_b = 8 m, H = 3.4 m, b = 1.8 m, and w = 4 m.

The width of the spill is

$$W = w + b = 5.8 \text{ m}$$

Because z_b is less than 15 m, Equation (23) is used to calculate the mass flow of the balcony spill plume:

$$m = 0.36(qW^2)^{1/3}(z_b + 0.25H) = 0.36[1000(5.8)^2]^{1/3} [8 + 0.25(3.4)] = 103 \text{ kg/s}$$

Smoke Layer Temperature

The smoke layer temperature is calculated from

$$T_s = T_o + \frac{Kq_c}{mC_p} \quad (27)$$

where

T_s = smoke layer temperature, °C
T_o = ambient temperature, °C
K = fraction of convective heat release contained in smoke layer
q_c = convective heat release rate, kW
C_p = specific heat of plume gases, 1.0 kJ/(kg·K)
m = mass flow rate of plume where it enters smoke layer, kg/s

Equation (27) applies to both axisymmetric plumes and balcony spill plumes. For atrium smoke control systems, it is believed that K varies from 0.5 to 1.0. For calculating the volumetric flow rate of smoke exhaust with Equation (23), use K = 1.0 because it results in the highest smoke exhaust, which is conservative. For plugholing calculations (see the following section on Number of Exhaust Inlets), use K = 0.5 because it results in the largest number of exhaust inlets, which is also conservative. Other values of K may be used for these applications if they are supported by test data or an engineering analysis. The mass flow rate is calculated from Equations (20) or (21).

Volumetric Flow of Smoke Exhaust

Volumetric flow of smoke exhaust is

$$V = \frac{m}{\rho} \quad (28)$$

where

V = volumetric flow rate of smoke exhaust, m³/s
m = mass flow rate of smoke exhaust, kg/s
ρ = density of smoke, kg/m³

The density of smoke can be calculated from

$$\rho = \frac{p_{atm}}{RT_s} \quad (29)$$

where

ρ = density of smoke, kg/m³
p_{atm} = atmospheric pressure, Pa
R = gas constant, 287 J/(kg K)
T_s = absolute temperature of smoke, K

The standard atmospheric pressure p_{atm} for many locations is provided in Chapter 2 of the *Smoke Control Handbook*.

Example 7. What is the volumetric flow rate for the mass flow rate from Example 5? A few minutes after system activation, the air temperature in the atrium is the same as that of the outdoors, and the largest volumetric flow rate happens during summer when it is hot outdoors. The summer outdoor design temperature is 35°C. The parameters are T_o = 35°C, m = 46.6 kg/s, q_c = 1470 kW, C_p = 1.0, R = 287 J/(kg·K), and p_{atm} = 101.3 kPa. For calculation of smoke exhaust, K = 1.

$$T_s = T_o + \frac{Kq_c}{mC_p} = 35 + \frac{1(1470)}{46.6(1)} = 67°\text{C (340 K)}$$

$$\rho = \frac{p_{atm}}{RT_s} = \frac{101\,300}{287(340)} = 1.04 \text{ kg/m}^3$$

Number of Exhaust Inlets

When the flow rate of a smoke exhaust inlet is relatively large, cold air from the lower layer can be pulled through the smoke layer into the smoke exhaust. This phenomenon is called **plugholing**. Multiple exhaust air inlets may be needed to prevent plugholing. The maximum volumetric flow rate that can be exhausted by a single exhaust inlet without plugholing is calculated by

$$V_{max} = 4.16\gamma d^{5/2}\left(\frac{T_s - T_o}{T_o}\right)^{1/2} \quad (30)$$

where

V_{max} = maximum volumetric flow rate without plugholing at T_s, m³/s
T_s = absolute temperature of smoke layer, K
T_o = absolute ambient temperature, K
d = depth of smoke layer below lowest point of exhaust inlet, m
γ = exhaust location factor

The ratio d/D_i should be greater than 2 where D_i is the diameter of the exhaust inlet. For exhaust inlets centered no closer than $2D_i$ from the nearest wall, γ = 1 should be used; for less than $2D_i$, γ = 0.5 should be used. For exhaust inlets on a wall, use γ = 0.5. For rectangular exhaust inlets, calculate D_i as

$$D_i = \frac{2ab}{a + b} \quad (31)$$

where

a = length of the inlet, m
b = width of the inlet, m

The variables a and b can be in any unit of length provided that they are both in the same units. For square inlets, D_i equals the side of the square. Where multiple inlets are needed to prevent plugholing, the minimum separation between inlets should be

$$S_{min} = 0.9V_e^{1/2} \quad (32)$$

where

S_{min} = minimum edge-to-edge separation between inlets, m
V_e = volumetric flow rate of one exhaust inlet, m³/s

Example 8. For the fire of Example 7, determine the number of smoke exhaust inlets and the minimum separation between them to prevent plugholing. The smoke layer is 3.2 m deep. Because the inlets in the ceiling are far from walls, γ = 1. Plugholing will be calculated for an ambient temperature of 21°C. The parameters are γ = 1, d = 3.2 m, T_o = 21°C (294 K), m = 46.6 kg/s, q_c = 1470 kW, C_p = 1.0, and V = 44.8 m³/s. For calculating the number of exhaust inlets, K = 0.5.

$$T_s = T_o + \frac{Kq_c}{mC_p} = 21 + \frac{0.5(1470)}{46.6(1.0)} = 36.8°\text{F (309.8 K)}$$

$$V_{max} = 4.16\gamma d^{5/2}\left(\frac{T_s - T_o}{T_o}\right)^{1/2}$$

$$= 4.16(1)(3.2)^{5/2}\left(\frac{309.8 - 294}{294}\right)^{1/2} = 17.7 \text{ m}^3\text{/s}$$

V/V_{max} is 44.8/17.7 = 2.6. This means that at least three inlets are needed to prevent plugholing.

$$V_e = 44.8/3 = 14.93 \text{ m}^3\text{/s}$$

$$S_{min} = 0.9V_e^{1/2} = 0.9(14.93)^{1/2} = 3.48 \text{ m}$$

$$V_e = 44.8/3 = 14.93 \text{ m}^3\text{/s}$$

$$S_{min} = 0.9V_e^{1/2} = 0.9(14.93)^{1/2} = 3.48 \text{ m}$$

An inlet velocity of 7.5 m/s is chosen. The area of each inlet is 14.93/7.5 = 1.99 m^2.

An inlet size of 1.3 by 1.53 m is chosen, and $D_i = 2ab/(a + b)$ = 2(1.3)(1.53)/(1.3 + 1.53) = 1.41 m.

Then d/D_i = 3.2/1.41 = 2.27, which meets the stipulation that this ratio has to be greater than 2.

These calculations indicate that the edges of the inlets need to be at least 3.48 m apart from each other, and at least $2D_i$ (2 × 1.41 = 2.82 m) from the nearest wall. If the edges of any inlets are closer to a wall, the calculations should be repeated with γ = 0.5. If the inlets were in the walls, γ would be 0.5.

Zone Fire Modeling

Zone fire modeling is a simple approach to simulating smoke transport. The idea of the zone fire model came from observations in early room fire experiments that a smoke plume rises above the fire, and a smoke layer forms under the ceiling. As the fire continues, the smoke layer descends, and smoke may flow out of doorways (a **doorjet**).

A zone fire model considers a fire compartment to be made up of an upper smoke layer and a lower nonsmoke layer. The mass flows of the smoke plume and the doorjet are calculated from empirical equations. For the zone model idealization, temperature and concentrations of constituents are considered to be constant throughout each layer. These properties change only as a function of time.

Most zone models consider that ceilings are flat and that rooms have uniform cross-sectional areas. The height of the discontinuity between these layers (the **smoke layer interface**) is considered to be the same everywhere. In the idealized model at an infinitesimal distance above the interface, the temperature and contaminant concentrations are those of the smoke layer. At an infinitesimal distance below the interface, the temperature and contaminant concentrations are those of the lower layer. Even with these simplifications, zone fire models have proven to be very useful tools for many applications, but they must be used with care. Because different zone models use different empirical equations implemented in different ways, the predictions of different zone models vary to some extent.

Many zone models were developed in the 1980s, and often had poor numerical convergence. **CFAST** is a multiroom zone fire model that has superior numerical convergence, many features, and a graphical interface (Peacock et al. 2017), and has been verified with full-scale fire data. CFAST and its documentation are available from NIST at no cost from pages.nist.gov/cfast. Probably for these reasons, CFAST has become the de facto standard zone fire model.

CFAST can be used to simulate atrium smoke filling, and is useful for calculating sprinkler activation time. To help new users of this model get started, Chapter 18 of the *Smoke Control Handbook* has general information about zone models plus some CFAST user information.

CFD Modeling

Atrium smoke control can be analyzed by CFD modeling. For general information about CFD modeling, see Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*. For information about fire applications of CFD modeling, see Chapter 20 of the *Smoke Control Handbook*.

The idea of CFD is to divide the space of interest into a large number of cells and to solve the governing equations for each cell. Often, millions of cells are necessary for atrium applications. The number of cells in the model should be large enough to simulate airflows around modeled obstructions faithfully, and this can be evaluated by a sensitivity analysis of cell size. Obstructions such as walls, balconies, and stairs should be taken into account, and conditions at the boundaries defined. Exhaust flow at or near the top of the atrium is specified, and makeup air conditions are also defined. This allows simulation of fluid flow in considerable detail.

Although CFD modeling has significant advantages in realistically simulating smoke flow, it is computationally intensive and requires a lot of computer memory and time; it is not uncommon for a CFD simulation to run for many hours and sometimes days. CFD produces so many numbers that graphical methods are needed to understand both general trends in the atrium and nuances in localized conditions.

Several general-purpose CFD models are commercially available that can be used for atrium smoke control. NIST has developed the Fire Dynamics Simulator (FDS) model (McGrattan et al. 2019) with visualization software called Smokeview (Forney 2019). FDS, specifically developed and verified for fire applications, can be obtained from NIST at no cost (pages.nist.gov/fds-smv/) and has become the de facto standard CFD model for fire applications.

15. TENABILITY SYSTEMS

The smoke control systems previously discussed are conventional systems intended either to keep smoke away from occupants or to allow only incidental smoke contact deemed to be negligible. Tenability systems are different: they are designed to allow occupants to come into contact with smoke provided that a tenable environment (i.e., one in which combustion products, including heat, are limited to a level that is not life threatening) is maintained. Analysis of a tenability system consists of a smoke transport analysis and a tenability evaluation.

Tenability Evaluation

Toxic gas, heat, and thermal radiation exposure are direct threats to life, the severity of which depends on the intensity and duration of exposure. Tenability evaluation considers the effects of exposure to these threats, as well as reduced visibility.

Reduced visibility does not directly threaten life, but it is an indirect hazard. It can reduce walking speed; also, when occupants and firefighters cannot see well, they can become disoriented and cannot get away from the smoke, thus prolonging their exposure. Another concern is that a disoriented person can fall from an atrium balcony, which can be fatal.

For information about calculating the effects of exposures to combustion gases and reduced visibility, see Chapter 6 of the *Smoke Control Handbook*. There is no broad consensus, but suggested visibility criteria range from 4 to 14 m. When combustion products from most materials are diluted enough to meet such visibility criteria, the hazards to life from toxic gases, heat, and thermal radiation are also eliminated for exposures up to 20 min. This means that, for most fires, tenability can be evaluated by calculating visibility, but the hazards of other exposures must also be checked.

CFD Models. CFD models have been used extensively to analyze smoke transport for tenability systems in atriums. In addition to analysis of smoke transport, the FDS model incorporates features that help evaluate tenability. An especially useful feature is the ability of FDS to calculate visibility at user-selected points.

Large Multi-Compartmented Buildings. It is not practical to use CFD to simulate smoke transport in large buildings, but CONTAM can handle this simulation in extremely large buildings. With CONTAM, the user inputs the temperatures, and zone fire models can be used to evaluate fire produced temperatures in building spaces. Chapter 19 of the *Smoke Control Handbook* discusses tenability analysis using CONTAM, including an example.

16. COMMISSIONING AND TESTING

Commissioning refers to the process of examining, comparing, testing, and documenting the installation and performance of a smoke control system to ensure that it functions according to an approved design. It demonstrates to an owner that the smoke control system installed in a project meets the project's design goals.

Special inspections are a means that an **authority having jurisdiction (AHJ)** uses to determine that a smoke control system meets the code requirements. The International Building Code (IBC) has requirements for a special inspection and describes the qualifications required for a special inspector (ICC 2012).

Commissioning Process

Commissioning begins at the start of the project and continues throughout the project. ASHRAE *Guideline* 1.5 provides methods for verifying and documenting that the performance of smoke control systems conforms with the intent of the design. For smoke control systems, an AHJ such as a building official or fire marshal typically enforces a combination of building codes, fire codes, and local standards. The intent is to determine that the system meets the owner's project requirements (OPR), including code requirements and inspections by the AHJ throughout the delivery of the project.

Witnessing and reporting are important parts of commissioning. For successful commissioning of a system, several different people typically are involved in the process. In addition to the building owner and AHJ, the system designer, general contractor, subcontractors, fire protection engineering consultants, and testing and balancing technicians can be involved. At the end of testing, documentation is provided that the system is working properly according to the design.

Commissioning activities can occur at multiple stages during the construction process. Duct inspections, duct leakage testing, and barrier inspections are activities that typically occur early in the construction process when the ducts and barriers are readily visible. Component testing, including airflow measurement, can occur at a midpoint in construction where power is provided to individual devices, but central monitoring and control has not yet been provided. Sequence of operations and final performance testing typically occurs when construction is nearly complete, often just before the building is intended to obtain its permits and open to the public.

Commissioning Testing

Commonly, testing and balancing (TAB) is required before formal acceptance testing to achieve the expected performance of all the components. TAB refers to the process where the as-built performance of smoke control systems is tested in the field and compared to the required design conditions. Adjustments to the installed system, such as refining the supply airflow rates, are made to ensure that the smoke control system is functioning as intended in the approved design documentation.

System performance testing is the phase where the code-specified performance parameters appropriate to the smoke control design are measured. For example, building codes require that a minimum pressure difference exist between a pressurized stairwell and other zones in the building, and that door-opening force must not exceed a specified amount. In this case, performance testing would focus on measuring the pressure difference across stairwell doors and door-opening forces. Some common parameters measured during smoke control system performance testing are (1) exhaust/supply airflow quantities, (2) airflow velocities at atrium or other large open space perimeters, (3) door-opening forces, and (4) pressure differences between zones.

Caution: Smoke Bomb Tests Not Recommended. Artificial smoke from smoke bombs (also called smoke candles) or any kind of artificial smoke generator is not recommended for any performance testing, because it lacks the buoyancy of hot smoke from a real building fire. Smoke near a flaming fire has a temperature in the range of 540 to 1100°C. Heating chemical smoke to such temperatures to emulate smoke from a real fire is not recommended unless precautions are taken to protect life and property.

Special Inspector

Some building codes require special inspections and tests of smoke control systems in addition to the ordinary inspection and test requirements for buildings, structures, and parts of buildings. These special inspections and tests should verify the proper commissioning of the smoke control design in its final, installed condition. Procedures for inspection and testing should be developed by the smoke control system's special inspector, with approval of the authorities having jurisdiction. The special inspector must understand the principles of smoke control, including code requirements, and should check that the system's components are as specified and are installed as intended, as well as whether the smoke control system performs as intended.

Periodic Testing

After a smoke control system has been commissioned, testing must still be performed periodically over the building's life to ensure the system is in proper operating condition in the event of a fire. Periodic testing includes manual testing involving ongoing inspection and maintenance, and automatic testing to determine that integral equipment is functional and operational. Automatic testing is often performed at a higher frequency than manual testing. Continued inspection and testing identifies adjustments and repairs needed to account for unforeseen changes to the building or failure of components.

Until recently, smoke control system reliability has been somewhat compromised because periodic testing was limited to manual testing. Inspections performed years after commissioning showed that some smoke control systems were inoperable, turned off, or made ineffective by modifications to equipment or the building. Reliability of smoke control systems should be significantly improved by using automatic weekly self testing of system components, available from Underwriters Laboratories (UL) listed equipment with the UUKL product designation.

Dampers that are part of code-mandated passive smoke barriers are not included in the automatic weekly self testing. Typically, codes require testing these dampers every four years, except in hospitals (every six years).

17. EXTRAORDINARY INCIDENTS

Most buildings are designed and built to be protected from ordinary incidents, but some buildings need protection from extraordinary incidents. Extraordinary incidents, whether caused by war, terrorism, accident, or natural disaster, can affect immediate human needs such as survival and safety, and also longer-term needs such as air, water, food, and shelter. Some buildings are designed with specific features intended to make them less susceptible to extraordinary incidents. It is recommended that actuation of systems for fire and smoke protection be of higher priority than possibly conflicting automatic strategies designed to respond to other extraordinary conditions.

Some acts of terrorism use fire, and those using bombs often lead to fires. It is well known that war, terrorist attacks, and natural disasters have the potential to disrupt utilities and interfere with firefighting, and this often allows any fires that occur to grow unchecked. For these reasons, simultaneous fire and other extraordinary incidents should be considered likely, and any features intended to mitigate extraordinary conditions should be designed accordingly. For more information, see ASHRAE's (2003) report, *Risk Management Guidance for Health, Safety and Environmental Security under Extraordinary Incidents*, and Chapter 61 of this volume.

18. SYMBOLS

A = area, m^2
a = dilution rate, air changes per minute; length of inlet, m
A_a = free area around elevator car, m^2
A_{BO} = flow area per stairwell between building and outdoors, m^2
A_e = effective area, m^2
A_i = flow area of path i, m^2
A_{ir} = leakage area between building and lobby, m^2
A_s = cross-sectional area of shaft, m^2
A_{SB} = flow area between stairwell and building, m^2
A_w = area of ventilation opening, m^2
b = distance from opening to balcony edge, m; width of inlet, m
C = flow coefficient; concentration of contaminant at time t
C_c = flow coefficient for flow around car
C_O = initial concentration of contaminant
C_p = specific heat of plume gases, 1.0 kJ/(kg·K)
C_w = pressure coefficient
d = depth of smoke layer below lowest point of exhaust inlet, m; distance from doorknob to knob side of door, m
D_i = diameter of exhaust inlet, m
F = total door-opening force, kg
F_{dc} = door closer force, kg
F_R = flow area factor
H = floor-to-ceiling height, m; height of balcony above fuel, m
H_J = thickness of ceiling jet, m
H_m = height limit, m
H_w = height of ventilation opening, m
K = fraction of convective heat release contained in smoke layer
m = mass flow rate, m^2/s
p_{atm} = atmospheric pressure, Pa
p_w = wind pressure, Pa
q = heat release rate, kW/s
q_c = convective heat release rate, kW/s
R = gas constant, 287 J/(kg·K)
S_{min} = minimum edge-to-edge separation between inlets, m
t = time, s
T_B = temperature in building, °C; absolute temperature in building, K
T_F = absolute temperature of fire compartment, K
t_g = growth time, s
T_{in} = absolute temperature of air into fire compartment, K
T_J = absolute temperature of ceiling jet, K
T_O = temperature of outdoors, °C or K
T_o = absolute ambient temperature, °C or K
T_{out} = absolute temperature of smoke leaving fire compartment, K
T_S = temperature of shaft or stairwell, °C or K
T_s = absolute temperature of smoke, K
U = elevator car velocity, m/s
U_H = velocity at wall height H, m/s
V = volumetric flow rate, m^3/s
V_e = volumetric flow rate of one exhaust inlet, m^3/s
V_{in} = volumetric flow rate of air into fire compartment, m^3/s
V_{max} = maximum volumetric flow rate without plugholing at T_s, m^3/s
V_{out} = volumetric flow rate of smoke out of fire compartment, m^3/s
W = door width or width of spill, m
w = width of opening from area of origin, m
z = distance above neutral plane or distance above base of fire, m
z_b = height of plume above balcony edge, m
z_l = limiting elevation, m

Greek

γ = exhaust location factor
Δp = pressure difference, Pa
Δp_{FS} = pressure difference from fire compartment to surroundings, Pa
Δp_{max} = maximum design pressure difference, Pa
Δp_{min} = minimum design pressure difference, Pa
Δp_{SO} = pressure difference from shaft to outdoors, Pa
$\Delta p_{u,si}$ = upper limit pressure difference from shaft to building, Pa
η = heat transfer factor
ρ = density, kg/m^3
ρ_o = outdoor air density, kg/m^3
χ_c = convective fraction

Radiant Cooling System Control 55.15

1. APPLICATIONS

BASED on the global push towards high performance buildings, current application knowledge and readily available equipment, there are now few limitations for radiant heating and cooling systems. The past concern over condensation has now been successfully addressed, with tighter enclosures to mitigate moisture infiltration, dedicated outdoor air systems for dehumidification of incoming ventilation air, and current technologies capable of integrating and regulating all control points within radiant based HVAC systems. Additionally, radiant systems technically offer the best coupling with solar and geothermal energy systems, heat actuated cooling systems and heat pumps by enabling such systems to operate at higher efficiencies and coefficients of performance. They can also be applied using district energy and CHP principles to stand alone multi-story buildings. Furthermore, high performing buildings particularly those with above normal sensible loads due in part to the use of electronic equipment are much better served with radiant absorption of long wave energy rather than increase recirculation of chilled air which in comparison, is neither comfortable nor efficient.

2. ARCHITECTURE OF RADIANT CEILINGS

Ceiling radiant cooling panels (CRCP) and heating panels are generally built as an architectural finish product (with necessary acoustical qualities, color, and pattern), compatible with the traditional drop ceiling "tee grid" system or as a free hanging element. Typically, a copper tube is embedded into an extruded aluminum saddle which is permanently affixed to the back of an architectural metal ceiling panel or is part of a built-up panel made from linear extrusions with integral tube saddles fastened together to make different width panels. The process of how the copper coil is thermally bonded with the radiant ceiling panel is crucial especially in cooling application. Panel piping arrangements are generally in a serpentine pattern; however, parallel header arrangements are also available. Typical panel construction is illustrated in Figure 1. As installed, the "drop in" radiant panels have a mass of 7.8 to 9.7 kg/m^2. A radiant ceiling panel also has an acoustic value. The acoustic signature can be achieved with a variety of perforations. In addition, a glass fiber blanket or non-woven sound-attenuating sheet is placed on the pack of the panel.

The lightweight construction results in a transient response "time constant" of only about 3 to 5 minutes from ambient room temperature to operating temperature once the cooling/heating fluid is applied. That means they respond rapidly to changing space sensible load conditions. Hydraulically, the ceiling panels are most frequently connected with flexible-push on coupling hoses for fast and safe installations, as illustrated in Figures 2 and 3.

Panels can be moved aside without disconnecting the hoses, for easy access above. They can also be easily removed and reconnected for either extensive maintenance or evolving space use requirements without breaking normal threaded or sweat solder plumbing connections.

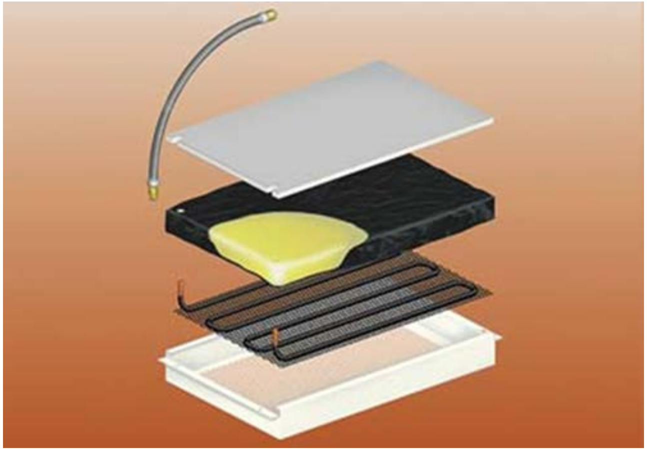

Fig. 1 Typical Composition of Radiant Modular or Pan-Type Ceiling Panel

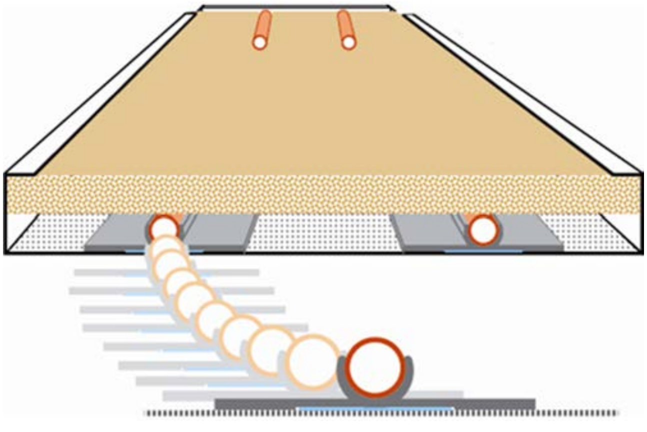

Fig. 2 Cutaway View of Typical Modular Radiant Ceiling Panel

Radiant ceiling panels promote architectural freedom in several ways. First, radiant cooling ceilings can be designed to be visually indistinguishable from regular ceilings to maintain aesthetic appeal. Secondly, the hardware in a radiant cooling system is smaller and more flexible. The size of the ceiling panels, the arrangement of the appliances within the ceiling, and the partitioning of the room all are

Fig. 3 Back View of Drop Ceiling: Piping Configuration with Flexible Hose and Quick-Connect Fittings

flexible. Units may also be quite large assembled from linear extrusions which maybe be as long as 4.8 m and widths (built of several extrusions side by side) to 609 mm or even to 1219 mm wide. These are also the typical style of panels used along building perimeters for heating applications. In perimeter heating, panels are typically 152 to 609 mm wide depending on the perimeter heat loss. Due to the reduction in sensible heating and cooling loads that must be carried in the air, the new minimal airflow requirements often permit designs where common mechanical air distribution devices such as diffusers and ductwork are made much smaller or are eliminated altogether.

3. DESIGN AND DIMENSIONING

Panels are dimensioned based on building/room loads for heating or cooling and sometimes both. For heating or cooling the room design temperature and supply water temperature and flow rates determine the capacity of the panels in watts per square metre. Once this capacity is determined it is divided into the load to determine the square feet of active panels required. The design then uses this information to layout the panels in the space. Heating panels should be placed within 1 m of the exterior walls. Cooling panels should be more evenly distributed throughout the space with some heavier weighting to the highest area of heat gains (i.e., windows.)

Cooling

In practice, the design cooling capacity per unit panel area (W/m^2) is determined from the panel manufacturer's catalog data. The unit panel cooling capacity can be selected from the design capacity tables provided by the panel manufacturer based on the difference between the room temperature and the mean panel surface temperature (or mean water temperature [MWT]).

Heating

In many climates, radiant cooling ceilings can also provide heating. For best applications, the structure should be well insulated, and outside temperatures should not be extremely low. In these cases, radiators are not needed, saving costs and making more floor space available.

Because humans sense heat from a hot ceiling more quickly than from hot air blown in from ducts, surface temperatures should not exceed 35°C. The reason the surface should not exceed 35°C is to permit humans to radiate a small amount of heat from their heads that are normally at 37°C to a slightly cooler surface. If the surface temperature exceeds 35°C, humans in the space will experience discomfort and may even experience headaches. This is only if the panel is right above the head sufficient separation should allow higher temperatures of 43.4 to 48.9°C max for normal ceiling heights of 2.7 to 3.3 m or even higher temperatures if placed at the perimeter walls where panels are not directly over the heads of occupants.

Radiant panels radiate heat to the surrounding surfaces including people, furnishings, and the cold interior surface of the window. The cold window surface, loses heat via transmission to the cold outside. Without radiant heating, the cold window surface cools the air passing over it, creating a significant convection down draft. Normally the baseboard radiators balance this action. With radiant heating, the interior surface of the glass is warmed through direct radiation, significantly reducing the convection down draft produced. The small down draft current produced, typically less than 0.1 to 0.15 m/s, creates a vacuum effect under the radiant heat panels. The low-pressure area formed draws the warm room air at the ceiling towards this area where it is further warmed by the radiant heat panels. Thus, the air becomes even more buoyant, and it has a tendency not to convect down the outer wall. The net effect is a surface boundary layer of "dead air" created very near the window. The down draft is below the minimum threshold felt by humans. Therefore, in some cases the baseboard radiators can often be eliminated, reducing capital costs and increasing usable floor area.

Another consideration in the heating mode, the convection is lower, and the ceiling's capacity is proportionally reduced. In most cases, the internal heat loads can provide sufficient heat. To prevent cold airdrop from the windows, the radiant heating portion of the ceiling needs to be installed along the perimeter of the room (typically within 1 m of the exterior wall).

4. DESIGN ASPECTS OF RADIANT CEILING SYSTEMS

Technically speaking, a radiant cooling ceiling is simply a large heat exchanger suspended from a room's ceiling. It exchanges energy with the room via radiation and convection. Accordingly, cooling ceilings can be rated based on the temperature difference between the panel's MWT and the room design temperature. Heat transfer from the room to the ceiling surface (or the other way around in the case of heating) is a function of the average ceiling surface temperature and the room temperature. The objective of every radiant cooling ceiling developer is to get the ceiling surface temperature as close as possible to the water temperature. The smaller the temperature difference between chilled water and ceiling surface, the more efficient the system.

The overall heat exchange between ceiling panels and the flow in the water piping obeys the following equation:

$$Q = kA\,\Delta T \qquad (1)$$

where ΔT is the smallest possible temperature difference between the contact point of the ceiling panel and the fluid flowing in the piping. This path includes the conductance between the panel and the pipe, conductance through the pipe, and the convection from the inner pipe surface to the fluid. Thus, k is the equivalent thermal conductivity. The removed heat by the fluid flow in the piping Q should be as large as possible. Therefore, the overall k-value and the heat conducting areas A must be made as large as possible.

Panel dimensions can be chosen freely within manufacturing and building installation constraints. The only definitive design constraint to the architect is that active tubing attachment side must be flat.

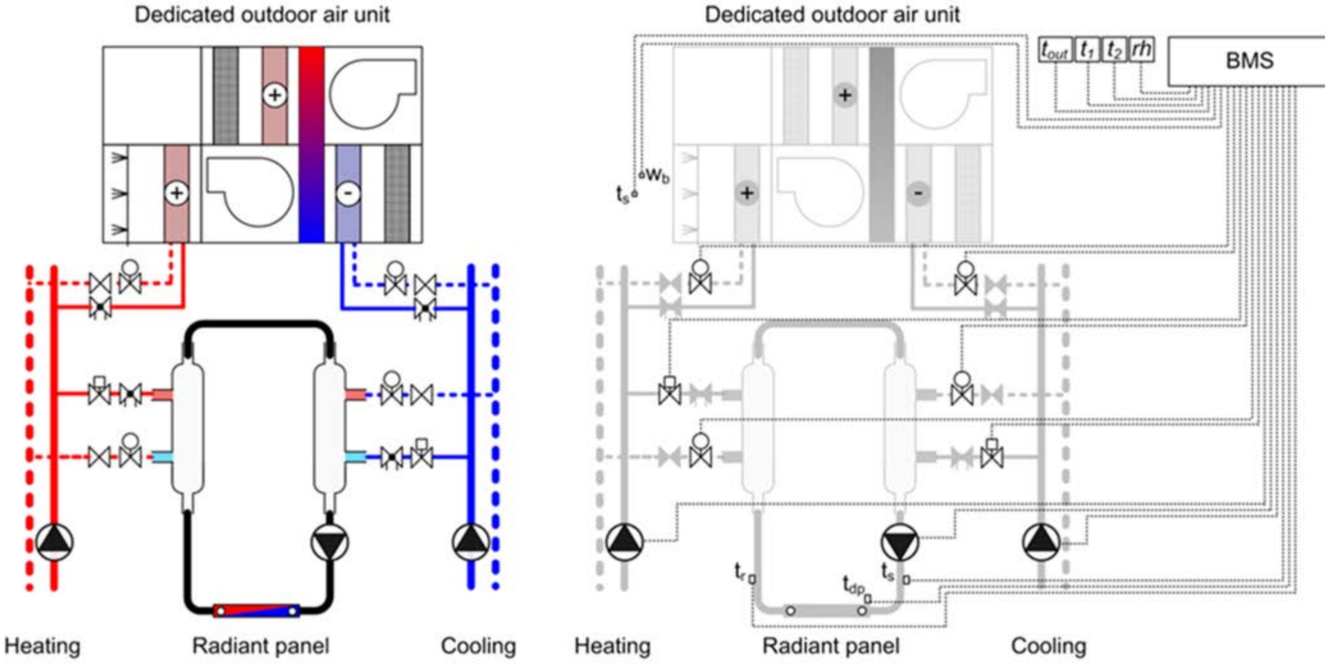

Fig. 4 Typical Control Schematic for Radiant System with Injection Control Valves in Four-Pipe/Two-Pipe System

5. ACOUSTIC FEATURE OF RADIANT CEILING PANELS

Room acoustics also are handled conventionally. The following addresses commonly applied strategies for improving acoustics in rooms with cooling ceilings.

Acoustic Inlay Mats

Mineral fiber mats 30 mm thick and 40 kg/m^3 are applied on the back of a perforated radiant ceiling tile to meet required acoustic values.

Acoustic Fleece

In environments such as clean rooms and hospitals where fiber rub-off is not expected under any circumstances, acoustic fleece may be used. The black fleece is bonded to the rear of the perforated ceiling panel. To prevent a decrease in the heat exchange between the heat conducting rails and the ceiling panel, the fleece is bonded between the heat-conducting rails. Acoustic fleece must have a minimum plenum height of 300 mm to be effective.

Panel Perforation

The ceiling panels might feature certain perforation pattern to enhance acoustic performance or personalize the visual aspect of the ceiling. The perforation pattern is often specified with hole diameter and free area (open cross sections etc.).

6. CONTROLS

The design of control system should take into account the building, its intended use and the effective functioning of the heating/cooling system, efficient use of energy and avoiding heating/cooling the building to full design conditions when not required. This should include keeping distribution heat losses as low as possible, e.g. reducing flow temperature when normal comfort temperature level is not required. Control and operation of the system help to handle the conditioning systems with savings of operational costs and enable the maintenance of required indoor environmental conditions.

Hydronic radiant controls systems have two primary functions: controlling room temperature and preventing condensation on the ceiling surface. For proper operation and maximum energy savings, radiant ceiling systems require the use of precision electronic or direct digital controls.

Two-Port Control Valves

The two-port valve controls the heat loads by permitting more or less chilled water to flow through the valve and through the cooling ceiling (Figures 4 and 5). The supply water temperature stays constant. A humidity sensor closes the valve as soon as the chilled water supply temperature reaches dew point.

This type of control is very affordable and simple. The only disadvantage is dew point control. The cooling ceiling must be turned off as soon as a risk of condensation occurs.

Controls are generally applied to influence both pressure (flow) and temperature.

Accordingly, there are two control strategies: using (1) a two-way control valve to control water flow or (2) an injection circuit to control water temperature.

Controlling Water Temperature/Injection Circuit

Using an injection circuit requires a circulating pump to provide a constant flow of water through the ceiling (Figures 6, 7, and 8). Depending on the heat loads, a two- or three-way valve injects more or less chilled water to the ceiling supply. The same water quantity is sent to the system return. The supply water temperature for the ceiling is controlled by the quantity of the water injected. If risk of condensation occurs, the temperature of the supply water can be raised. The ceiling loses some of its capacity but can be kept in operation.

The injection circuit ensures both effective operation and the maximum possible mean temperature difference for cooling ceilings. As each control zone needs a pump, a humidity sensor, and a controller (which constantly calculates dew point and compares it

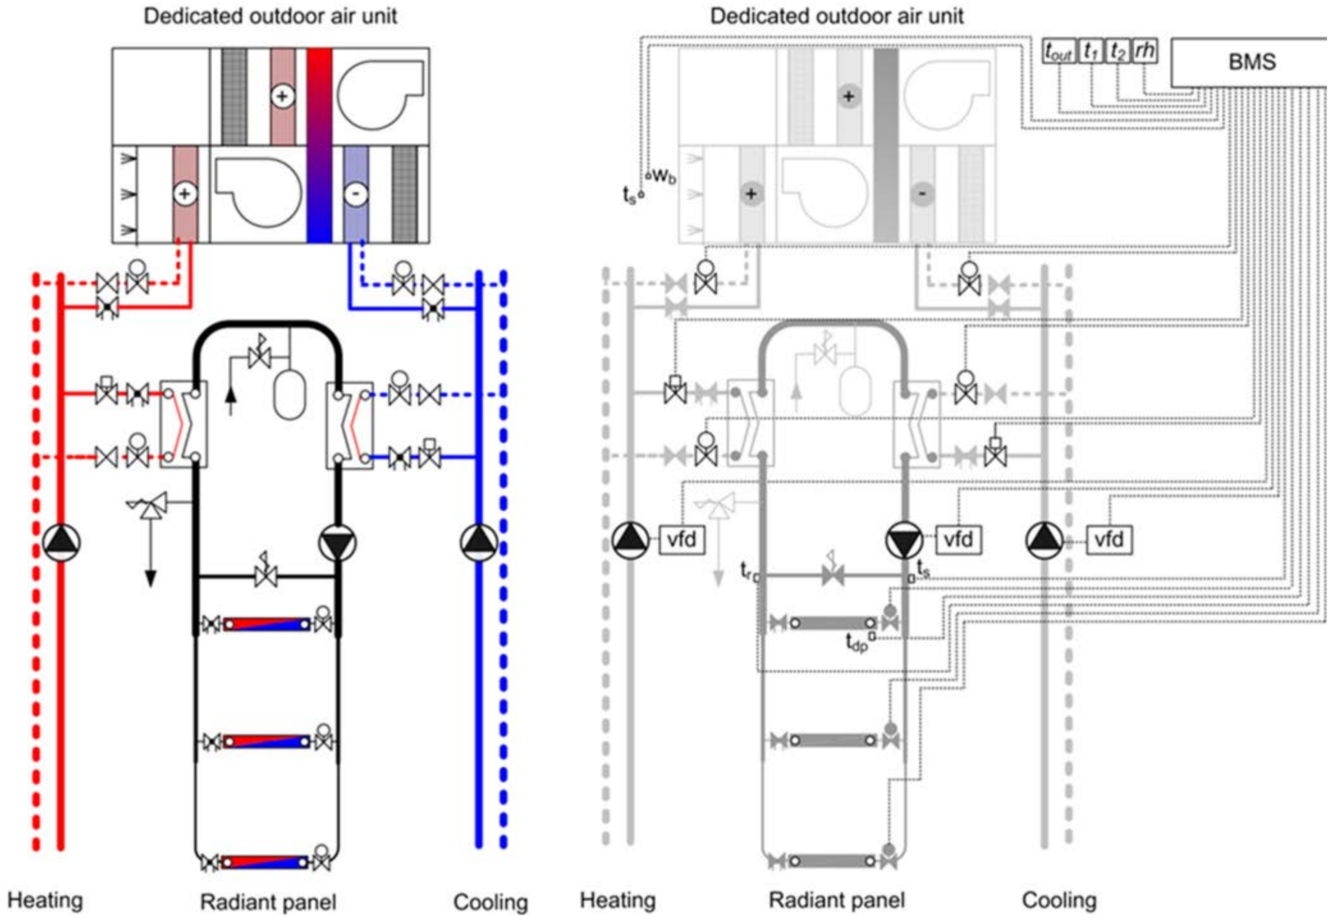

Fig. 5 Advanced Control System for Radiant System with Heat Exchangers in Four-Pipe/Two-Pipe System (Some Items Removed for Clarity)

with the supply water temperature), this type of control is more expensive than the two-way control scheme.

Energy Savings with Radiant Cooling Ceiling Systems

Buildings with radiant ceiling cooling systems, Current systems almost always require 100% outdoor air systems and tight building envelopes to manage humidity. Energy saving are realized by significant reductions in air moving power (only the outdoor make-up air is distributed to the building) and the higher evaporator temperature of the chiller supplying cool water to the chilled ceiling panels.

7. DESIGN EXAMPLES

Classroom

Load calculations require that the space sensible load be 8.377 kW. The space has 30 occupants.

A 9 by 9 by 3 m classroom and a maximum occupancy of 30 people, is to be maintained at 23.3°C and 50% rh. From the psychometric chart, this gives a dew point temperature of 12.78°C and a moisture content of 0.0081 kg/kg.

Step 1. Determine the sensible and latent hourly heat gain for the room.

The sensible and latent hourly heat gains are found using accepted procedures found in the ASHRAE handbooks. For this example, assume sensible hourly heat gain = 8.377 kW.

Step 2. Determine the mean water temperature required for cooling.

Supply water temperature = 12.78°C

Assuming a temperature rise of 4 K, add half of this temperature rise to the inlet water temperature, giving 15°C.

Step 3. Determine the minimum air supply required for the room. According to ASHRAE tabulated data, the recommended air supply per person is

$$34\ \text{m}^3\text{/h per person} \times 30\ \text{persons} = 1019\ \text{m}^3\text{/h}$$

Step 4. Determine the latent load capacity of the air:

$$\text{NP} * \text{OCPL} \times 1.2 \times 2500 \times (\text{HRODA}_2 - \text{HRIDA}) = 1650\ \text{W}$$

Step Determine the sensible cooling capacity of the primary air:

$$V \times 1.2(\text{DBIDA} - \text{DBSUP}) = 4070\ \text{W}$$

where

NP = number of occupants in the space
OCPL = latent heat produced by the occupants
HRODA_2 = humidity ratio of space air
HRIDA = humidity ratio of space operating design condition
V = volumetric flow rate of the supply air
DBIDA = dry bulb temperature of space operating design condition
DBSUP = dry bulb temperature of supply air

30 occupants at 65 W/pp = 1950 W/pp and the moisture gain results in

$$\Delta\omega = q_L/(60 \times \rho h_{fg} \times \text{Airflow}) = 0.0022\ \text{kg/kg}$$

The moisture content of the space operating condition is 0.0103 kg/kg. From the psychometric chart, the dew point of the space operating temperature is 14°C.

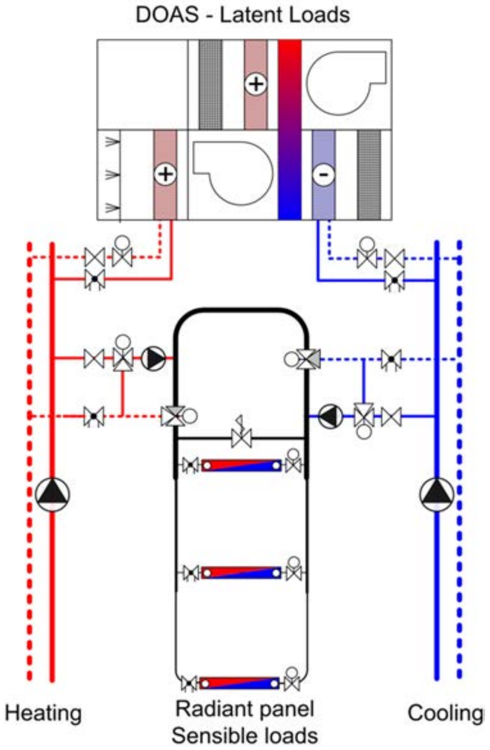

Fig. 6 Secondary Pumps with Mixing/Injection Control Valves on Four-Pipe/Two-Pipe System

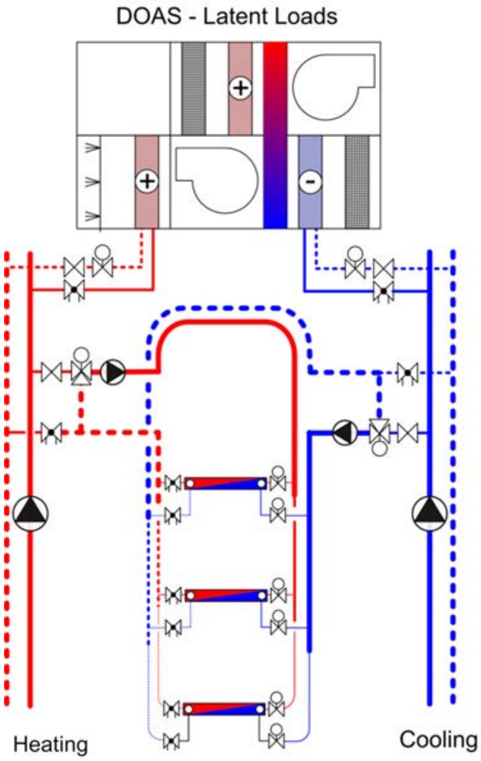

Fig. 7 Secondary Pumps with Mixing/Injection Control Valves on Four-Pipe System

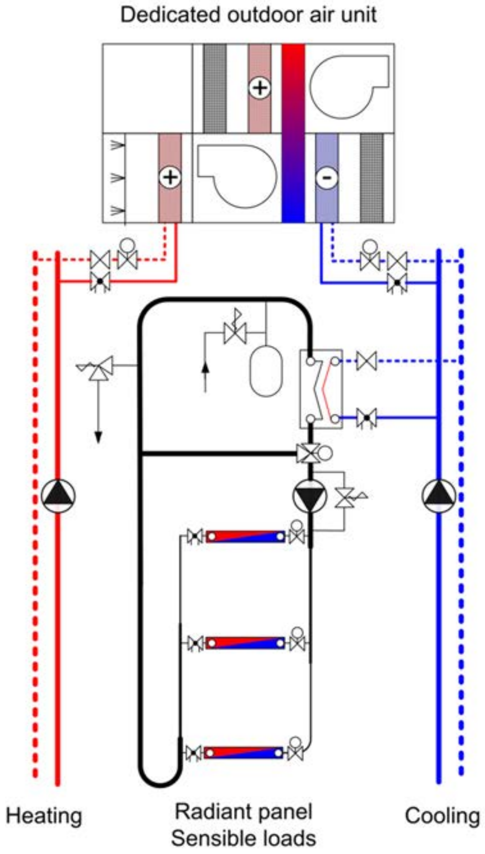

Fig. 8 Two-Pipe Cooling-Only System with Heat Exchanger

The space condition is calculated by including the sensible and latent loads to the space. From this condition the dew-point temperature is shown on the psychometric chart. The panel surface operating temperature is selected about 2 K higher than this temperature.

Step 5. Determine the sensible load capacity of the air with the following equation:

$$Q_s = QpC_p(t_{room} - t_{supply})60$$

$$Q_s = (1019\ \text{m}^3/\text{h})(1.2\ \text{kg/m}^3)[1\ \text{kJ/(kg·K)}](23 - 13) = 12{,}900\ \text{kJ/h} = 3.6\ \text{kW}$$

The sensible cooling required from the panels is 4.8 kW.

Step 6. Select a panel surface temperature at least 2 K higher than the space operating dew-point temperature (16.1°C) Thus, the required temperature is higher than the MWT calculated in step 2.

Step 7. From the 16.1°C panel operating temperature or panel mean water temperature, derive the supply water temperature and water temperatures to and from the panels. Typically, the difference supply and return water temperature is 4 K, so the panel water supply temperature in this case is 13.88°C and the panel return water temperature is 18.33°C.

Step 8. Figure 9 shows the panel output.

Step 9. The required sensible cooling output from the panel is 4768 kW at 16.1°C MWT and therefore the required panel area is 4768 W/147 = 32.4 m^2. The classroom has a ceiling area of 83.61 m^2. The ratio of ceiling panel to ceiling is 69%.

Office

The office has a sensible cooling load of 2 kW, which is obtained from the load calculations. There will be two occupants in the office.

A 4 × 5 × 2.4 m interior office with a 0.6 × 1.2 m T-bar ceiling and a maximum occupancy of two people is to be maintained at 24°C

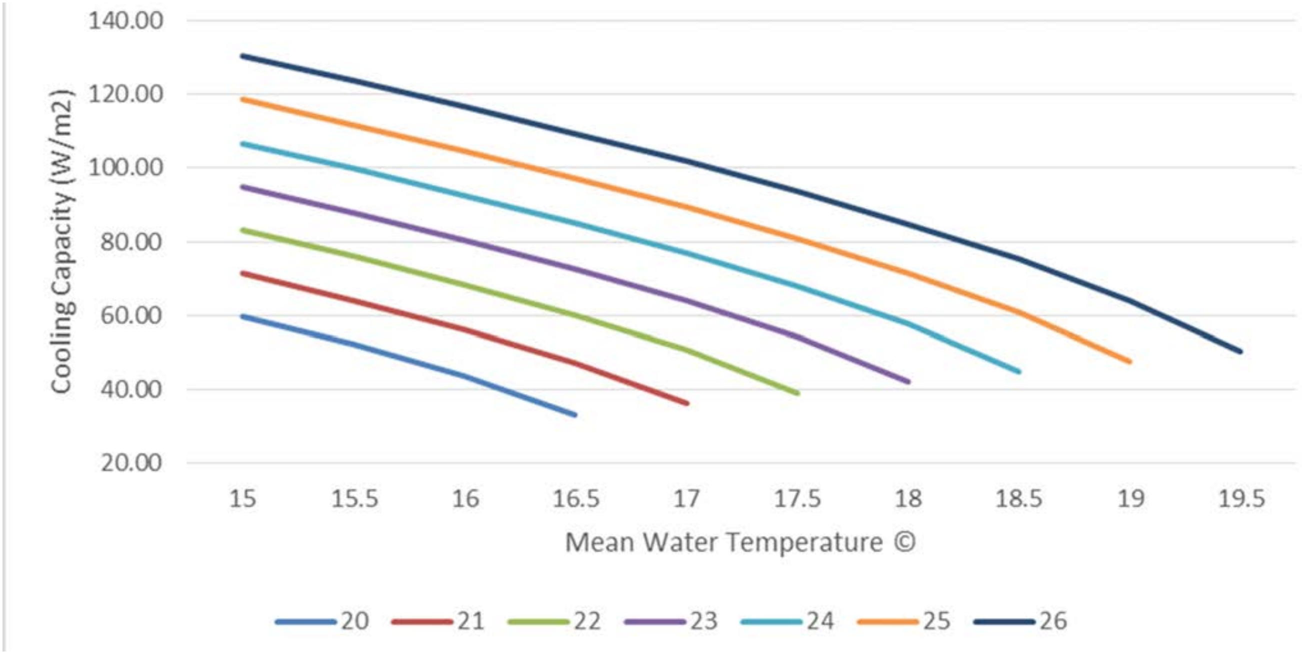

Fig. 9 Panel Output for Classroom Example: 98 W/m² at Room Temperature of 24°C and MWT of 15°C, and 75 W/m² at Updated MWT of 16.5°C

and 45% rh. From the psychometric chart, the dew-point temperature is 12.7°C and moisture content is 0.009 kg/kg.

Step 1. Determine the portion of the load to be provided by the radiant ceiling and the portion of the load to be provided by the ventilation system. As a rule of thumb, the area of radiant panels is 70% of the ceiling area of the space. For this application, the preliminary output from the radiant ceiling is 1319 W.

Subtract the output of the radiant ceiling from the required sensible cooling load: 2000 – 1319 = 679 W.

The required volume of supply air to meet the rest of the load can be calculated as

$$Q_s = \text{Airflow} \times 1.085\,\Delta T$$

$$Q_s = 0.05\ \text{m}^3/\text{s} = 180\ \text{m}^3/\text{h}$$

Determine the sensible load capacity of the air:

$$Q_s = QpC_p(t_{room} - t_{supply})60$$

$$Q_s = 715\ \text{W}$$

The sensible cooling required from the panels is 2000 – 715 = 1284 W.

Step 2. Determine the latent load capacity of the air:

$$q_L = Qph_{fg}(\omega_{room} - \omega_{supply}) \times 60$$

Two occupants = 146 W

Moisture gain = 0.00091 kg/kg

The moisture content of the space operating condition is 0.00991 kg/kg. The dew point of the space operating temperature from the psychometric chart is 13.8°C.

Step 3. Determine the MWT required for cooling. Supply water temperature = 12.7°C. Assuming a temperature rise of 4 K, add half of this temperature rise to the inlet water temperature:

$$\text{MWT} = 12.7°\text{C} + 4/2 = 14.7°\text{C}$$

The dew-point temperature of the space operating condition is shown on the psychometric chart in Figure 10. The operating surface temperature of the ceiling panels is kept about 2 K higher than the space dew-point temperature.

Step 4. Select a panel surface temperature at least 1.5 K higher than the operating dew temperature, which is 13.8°C +1.5 K = 15.3°C.

Step 5. From the 15°C panel operating temperature or panel MWT, derive the supply water temperature and water temperatures to and from the panels. Typically, the difference between supply and return water temperature is 4 K, so the panel water supply temperature in this case is 15°C – 2 = 13°C and the panel return water temperature is 15°C + 2 = 17°C.

Step 6. Figure 11 shows the panel output, the flow rate, and the cooling output in comparison with the air temperature MWT.

Step 7. The required sensible cooling output from the panel is 1284 W; therefore, the required panel area is 13.6 m². The office has a ceiling area of 20 m². The ratio of ceiling panel to ceiling is 68%.

8. CONDENSATION CONTROL

When the dew-point temperature of the space air has been determined, the surface temperature of the radiant ceiling can be controlled to be above the dew point and therefore avoiding the risk of condensation. Monitoring the space air temperature and the space humidity levels will provide the space moisture content. In simple terms the supply water temperature to the panels must be controlled to avoid the possibility of condensation.

The only possibility of condensation occurring is when radiant cooled ceilings are used in a space with operable windows. From practice it is known that operable windows can induce up to 6 ACH through a space.

From the previous example the dew point temperature of the room condition is 13.8°C, so if this condition were to come into contact with a radiant panel with a surface temperature of 13.3°C and condensation would occur.

A very simple control methodology to avoid condensation is to elevate the panel surface temperature to roughly 1 to 1.5 K above the space air dew point temperature of 13.8°C, which would give a panel surface temperature of 15.5°C.

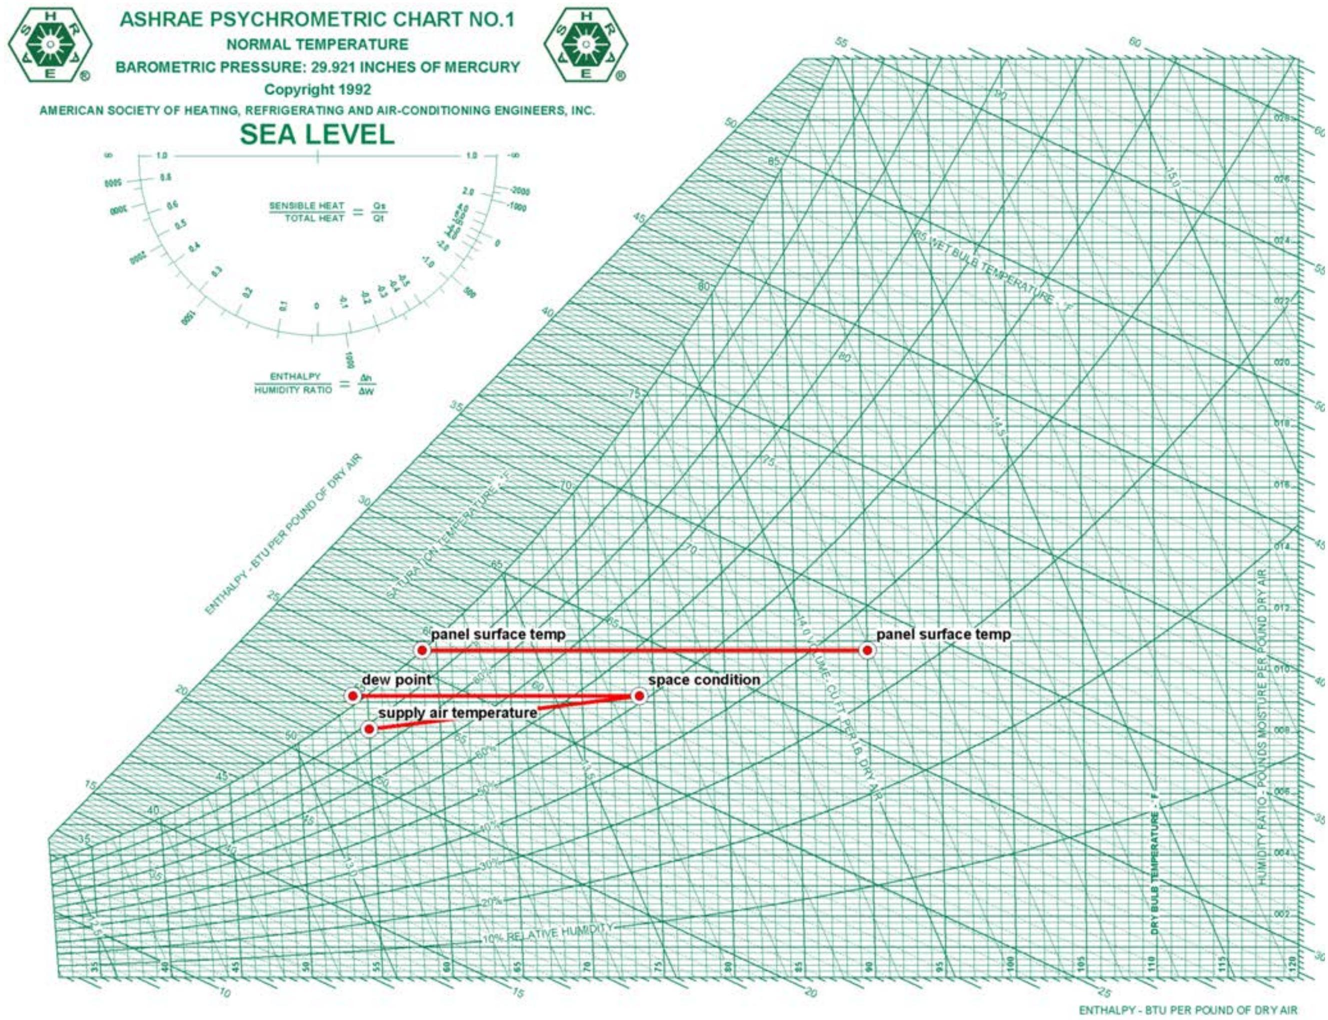

Fig. 10 Dew Point of Space Based on Operating Temperatures

Primary Air Conditioning

Control of the building humidity level is paramount when panels systems are used. Space ventilation and humidity control are solely provided by the supply air delivered from the air handling unit. The minimum supply airflow rate should be sufficient to provide both functions. The indoor dew point is determined by the latent load to the space and the condition of the supply air. To avoid the risk of condensate formation on the panels, the AHU must condition the primary air to be sufficiently dry so as to absorb the moisture generated in or infiltrating into the building.

Commissioning of the AHU control system must ensure that the supply air conditions are achieved without significant oscillations. A range of air conditioning technologies may be applied provided that the supply dry bulb and dew point temperature are both precisely controlled.

Condensation Prevention

The implementation of an adequate chilled-water temperature control system, together with the supply of an adequate amount of correctly conditioned primary air, is sufficient to avoid the occurrence of condensation on the panels.

Water supply to panels should not be activated when space dew point temperatures are above the zone chilled-water supply temperature. It must be ensured that the panels system chilled-water supply is shut off any time the air handler is not in operation and only restored when the space dew-point temperature is safe for non-condensing panels operation. In the transition from spring to summer, or from summer to winter, the outdoor air condition may result in a higher dew point and therefore the system can remain in operation.

In practice, a moisture sensor on the supply pipe work, or a dew point calculation warns of the possibility of condensation. The formation, and subsequent falling, of water droplets on the panel surface lags the onset of conditions that could cause condensation. It is common for panels to operate with chilled-water temperatures below the zone dew point without significant moisture collection on the panels surface with condensation forming first on the uninsulated surface of the chilled-water pipework feeding the panel.

Condensation prevention can be implemented with either reactive or proactive strategies, or a combination of both. In a proactive strategy, the control system acts to avoid or prevent the formation of condensate. In a reactive strategy, the control system acts in response to condensate that has formed.

Proactive Strategies

In a proactive strategy, the dew point can be monitored via contact humidistats by attaching the sensor to an uninsulated portion of

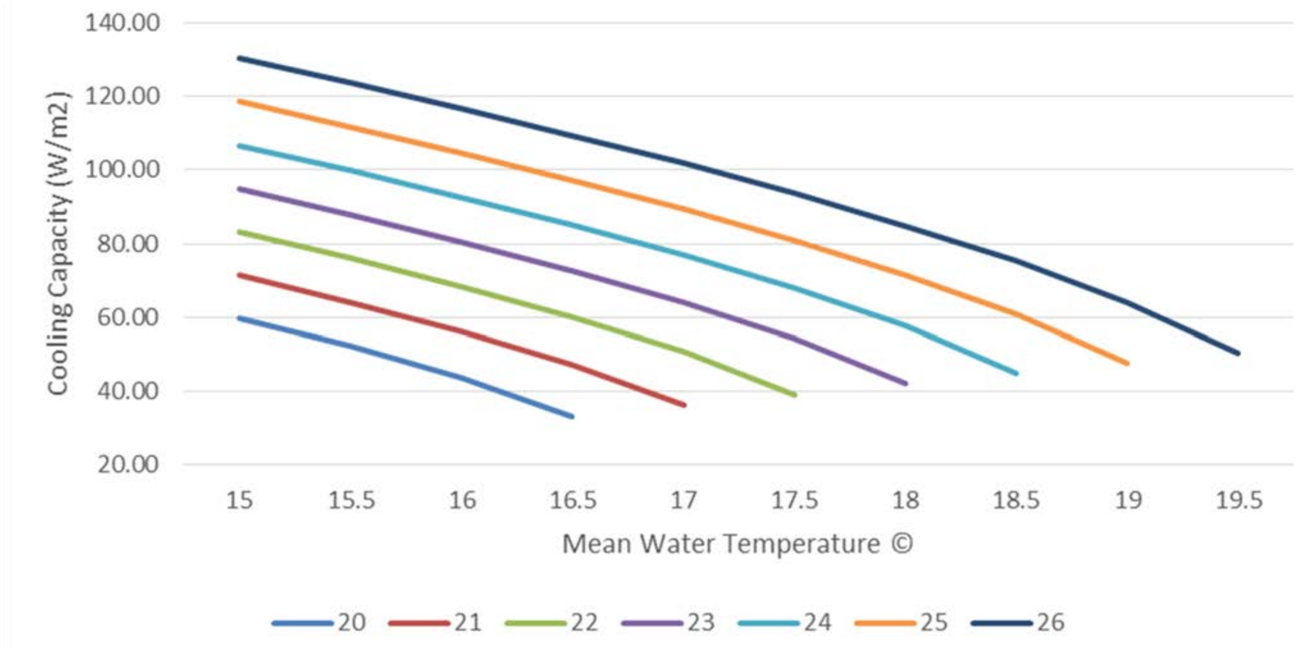

Fig. 11 Panel Output for Office Example: 98 W/m² at Room Temperature of 24°C and MWT of 15°C, and 75 W/m² at Updated MWT of 16.5°C

Fig. 12 Surface Condensation Sensor

the piping, immediately prior to the supply connection to the panels' panel (Figure 12).

The dew point temperature of the space air is determined by continuous sensing of the space air temperature, and relative humidity. The calculated dew point must then be compared to the supply water temperature.

In response to the sensor feedback, chilled water supply temperature set point can be reset above the room dew point, or the supply water to the zone can be halted.

Figure 13 presents a control strategy where the chilled-water supply temperature is varied in accordance with the space dew-point temperature. In this case the panel's chilled-water temperature control system maintains a minimum differential between the space dew-point temperature and its chilled-water supply. To maintain this differential, the dew-point temperature must be monitored or calculated. This can be done by monitoring the humidity either in the return air duct or directly in the zone. This strategy allows the panel within the panels to continue to contribute to the space sensible cooling even during periods of elevated space moisture levels.

Figure 14 shows a strategy whereby the panel's chilled-water flow is interrupted when the measured space dew-point temperature rises above the panel's chilled-water supply temperature.

Reactive Strategies

Condensation sensors such as those shown in Figure 12 used to detect moisture on the chilled-water supply pipe. When an indication of moisture is received from the sensor, the water supply is stopped, or its supply temperature is increased. This is a reactive method that can stand alone or form part of a total strategy.

Modern condensate sensors are very sensitive to the smallest amount of moisture forming. Condensation detected on the supply pipe work does not mean that the chilled panels will start to condensate and then drip; in fact, condensation can exist on the supply pipe for a very long period and still none present on the chilled panels. The protection provided by these devices must be weighed against the probability that more thermal complaint calls may arise when and if the chilled-water supply is discontinued during periods where an inconsequential amount of moisture is detected by the contact switch.

Figure 15 shows a reactive control strategy that relies on surface moisture sensors affixed to the chilled-water supply pipe. In the event condensation formation has been detected, the sensors override the space temperature sensor and close the chilled-water supply valve until the moisture has evaporated. If the flow of water is halted in response to a moisture sensor, then a control scheme will need to be developed to address when to turn the water system back on since the stoppage of water flow would typically halt the formation of moisture on the chilled-water supply pipe, even if the differential between the zone humidity level and the chilled-water supply temperature has not been restored.

Spaces with Operable Windows or Doors

For applications in spaces with operable windows or doors, occupants and staff should be educated on the effect opening them can have on their thermal environment. When windows or doors are opened, the supply of chilled water should be halted to avoid risk of condensation and/or prevent loss of cooling energy.

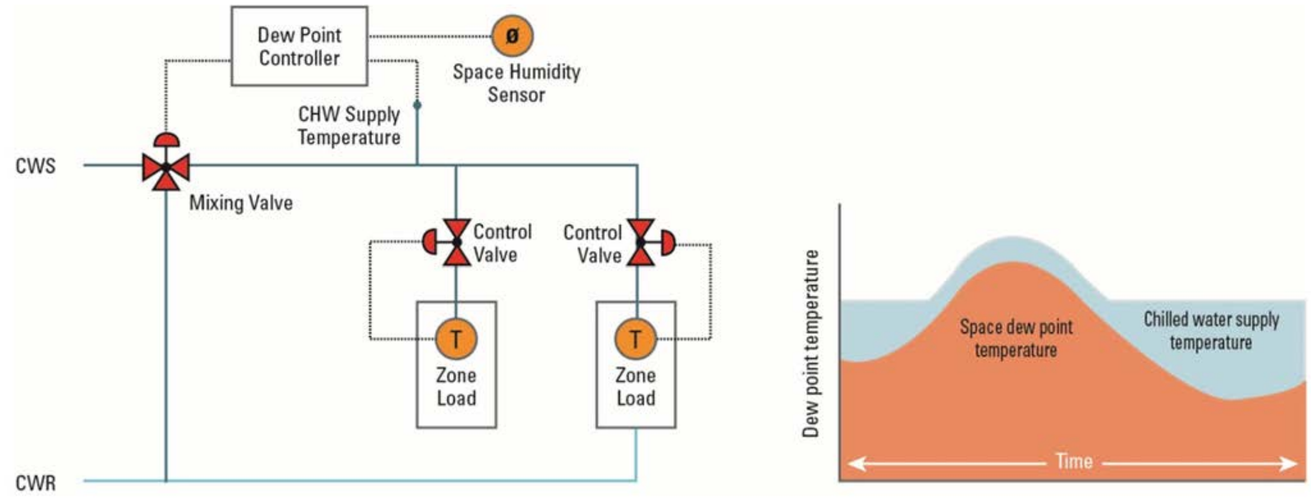

Fig. 13 Condensation Prevention Strategy Involving Reset of Panel's Chilled-Water Supply Temperature

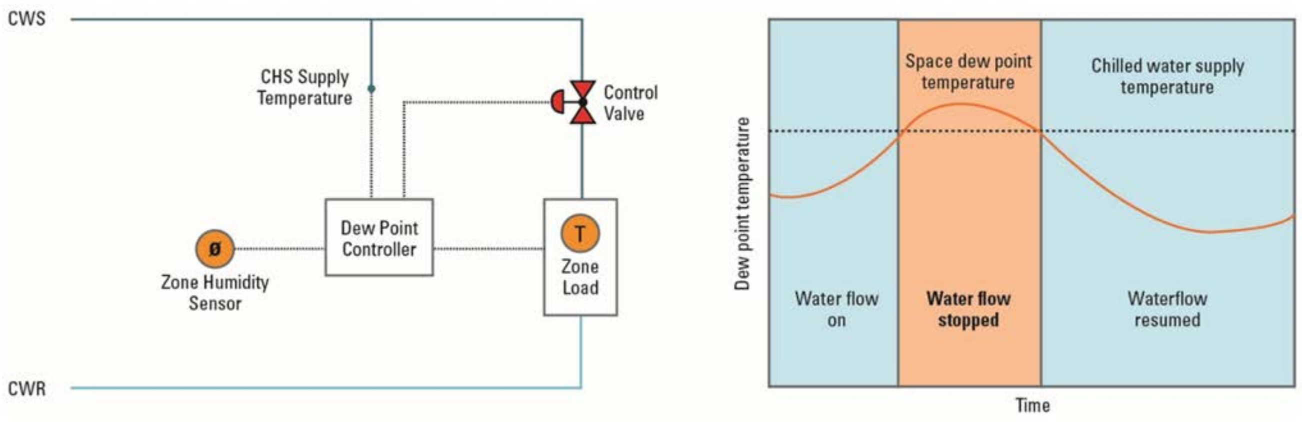

Fig. 14 Condensation Prevention Strategy Where Water Flow Is Discontinued When Chilled-Water Temperature Is Below Space Dew-Point Temperature due to Rise in Humidity in Zone or Temperature Drop

Detection of a window being opened can be accomplished by the employment of window contact switches. Alternatively, moisture sensors such as that shown in Figure 12 may be used to discontinue the chilled-water flow during periods of condensation risk. When these are applied, one sensor should be installed on the chilled water supply pipe in each room (with operable windows or doors) the system serves. It must be remembered that the chilled water flow will not be restored until the sensor determines that all moisture has been evaporated from the surface of the pipe.

Figure 16 illustrates a proactive sequence where a sensor detects the opening of a window and interrupts the chilled-water flow to the space. A surface moisture sensor is also used to ensure that the space dew-point temperature is acceptable for restoring the chilled-water flow once the window is closed. Now the control system could boost the airflow to the space to reduce the time to restoring the chilled water.

9. EMBEDDED SYSTEMS

An embedded system is a surface cooling and heating system where water tubes as well as electric cables are integrated within the floor, wall, or ceiling. Radiant systems have been successfully used worldwide for heating and cooling of buildings. A radiant system provides a very good method of discharging high specific heating and cooling loads while maintaining thermal comfort at relatively low operation costs. The most popular use of radiant systems is radiant floor heating (Figure 17); however, ceiling as well as wall heating are also used (Figure 18).

Radiant systems are dimensioned in accordance to the ensuing radiant heat exchange in the space. Radiant systems usually designed as a hydronic system therefore the amount of space necessary for the installation is considerably smaller than a conventional air conditioning system. Because of the low plenum height necessary to accommodate the installations, more architectural freedom is provided. The radiant system can be installed so that both individual and zone control can be achieved.

Many hospitals have radiant systems, and commercial buildings are starting to use the potential of radiant floors and ceilings. In Europe, several buildings such as the PGEM in Arnhem and the Groninger Museum have successfully used radiant systems to control the indoor environment. There has also been advancement in simulation programs that allow more detailed analysis of the indoor environment. With these advanced simulation tools and the individual elements necessary for the creation of a comfortable indoor climate using the predicted mean vote (Fanger 1972), radiant heat exchange can be studied. Because each individual surface temperature and its relationship (i.e., position to the other surfaces) can be determined a solution to the comfort balance equation can easily be found.

When incorporating a radiant system and a constant-volume ventilating system, the ventilation system may only be dimensioned to supply outdoor air for each person and to remove the latent as well as the material load if the radiant system is selected to remove the remaining cooling loads. Simmonds (1994) reported on some of these designs and how effective they are in providing an effective means of comfort climate.

Because cooling surfaces make no contribution to air renewal, they may always be operated in conjunction with a ventilating or air-conditioning plant, which also ensures the probably necessary dehumidification. However, also a combination with a natural ventilation system as well as operable windows may also be possible.

Radiant cooled floors have been successfully used on many projects over the past ten years and many ASHRAE and other peer-reviewed publications have been written on these projects. However, many questions still arise regarding the performance of radiant cooled floors when subjected to solar radiation. The convective cooling performance of a cooled floor has been reported by Olesen, Simmonds; Borressen (1994) reported on the solar absorption of a radiant cooled floor, this was further reported by Simmonds et al. (1996). Even with this research, many questions are still being raised regarding the performance of a radiant cooled floor when absorbing solar radiation. This section explains the performance of the floor, including some limitations of the presented calculation method, but also includes information on the controllability.

This section outlines the performance of a radiant cooled floor subjected to different solar radiation intensities and will look further into the controllability of the radiant cooled floor to maintain certain conditions such as space temperatures and floor surface temperatures. The influence of floor coverings on radiant cooled floors will also be discussed.

Previous papers by Simmonds (1994) have shown that radiant cooled floors are capable of removing 35 to 40 W/m^2 from spaces. Borressen (1994) and Simmonds et al. (1996) have shown that radiant cooled floors are capable of removing up to 85 W/m^2 of energy from a space 35 W/m^2 by convection and 50 W/m^2 by solar absorption. This section uses a simple steady-state equation to explain the performance of a radiant cooled floor when performing at its maximum capacity of both reducing the space air temperature and absorbing solar radiation that is reaching the floor. There are several dynamic simulation programs that accomplish the dynamic performance of a radiant floor. Many papers have been written on the performance of radiant floor for heating. MacCluer, Athienitis, and Simmonds. Olesen and Meirhans have reported on the performance of active concrete systems.

There has been advancement in simulation programs that have permitted a more detailed analysis of the indoor environment. With these advanced simulation tools, the individual elements necessary for the creation of a comfortable indoor climate using the predicted mean vote (PMV as determined by Fanger 1972), which has been adopted in ASHRAE *Standard* 55-2017 and radiant heat exchange can be studied. Because each individual surface temperature and its relationship (i.e., position to the other surfaces) can be determined a solution to the comfort equation can be found. The PMV/PPD comfort equation, derived by Fanger and shown in ASHRAE *Standard* 55-2017, can be influenced by the control or balance of the radiant heat exchange in a space. When operating a radiant heated or cooled floor correctly, the surface temperature of the floor can be regulated. Absorbing a major portion of the solar radiation entering

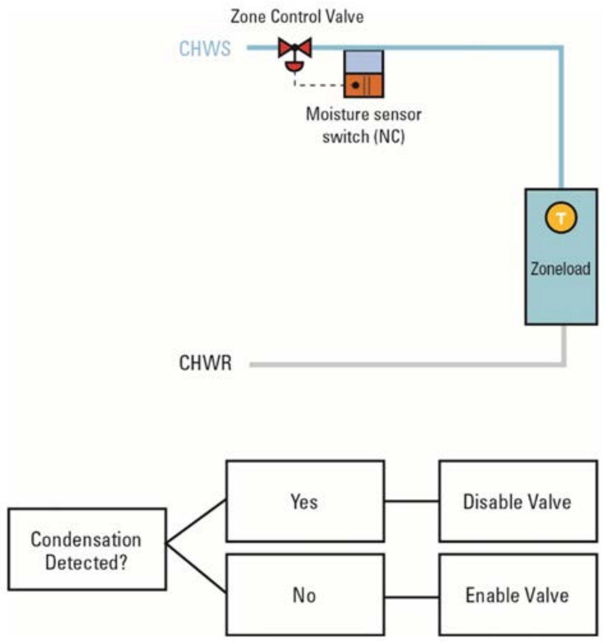

Fig. 15 Control Strategy Where Chilled-Water Supply Halts When Moisture Is Detected on CHWS Pipe

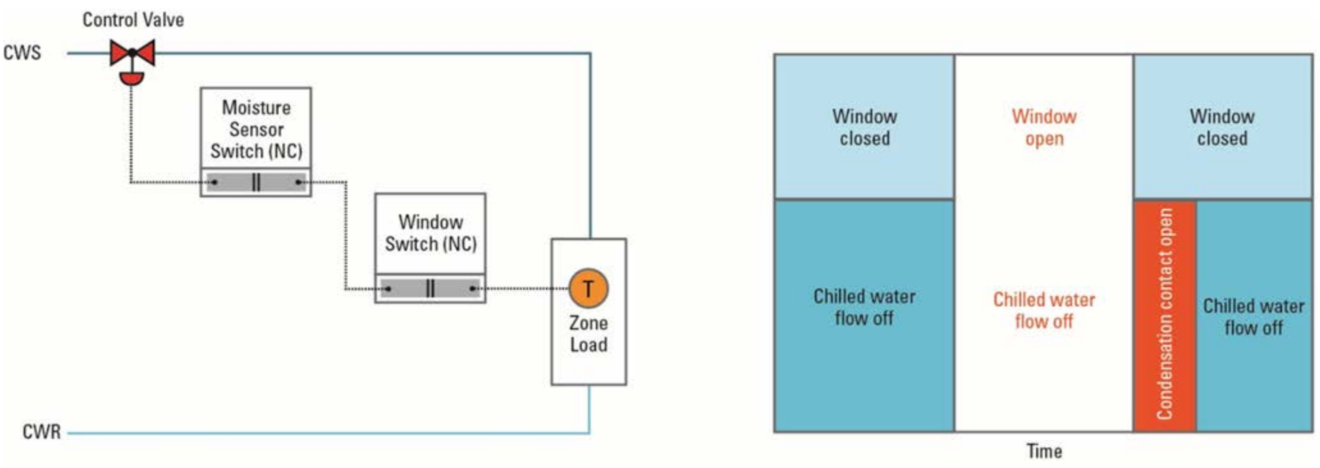

Fig. 16 Condensation Prevention Strategy Involving Interruption of Water Flow After Window Opening

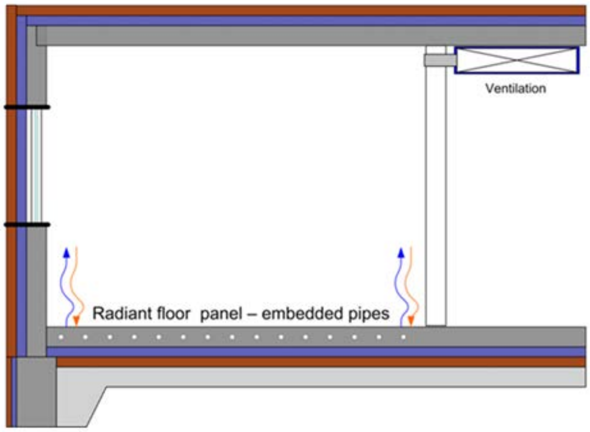

Fig. 17 Radiant Floor Heating

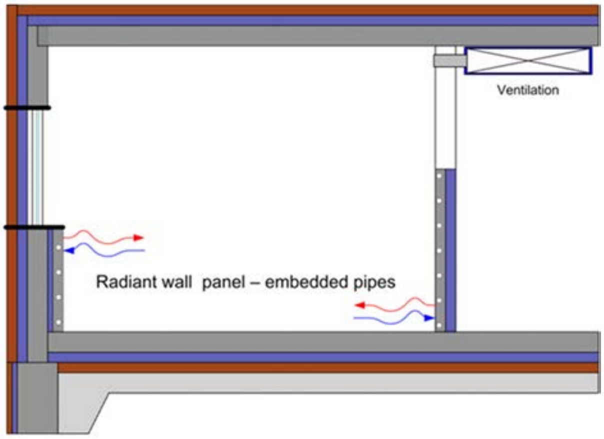

Fig. 18 Radiant Wall Heating

the space also prevents the floor from emitting thermal energy, in the form of long-wave radiation, back into the space and onto other surfaces.

Because cooling surfaces make no contribution to air renewal the surfaces usually operated in conjunction with a ventilating or airconditioning plant, which also ensures the necessary dehumidification is provided. The combination of a radiant cooled system with a natural ventilation system and operable windows may also be possible in certain climate conditions.

10. FUNDAMENTALS

A radiant floor system exchanges thermal energy with the space by means of convection, short-wave radiation, and long-wave radiation. Because the understanding of the three different kinds of heat transfer is very important to calculate and optimize a radiant floor system, this section contains a detailed narrative and mathematical description. Figure 19 shows a radiant floor with edge and back insulation.

The three different types of heat transfer of the radiant floor are:

- **Convection:** heat transfer between the floor surface and the conduction air of the space.
- **Long-wave radiation:** heat flux between the floor surface and the room surfaces; its quantity and wavelength are temperature dependent
- **Short-wave radiation:** sources include high-temperature surfaces such as the sun and electric lights. The transfer of short-wave radiation within a room does not depend on the temperature of surfaces. Short-wave radiation on the floor will be either absorbed or reflected, but the radiant floor itself is not a source of short-wave radiation. The main source of short- radiation in a space is from the direct sunlight entering the space and from electrical lighting.

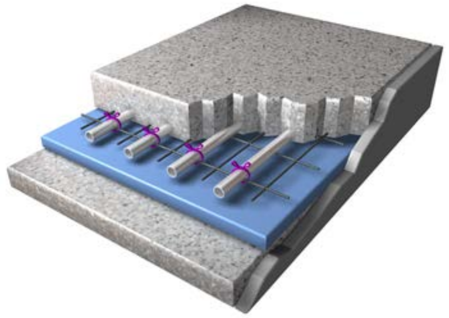

Fig. 19 Typical Radiant Floor with Edge and Back Insulation

11. METHOD TO DETERMINE HEATING AND COOLING CAPACITY

A given type of surface (floor, wall, and ceiling) delivers, at a given average surface temperature and indoor temperature (operative temperature θ_i), the same heat flow intensity (specific thermal output) in any space independent of the type of embedded system. It is therefore possible to establish a basic formula or characteristic curve for cooling and a basic formula or characteristic curve for heating, for each of the type of surfaces (floor, wall, and ceiling), independent of the type of embedded system, which is applicable to all heating and cooling surfaces.

Based on the calculated average surface temperature at given combinations of medium (water) temperature and space temperature, it is possible to determine the steady state heating and cooling capacity.

Heat Exchange Coefficient Between Surface and Space

The relationship between heat flow density and mean differential surface temperature (see Figure 20 and Equations [1] to [4]) depends on the type of surface (floor, wall, ceiling) and whether the temperature of the surface is lower (cooling) or higher (heating) than the space temperature.

For floor heating and ceiling cooling in Figure 20, the heat flow density q is given by

$$q = 8.92(\theta_{S,m} - \theta_i)1.1 \tag{1}$$

where $\theta_{S,m}$ is the average surface temperature and θ_i is the nominal indoor operative temperature.

For other types of surface heating and cooling systems, the heat flow intensity q is given by

$$\text{Wall heating and wall cooling: } q = 8(|\theta_{S,m} - \theta i\,|) \tag{2}$$

$$\text{Ceiling heating: } q = 6(|\theta_{S,m} - \theta_i|) \tag{3}$$

$$\text{Floor cooling: } q = 7(|\theta_{S,m} - \theta_i\,|) \tag{4}$$

12. THERMOACTIVE BUILDING SYSTEMS (TABS)

Thermoactive building systems exploit the high thermal inertia of the slab in order to perform the peak-shaving. The peak-shaving consists in reducing the peak in the required cooling power (Figure

21), so that it is possible to cool the structures of the building during a period in which the occupants are absent (during nighttime, in office premises). This way the energy consumption can be reduced, and lower night time electricity rate can be used. At the same time a reduction in the size of heating/cooling system components (including the chiller) is possible.

TABS may be used both with natural and mechanical ventilation (depending on weather conditions). Mechanical ventilation with dehumidifying may be required depending on external climate and indoor humidity production. In the example in Figure 22, the required peak cooling power needed for dehumidifying the air during daytime is sufficient to cool the slab during night time.

As regards the design of TABS, the planner needs to know if the capacity at a given water temperature is sufficient to keep the room temperature within a given comfort range. Moreover, the planner needs also to know the heat flow on the water side to be able to dimension the heat distribution system and the chiller/boiler. The present document provides methods for both purposes.

When using TABS (Figure 23), the indoor temperature changes moderately during the day and the aim of a good design of TABS is to maintain internal conditions within the range of comfort, i.e. –0.5 < PMV < 0.5, during the day, according to ISO *Standard* 7730 and ASHRAE *Standard* 55-2017.

Some detailed building-system calculation models have been developed, as for the determination of the heat exchanges under unsteady state conditions in a single room, determination of thermal and hygrometric balance of the room air, prediction of comfort conditions, check of condensation on surfaces, availability of control strategies and calculation of the incoming solar radiation. The use of such detailed calculation models is, however, limited due to the high amount of time needed for the simulations. The development of a more user-friendly tool is required.

The diagrams in Figure 22 show an example of the relation between internal heat gains, water supply temperature, heat transfer on the room side, hours of operation and heat transfer on the water side. The diagrams refer to a concrete slab with raised floor (R = 0.45 [m^2·K]/W) and an allowed room temperature range of 21 to 26°C.

The upper diagram shows on the *y* axis the maximum permissible total heat gain in space (internal heat gains plus solar gains), and on the *x* axis the required water supply temperature. The lines in the

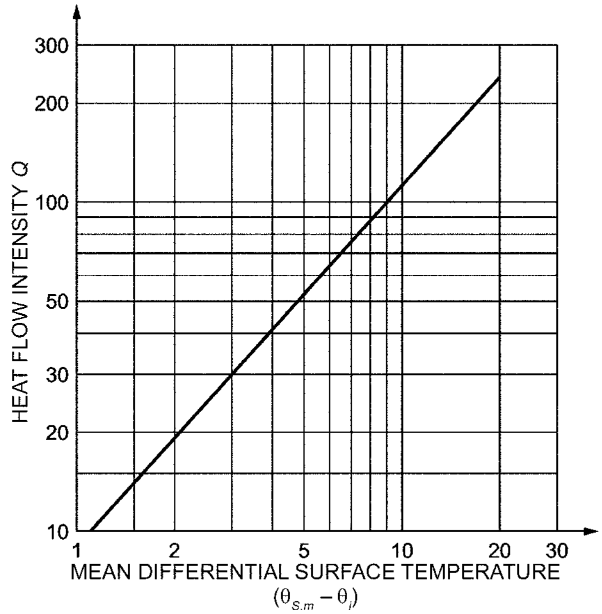

Fig. 20 Basic Characteristic Curve for Floor Heating and Ceiling Cooling

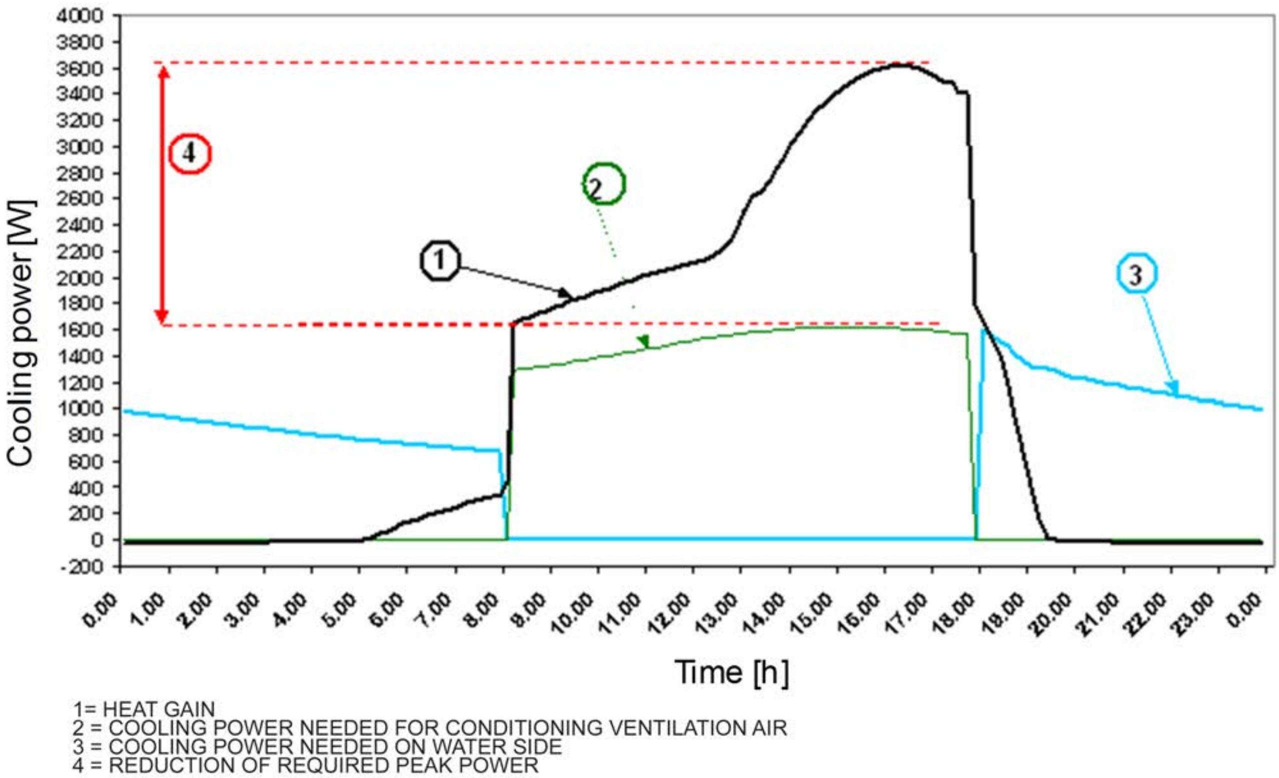

Fig. 21 Example of Peak-Shaving Effect

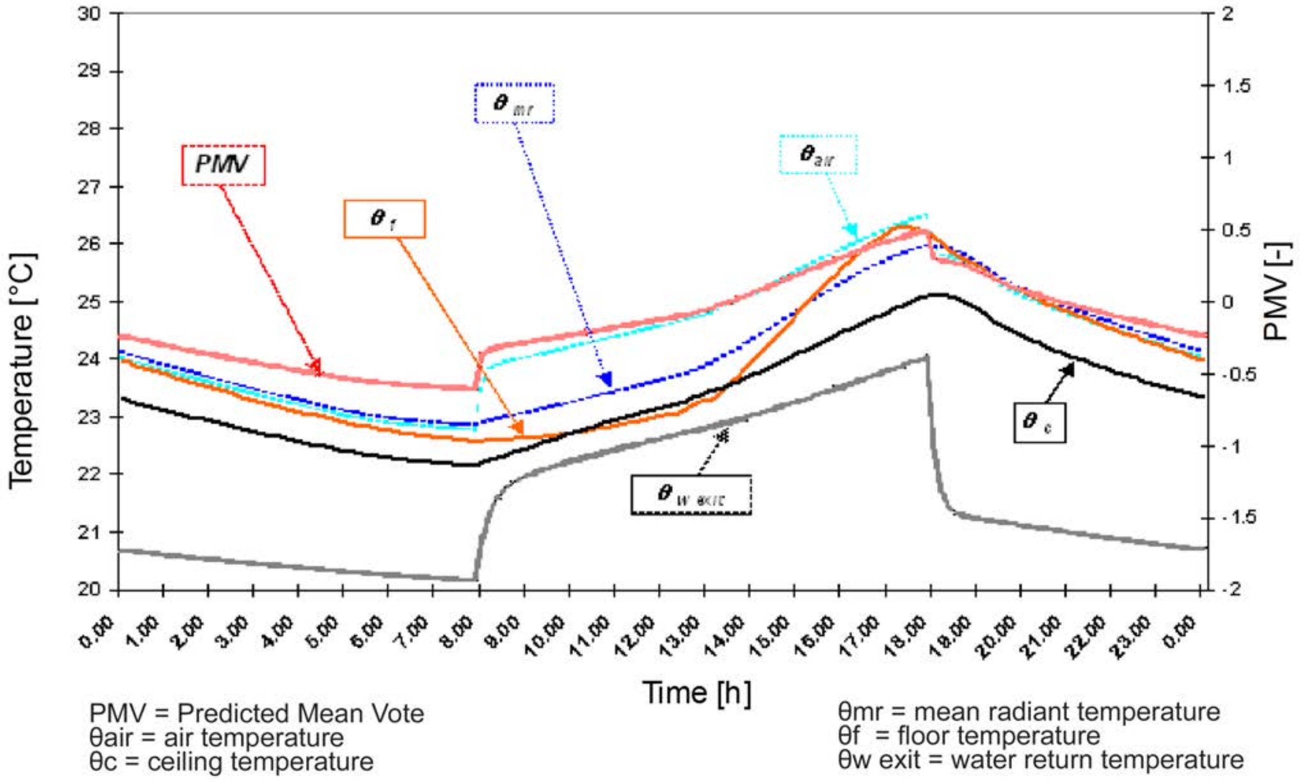

Fig. 22 Example of Temperature Profiles and PMV Values Versus Time

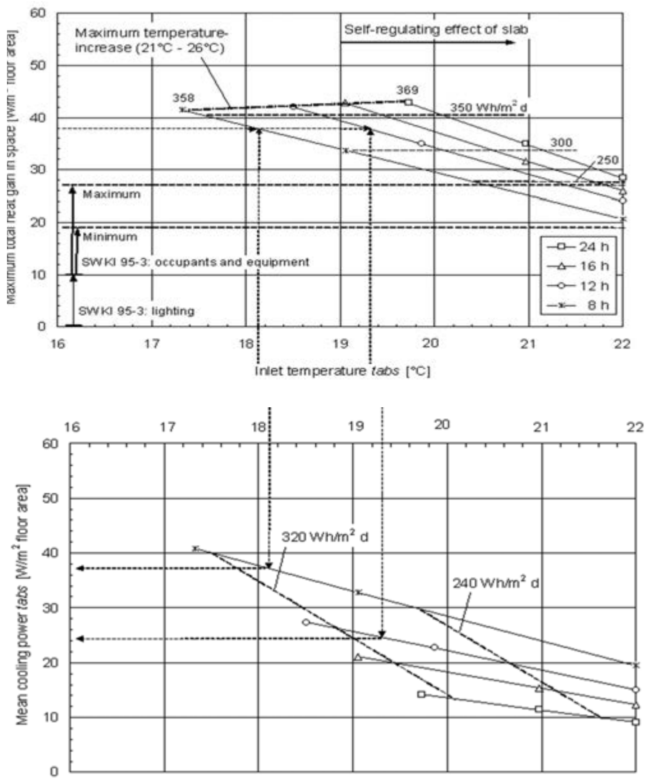

Fig. 23 Working Principle of TABS

diagram correspond to different operation periods (8, 12, 16, and 24 h) and different maximum amounts of energy supplied per day.

The lower diagram shows the cooling power required on the water side (to dimension the chiller) for thermoactive slabs as a function of supply water temperature and operation time. Further, the amount of energy rejected per day is indicated.

The example shows that, for a maximum internal heat gain of 38 W/m^2 and 8 h operation, a supply water temperature of 18.2 °C is required. If, instead, the system is in operation for 12 h, a supply water temperature of 19.3°C is required. In total, the amount of energy rejected from the room is approximately 335 Wh/m^2 per day. In the same conditions, the required cooling power on the water side is 37 W/m^2 (for 8 h operation) and 25 W/m^2 (for 12 h operation) respectively. Thus, by 12 h operation, the chiller can be much smaller.

13. EMBEDDED SYSTEMS CONTROLS

Over the years there have been many different control solutions provided for embedded systems; most of these have been for heating systems. With the advent of cooling systems different approaches have been taken; not all of these have been successful. The control systems described in this section are some of the most successful used to control an embedded system for both heating and cooling. The control system will be capable of varying heating or cooling outputs as well as maintaining predetermined surface temperatures.

Control of the heating and cooling system shall enable the specified designed indoor temperatures to be achieved under the specified variation on internal loads and external climate and, if specified, protect buildings and equipment against frost and moisture damage where necessary (when normal comfort temperature level is not required).

The design of control system shall take into account the building, its intend use and the effective functioning of the heating system, efficient use of energy and avoiding heating the building to full design conditions when not required. This includes keeping distribution heat losses as low as possible (e.g., reducing flow temperature when normal comfort temperature level is not required). Control and operation of the system help us to handle the conditioning systems with savings of operational costs and enable the maintenance of required indoor environmental conditions.

To maintain the stable thermal environment, the control system is required to keep the balance between supplied heat from the system and the losses/gains of building environment under transient conditions. Slowly varying energy flows in form of heat losses through the envelope are determined by indoor and outdoor temperature, and direction and speed of wind. The envelope properties of building materials and windows, ventilation systems, building tightness and orientation play the key role in terms of heat flow quantity. The thermal capacity of building envelope (when active) can remove quickly varying uncontrolled internal heat gains (occupants, artificial lighting, equipment) and window shading elements eliminate quickly varying periodic and predictable external heat gains from sun radiation. These uncontrolled gains play a significant role in the fall and the spring. Principally, the control strategy depends on the design characteristics, such as building envelope, thermal inertia, the system response times and others. The heating control modes are based on three system levels:

- Local (individual) control, where the heat supplied to heated space is controlled
- Zone control heat supplied to a zone normally consisting of several spaces (rooms) is controlled
- Central control heat supplied to the whole building is controlled by a central system

The control system classification is based on performance level:

- Manual: heat supply to the heated space is only controlled by a manually operated device
- Automatic: a suitable system or device automatically controls heat to the heated spaces
- Timing function: heat supplied to heated space is shut off or reduced during scheduled periods (e.g., night setback)
- Advanced timing function

Heat supply to the heated space is shut off or reduced during scheduled periods (e.g., daytime with more expensive electricity tariff). Restarting the heat supply is optimized based on various considerations, including reduction of energy use.

Several years ago, most of the controls were manual (i.e., the user could regulate a water temperature or a water flow rate by manually adjusting a valve, or the system could be turned on or shut off). Today, automatic controls are used everywhere and have in the last decade developed significantly (fuzzy logic, wireless data transmission, introduction of protocols for data communication, etc.).

For a floor heating and cooling system, the control is normally split up in a central control and an individual room control. The central control will accord the outdoor climate (based on the heating curve, which is influenced by building mass, heat loss, and differences in heat required by the individual rooms) to control the supply water temperature to the floor system. The room control will then control the water flow rate or water temperature individually for each room, according to the point selected by the user.

Central Control (Heating Only)

Instead of controlling the supply water temperature, it is recommended to control the average water temperature (mean value of supply and return water temperature) according to outdoor and/or indoor temperatures. This is more directly related to the heat flux into the space. If, during the heating period, for example, the internal load in the space increases, the heat output of the floor system will decrease and the return temperature will increase. If the central control is controlling the average water temperature, the supply temperature will automatically decrease due to the increase in return temperature. This will result in a faster and more accurate control of the heat in put to the space and will give about 15% better energy performance than controlling the supply water temperature. If the heating system is operated intermittently (night and/or weekend setback) the central control is also important for providing high enough water temperatures (boost effect) during the preheat period in the morning (additional 10 to 15%; the absolute heat requirement compared to no night setback will be lower). The energy savings by night setback in residential buildings are, however, relatively low due to the high thermal insulation standard in new houses.

Individual Control

Installation of individual room temperature controls is recommended to improve comfort and the possible energy savings. Besides the energy benefits it is essential for the thermal comfort of the occupants, that they have a possibility for individual adjustment of the room temperature set point from room to room.

The influence of the individual room control strategy for floor heating and radiators have shown a 15 to 30% energy saving by using an individual room control compared to central control only. Also the effect of night set back and boost by reheating in the morning was studied, the advantage of a boost heating (i.e., the water temperature is increased above the temperature corresponding to the heating curve during the beginning of the preheat period in the morning). This reduces the preheat time and a longer setback period is possible. Boost reheating improves the energy performance by around 8%.

Room Thermostats/Sensors

In case of a floor heating system, the valve on the manifold is controlled by and connected to a room sensor by wiring.

In terms of comfort, it is preferable to control the room temperature as a function of the operative temperature in the area occupied by the person. Besides the position, it is important to consider the shape, size, and color (important for short-wave radiation, sunlight) of the sensor in order to express convective and radiant heat exchange between sensor and space similarly as for the person.

The positioning of the room temperature sensor in the area occupied also save energy in comparison to positioning on the wall. By positioning in the occupied area, the variations in the room temperature are smaller.

Time Delay, Time Response

Floor mass is naturally closely linked to system time response. Unpredictable thermal gains/losses leading to reduced/increased heating load with characteristic times shorter than time constant cannot be compensated by the control system. An obvious consequence of the response time of a conventional floor structures is that the instant control of the heating power is not necessary. Hence, regulating the energy supply to the floor system within a time interval correlated to the response time is not different from a continuous power control.

Self-Regulating Effect

Due to the high impact the quickly varying heat gains (sunshine through windows) may have on the room temperature, it is necessary that the heating system can control for that (i.e., reduce or increase the heat output). For a low-temperature heating system like floor heating, a significant effect is so-called self control (Figure 24), which depends partly on the temperature difference between room and floor surface and partly on the difference between room

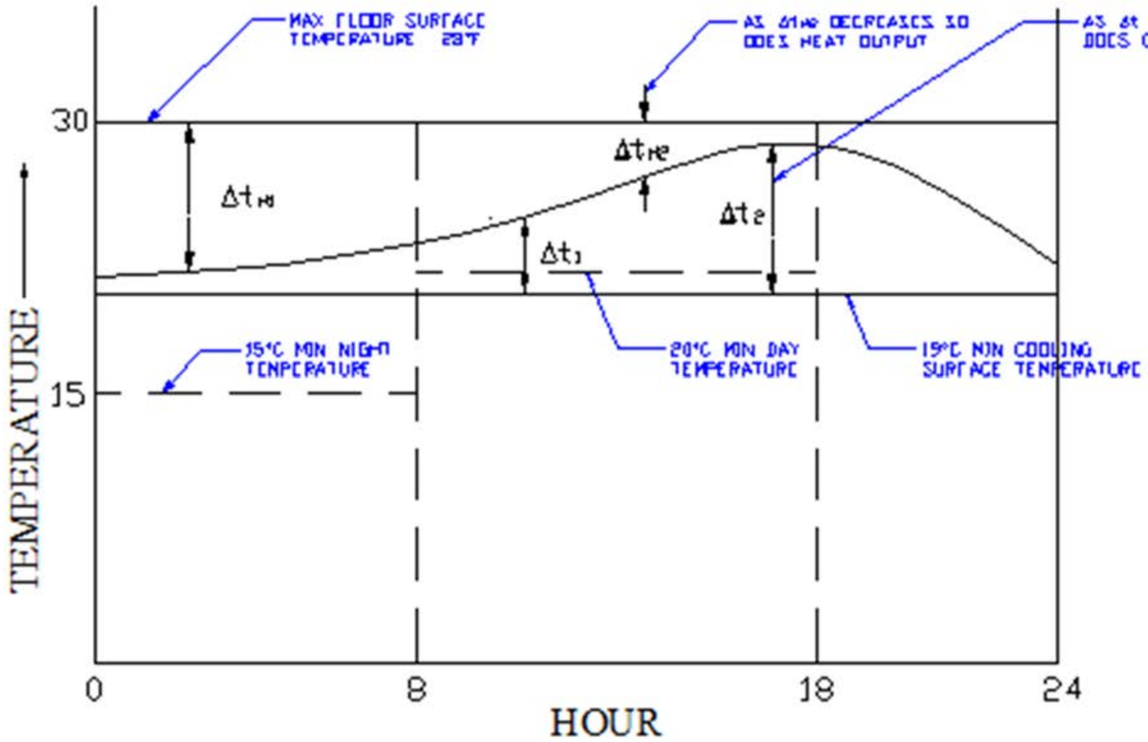

Fig. 24 Self-Regulating Effect from Radiant Floor: As Temperature Differential Between Floor Surface and Space Dry-Bulb Temperature Increases, so Does Cooling Output from Floor for both Heating and Cooling

and the average temperature in the layer, where the tubes are embedded. It means that fast change of operative temperature will equally change of heat exchange and result in great influence of total heat exchange.

14. RADIANT COOLING SYSTEM CONTROL

The cooling output of radiant heat exchange may be limited to avoid condensation on the surface and in the building structure.

A central control is also essential when using floor cooling. Due to the limitation of the cooling capacity a floor system will not always be able to control the room temperature at a fixed level. Basically, the control should provide the maximum cooling power taking into account comfort (floor temperature, room temperature) and the risk for condensation (dew point temperature). The central control for floor cooling must then take into account the dew point in the building/space, when controlling the supply water temperature. This is done by adding a humidity sensor in the building/space connected to the central control unit.

Control of TABS

In this case, individual room control is not reasonable, but a zone control (south to north), where the supply water temperature, average water temperature, or flow rate may differ from zone to zone, is available. The zoning should consider the external and/or internal heat loads. Relative small temperature differences between the heated or cooled surface and the space are typical for TABS systems. This matter results in a significant degree of self control in specific cases by well-designed systems with low heating/cooling load, a concrete slab can be controlled at a constant core (water) temperature year round. If, for example, the core is kept at 22°C, the system will heat at room temperature below 22°C, and cool above the room temperature of 22°C.

To avoid condensation (on or under surface), the water temperature or the surface temperature and the absolute humidity have to be controlled. One possibility is to set a lower limit for the supply

If the supply water temperature is limited, so it will never be below the dew point, then all temperatures (water, floor surface) after the mixing valve will be higher than the dew point, and there is no risk for condensation on the pipes, in the floor construction or on the floor.

Control System Components

Figure 24 shows the control system components which comprise a closed circuit complete with circulating pumps. This circuit is connected to the supply and return header. The circuit is also provided with all the necessary isolating and balancing valves. There are two mixing pipes installed in the circuit. One is for heating and the other is for cooling. The heating mixing pipe is connected to a heating supply which can have a variable temperature together with a return. The cooling mixing pipe is connected to a cooling supply which can have a variable temperature together with a return.

This section will outline the performance of a radiant cooled floor subjected to different solar radiation intensities and will look further into the controllability of the radiant cooled floor to maintain certain conditions such as space temperatures and floor surface temperatures. Cooled floors with and without coverings will also be analyzed to assess the influence of floor coverings.

Temperature Differences and Flow Rates

Figure 25 shows an example layout for dimensioning the flow through the embedded system. The flow rate is generally determined for cooling as this is more critical. Typical supply and return temperatures through the floor are 13°C and 17°C, so to provide a certain cooling output the flow rate can be determined. The flow rate through the embedded system is constant volume. Variable-volume

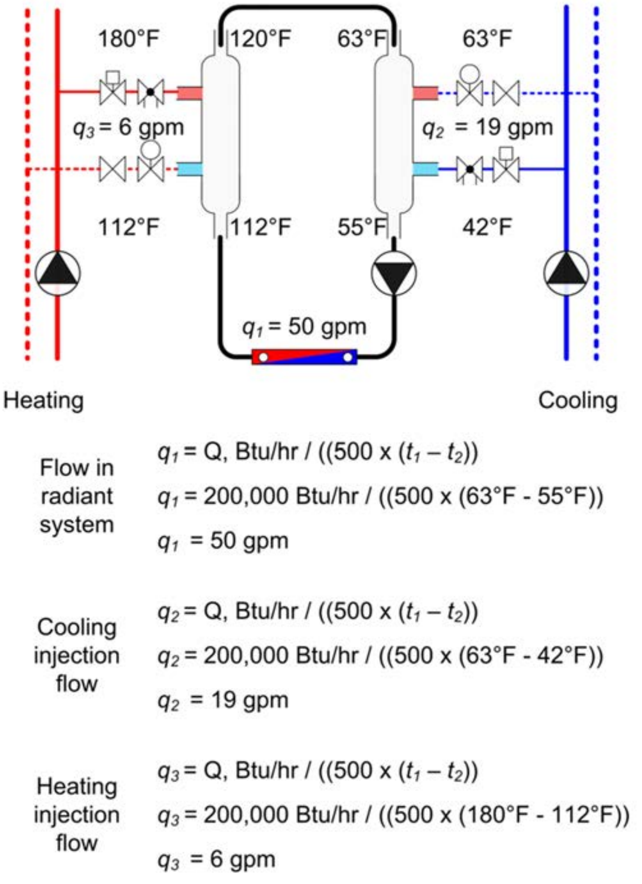

Fig. 25 Heating and Cooling Connections to Radiant Floor Loop

systems can also be used and these will also be described in this section.

For example, assume the embedded system will have a cooling capacity of 1000 W (1 kW).

Assuming a supply water temperature of 13°C and a return water temperature of 17°C, the flow rate through the embedded system will be 0.0595 kg/s.

This is the constant-volume flow through the embedded system. As shown in Figure 25, there are both heating and cooling connections to the control loop.

Assuming that the floor is in full design cooling capacity, then the return water from the embedded system will be 17°C, and this will have to be cooled to 13°C to provide the required cooling from the embedded system. The mixing pipe is connected to a chilled-water supply and return. Again, we can assume that the chilled-water supply temperature to the mixing pipe is 6°C. The amount of cooling required from the primary chilled water is the same as the cooling output from the embedded system (1 kW). The temperature differential through the mixing pipe is 17°C return from the loop and a 6°C supply, so the $\Delta t = 17 - 6 = 11$ K.

The flow rate through the primary chilled-water connection to the mixing pipe is 0.02 kg/s.

By keeping the primary flow rate lower than the circuit flow rate, the primary connections are also smaller, which enables the two-way control valve in the chilled water connection to have an improved C_v value and authority.

Another reason for this design option is that the primary chilled-water flow rate is much lower than the circuit loop flow rate and this

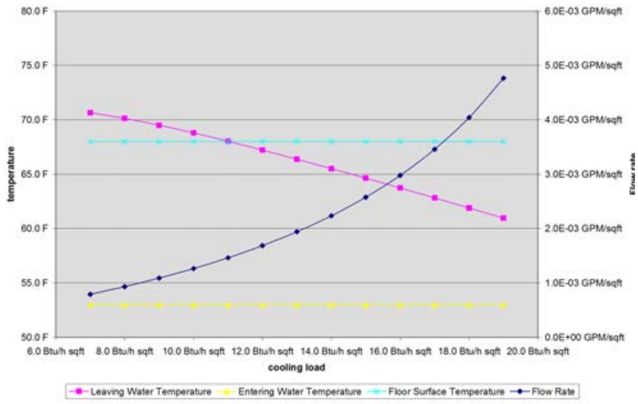

Fig. 26 Characteristics of Variable-Flow Constant-Temperature Control

limits the amount of 6°C water that could be circulated through the floor.

For heating, it is a very similar situation. The flow rate through the loop remains the same constant flow rate. The maximum surface temperature of an embedded system for heating is 28°C. Typical heating supply and return temperatures in the circuit are 60 to 52°C, but the maximum heating water primary supply to the mixing pipe could be 90°C. The flow rate to the mixing pipe would then be 0.0079 kg/s.

This is about 1/10 of the loop flow rate. Again, this keeps the primary connections smaller than the circulating loop, which keeps the pipe connection smaller, which in turn keeps the control valve to a small size which improves the C_v and the valve authorities.

For **variable-flow, constant-temperature control** (Figure 26), the water supply temperature to the floor is kept at a constant 12°C, and the floor surface temperature is maintained at 20°C. As the cooling output to the space increases to maintain space set-point temperature, the water flow through the floor is increased. For this control option, the water flow rate through the floor is proportional to the cooling output from the floor. As the water flow rate increases to provide the cooling output from the floor the leaving water temperature from the floor decreases to a minimum of 17°C.

For **constant-flow, variable-temperature control** (Figure 27), the water supply temperature to the floor is varied, the floor surface temperature is maintained at 20°C. As the cooling output to the space increases to maintain space set-point temperature, the water flow through the floor is constant. For this control option, the supply water temperature to the floor is varied from 16.1 to 11.1°C, which is proportional to the cooling output from the floor. As the supply water temperature decreases to provide the cooling output from the floor the leaving water temperature from the floor decreases to a minimum of 17°C.

For **constant-flow, constant-temperature control** (Figure 28), the water supply temperature to the floor is kept at a constant 12.7°C, The floor surface temperature is varied from 16.6 to 21.6°C. As the cooling output to the space increases to maintain space set-point temperature, the water flow through the floor is constant. For this control option, the leaving water temperature from the floor is proportional to the cooling output from the floor. As the cooling output increases to provide the cooling output from the floor surface temperature is also increased.

From these three alternatives, constant flow, variable temperature provides the smoothest control.

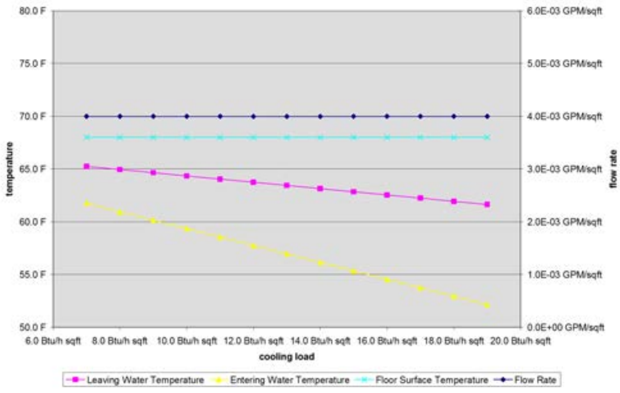

Fig. 27 Constant-Flow, Variable-Temperature Control

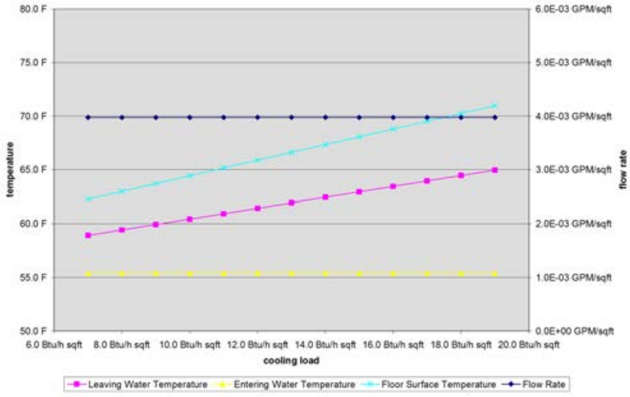

Fig. 28 Constant-Flow, Constant -Temperature Control

Dew-Point

The floor surface temperature of the radiant floor is lower than the air temperature in the space. Therefore, if the surface temperature of the floor falls down below the space air dew point at any area, water falls out and the floor gets wet. The floor surface temperature is dependent on the water temperature at the specific area, the cooling load of this area and the distance between the tubes within the floor construction. Because of the distance between the tubes, the floor surface temperature is not constant. It is recommended to select a minimal EWT equal to the supposed maximal dew point temperature to avoid a condensation on the floor surface and to guarantee the selected cooling capacity of the radiant system. Additional, the EWT should be controlled by a humidity control sensor.

If on any reason an EWT below the supposed dew point is selected, the minimal possible surface temperature of the floor in areas with reduced loads must be calculated carefully.

For example, if the indoor air is controlled of a dry bulb temperature of 24°C and a relative humidity of 50%, the suggested dew point is approximately 13°C. Therefore, a minimal EWT of 13°C may be selected. The combination of the radiant floor cooling system with a natural ventilation concept requires an accurate calculation of the maximal suggested dew points within the space, considering the outdoor air conditions as well as the latent loads of the space.

Room Control

In some buildings, it may be necessary to control individual rooms separately from other rooms without adjusting the weather-compensation control. One way to accomplish this is with valve actuators attached to individual manifold loops that service the rooms where control is desired.

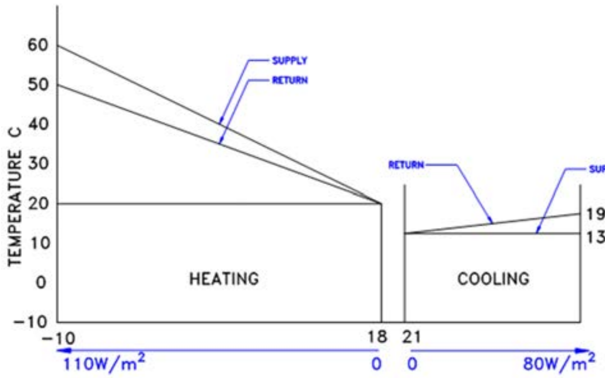

Fig. 29 Control Strategy for Combined Radiant Heating and Cooling Floor

Figure 29 shows the principles that may be applied for a space with mainly outdoor cooling and heating loads, with a combined radiant heating and cooling floor. Spaces with a high amount of interior cooling loads are quite more difficult to control if the radiant floor is used both for heating and cooling.

Control Strategy for Office Buildings

The control strategy for office buildings with its high number of internal loads, which are independent of outdoor conditions (weather), requires more considerations.

Interior Zones. The interior zones may have only cooling loads. There, the radiant floor may provide only cooling to the zone. The EWT may be kept constant and the water flow (on or off) is controlled by a space thermostat. It is important to avoid an under cooling of the space during the night or during unoccupied periods. The water flow should switch off, if the space temperature decreases under the allowed level. It is important to consider, that there is a defined amount of cooling power stored within the construction slab, so the switch-off level should be higher than the allowed minimal temperature level.

Perimeter Zones. Perimeter zones may be equipped with a radiant floor system that provides both heating and cooling to the space. If the radiant floor is the only heating system, the radiant floor must be selected for the heating loads. The EWT may be controlled by a weather compensation control combined with a zone control system. In cooling mode, the EWT should be kept on a constant level. In most cases, the radiant floor cooling system for a perimeter zone is combined with either a mechanical ventilation or a natural ventilation system to provide the remaining cooling capacity and the necessary fresh air and to reduce the latent loads. It is important to avoid the cooling of a heated floor slab or the reverse situation during normal weather situations. The following strategy may be used.

During periods where heating and cooling is necessary during the same day, the radiant floor should provide only heating to the space. The space cooling should be provided by the additional system (may be through operable windows). This can be designed by using a delay element of at least 1 day to switch the radiant floor system between heating and cooling mode. Outside temperatures are usually not as high during periods that require heating and cooling during the same day. So the additional air ventilation system may be used in economizer mode.

During periods where usually no heating is necessary, the floor is used only for cooling as the first cooling system in a same way as in the interior zones.

ALMOST all inhabited areas of the world are susceptible to the damaging effects of either earthquakes or wind. Restraints that are designed to resist one may not be adequate to resist the other. Consequently, when exposure to either earthquake or wind loading is a possibility, strength of equipment and attachments should be evaluated for all appropriate conditions.

Earthquake damage to inadequately restrained HVAC&R equipment can be extensive. Mechanical equipment that is blown off the support structure can become a projectile, threatening life and property. The cost of properly restraining the equipment is small compared to the high costs of replacing or repairing damaged equipment, liability for loss of life, or compared to the cost of building downtime due to damaged facilities.

Design and installation of seismic and wind restraints have the following primary objectives:

- To reduce the possibility of injury and the threat to life.
- To reduce long-term costs due to equipment damage and resultant downtime.

Note: The intent of building codes with respect to seismic design is not to prevent damage to property or the restrained equipment itself.

This chapter covers the design of restraints to limit equipment movement and to keep the equipment captive during an earthquake or extreme wind loading. Seismic restraints and isolators do not reduce the forces transmitted to the restrained equipment. Instead, properly designed and installed seismic restraints and isolators have the necessary strength to withstand the imposed forces. However, equipment that is to be restrained must also have the necessary strength to remain attached to the restraint.

The *International Building Code*® (IBC) (ICC 2009) provides a prescriptive approach for applying an equivalent static force representing the dynamic forces transmitted to the equipment by seismic or high-wind events. For mechanical systems, analysis of seismic and wind loading conditions can use static analysis from the prescriptive approach. Conservative safety factors are applied to reduce the complexity of earthquake and wind loading response analysis and evaluation. The following three aspects are considered in a properly designed restraint system:

- *Attachment of equipment to restraint.* The equipment must be positively attached to the restraint, and must have sufficient strength to withstand the imposed forces and to transfer the forces to the restraint.
- *Restraint design.* The restraint also must be strong enough to withstand the imposed forces. This should be determined by the manufacturer by tests and/or analysis.
- *Attachment of restraint to substructure.* Attachment may be by bolts, lag bolts, welds, or concrete anchors. The substructure must be capable of surviving the imposed forces.

1. SEISMIC-RESISTANT DESIGN

Most seismic requirements adopted by local jurisdictions in North America are based on model codes developed by the International Code Council (ICC), such as the *International Building Code* (IBC). The *National Building Code of Canada* (NRC-IRC 2010) is Canada's equivalent version of the IBC. Local building officials must be contacted for specific requirements that may be more stringent than those presented in this chapter.

Other sources of seismic restraint information include

- *Seismic Restraint Manual: Guidelines for Mechanical Systems* (SMACNA 2008), includes seismic restraint information for mechanical equipment subjected to seismic forces of up to 1.0*g*.
- The most current National Fire Protection Association (NFPA) standards on restraint design are compliant with the IBC.
- U.S. Department of Energy DOE 430.1A and ASME AG-1 cover restraint design for nuclear facilities.
- DOD (2007) provides guidance for seismic design for U.S. Department of Defense (DoD) and Department of State (DoS) facilities, and DOD (2005) provides the seismic and wind design constants.
- *A Practical Guide to Seismic Restraint* (ASHRAE 2000) covers a broad range of seismic restraint design issues.
- *Federal Emergency Management Agency (FEMA)* installation manuals FEMA-412, FEMA-413, and FEMA-414 are available at the FEMA Web site. They provide a step-by-step process with details for installing seismic restraint devices.

In seismically active areas where governmental agencies regulate the earthquake-resistive design of buildings (e.g., California), the HVAC engineer usually does not prepare the code-required seismic restraint calculations. The HVAC engineer selects the heating and cooling equipment and, with the assistance of the acoustical engineer (if applicable to the project), selects the required vibration isolation devices. Seismic restraint calculations are performed for nonstructural components, and designs for piping, ductwork, and conduits are designed and detailed. For design-build projects, the design is reviewed by the registered design professional. Nonstructural restraint components are designed and constructed to resist the aftereffects of earthquake motions as required by the applicable code

The preparation of this chapter is assigned to TC 2.7, Seismic and Wind Resistant Design.

and in accordance with local building officials. Reviewed designs are submitted for approval by the authority having jurisdiction.

To ensure proper design factors are used, a designer should obtain information on the seismic design conditions (site class and occupancy category). The importance of the equipment and systems affected should be understood for code applications to include those items that must be functional after seismic events.

The owner or building officials maintain the code-required quality control over the design by requiring construction documents, special inspection requirements, and certification requirements prepared by the registered design professional and approved by the authority having jurisdiction. Upon completion of installation, the supplier of the seismic restraints, or a qualified representative, should inspect the installation and verify that all restraints and force-resisting systems are installed properly and comply with specifications.

1.1 TERMINOLOGY

Base plate thickness. Thickness of the equipment bracket fastened to the floor.

Effective shear force V_{eff}. Maximum shear force of one seismic restraint or tie-down bolt.

Effective tension force T_{eff}. Maximum tension force or pullout force on one seismic restraint or tie-down bolt.

Equipment. Any HVAC&R component that must be restrained from movement during an earthquake.

Resilient support. An active seismic device (such as a spring with a bumper) to prevent equipment from moving more than a specified amount.

Response spectra. Relationship between the acceleration response of the ground and the peak acceleration of the earthquake in a damped single degree of freedom at various frequencies. The ground motion response spectrum varies with soil conditions.

Rigid support. Passive seismic device used to restrict any movement.

Shear force V. Horizontal force generated at the plane of the seismic restraints, acting to cut the restraint at the base.

Seismic restraint. Device designed to withstand seismic forces and hold equipment in place during an earthquake.

Seismic force levels. The geographic location of a facility determines its seismic spectral response acceleration levels, as given in the *International Building Code*.

Snubber. Device made of steel-housed resilient bushings arranged to prevent equipment from moving beyond an established gap.

Tension force T. Force generated by overturning moments at the plane of the seismic restraints, acting to pull out the bolt.

1.2 CALCULATIONS

Sample calculations presented here assume that the equipment support is an integrated resilient support and restraint device. When the two functions of resilient support and motion restraint are separate or act separately, additional spring loads may need to be added to the anchor load calculation for the restraint device. Internal loads within integrated devices are not addressed in this chapter. These devices must be designed to withstand the full anchorage loads plus any internal spring loads.

Both static and dynamic analyses reduce the force generated by an earthquake to an equivalent statically applied force, which acts in a horizontal or vertical direction at the component's center of gravity. The resulting overturning moment is resisted by shear and tension (pullout) forces on the tie-down bolts. Static analysis is used for both rigidly mounted and resiliently mounted equipment.

Dynamic Analysis

Dynamic analysis of the isolation and snubber systems may be based on ground-level response spectra given in the IBC and reference standard ASCE 7 (ASCE 2005), which can be used as input for a dynamic analysis.

Response spectra applied to nonstructural components can be developed from ICC-ES acceptance criteria AC 156 (ICC-ES 2007). Site-specific ground response spectra developed by a geotechnical or soils engineer may be used, as well. The computer analysis used must be capable of analyzing nonlinear supports and site-specific ground motions. This dynamic analysis provides the maximum seismic input accelerations to the equipment components, allowing comparison to three-dimensional shock (drop) or shaker test fragility levels to determine equipment survivability. Actual drop or shaker test data for all HVAC equipment may not be available for the next several years.

Using the response spectra in the code for ground-floor inputs, or the spectra in ATC 29-2 for upper floors, a dynamic analysis can yield maximum input accelerations to equipment components. Comparing them to the allowable acceleration values in the table helps the engineer assess equipment survivability. Dynamic analysis can also provide maximum movement at all connections and, when added to the floor-to-ceiling code-mandated movements, allows the engineer to design these flexible connections and avoid pull-out or shear failures at these locations.

Under some conditions, Chapter 17 of IBC requires certificates of compliance for components and their attachments for a component importance factor I_p of 1.0 or 1.5. This is a life-safety issue as well as an essential equipment issue. Essential equipment with an I_p = 1.5 must have a certificate of compliance. Issuance of a certificate of compliance to the engineer of record and building official can be based on dynamic analysis. Most building officials require a stamp by a registered professional to be part of the calculations and certificate of compliance. Table 1 provides guidance on type of analysis (static or dynamic) and certificate of compliance documentation is required. Sample dynamic analysis is beyond the scope of this chapter and should be provided by experienced registered professionals. A common approach assumes an elastic response spectrum. The results of the dynamic analysis can then be scaled up or down as a percentage of the total lateral force obtained from the static analysis performed on the building.

Dynamic analysis of piping, ductwork, and equipment reflects the response of the equipment for all earthquake-generated frequencies. Especially for piping and equipment, when the earthquake forcing frequencies match the natural frequencies of the system, the resulting applied forces increase.

Static Analysis as Defined in the *International Building Code*

The IBC specifies a design lateral force F_p for nonstructural components as

$$F_p = (0.4 a_p S_{DS} W_P) \frac{I_p}{R_p}\left(1 + 2\frac{Z}{h}\right) \quad (1)$$

but F_p need not be greater than

$$F_p = 1.6 S_{DS} I_p W_p \quad (2)$$

nor less than

$$F_p = 0.3 S_{DS} I_p W_p \quad (3)$$

where S_{DS} is determined by

$$S_{DS} = 2F_a S_S/3 \quad (4)$$

where

a_p = component amplification factor in accordance with Table 2.
S_{DS} = design spectral response acceleration at short periods. S_S is the mapped spectral acceleration from Tables 4 and 5. (*Note*: More

Source: IBC (2006).

detailed maps for the United States are available at the U.S. Geological Survey Web site: www.usgs.gov.)

F_a = function of site soil characteristics and must be determined in consultation with either project geotechnical (soils) or structural engineer. Values for F_a for different soil types are given in Table 3. (*Note*: Without an approved geotechnical report, the default site soil classification is assumed to be site class *D*.)

R_p = component response modification factor in accordance with IBC.

I_p = component importance factor (see the IBC for explanation and determination of I_P).

$1 + 2z/h$ = height amplification factor where z is the height of attachment in the structure and h is the average height of the roof above grade. The value of $z \geq 0$ and z/h need not exceed 1.

$W_p(D)$ = mass of equipment, which includes all items attached or contained in the equipment.

The forces acting on the equipment are the lateral and vertical forces resulting from the earthquake, the force of gravity, and the forces of the restraint holding the equipment in place; these act on the center of gravity. The analysis assumes the equipment does not move during an earthquake; thus, the sum of the forces and moments must be zero. When calculating the overturning moment, including an uplift factor, the vertical component F_{pv} at the center of gravity is typically defined (for the IBC) to be

$$F_{pv} = 0.2 S_{DS} D \quad (5)$$

If the equipment being analyzed is isolated, the final computed force must be doubled per section 1621.3.1 of the code.

Per section 1621.1.7 of the code, forces used when computing the loads for shallow (under 8 bolt diameter) embedment anchors are to be increased by a factor of $1.3R_p$.

Per section 1621.3.12.2 of the code, the only permitted expansion anchors for non-vibration-isolated equipment over 7.46 kW are undercut anchors.

Tables 4 and 5 contain brief listings of S_s factors that can be used to calculate the magnitude of the horizontal static seismic force acting at the equipment center of gravity. Values for IBC 2006 are

available on the USGS web site for U.S. locations or in Tables F-2 and G-2 of DOD (2005) for worldwide locations.

1.3 APPLYING STATIC ANALYSIS

The prescriptive method in the IBC allows that an equivalent static force can be calculated that represents the dynamic motions of an earthquake. The static forces acting on a piece of equipment are vertical and lateral forces resulting from the earthquake, the force of gravity, and forces at the restraints that hold the equipment in place. The analysis assumes that the equipment does not move during the earthquake and that the relative accelerations between its center of gravity and the ground generate forces that must be balanced by reactions at the restraints. Guidance from the code bodies indicates that equipment can be analyzed as though it were a rigid component; however, a factor a_p is applied in the computation to address flexibility issues on particular equipment types or flexible mounting arrangements. (*Note*: for dynamic analysis, it is common to use a 5% damping factor for equipment and a 1% damping factor for piping.) Although the basic force computation is different, the details of load distribution in the examples that follow apply independently of the code used.

The forces acting on the restraints include both shear and tensile components. The application direction of the lateral seismic acceleration can vary and is unknown. Depending on its direction, it is likely that not all of the restraints will be affected or share the load equally. It is important to determine the worst-case combination of forces at all restraint points for any possible direction that the lateral wave front can follow to ensure that the attachment is adequate.

*Nominal values based on ZIP codes. See www.usgs.gov for calculator to check actual S_s using latitude and longitude for best results.

Once the overall seismic forces F_p and F_{pv} have been determined (as indicated in the previous section or per the local code requirement), the loads at the restraint points can be determined. There are many different valid methods that can be used to determine these loads, but this section suggests a couple of simple approaches.

Under some instances (particularly those relating to life-support issues in hospital settings), newer code requirements indicate that critical equipment must be seismically qualified to ensure its continued operation during and after a seismic event. Special care must be taken in these situations to ensure that equipment has been shaker

Table 6 Load Combinations
(Equation Numbers as Referenced in IBC)

ASD	LRFD
5. $(1.0 + 0.14S_{DS})D + H + F + 0.7\rho Q_E$	5. $(1.2 + 0.2S_{DS})D + \rho Q_E + L + 0.2S$
8. $(0.6 + 0.14S_{DS})D + 0.7\rho Q_E + H$	7. $(0.9 - 0.2S_{DS})D + \rho Q_E + 1.6H$

tested or otherwise certified to meet the maximum anticipated seismic load. Table 6 illustrates some load combination calculations.

1.4 COMPUTATION OF LOADS AT BUILDING CONNECTION

ASCE *Standard* 7 is based on **load- and resistance-factor design (LRFD)**. In the past, building codes have been based on **allowable stress design (ASD)**. Both are allowed for seismic restraint design. Load factors and load combinations that must be considered in design are defined in Chapter 2 of ASCE *Standard* 7. If a component is anchored with post-installed anchors, the design is usually accomplished using provisions of LRFD.

The Load Combinations of Section 2.4.1 of ASCE *Standard* 7 must be considered in the design. Generally, for rigidly mounted components, Combination 8 is the critical combination to be considered.

The forces of the restraint holding the equipment in position include shear and tensile forces. It is important to determine the number of bolts that are affected by the earthquake forces. The direction of the lateral force should be evaluated in both horizontal directions, as shown in Figure 1. All bolts or as few as a single bolt may be affected.

Simple Case

Figure 1 shows a rigid floor-mount installation of a piece of equipment with the center of gravity at the approximate center of the restraint pattern. To calculate the shear force, the sum of the forces in the horizontal plane is

$$0 = F_p - V \quad (6)$$

The equipment shown in Figure 1 has two bolts on each side, so that four bolts are in shear. Using a single-axis moment equation to calculate the tension force, the sum of the moments for overturning results in an overturning moment (OTM) and resisting moment (RM).

For Figure 1, two bolts are in tension. See Example 1 for applications of the OTM and RM. See ASCE *Standard* 7 for load combinations that adjust the D (dead load) and E (earthquake load). Shear and tension forces V and T should be calculated independently for both axes, as shown in the front and side views. See the examples for complete analysis.

General Case

The classic method used to distribute seismic loads equally distributes lateral loads among the restraints and then modifies these loads as a function of the mass eccentricity. Worst-case mass, vertical seismic load, and overturning components are combined to determine a maximum vertical load component. This **polar method** is in common use and works well for most applications.

A second, **lump mass method**, proportions the restraint loads based on the equipment mass and distribution. When working with larger seismic forces or unstable equipment, this offers the option of more evenly distributing the seismic load, reducing anchor size and peak restraint requirements. Eccentric center of gravity (cg) loads are not required to be carried out to the corner restraints as in the polar method; this technique deemphasizes stresses in the equipment frame and is more suitable for nonrigid equipment types. Eccentric loads can be addressed with either the polar method or the lump mass method.

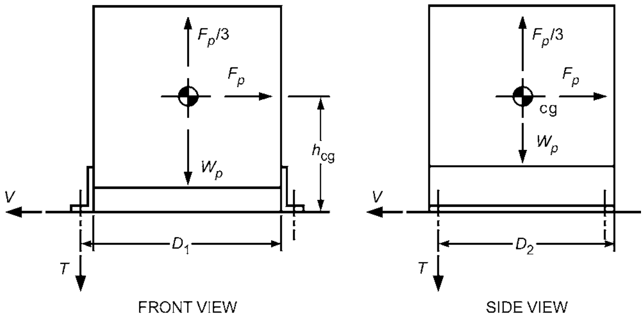

Fig. 1 Equipment with Rigidly Mounted Structural Bases

Note: Although only two methods of computing forces for more general equipment cases are illustrated here, there are many other valid methods that can be used to distribute the restraint forces. It is important that any method used include the ability to account for equipment mass, seismic uplift forces, overturning forces, and an offset center of gravity within the equipment.

Polar Method

Lateral forces are equally distributed among the restraints. If the equipment's center of gravity does not coincide with its geometric center, a rotational factor is added to account for the imbalance. This factor is determined in three steps. First, compute the true chord length in the horizontal plane between the equipment's center of gravity and the restraints' geometric center. Second, multiply the equipment total seismic lateral force by this length (to obtain a rotational moment). Third, divide this figure by the number of moment-resisting restraints times their distance from the geometric center. (The moment-resisting restraints are those farthest and equally spaced from the geometric center.) The resulting load can then be added to the original (balanced) figure. This method transfers all imbalance loads to the corner restraints and provides a valid method of restraint as long as the equipment acts as a rigid body. The assumption that a piece of equipment can transfer these loads out to the corners becomes less accurate as the equipment becomes less rigid.

Calculation of the tensile/compressive forces at the restraints is more complex than that for determining the shear loads, and must include mass, vertical seismic force, overturning forces, and (if isolated) the type of isolator/restraint system used. The total tensile and compressive forces are the worst-case summation of each of these components. For clarity, each component is addressed here as a separate entity.

The nominal mass component at each restraint is simply the total operating mass divided by the number of restraints. The vertical seismic force is simply the mass component at each location multiplied by the vertical seismic force factor in terms of the total F_{pv} load expressed in *g*s, the gravitational constant (F_{pv}/W_p, where F_{pv} is the vertical seismic load component as defined by the code and W_p is the total operating mass of the equipment). This can be directed either upward or downward when summing forces.

Lump Mass Method

In the lump mass method, the total equipment mass is distributed among the restraints in a manner that reflects the equipment's actual mass distribution. There are many methods of determining the distribution analytically or by testing, although they are not addressed in this section. Frequently, a mass distribution can be obtained from the equipment manufacturer.

Once the static point loads are obtained or computed for each restraint location, they can be multiplied by the lateral seismic acceleration factor (F_p/W_p) to determine lateral forces at each restraint point. Thus, if the mass at each restraint point is W_n, then

$$V_{eff} = (F_p/W_p)W_n \quad (7)$$

This method considers the loads at all the restraints individually and computes the overturning forces for each in 1° increments for a full 360° of possible seismic wave front angle; it is only practical to perform using a spreadsheet. The total lateral seismic force F_p is divided into *x*- and *y*-axis components for each possible wave front approach angle. These forces are multiplied by the height of the equipment center of gravity above the point of restraint h_{cg}. The resulting moments are then resolved into forces at each restraint based on the *x*- and *y*-axis moment arms associated with the particular restraint location and the proportion of the load that it will bear.

Resilient Support Factors

If the equipment being restrained is isolated, the following three factors must be considered:

- For all forces that are not directed along the principal axes, only the corner restraints can be considered to be effective. Thus, for either distribution method, only the corner restraints can be considered capable of absorbing vertical loads.
- If the restraints are independent (separate entities) from the spring isolation elements and if, when exposed to uplift loads, vertical spring forces are not absorbed within the housing of an integral isolator/restraint assembly, the mass factor determined in the first step of the vertical load analysis should be ignored. (This is because any effect that a mass reduction has on the attachment hardware forces is replaced by an approximately equal vertical force component from the spring.)
- If the gap in the restraint element exceeds 6 mm, the final computed forces must be doubled per the IBC.

Building Attachment

The common attachment arrangements are directly bolting with steel bolts and lag bolts, welding, or anchoring to concrete using post-installed anchors. To evaluate the combined effective tensile and shear forces that act simultaneously on these connections, a separate analysis is required.

If allowable stress design (ASD) data are used to size hardware for through-bolted connections for the IBC codes, which are strength based, the loads may be reduced by a factor of 1.4. If LRFD is used when selecting for the hardware, the 1.4 factor does not apply. All allowable capacities used for concrete post-installed anchor bolts selection should be drawn from ICC-ES test reports. These values reflect test data on a single anchor and should be derated for applications where embedment, edge distances, spacing, or location vary from the test conditions. Anchor manufacturers may have selection software to determine anchor bolt capacities that consider installation conditions. It should also be noted that the values published in ES reports may be either ASD or LRFD values and may need to be converted for compatibility with the (LRFD) IBC code being used.

1.5 ANSI STEEL BOLTS

For direct attachment with through bolts using ASD criteria, the design capacity of the attachment hardware should be based on criteria established in the American Institute of Steel Construction (AISC) manual. Based on the use of A307 bolts, the basic formula for computing allowable tensile stress when shear stresses are present is

$$T_{allow} = 179 - 1.8 S_v \quad (8)$$

where S_v is the shear stress in the bolt in megapascals. T_{allow}, the maximum allowable tensile stress, must not exceed 138 MPa.

However, because these stresses are appropriate for dead- plus live-load combinations, they can be appropriately inflated by 1.33 when allowable stress design provisions are used and when they are used to resist wind and seismic loads as well. Peak bolt loads are based on the maximum permitted stress multiplied by the nominal bolt area.

1.6 LAG SCREWS INTO TIMBER

Acceptable loads for lag screws into timber can be obtained from the *National Design Specification®* (NDS®) *for Wood Construction* (AWC 2005). Selected fasteners must be secured to solid lumber, not to plywood or other similar material. Withdrawal force design values are a function of the screw size, penetration depth, and wood density and can be increased by a factor of 1.6 for short-term seismic or wind loads. Table 9.2A in the NDS identifies withdrawal forces on a force/embedment depth basis. Note that the values published in this table are capacities in both ASD and LRFD. In addition, NDS Table 9.4.2 introduces deration factors for reduced edge distance and bolt spacing.

In timber construction, the interaction formula given in Equation (8) does not apply. Instead, per Section 9.3.5 of the NDS, the equation is

$$Z_a' = (W'p)Z'/[(W'p)\cos^2\alpha + Z'\sin^2\alpha] \quad (9)$$

where

Z' = shear capacity drawn from Table 9.3A
W' = side grain withdrawal force = $1800 G^{3/2} D^{3/4}$
G = specific gravity of the timber
D = diameter
p = embedment depth of screw
α = angle of composite force measured flat with surface of timber

1.7 CONCRETE POST-INSTALLED ANCHOR BOLTS

Capacities are manufacturer/anchor-type specific. Capacity data should be obtained from the anchor's current ES report. Where failure of the steel does not govern the tensile load, strength-based design (LRFD) should be used. Obtain anchor information from the anchor ICC-ES (formerly ICBO-ESR) report based on anchor and installation factors. For groups of anchors, special factors are required and American Concrete Institute *Standard* 318-08 should be consulted.

ASD Applications

Interaction Formula. To evaluate the combined effective tension and shear forces that act simultaneously on the bolt, use the either of the following equations:

$$(T_{eff}/T_{allow\ ASD})^{5/3} + (V_{eff}/V_{allow\ ASD})^{5/3} \leq 1.0 \quad (10)$$

or

$$(T_{eff}/T_{allow\ ASD}) + (V_{eff}/V_{allow\ ASD}) \leq 1.2 \quad (11)$$

However, if $T_{eff} \leq 0.2$; $T_{allow\ ASD}$ the full T_{eff} can equal $T_{allow\ ASD}$, or if $V_{eff} \leq 0.2$; $V_{allow\ ASD}$ the full V_{eff} can equal $V_{allow\ ASD}$.

LRFD Applications

The engineer must select an anchor for use from a current evaluation report for anchors that satisfy provisions of ACI 318 Appendix D or ACI 355 (the provisions are the same). From ACI 318, the capacity of the anchor must be reduced in accordance with the following:

$$T = 0.75\phi N \quad (12)$$

$$V = 0.75\phi V \quad (13)$$

The interaction equation for LFRD is modified as follows:

$$(T_{eff}/T_{allow}) + (V_{eff}/V_{allow}) \leq 1.2 \quad (14)$$

Types of Concrete Post-Installed Anchors

Several types of anchor bolts for insertion in concrete are manufactured. Wedge and undercut anchors perform better than self-drilling, sleeve, or drop-in types. Adhesive anchors are stronger than other anchors, but lose their strength at elevated temperatures (e.g., on rooftops and in areas damaged by fire).

Wedge anchors have a wedge on the end with a small clip around the wedge. After a hole is drilled, the bolt is inserted and the external nut tightened. The wedge expands the small clip, which bites into the concrete.

Undercut anchors expand to seat against a shoulder cut in the bottom of the anchor hole. Although these have the highest capacity of commonly available anchor types, the cost of the extra operation to cut the shoulder in the hole greatly limits the frequency of their use in the field.

A **self-drilling anchor** is basically a hollow drill bit. The anchor is used to drill the hole and is then removed. A wedge is then inserted on the end of the anchor, and the assembly is drilled back into place; the drill twists the assembly fully in place. The self-drilling anchor is heavily affected by the skill of the craft and usually not rated for seismic applications.

Drop-in expansion anchors are hollow cylinders with a tapered end. After they are inserted in a hole, a small rod is driven through the hollow portion, expanding the tapered end. These anchors are only for shallow installations because they have no reserve expansion capacity. These anchors are usually not rated for seismic applications.

A **sleeve anchor** is a bolt covered by a threaded, thin-wall, split tube. As the bolt is tightened, the thin wall expands. Additional load tends to further expand the thin wall. The bolt must be properly preloaded or friction force will not develop the required holding force. These anchors are typically not used in seismic applications because of the limited reserve capacity.

Large screw anchors are one-piece anchors that have a concrete cutting thread. These anchors were initially designed to be installed without a specified torque, but torque is used to ensure contact at the rated embedment

Adhesive anchors may be in glass capsules or installed with various tools. Pure epoxy, polyester, or vinyl ester resin adhesives are used with a threaded rod supplied by the contractor or the adhesive manufacturer. Some adhesives have a problem with shrinkage; others are degraded by heat. However, some adhesives have been tested without protection to 590°C before they fail (all mechanical anchors will fail at this temperature). Where required, or if there is a concern, anchors should be protected with fire retardants similar to those applied to steel decks in high-rise buildings.

The manufacturer's instructions for installing the anchor bolts should be followed. ES reports have further information on allowable forces for design. Use a safety factor of 2 or as required by ES reports if the installation has not been inspected as required by the IBC Chapter 17 on special inspection.

Stainless steel anchors are required for use in outdoor applications noted in the latest versions of the IBC code.

1.8 WELD CAPACITIES

Weld capacities may be calculated to determine the size of welds needed to attach equipment to a steel plate or to evaluate raised support legs and attachments. A static analysis provides the effective tension and shear forces. The capacity of a weld is given per unit length of weld based on the shear strength of the weld material. For steel welds, the allowable shear strength capacity is110 MPa on the throat section of the weld. The section length is 0.707 times the specified weld size.

For a 1.5 mm weld, the length of shear in the weld is 0.707 × 1.5 mm. The allowable weld force $(F_w)_{allow}$ for a 1.5 mm weld is

$$(F_w)_{allow} = 1.06 \times 110 = 117 \text{ N per millimetre of weld} \quad (15)$$

For a 3 mm weld, the capacity is 233 N.

The effective weld force is the sum of the vectors calculated in terms of effective shear and tension shall be reduced. Because the vectors are perpendicular, they are added by the method of the square root of the sum of the squares (SRSS), or

$$(F_w)_{eff} = \sqrt{(T_{eff})^2 + (V_{eff})^2} \quad (16)$$

The length of weld required is given by the following equation:

$$\text{Weld length} = (F_w)_{eff}/(F_w)_{allow} \quad (17)$$

1.9 SEISMIC SNUBBERS

Several types of snubbers are manufactured or field fabricated. All snubber assemblies should meet the following minimum requirements to avoid imparting excessive accelerations to HVAC&R equipment:

- Impact surface should have a high-quality elastomeric surface that is not cemented in place.
- Resilient material should be easy to inspect for damage and be replaceable.
- Snubber system must provide restraint in all directions.
- Snubber capacity should be verified either through test or by analysis and should be certified by an independent, registered engineer to avoid serious design flaws.

Typical snubbers are classified as Types A through J (Figure 2).

Type A. Snubber built into a resilient mounting. All-directional, molded bridge-bearing quality neoprene element is a minimum of 3.2 mm thick.

Type B. Isolator/restraint. Stable isolation spring bears on the base plate of the fixed restraining member. Earthquake motion of isolated equipment is restrained close to the base plate, minimizing pullout force to the base plate anchorage.

Type C. Spring isolator with built-in all-directional restraints. Restraints have molded neoprene elements with a minimum thickness of 3.2 mm. A neoprene sound pad should be installed between the spring and base plate. Sound pads below the base plate are not recommended for seismic installations.

Type D. Integral all-directional snubber/restrained spring isolator with neoprene element.

Type E. Fully bonded neoprene mount capable of withstanding seismic loads in all directions with no metal-to-metal contact.

Type F. All-directional three-axis snubber with neoprene element. The neoprene element of bridge-bearing quality is a minimum of 4.8 mm thick. Snubber must have a minimum of two anchor bolt holes.

Type G. Lateral snubber. Neoprene element is a minimum of 6.4 mm thick. Upper bracket is welded to the equipment.

Type H. Restraint for floor-mounted equipment consisting of interlocking steel assemblies lined with resilient elastomer. Bolted to equipment and anchored to structure through slotted holes to allow field adjustment. After final adjustment, weld anchor to floor bracket and weld angle clip to equipment or, alternatively, fill slots with adhesive grout to prevent slip.

Type I. Single-axis, single-direction lateral snubber. Neoprene element is a minimum of 6.4 mm thick. Minimum floor mounting is with two anchor bolts. Must be used with a minimum of eight, two per corner.

Type J. A telescopic snubber for floor-mounted equipment, with a molded neoprene element, designed to distribute the seismic force to a larger surface area in a pipe section. This snubber is an

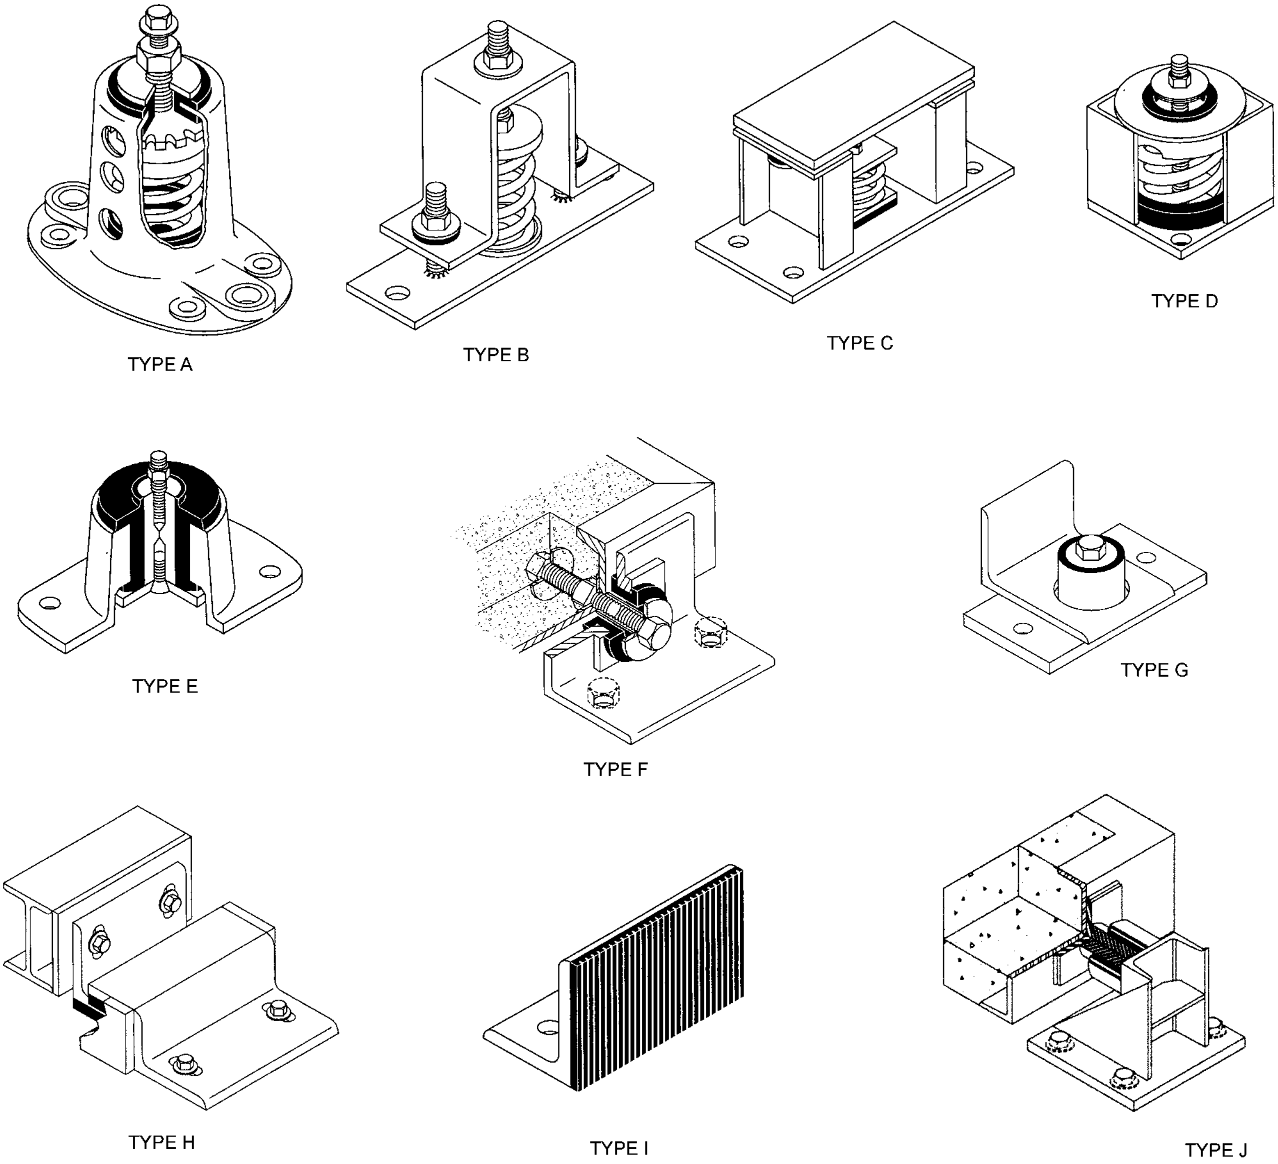

Fig. 2 Seismic Snubbers

all-directional restraint system when a minimum of four snubbers are installed. The molded neoprene element is a minimum of 6.3 mm thick and is installed with an air gap of 4.8 mm not to exceed 6.3 mm.

1.10 SEISMIC RESTRAINTS

For suspended equipment, pipes, ducts, and raceways, it is necessary to restrain lateral movement resulting from seismic acceleration applied to the component. Unrestrained, suspended equipment and related systems will sway violently back and forth, impacting nearby building material and possibly overstressing the hanger rods. The overstressed rods will eventually break and the equipment crash down. To prevent this swaying, suspended components are restrained by one of two methods: a wire rope system, or a rigid brace using steel struts, angles, or other steel elements.

Wire rope restraints are a restraint assembly for suspended equipment, piping, or ductwork consisting of high-strength, galvanized steel aircraft cable. A typical cable restraint system is shown in Figure 3. Cable should have a certified break strength. Some models are color-coded for easy field verification. Cable must be manufactured to meet or exceed minimum materials and standard requirements. Break strengths must be per ASTM E-8 procedures. A safety factor of 2 may be used when prestretched cable is used with end connections designed to meet the cable break strength. Cables are installed to prevent excessive seismic motion and arranged so they do not engage during normal operation. Equipment suspended with vibration isolators must use cable restraints to avoid degrading the isolation. Rigid type bracing will short out the vibration isolators. To prevent buckling of the hanger rods, add a rod stiffener as shown in Figure 4.

Secure the cable to structure and to the braced component through a bracket or stake eye designed to meet the cable restraint rated capacity. Cables are typically secured using one of the following methods:

- Factory-installed permanent stake eye
- Field-looped through bracket and secured with cable grips
- Field-looped through bracket and secured with oval sleeve
- Factory brackets with integral cable clamps to secure cable

When cables are looped through a field-supplied bracket or support hole, a cable thimble should be used to protect the cable. Many factory-supplied brackets are designed specifically for allowing a looped cable through without a thimble. See the manufacturer's instructions for details. Figure 5 shows typical cable restraint details with various attachment methods. Typical attachment methods to secure the rigid brace to the structure and component are shown in Figure 6.

1.11 RESTRAINT OF PIPE AND DUCT RISERS

When piping and ductwork run vertically through a structure, they are identified as risers. They are subject to the same seismic and (less commonly) wind forces as are piping and ductwork oriented horizontally. The primary difference is that the forces that act along the axis of the riser are the summation of the vertical seismic forces and gravity loads, whereas on horizontal systems, the axial forces are simply the horizontal seismic or wind force.

It is also important to recognize, when providing restraint, that risers of any significant length and variation in temperature require support that allows thermally driven changes in the riser's overall length to be accommodated. Because the vertical seismic and wind forces are small compared to gravity forces, axial restraint for the riser can normally be provided with only minor increases in the size of the specialized components used to support the system. Because of the potential of damage to the restraint or support systems as the system grows or shrinks, it is not recommended that redundant axial restraint systems be fitted to a riser. Instead, the primary support system should be designed or selected to meet the job requirement.

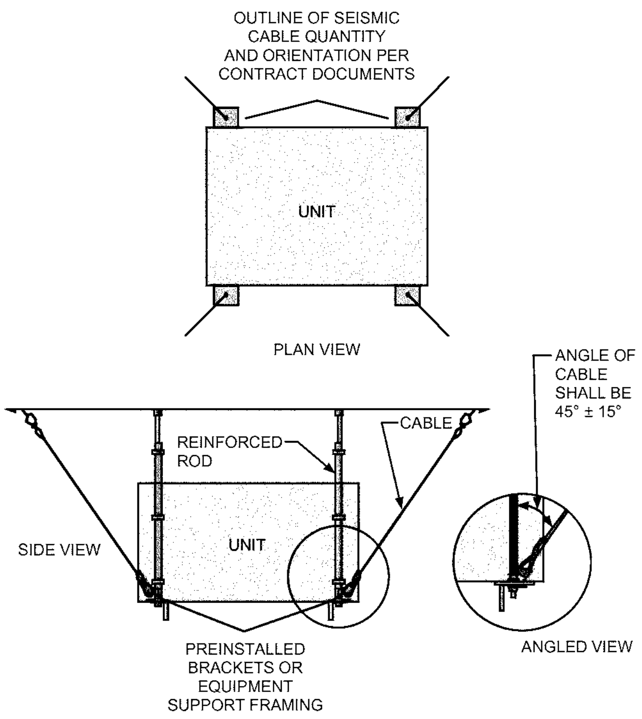

Fig. 3 Cable Restraint

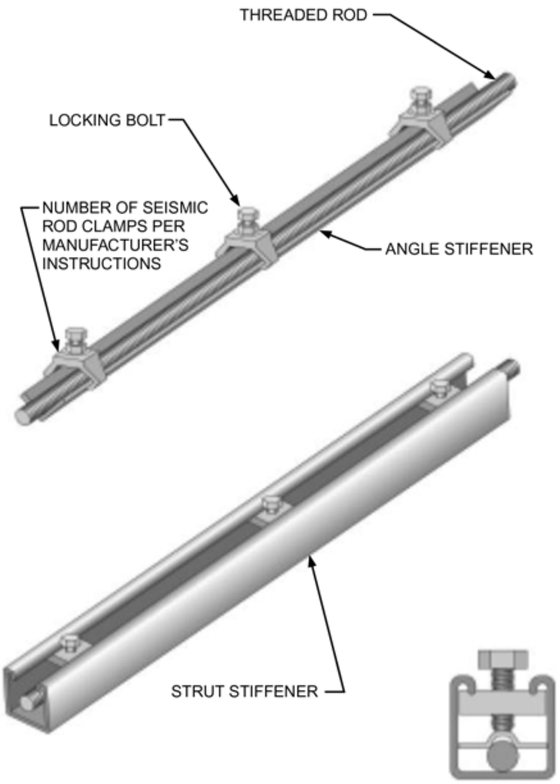

Fig. 4 Rod Stiffener

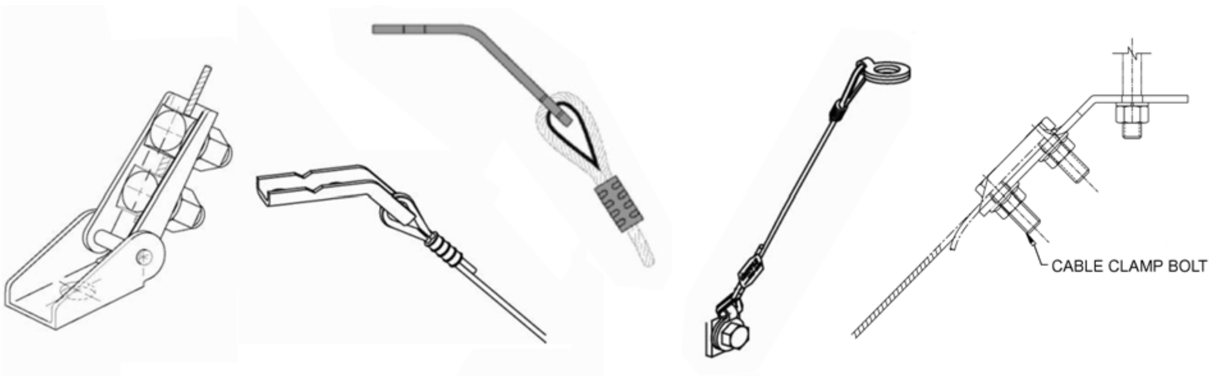

Fig. 5 Types of Cable Connections

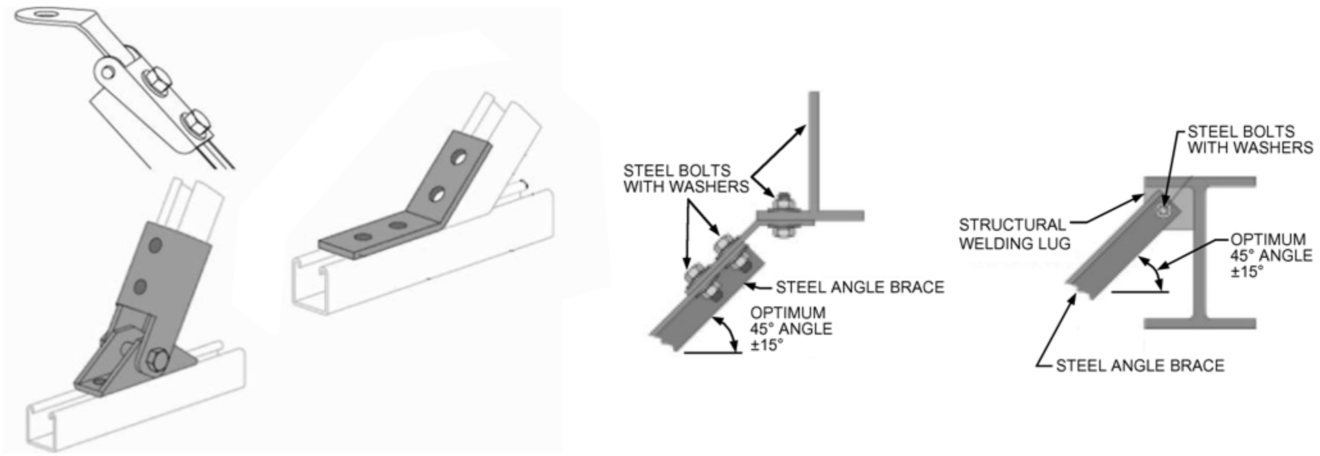

Fig. 6 Strut End Connections

Risers of significant length are also fitted with some type of stabilization devices. These can be as simple as snug-fitting holes in the floors that the risers penetrate, to specialized brackets or guiding devices that maintain the alignment of the piping or duct while still allowing it to expand or contract. As is the case with the vertical forces, the components used for guidance can frequently be used to provide resistance against seismic or wind events if they are sized and attached appropriately.

If, in the lateral load case, the components used to provide guidance are not adequate to resist the design seismic or wind load conditions, redundant, seismically qualified systems should be fitted to perform this task.

All axial and lateral restraints fitted to risers must be effective against forces that may act in any horizontal or vertical direction as applicable. In addition, the attachment hardware used must be seismically qualified components (e.g., anchors), installed in accordance with seismically qualified procedures.

1.12 EXAMPLES

The following examples are provided to assist in the design of equipment anchorage to resist seismic forces. For Examples 1 through 4, assume the provisions contained in ASCE 7-05 apply, $I_p = 1.5$, $S_s = 0.85$, site soil class is C, and the equipment is located at the top of a 50 m building. Also include an uplift force component $F_{pv} = 0.2 S_{DS} D$ where D is the dead load for all examples. Examples 1 through 5 are solved using the polar method of analysis while Example 6 is solved by the lump mass method.

Note: These examples assume that $I_p = 1.5$. This assumes that the equipment being considered is essential to the continued function of the building following an earthquake or contains hazardous materials. ASCE 7-05 Section 13.2.2 requires that this equipment be certified as being operable after the design earthquake.

Example 1. Anchorage design for equipment rigidly mounted to the structure (see Figure 7).

From Equations (1) to (4), calculate the lateral seismic force and its vertical component. Note that for post-installed, if the anchor satisfies the requirements of ASCE 7, Section 13.4.2, the value of R_p is the same as the component being considered. Post-installed anchors with current evaluation reports published by ICC or other agencies are deemed to be compliant with the provisions of ACI 355 or 318 Appendix D and thus satisfy Section 13.4.2. For rigidly mounted mechanical equipment (period < 0.06 s or > 16.7 Hz), a_p from Table 2 is 1.0, otherwise $a_p = 2.5$.

ASCE 7 is based on load and resistance factor design (LRFD). In the past, building codes have been based on allowable stress design (ASD). Load factors and load combinations defined in Chapter 2 of ASCE 7

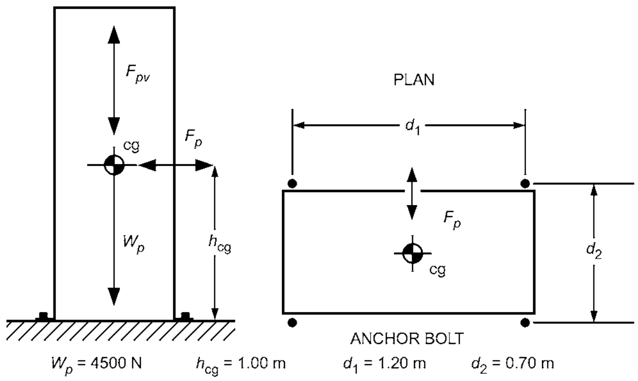

Fig. 7 Equipment Rigidly Mounted to Structure (Example 1)

must be considered in design. If a component is anchored with post-installed anchors, the design can only be accomplished using LRFD.

The first step in the load determination process is to determine S_{DS} using the following equation and $F_a = 1.1$ (from Table 3, site class C):

$$S_{DS} = 2F_a S_s/3 = 2 \times 1.1 \times 0.85/3 = 0.623$$

Using this value for S_{DS} Equation (1) gives

$$F_P = \left[\frac{0.4 \times 1.0 \times 0.623 \times 4500}{\frac{2.5}{1.5}}\right]\left(1 + 2 \times \frac{15}{15}\right) = 2020 \text{ N}$$

Equation (2) shows that F_p need not be greater than

$$1.6 \times 0.623 \times 1.5 \times 4500 = 6728 \text{ N}$$

Equation (3) shows that F_p must not be less than

$$0.3 \times 0.623 \times 1.5 \times 4500 = 1262 \text{ N}$$

Therefore $F_p = 2020$ N.

When considering provisions of LRFD, a vertical acceleration component must be considered per ASCE 7, Section 12.4.2.2.

$$F_{PV} = 0.2 \times S_{DS} \times D = 0.2 \times 0.623 \times 4500 = 561 \text{ N}$$

For Allowable Stress Design (ASD)

The load combinations of Section 2.4.1 of ASCE 7 must be considered in the design. For rigidly mounted components, Combination 8 is generally the critical combination to be considered.

Calculate the overturning moment OTM:

$$\text{OTM} = F_P h_{cg} = 2020 \times 1.0 = 2020 \text{ N} \cdot \text{m} \quad (18)$$

Calculate the resisting moment RM:

$$RM = W_P\left(\frac{d_{min}}{2}\right) = 4500\left(\frac{70}{2}\right) = 1575\ \text{N·m} \qquad (19)$$

$$T = [2020(0.7) - 1575(0.6)]/0.70 = 670\ \text{N} \qquad (20)$$

Calculate T_{eff} per bolt:

$$T_{eff} = 670/2 = 335\ \text{N per through-bolt or lag screw} \qquad (21)$$

Calculate shear force per bolt:

$$V_{eff} = 2020/(4 \times 1.4) = 361\ \text{lb per through-bolt or lag screw} \qquad (22)$$

Load and Resistance Factor Design (LRFD)

The load combinations of Section 2.3.2 of ASCE 7 must be considered in the design. For rigidly mounted components, Combination 7 is generally the critical combination to be considered.

$$RM = (W_p - F_{pv})d_{min}/2 = (4500 - 561)0.70/2 = 1379\ \text{N·m} \qquad (23)$$

$$T_{eff} = [2020 - 0.9(1379)]/0.70(2) = 556\ \text{N} \qquad (24)$$

Per ASCE 7 Section 13.4.2, if post-installed anchors are used, an additional 1.3 factor is applied to all E loads. The 1.3 factor applies for projects using ASCE 7-05. This factor is not required for applications using ASCE 7-10.

$$OTM = 2020(1.3) = 2626\ \text{N·m} \qquad (25)$$

$$T_{eff} = [2626 - 1379(0.9)]/0.70(2) = 989\ \text{N} \qquad (26)$$

To convert in·lb to N·m, multiply by 0.113.

Case 1. *Equipment attached to a timber structure*

Before computing interaction forces, the computed loads must be reduced by a factor of 1.4 to make them compatible with the capacity data listed in the *National Design Specification*® (*NDS*®) *for Wood Construction* (AWC 1997). The lateral load V_{eff} becomes 361/1.4 or 258 N per bolt and the pullout load T_{eff} becomes 335/1.4 = 239 N per bolt. For the capacity of the connection, a resulting combined load and angle relative to the mounting surface must be computed. The combined load is

$$T\alpha_{eff} = \sqrt{(T_{eff})^2 + (V_{eff})^2} = \sqrt{(258)^2 + (239)^2} = 352\ \text{N}$$

The angle α = arcs in $(T_{eff}/Z'_\alpha) = 42.5°$, where $Z\alpha$ is the allowable lag screw load multiplied by applicable factors and $Z'_\alpha\alpha$ is the factored allowable lag screw load at angle α from the mounting surface.

Selected fasteners must be secured to solid lumber, not to plywood or other similar material. The following calculations are made to determine whether a 13 mm diameter, 100 mm long lag screw in redwood will hold the required load. For this computation, it is assumed that bolt spacing, edge distance, temperature, and other factors do not reduce the bolt capacity (see NDS for further details) and that the load allowable factor for short-term wind or seismic loads is 1.6.

From Table 9.3A in the NDS, for redwood, $G = 0.37$, and Z perpendicular to the grain is 2277 N.

From Table 9.2A in the NDS, for $G = 0.37$ and 90 mm full thread, $W = 66.7 \times 90 = 6003$ N.

Substituting into the combined load for lag bolts [Equation (9)] gives Z'_α =

$$\frac{(66.7 \times 90)2277}{(66.7 \times 90)42.5 + 2277\sin^2 42.5} = 3177\ \text{N}$$

Therefore, a 13 mm diameter, 100 mm long lag screw can be used at each corner of the equipment.

Case 2. *Equipment attached to steel*

For equipment attached directly to a steel member, analysis is the same as that shown in case 1. Capacities for the attaching bolts are given in the *Manual of Steel Construction* (AISC 1989). See Chapter J of the AISC Specification for design provisions.

For this example $T_{eff}/T_{ASD} = 556/4410 = 0.126 < 0.2$; therefore a combined tension shear check need not be performed on the connection.

Therefore, 13 mm diameter bolts can be used.

Example 2. Anchorage design for equipment supported by external spring mounts (Figure 8) and attached to concrete using nonshallow post-installed anchors.

A mechanical or acoustical consultant should choose the type of isolator or snubber or combination of the two. Then the product vendor should select the actual spring snubber.

Using ASCE 7, the lateral force F_p must be recalculated using new factors. S_{DS} remains as in Example 1. For expansion anchors, $R_p = 1.5$, and for resiliently mounted mechanical equipment, a_p from Table 2 is 2.5.

The basic force equation is then (*Note*: using $R_p = 1.5$ is conservative, because the anchors must comply with 13.4.2 of ASCE 7. The numbers could be modified)

$$F_P = \left(\frac{0.4 \times 2.5 \times 0.623 \times 4500}{\frac{1.5}{1.5}}\right)\left(1 + 2 \times \frac{50}{50}\right) = 8411\ \text{N}$$

Equation (2) indicates that F_p need not be greater than

$$1.6 \times 0.623 \times 1.5 \times 4500 = 6728\ \text{N}$$

Equation (3) indicates that F_p must not be less than

$$0.3 \times 0.623 \times 1.5 \times 4500 = 1262\ \text{N}$$

The vertical force F_{pv} equals

$$F_{PV} = 0.2 S_{DS} D = 0.2 \times 0.623 \times 4500 = 561\ \text{N}$$

Because the equipment is resiliently supported, footnote b to Table 13.6-1 of ASCE 7 indicates that the computed forces may need to be doubled. Therefore, F_p is 6728 × 2 = 13.5 kN and F_{pv} is 561 × 2 = 1.1 kN.

Assume that the center of gravity cg of the equipment coincides with the center of gravity of the isolator group.

If T = maximum tension on isolator and C = maximum compression on isolator, then

$$T, C = \frac{-W_P + F_{PV}}{4} \pm F_P h_{cg}\frac{\cos\theta}{2b} + F_P h_{cg}\frac{\sin\theta}{2a}$$
$$= \frac{-W_P + F_{PV}}{4} \pm \frac{F_P h_{cg}}{2}\left(\frac{\cos\theta}{b} + \frac{\sin\theta}{a}\right) \qquad (27)$$

To find maximum T or C, set $dT/d\theta = 0$:

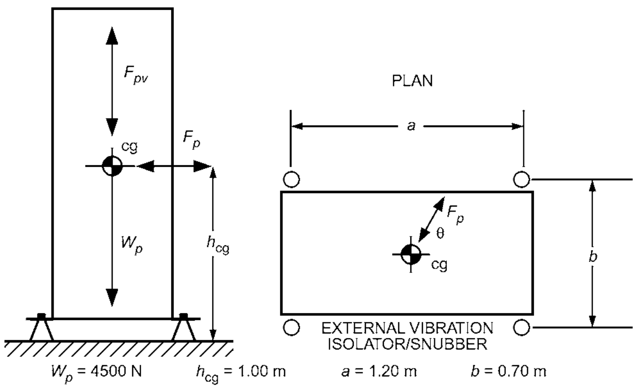

Fig. 8 Equipment Supported by External Spring Mounts

$$\frac{dT}{d\theta} = \frac{F_P h_{cg}}{2}\left(\frac{\cos\theta}{b} + \frac{\sin\theta}{a}\right) = 0 \quad (28)$$

$$\theta_{max} = \tan^{-1}(b/a) = \tan^{-1}(0.7/1.2) = 30.26° \quad (29)$$

$$T = \frac{-W_P + F_{PV}}{4} + \frac{F_P h_{cg}}{2}\left(\frac{\cos\theta_{max}}{b} + \frac{\sin\theta_{max}}{a}\right) \quad (30)$$

$$C = \frac{-W_P + F_{PV}}{4} - \frac{F_P h_{cg}}{2}\left(\frac{\cos\theta_{max}}{b} + \frac{\sin\theta_{max}}{a}\right) \quad (31)$$

$$T = \frac{-4.5 + 1.12}{4} + \frac{13.5 \times 1}{2}\left(\frac{\cos 30.26}{0.7} + \frac{\sin 30.26}{1.2}\right) = 10.3 \text{ kN}$$

$$T = \frac{-4.5 + 1.12}{4} + \frac{13.5 \times 1}{2}\left(\frac{\cos 30.26}{0.7} + \frac{\sin 30.26}{1.2}\right) = -12.0 \text{ kN}$$

Calculate the shear force per isolator:

$$V = (F_P/N_{iso}) = 13\,500/4 = 3375 \text{ N} \quad (32)$$

This shear force is applied at the operating height of the isolator. Uplift tension T on the vibration isolator is the worst condition for the design of the anchor bolts. The compression force C must be evaluated to check the adequacy of the structure to resist the loads.

$$(T_1)_{eff} \text{ per bolt} = T/2 = 10\,300/2 = 5150 \text{ N} \quad (33)$$

The value of $(T_2)_{eff}$ per bolt due to overturning on the isolator is

$$(T_2)_{eff} = V \times \text{operating height}/dN_{bolt} \quad (34)$$

where d is the distance from edge of isolator base plate to center of bolt hole.

$$(T_2)_{eff} = (3375 \times 8)/(3 \times 2) = 4500 \text{ N} \quad (35)$$

$$(T_{max})_{eff} = (T_1)_{eff} + (T_2)_{eff} = 5150 + 4500 = 9650 \text{ N} \quad (36)$$

$$V_{eff} = 3375/2 = 1688 \text{ N} \quad (37)$$

See Example 1 for the design of the connections to the structural system.

Example 3. Anchorage design for equipment with a center of gravity different from that of the isolator group (Figure 10).

Anchor properties

$$I_x = 4B^2 \qquad I_y = 4L^2 \quad (38)$$

Angles:

$$\theta = \tan^{-1}(B/L) \quad (39)$$

$$\alpha = \tan^{-1}(e_x/e_y) \quad (40)$$

$$\beta = 180\,|\alpha - \theta\,| \quad (41)$$

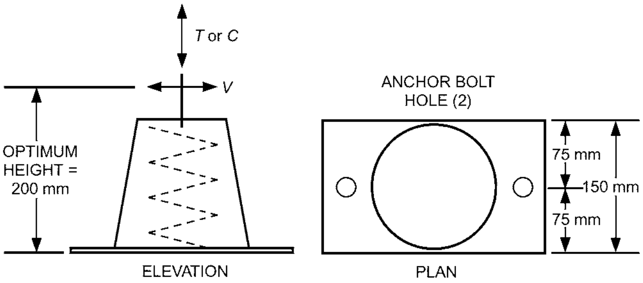

Fig. 9 Spring Mount Detail (Example 2)

$$\phi = \tan^{-1}(LI_x/BI_y) \quad (42)$$

Vertical reactions

$$(W_n)_{max/min} = W_p \pm F_{pv} \quad (43)$$

Vertical reaction caused by overturning moment

$$T_m = \pm F_P\left(\frac{Bh_{cg}}{I_x}\cos\theta + \frac{Lh_{cg}}{I_y}\sin\theta\right) \quad (44)$$

Vertical reaction caused by eccentricity

$$(T_e)_{max/min} = (W_n)_{max/min}\left(\frac{Be_y}{I_x} + \frac{Le_y}{I_y}\right) \quad (45)$$

Vertical reaction caused by W_p

$$(T_w)_{max/min} = (W_n)_{max/min}/4 \quad (46)$$

$$T_{eff} = T_m + (T_e)_{max} + (T_w)_{max} \text{ (always compression)} \quad (47)$$

$$T_{eff} = -T_m + (T_e)_{min} + (T_w)_{min} \text{ (tension if negative)} \quad (48)$$

Horizontal reactions

Horizontal reaction caused by rotation

$$V_{rot} = F_P\left(\frac{e_x^2 + e_y^2}{16(B^2 + L^2)}\right)^{0.5} \quad (49)$$

$$V_{dir} = F_p/4 \quad (50)$$

$$V_{max} = (V_{rot}^2 + V_{dir}^2 - 2V_{rot}V_{dir}\cos\beta)^{0.5} \quad (51)$$

See Example 1 for the design of the connections to the structural system.

The values of T_{min} and V_{max} are used to design the anchorage of the isolators and/or snubbers, and T_{max} is used to verify the structure's adequacy to resist the vertical loads.

Example 4. Anchorage design for equipment with supports and bracing for suspended equipment (Figure 11). Equipment mass W_p = 2200 N.

Because post-installed anchors may not withstand published allowable static loads when subjected to vibratory loads, vibration isolators should be used between the equipment and the structure to damp vibrations generated by the equipment.

Anchor properties

$$I_x = 4B^2 \qquad I_y = 4L^2 \quad (52)$$

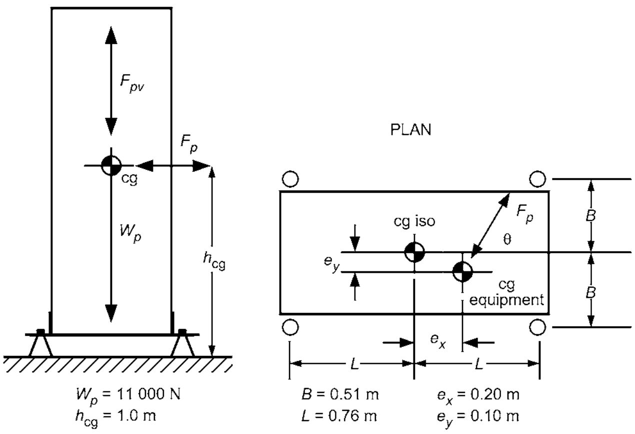

Fig. 10 Equipment with Center of Gravity Different from Isolator Group (in Plan View)

Angle

$$\phi = \tan^{-1}(LI_x/BI_y) = 36.86° \quad (53)$$

From Equation (43),

$$(W_n)_{max/min} = 2200 \pm 548 = 2748 \text{ N or } 1652 \text{ N}$$

From Equation (44),

$$T_m = \pm 4934(0.132 + 0.075) = \pm 1021 \text{ N}$$

From Equation (45),

$$T_e = 0$$

From Equation (46),

$$(T_w)_{max/min} = 687 \text{ N or } 413 \text{ N}$$

From Equation (47),

$$(T_{eff})_{max} = 1021 + 0 + 687 = 1708 \text{ N (downward)}$$

From Equation (48),

$$(T_{eff})_{max} = -1021 + 0 + 413 = -608 \text{ N (upward)}$$

Forces in the hanger rods:

Maximum tensile = 1708 N

Maximum compression = 608 N

Force in the splay brace = $F_P\sqrt{2}$ = 6978 N at a 1:1 slope.

Because of the force being applied at the critical angle, as in Example 2, only one splay brace is effective in resisting the lateral load F_p.

Design of hanger rod/vibration isolator and connection to structure

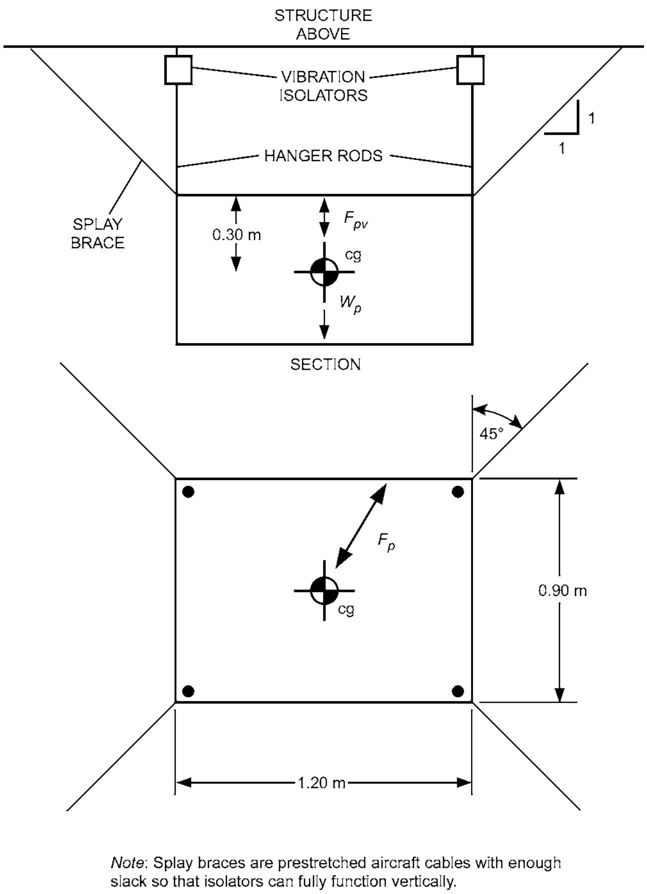

Fig. 11 Supports and Bracing for Suspended Equipment

When post-installed anchors are mounted to the underside of a concrete beam or slab, the allowable tension loads on the anchors must be reduced to account for cracking of the concrete. A general rule is to use half the allowable load. Some manufacturers have ICC reports that provide allowable values for anchors installed under the slab.

Determine whether a 13 mm wedge anchor with special inspection provisions will hold the required load.

$$T_{allow} = 2600 \times 0.5 \times 2 = 2600 > T_{eff} = 1708 \text{ N}$$

Therefore, a 13 mm rod and post drill-in anchor should be used at each corner of the unit.

For anchors installed without special inspection,

$$T_{allow} = 2600 \times 0.5 = 1300 > T_{eff} = 1708 \text{ N}$$

Therefore, a larger anchor should be chosen.

Determine if the 13 mm hanger rod would require a stiffener if it is 1 m long.

Design of splay brace and connection to structure

Force in the slack cable = 6978 N.

Because all of the load must be resisted by a single cable, the forces in the connection to the structure are

$$V_{max} = 4934 \text{ N} \quad T_{max} = F_p = 4934 \text{ N}$$

Because the cable forces are relatively small, a 9.5 mm aircraft cable attached to clips with cable clamps should be used. The clips, in turn, may be attached to either the structure or the equipment.

The design of a post-installed anchor installation is similar to that shown in Example 1. Anchors installed through a metal deck will have lower capacities than anchors installed in a flat slab because of limited embedment depths. Take care to ensure that the design also satisfies the requirements contained in the evaluation report for the anchor specified.

Prescriptive provisions of ASCE 7 can be summarized as follows:

- Formulas for relative displacement of floor and ceiling can be conservatively estimated at 1% of the floor-to-ceiling height. This displacement must be used to determine the required horizontal flexibility of the pipe, duct, or electrical connections at the equipment interface.
- In ASCE 7, using all-directional snubbers with clearance of more than 7 mm increases F_p by a factor of 2.
- Component supports must be designed to accommodate component movement to prevent pounding on the structure or other components. This affects internal isolators and snubbers.
- Equipment components exposed to seismic impact forces and using nonductile housings must be designed using 25% of material yield stresses.
- Nonessential equipment, failure of which can cause essential equipment failure, must be designed as essential equipment.
- If the structure's site class is not provided in the contract documents, assume site class D, subject to change by the building official.
- For pipe or duct on any given run, if the distance from the bottom of the structure to the top of the support is 305 mm or less for all supports in that run, then that run does not need sway braces.
- Pipe and ducts may not be required to have sway braces, depending on size, material content, and importance factor. These conditions are defined in Chapter 13 of ASCE 7.

1.13 INSTALLATION PROBLEMS

The following should be considered when installing seismic restraints.

- Anchor location affects the required strengths. Concrete anchors should be located away from edges, stress joints, or existing fractures. The evaluation report for the chosen anchor should be followed as a guide for edge distances and center-to-center spacing.

- Supplementary steel bases and frames, concrete bases, or equipment modifications may void some manufacturers' warranties. Snubbers, for example, should be properly attached to a subbase. Bumpers may be used with springs.
- Static analysis does not account for the effects of resonant conditions within a piece of equipment or its components. Because all equipment has different resonant frequencies during operation and nonoperation, the equipment itself might fail even if the restraints do not. Equipment mounted inside a housing should be seismically restrained to meet the same criteria as the exterior restraints.
- Snubbers used with spring mounts should withstand motion in all directions. Some snubbers are only designed for restraint in one direction; sets of snubbers or snubbers designed for multidirectional purposes should be used.
- Equipment must be strong enough to withstand the high deceleration forces developed by resilient restraints.
- Flexible connections should be provided between equipment that is braced and piping and ductwork that need not be braced.
- Flexible connections should be provided between isolated equipment and braced piping and ductwork.
- Bumpers installed to limit horizontal motion should be outfitted with resilient neoprene pads to soften the potential impact loads of the equipment.
- Anchor installations must be inspected (usually required for anchors resisting seismic forces); in many cases, damage occurs because bolts were not properly installed. To develop the rated restraint, bolts should be installed according to manufacturer's recommendations.
- Brackets in structural steel attachments should be matched to reduce bending and internal stresses at the joint.
- With the exception of heavy-duty clamps used to attach longitudinal restraints to piping systems, friction must not be relied on to resist any load. All connections should be positive and all holes should be tight-fitting or grouted to ensure minimal clearance at the attachment points.

2. WIND-RESISTANT DESIGN

Damage done to HVAC&R equipment by both sustained and gusting wind forces has increased concern about the adequacy of equipment protection defined in design documents. Two main areas of the HVAC&R system are exposed to wind events: the HVAC&R equipment and the exterior wall-mounted cladding components, such as intake and exhaust louvers. For HVAC&R equipment, the following calculative procedure generates the same type of total design lateral force used in static analysis of the seismic restraint. The value determined for the design wind force F_w can be substituted for the total design lateral seismic force F_p when evaluating and choosing restraint devices. For wall-mounted components, a design wind pressure P is determined, which can be used to specify equipment performance levels and design anchors to adequately brace wall-mounted cladding components to the building structure.

The American Society of Civil Engineers' (ASCE) *Standard* 7-05 includes design guidelines for wind, snow, rain, and earthquake loads. Note that the equations, guidelines, and data presented here only cover nonstructural components. The current standard (2005) includes more comprehensive and rigorous procedures for evaluating wind forces and wind restraint. Refer to the latest version of ASCE *Standard* 7 adopted by the local jurisdiction.

2.1 TERMINOLOGY

Classification. Buildings and other structures are classified for wind load design exposure according to Table 7.

Table 7 Definition of Exposure Categories

Exposure B. Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions the size of single-family dwellings or larger. Use of this exposure category is limited to those areas for which terrain representative of Exposure B prevails upwind for at least 800 m or 20 times the height of the building or structure, whichever is greater.

Exception: For buildings with mean roof height less than or equal to 9 m, the upwind distance may be reduced to 460 m.

Exposure C. Open terrain with scattered obstructions having heights generally less than 9 m. This category includes flat open country, grasslands, and all water surfaces in hurricane-prone areas. Exposure C applies for all cases where Exposure B or D do not apply.

Exposure D. Flat, unobstructed areas exposed to wind and flowing over open water outside of hurricane-prone regions for a distance of at least 1600 m. This exposure applies to structures exposed to the wind coming from over the water as well as smooth mud flats, salt flats, and unbroken ice.

Reprinted with permission from ASCE (2005).

Notes:
1. For a site located in a transition zone between exposure categories, the exposure resulting in the largest wind forces must be used.
2. Exposure Category D extends into downwind areas of Exposures B or C for a distance of 200 m or 20 times the height of the building, whichever is greater.
3. The responsibility for determining the exposure category for a given new building project falls on the structural engineer of record. This value is documented in the structural notes drawing (the first of the structural drawings) for the project.

Table 8 Wind Importance Factor *I* (Wind Loads)

Category	*I*
I	0.87
II	1
III	1.15
IV	1.15

Note: See Table 9 for categories.

Basic wind speed. The fastest m/s wind speed at 10 m above the ground of Terrain Exposure C (see Table 7) having an annual probability of occurrence of 0.02. Data in ASCE *Standard* 7 or regional climatic data may be used to determine basic wind speeds. ASCE data do not include all special wind regions (such as mountainous terrains, gorges, and ocean promontories) where records or experience indicate that the wind speeds are higher than what is shown in appropriate wind data tables. For these circumstances, regional climatic data may be used provided that both acceptable extreme-value statistical analysis procedures were used in reducing the data and that due regard was given to the length of record, averaging time, anemometer height, data quality, and terrain exposure. One final exclusion is that tornadoes were not considered in developing the basic wind speed distributions.

Components and Cladding. Elements of the building envelope that do not qualify as part of the main wind-force resisting system.

Corner Zone. Areas of building walls and roofs adjacent to building corners that experience increased external pressure from wind.

Design wind force. Equivalent static force that is assumed to act on a component in a direction parallel to the wind and not necessarily normal to the surface area of the component. This force varies with respect to height above ground level.

Importance factor *I*. A factor that accounts for the degree of hazard to human life and damage to HVAC components (Table 8). For hurricanes, the value of the importance factor can be linearly interpolated between the ocean line and 160 km inland because wind effects are assumed negligible at this distance inland.

Table 9 Exposure Category Constants

Exposure Category	α	Z_g, m	Gust Factor G
B	7	360	0.85
C	9.5	270	0.85
D	11.5	210	0.85

Reprinted with permission from ASCE (2005).
Note: See Table 7 for definitions of exposure categories.

Table 10 Force Coefficients for HVAC Components, Tanks, and Similar Structures

Shape	Type of Surface	C_f for h/D Values of 1	7	25
Square (wind normal to face)	All	1.3	1.4	2.0
Square (wind along diagonal)	All	1.0	1.1	1.5
Hexagonal or octagonal $D\sqrt{Q_z} > 2.5$	All	1.0	1.2	1.4
Round $D\sqrt{Q_z} > 2.5$	Moderately smooth	0.5	0.6	0.7
	Rough ($D'/D = 0.02$)	0.7	0.8	0.9
	Very rough ($D'/D = 0.08$)	0.8	1.0	1.2
Round $D\sqrt{Q_z} \le 2.5$	All	0.7	0.8	1.2

Reprinted with permission from ASCE (2005).
Notes:
1. Design wind force calculated based on area of structure projected on a plane normal to the wind direction. Force is assumed to act parallel to wind direction.
2. Linear interpolation may be used for h/D values other than shown.
3. Nomenclature:
   - D = diameter or least horizontal dimension, m
   - D' = depth of protruding elements such as ribs and spoilers, m
   - h = structure (top of equipment) height (above ground), m
   - Q_z = velocity pressure evaluated at height z above ground level, Pa

Gust response factor *G*. A factor that accounts for the fluctuating nature of wind and the corresponding additional loading effects on HVAC components

Minimum design wind load. The wind load may not be less than 0.48 kPa multiplied by the area of the HVAC component projected on a vertical plane that is normal to the wind direction.

2.2 CALCULATIONS

Two procedures are used to determine the design wind load on HVAC components. The **analytical procedure**, described here, is the most common method for standard component shapes, based on the requirements in ASCE 7. The second method, the **wind-tunnel procedure**, is used in the analysis of complex and unusually shaped components or equipment located on sites that produce wind channeling or buffeting because of upwind obstructions. The analytical procedure produces design wind forces that are expected to act on HVAC components for durations of 1 to 10 s. The various factors, pressure, and force coefficients incorporated in this procedure are based on a mean wind speed that corresponds to the fastest wind speed.

Analytical Procedure

The design wind force is determined by the following equation:

$$F_w = Q_z G C_f A_F \quad (54)$$

where

F_w = design wind force, N
Q_z = velocity pressure evaluated at height z above ground level, Pa
G = gust response factor for HVAC components evaluated at height z above ground level
C_f = force coefficient (Table 10)
A_f = area of HVAC component projected on a plane normal to wind direction, m²

Certain of the preceding factors must be calculated from equations that incorporate site-specific conditions that are defined as follows:

Velocity Pressure. The design wind speed must be converted to a velocity pressure that is acting on an HVAC component at a height z above the ground. The equation is

$$Q_z = 0.613 K_z K_{zt} K_d V^2 I \quad (55)$$

where

K_z = velocity pressure exposure coefficient from Table 12
K_{zt} = topographic factor = 1.0
K_d = wind directionality factor = 1.0
V = velocity from Figure 12, m/s
I = importance factor from Table 8

The force generated by the wind is calculated by

$$F_w = Q_z G C_f A_f \quad (56)$$

where

F_w = design wind force, N
Q_z = velocity pressure evaluated at height z above ground level, Pa
G = gust response factor for HVAC components evaluated at height z above ground level
C_f = force coefficient (Table 10)
A_f = area of HVAC component projected on a plane normal to wind direction, m²

The following example calculations are for a 1400 kW cooling tower:

Tower height h = 3 m
Tower width D = 3 m
Tower length l = 6 m
Tower operating mass W_p = 8650 kg

Tower diagonal dimension = $\sqrt{3^2 + 6^2}$ = 6.71 m
Area normal to wind direction A_f = 3 × 6.71 = 20.1 m²

From Table 10, C_f = 1.0 for wind acting along diagonal with h/D = 3/3 = 1.

Example 5. Suburban hospital in Omaha, Nebraska. The top of the cooling tower is 30 m above ground level. Building width normal to the wind B = 1000 m, and building height H = 35 m.

Solution:
From Figure 12, the design wind speed is found to be 40 m/s.
From Table 9, use Category IV.
From Table 7, use Exposure B.
From Table 8, I = 1.15.
From Table 12, K_z = 1.07.
From Figure 13, K_d = 0.9.
From Table 9, G = 0.85.

Substitution into Equation (58) yields

$$Q_z = 0.613 \times 1.07 \times 1.0 \times 0.9 \times (40)^2 \times 1.15 = 1086 \text{ Pa} = 1.1 \text{ kPa}$$

Building height is greater than 20 m; therefore, E_f = 1.0.
Substitution into Equation (54) yields the design wind force as

$$F_w = 1086 \times 0.85 \times 1.0 \times 20.1 \times 1.0 = 19\,460 \text{ N}$$

Example 6. Office building in New York City. Top of tower is 200 m above ground level. Building wall normal to the wind B = 180 m and building height H = 190 m.

Solution:
From Figure 12, the design wind speed is 54 m/s.
From Table 9, use Category II.

From Table 7, use Exposure B.
From Table 8, $I = 1.0$.
From Figure 13, $K_d = 0.9$.
Because $z > 150$ m, K_z must be determined from Note 2 of Table 12.
From Table 9, $\alpha = 7.0$, $z_g = 1200$, and $G = 0.85$.

Substituting into the first equation in Note 2 yields

$$K_z = 2.10(Z/Z_g)^{2/\alpha} = 1.72$$

Substituting into Equation (55) yields

$$Q_z = 0.613 \times 1.72 \times 1.0 \times 0.9 \times (54)^2 \times 1.15 = 3182 \text{ Pa}$$

Building height is greater than 20 m, therefore $E_f = 1.0$.

Substituting into Equation (56) yields the design force wind as

$$F_W = 3182 \times 0.85 \times 1.0 \times 20.1 \times 1.0 = 54\,364 \text{ N}$$

Example 7. Church in Key West, Florida. The top of the tower is 15 m above ground level. Building wall normal to the wind B = 110 m and building height H = 12 m.

Solution:

From Figure 12, the design speed is found to be 67 m/s.
From Table 9, use Category III.
From Table 5, use Exposure C (as this is a hurricane-prone region).
From Table 16, $I = 1.15$.
From Table 17, $G = 0.85$.
From Table 13, $K_d = 0.9$.
From Table 12, $K_z = 1.09$ (for exp category C).
From Equation (55):

$$Q_z = 0.613 \times 1.09 \times 1.0 \times 0.9 \times (67)^2 \times 1.15 = 3104 \text{ Pa}$$

Building height is less than 20 m, $A_f/(B \times H) = 224/(300 \times 40) = 0.02$, therefore, $E_f = 1.9$

Substituting into Equation (56) gives the design wind force as

$$F_w = 3104 \times 0.85 \times 1.0 \times 20.1 \times 1.9 = 100\,760 \text{ N}$$

2.3 WALL-MOUNTED HVAC&R COMPONENT CALCULATIONS (LOUVERS)

For many projects, the structural engineer of record will determine the components and cladding wind pressures provided on the structural notes drawing. If these wind pressures are not provided, the two following procedures (described previously) are used to determine the design wind load on HVAC cladding components.

Analytical Procedure

Velocity Pressure. The design wind speed must be converted to a velocity pressure that is acting on an HVAC component at height z above the ground. This is done using Equation (54). Once the

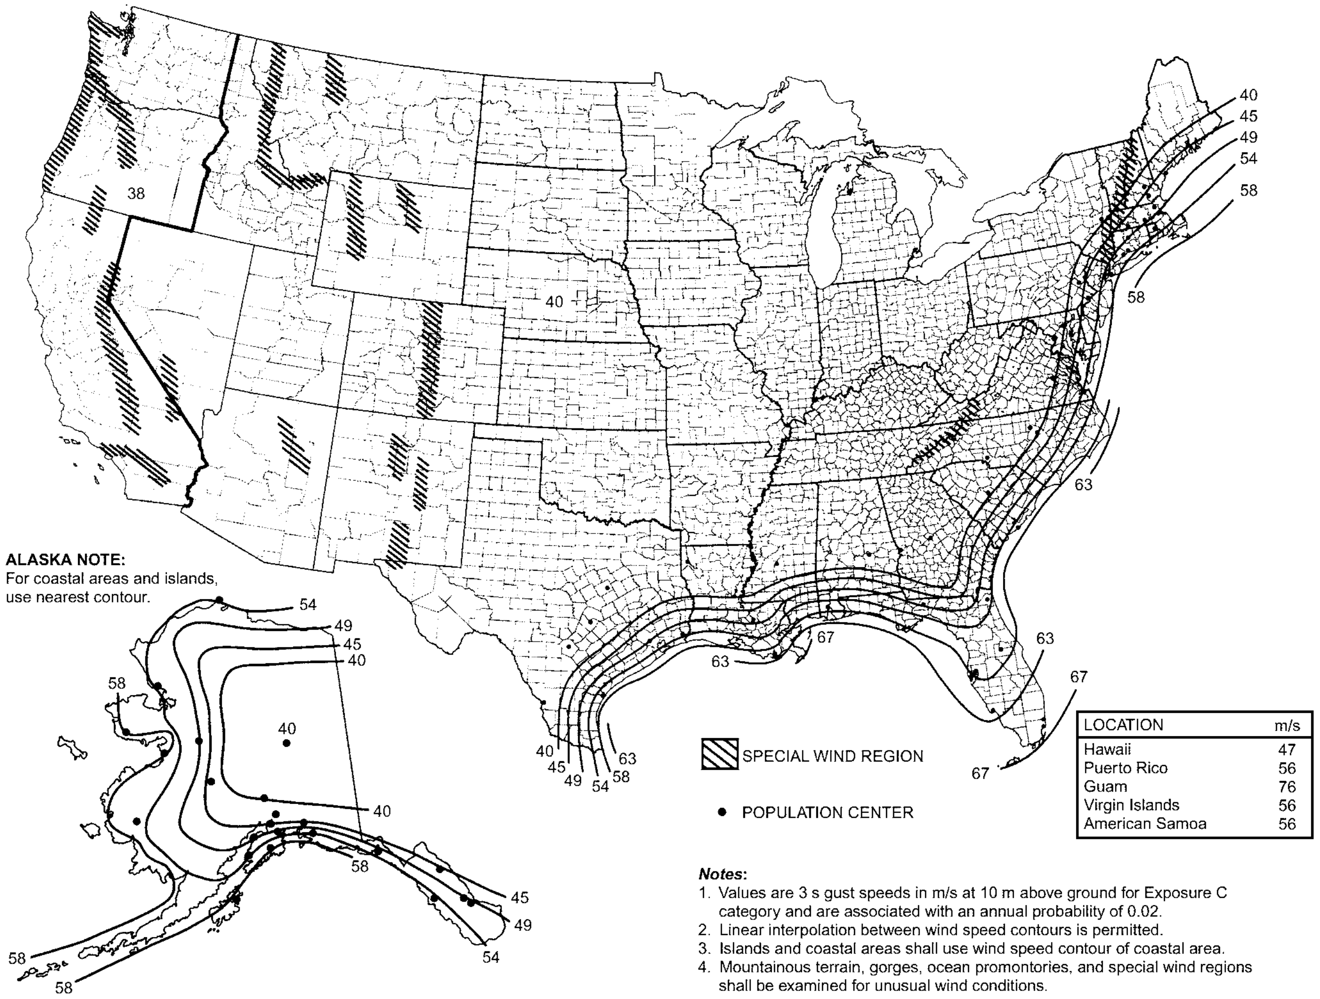

Fig. 12 Wind Speed Data
Reprinted with permission from ASCE (2005)

velocity pressure has been determined, the design wind pressure can be calculated.

Low-Rise Buildings and Buildings with h $\le$ *18.3 m*

The design wind pressure for cladding is determined by the following equation:

$$P_w = Q_h(GC_p - GC_{pi}) \quad (57)$$

where

P_w = design wind pressure, N/m²
Q_h = velocity pressure evaluated at mean roof height h above ground level, Pa
GC_p = external pressure coefficient given in Figure 13
GC_{pi} = internal pressure coefficient given in Table 14

Buildings with h > *18.3 m*

The design wind pressure is determined by the following equation:

$$P_w = Q(GCp) - q_i(GC_{pi}) \quad (58)$$

where

P_w = design wind pressure, N/m²
Q_z = velocity pressure for windward walls calculated at height z above the ground of the component being examined
Q_h = velocity pressure for leeward walls, side walls and roofs, evaluated at height h of the roof
Q_i = velocity pressure for windward walls, side walls, leeward walls, and roofs, evaluated at height h of the roof
GC_p = external pressure coefficient given in Figure 14
GC_{pi} = internal pressure coefficient given in Table 14

Example 8. Office building in Houston, Texas. The top of the building is 9.1 m above grade located in a newly developed suburban area. It is necessary to determine the wind pressures on louver 1 and louver 2 shown on the building elevation in Figure 15.

Solution:

From Figure 12, the design speed is found to be 54 m/s.
From Table 9, use Category II.
From Table 7, use Exposure C.
From Table 8, I = 1.0.
From Table 12, K_z = 0.98, at roof height, h = 9.1 m.
From Table 13, K_d = 0.85.
K_{zt} assumed to be 1.0.

Determine GC_p: Building height h is less than 18.3 m; therefore, Equation (55) is used for the pressure evaluations. GC_p must be determined from Figure 15 for each of the louvers.

Louver 1: from the notes on Figure 15, it is necessary to determine the a dimension, which establishes the corner zone 5. The least horizontal dimension coming into the corner is 9.8 m from the plan view. Ten percent of this value is 1 m. The minimum value for the corner dimension is 0.9 m. Louver 1 is located 0.37 m from the corner and is therefore in corner zone 5.

From Figure 15, GC_p = = +0.95 or –1.3 for a 1.9 m² wind area. A positive GC_p indicates a positive pressure on the windward side of the building. A negative GC_p indicates a suction pressure on the leeward side of the building. Both cases must be evaluated.

Louver 2: based on the corner calculation, louver 2 is in noncorner zone 4. From Figure 15, GC_p = +0.9 or –1.0 for a 2.8 m² wind area.

Determine GC_{pi}: See Figure 14. Most buildings without significant wall openings are enclosed buildings. For the purposes of this example, an enclosed building is assumed. GC_{pi} = +0.18 or –0.18. A positive sign indicates pressure outward on all structure walls. A negative sign indicates pressure inward on all structure walls.

Determine velocity pressure at roof elevation h from Equation (55):

$$Q_h = 0.613 \times 0.98 \times 1.0 \times 0.85 \times (54)^2 \times 1.0 = 1489 \text{ Pa}$$

Determine design wind pressure P from Equation (56):
Louver 1, case 1: positive external, positive internal

$$P = 1489 \times (0.95 - 0.18) = 1147 \text{ Pa}$$

Louver 1, case 2: positive external, negative internal

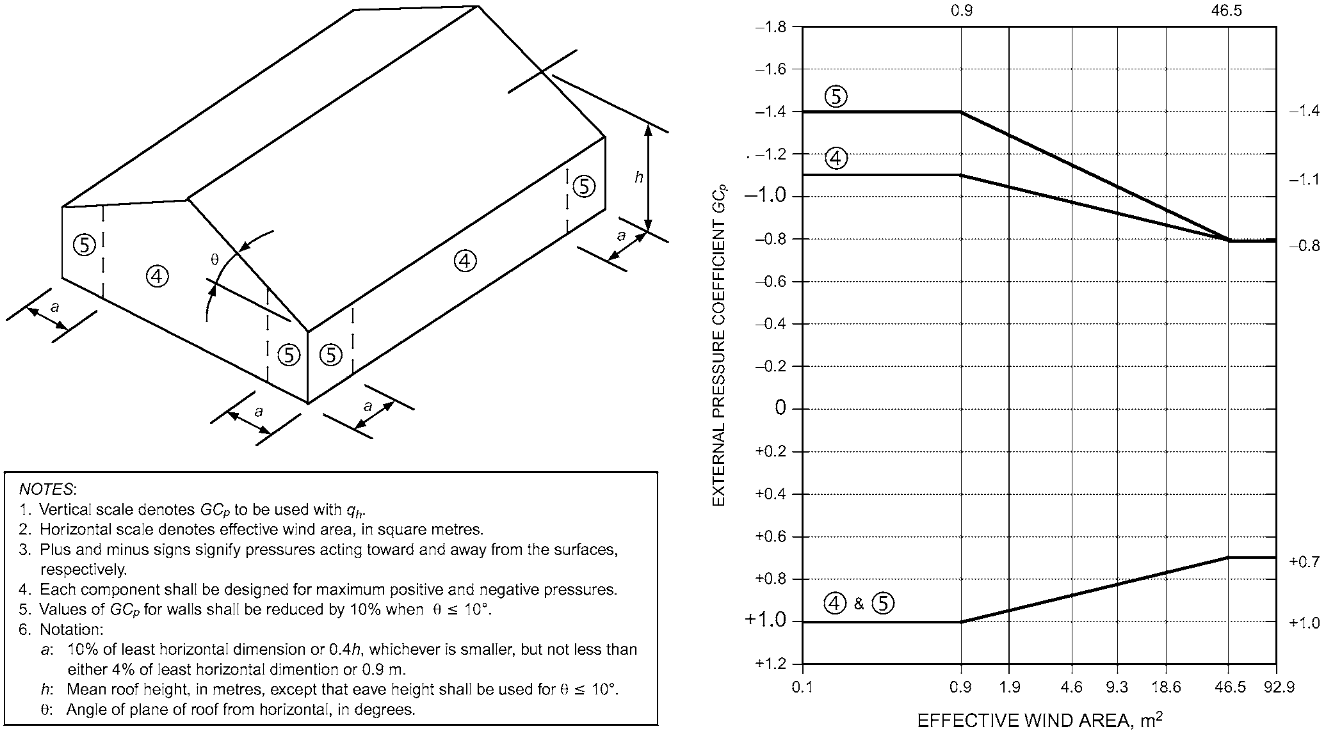

Fig. 13 External Pressure Coefficient GC_p for Walls for $h \le$ 18.3 m
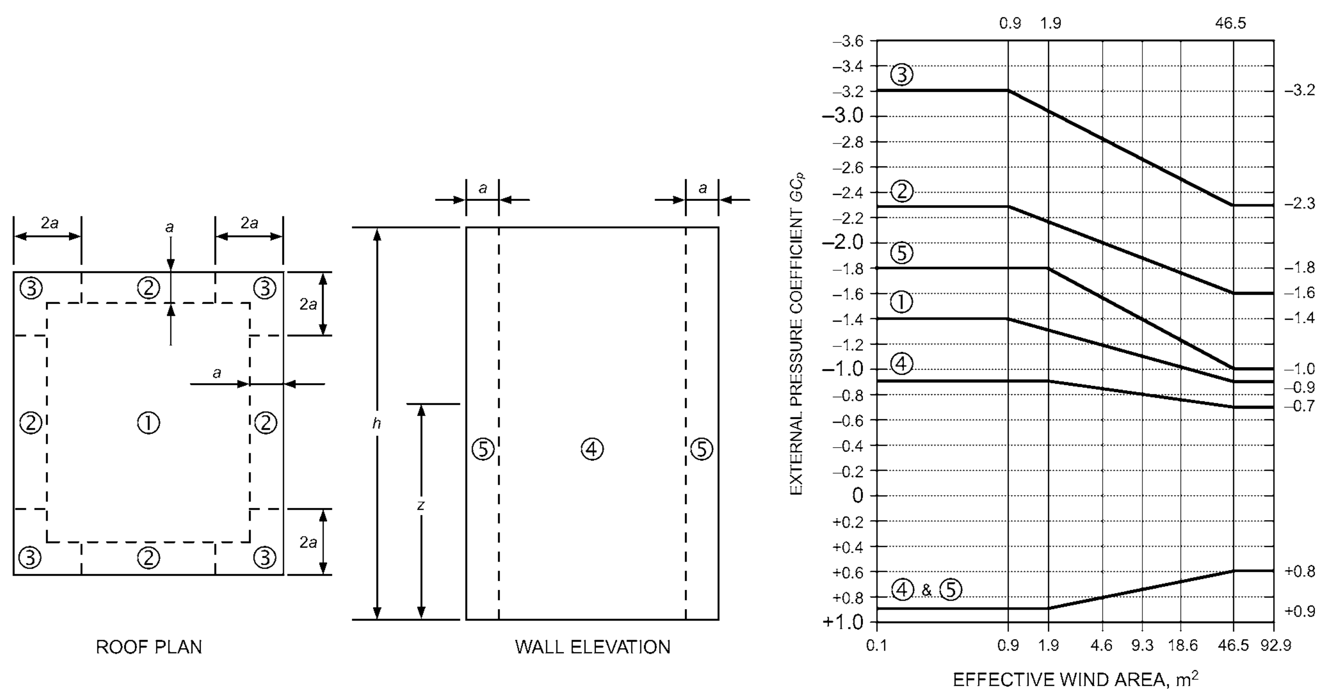
Reprinted with permission from ASCE (2005)



NOTES:

1. Vertical scale denotes GC_p to be used with appropriate q_z or q_h.
2. Horizontal scale denotes effective wind area *A*, in square metres.
3. Plus and minus signs signify pressures acting toward and away from the surfaces, respectively.
4. Use q_z with positive values of GC_p and q_h with negative values of GC_p.
5. Each component shall be designed for maximum positive and negative pressures.
6. Coefficients are for roofs with angle $\theta \le 10°$. For other roof angles and geometry, use GC_p values from Figure 6-11 and attendant q_h based on exposure defined in 6.5.6.
7. If a parapet equal to or higher than 0.9 m is provided around the perimeter of the roof with $\theta \le 10°$, Zone 3 shall be treated as Zone 2.
8. Notation:
   - *a*: 10% of least horizontal dimension, but not less than 0.9 m.
   - *h*: Mean roof height, in metres, except that eave height shall be used for $\theta \le 10°$.
   - *z*: Height above ground, in metres.
   - θ: Angle of plane of roof from horizontal, in degrees.

Fig. 14 External Pressure Coefficient GC_p for Walls for h > 18.3 m

Reprinted with permission from ASCE (2005)

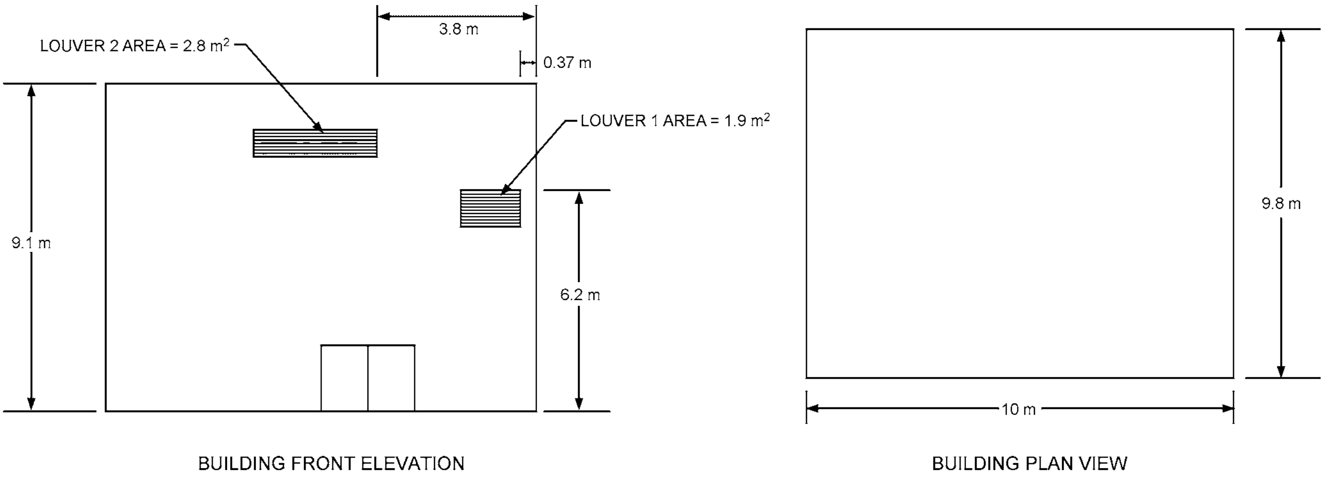


Fig. 15 Office Building, Example 10

$$P = 1489 \times [0.95 - (-0.18)] = 1683 \text{ Pa}$$

Louver 1, case 3: negative external, positive internal

$$P = 1489 \times [(-1.3) - 0.18] = -2204 \text{ Pa}$$

Louver 1, case 4: negative external, negative internal

$$P = 1489 \times [(-1.3) - (-0.18)] = -1667 \text{ Pa}$$

The controlling values for *P* for louver 1 are 1683 Pa, –2204 Paand should be used to specify equipment performance levels.

Louver 2, case 1: positive external, positive internal

$$P = 1489 \times (0.90 - 0.18) = 1072 \text{ Pa}$$

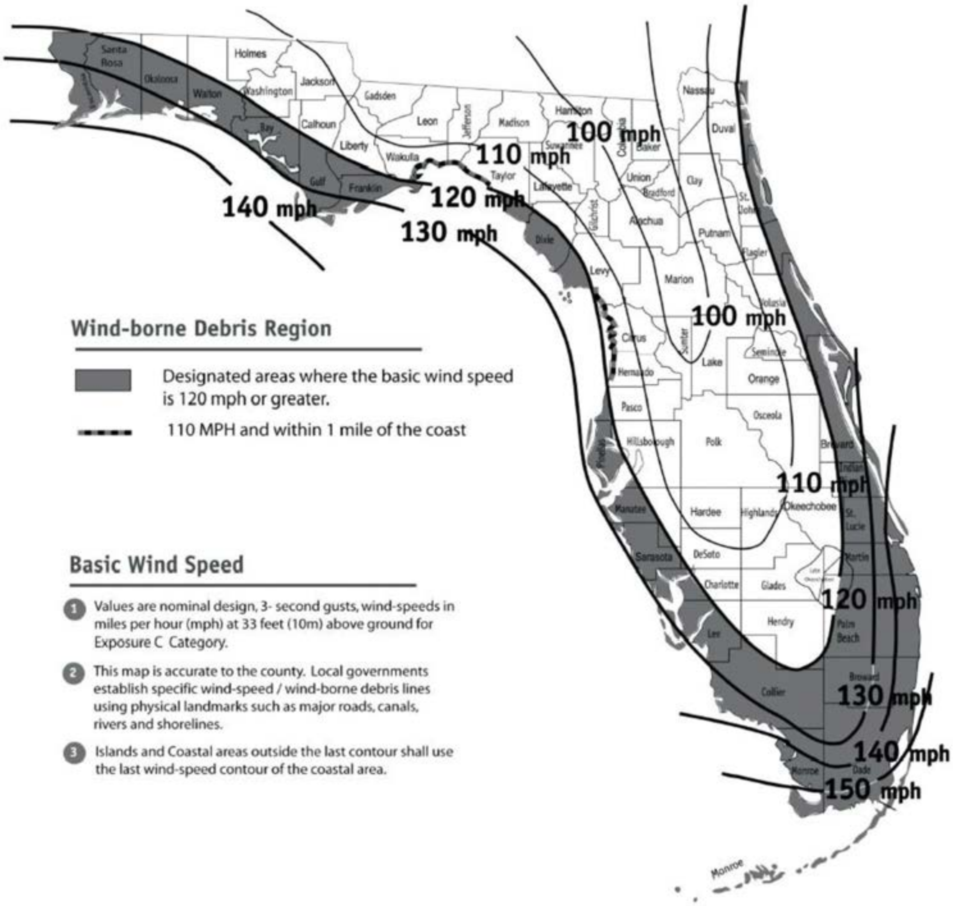

Fig. 16 State of Florida Windborne Debris Regions mph × 1.609 = km/h
ICC (2007)

Louver 2, case 2: positive external, negative internal

$$P = 1489 \times [0.90 - (-0.18)] = 1608 \text{ Pa}$$

Louver 2, case 3: negative external, positive internal

$$P = 1489 \times [(-1.0) - 0.18] = -1757 \text{ Pa}$$

Louver 2, case 4: negative external, negative internal

$$P = 1489 \times [(-1.0) - (-0.18)] = -1221 \text{ Pa}$$

The controlling values for P for louver 2 are 1608 Pa, –1757 Pa and should be used to specify equipment performance levels.

2.4 CERTIFICATION OF HVAC&R COMPONENTS FOR WIND

Some jurisdictions require certifications of performance of HVAC&R components for wind resistance. These certifications focus on (1) the equipment's ability to remain intact and/or (2) the equipment restraints and anchors to keep the item in place during a wind event.

In the United States, the State of Florida and the Building Code Compliance Office of Miami-Dade County have certification requirements that affect HVAC&R system designers. The HVAC products may have special requirements for wind performance and may need approval of the State of Florida. In addition to wind performance, the Florida Building Code (ICC 2007) requires impact resistance and wind-pressure resistance for items that protect openings in buildings in windborne debris regions. The windborne debris regions can be viewed in Figure 16. HVAC products provided for projects located in these regions may be required to have testing and product certification from the State of Florida before installation. Other states, such as Texas, also have requirements for wind-pressure and impact testing. To ensure that the HVAC&R equipment supplied is compliant, designers should contact the local building code official in their project location.

Some of the testing protocols for the State of Florida are

- TAS 201-94: Impact Testing Procedures

Notes:

1. Linear interpolation for intermediate values of height z is acceptable.
2. For values of height z greater than 152.4 m, K_z must be calculated using the following equations:

$$K_z = 2.01(z/z_g)^{2/\alpha} \quad \text{For} \quad 4.5\text{ m} \le z \le z_g$$

or

$$K_z = 2.01(15/z_g)^{2/\alpha} \quad \text{For} \quad z < 4.5\text{ m}$$

3. Exposure categories are defined in Table 7.
4. Values for alpha (α) and z_g are found in Table 9.

Table 13 Directionality Factor K_d

Structure Type	Directionality Factor K_d*
Buildings	
Main wind-force-resisting system	0.85
Components and cladding	0.85
Arched roofs	0.85
Chimneys, tanks, and similar structures	
Square	0.90
Hexagonal	0.95
Round	0.95

Safety ... 56.1
Performance ... 56.2
Electrical System Components and Concepts ... 56.2
Power Quality Variations ... 56.7
Billing Rates ... 56.13
Codes and Standards ... 56.15

PRODUCTION, delivery, and use of electricity involve countless decisions made along the way, by hundreds of people and companies. This chapter focuses on the decisions to be made about the building and equipment. Creating a building that works means including the best designs available, communicating needs and capabilities, and planning ahead.

For an owner-occupied building, the benefits of a properly designed building return to the owner throughout the building's life. For tenant-occupied spaces, good design means fewer problems with tenant and building system interference (e.g., lighting or appliances in one suite disrupting computers in a neighboring suite).

Because HVAC&R equipment can have a large effect on buildings, it is necessary to address electrical issues in buildings that specifically are caused by or have an effect on HVAC&R equipment.

1. TERMINOLOGY

Electricity: fundamental form of energy found in positive and negative forms and expressed in terms of the movement and interaction of electrons.

Volt (V): practical unit of electric pressure; the pressure that will produce a current of 1 A against a resistance of 1 Ω; equal to 1 J/s. Also called the **electromotive force (emf)**.

Current (*I*): movement of electrons through a conductor; measured in amperes.

Ampere (A): practical unit of electric current flow. If a 1 Ω resistance is connected to a 1 V source, 1 A will flow.

Alternating current (ac): a current that reverses at regular, recurring intervals of time and that has alternately positive and negative values. The values vary over time in a sinusoidal manner.

Direct current (dc): a current where electrons move steadily in one direction.

Watt (W): unit of real electrical power, equal to the power developed in a circuit by a current of 1 A flowing through a potential difference of 1 V.

Volt-ampere (VA): amount of apparent power in an alternating current circuit equal to a current of 1 A at an emf of 1 V. It is dimensionally equivalent to watts. Volt-ampere is equal to watts when voltage and current are in phase.

Volt-ampere-reactive (VAR): unit for reactive power. The symbols Q and sometimes N are used for the quantity measured in VARs. VARs represent the power consumed by a reactive load (i.e., when there is a phase difference between applied voltage and current).

Power factor: for an ac electric power system, the ratio of the real power to the apparent power, or W/VA.

Three-phase power: supplied by three conductors, with the currents (or voltages) of any two 120° out of phase with each other.

The preparation of this chapter is assigned to TC 1.9, Electrical Systems.

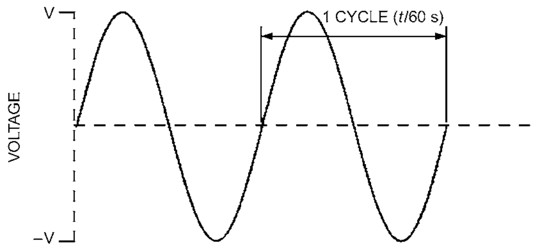

Fig. 1 Fundamental Voltage Wave

Y (or "wye") connection: a configuration of wiring so that each winding of a polyphase transformer (or three single-phase transformers) is connected to a common point, the "neutral."

Delta-connected circuit: a three-phase circuit that is mesh connected, so the windings of each phase of a three-phase transformer are connected in a series for a closed circuit (i.e., in a triangle or "delta" configuration).

Fundamental voltage: produced by an electric ac generator and has a sinusoidal waveform with a frequency of 60 cycles per second, or 60 Hz (in the United States). Other countries may have a similar waveform but at 50 cycles per second of 50 Hz.

Cycle: the part of the fundamental waveform where the electrical potential goes from zero to a maximum to zero to a minimum, and back to zero again (i.e., one complete wave; see Figure 1). At 60 Hz, there are 60 cycles in 1 second.

RMS (root-mean-squared) voltage: an effective way to compare ac to dc value. For a pure sinusoidal waveform, RMS value is equal to 0.707 times the peak magnitude.

System voltage: the RMS phase-to-phase voltage of a portion of an ac electric utility system. Each system voltage pertains to a part of the system bounded by transformers or end-use equipment.

Service voltage: the voltage at the point where the electric systems of the supplier and the user are connected.

Utilization voltage: the voltage at the terminals of the utilization equipment.

Nominal system voltage: the rated system voltage level (i.e., 480 volts) at which the electrical system normally operates. To allow for operating contingencies, utility systems generally operate at voltage levels within –5% to +5% of nominal system voltage.

2. SAFETY

The greatest danger from electricity is that it is taken for granted and not taken seriously as a hazardous energy source. Electricity can produce bodily harm and property damage, and shut down entire operations. The type of damage from electricity ranges from a mild shock to the body to a major electrical fire. Electrical safety is important in all occupational settings. See information on safety codes in the Electrical Codes section.

3. PERFORMANCE

In the United States, the *National Electrical Code*® (NEC; NFPA *Standard* 70) is generally accepted as the minimum safety requirements for wiring and grounding in a structure. Other countries have similar requirements. The NEC ensures building design is safe, but may not provide the performance that a modern building requires. Rapid changes in electronic technologies have rendered many traditional electrical distribution practices obsolete and must be replaced with new designs. Electrical power distribution decisions made during design affect occupants' productivity for the life of the building. Many improvements over the minimum requirements are relatively inexpensive to implement during building construction.

Power quality, like quality in other goods and services, is difficult to define. There are standards for voltage and waveshape, but the final measure of power quality is determined by the performance and productivity of the building occupant's equipment. If the electric power is inadequate for those needs, then the quality is lacking.

Specifications for electric power are set down in recognized national standards. These are voltage levels and tolerances that should be met, on the average, over a long period of time. Electric utilities and building distribution systems generally meet such specifications. Voltage drop in a building is a fundamental reason for calculating the size of electrical conductors. Brief disturbances on the power line are not addressed in these time-averaged specifications; new standards are being developed to address these concerns.

Interaction between tenants' electrical equipment is an ongoing problem. Often, a large load in one tenant's space can disrupt a small appliance or computer in another part of the building. Voltage drop along building wiring and harmonic distortion are often the causes of the problem. **Dedicated circuits** usually solve the voltage drop problem, but harmonic distortion must be solved at the contributing loads. By eliminating much of the wiring common to both pieces of equipment, the original performance of each is restored. With modern electronic loads, the interaction might easily involve a large load that interferes with smaller, more sensitive equipment. Disturbances might travel greater distances or through nondirect paths, so diagnostics are more difficult.

For tenants of a building with ordinary power distribution, lost productivity associated with power quality problems is an additional operating expense. The disturbance may last only milliseconds, but the disruption to business may require hours of recovery. This multiplication of lost time makes power quality a significant business problem.

Lost productivity may be the time it takes to restart a chiller, to repair a critical piece of equipment, or to retype a document. Another aspect of lost productivity is the stress on employees whose work is lost. The building owner may suffer loss, as well. Certainly the building equipment itself may suffer from the same damage or losses as tenant equipment. Sophisticated energy management systems, security systems, elevator controls, HVAC&R systems, and communications facilities are susceptible to disruption and vulnerable to damage.

4. ELECTRICAL SYSTEM COMPONENTS AND CONCEPTS

Voltage differential causes electrons to flow. In a direct current (dc) electrical system, electrons flow in only one direction. In an alternating current (ac) electrical system, electrons continually alternate or change direction at a prescribed number of times per second. The main disadvantage of dc voltage is its inability to be boosted or attenuated easily and efficiently. The alternating magnetic fields of ac make boosting or decreasing voltage with transformers feasible, which is why ac has been widely adopted. Electrons flow more efficiently at lower currents because I^2R losses are minimized. For the same load, raising the voltage level reduces the current while delivering the same power. When long distances are involved, electric utility companies step up voltages to very high levels for transmission. However, these voltages are extremely dangerous, so they must be stepped down to a safer, lower, usable voltage before use. Transformers offer an efficient way to change voltage levels (step-up or step-down) for an alternating current power source.

Electrical Wiring (Conductors for General Wiring)

Just because a conductor is insulated does not mean it is suited for a specific application. NFPA *Standard* 70 list designations of wires and cables that meet minimum fire, electrical, and physical requirements of relevant standards. Unless otherwise specified by codes, conductors must be aluminum, copper-clad aluminum, or copper.

To find allowable ampacities for insulated conductors at various temperatures, consult Tables 310.15(B)(16) to 310.15(B)(20) of NFPA *Standard* 70-2014. Tables 310.15(B)(2)(a) and 310.15(B)(2)(b) of that standard have correction factors for ambient temperatures other than 30 or 40°C. If more than one ampacity could apply for a given circuit, use the lowest value.

Transformers

Transformers are used to change one voltage to another voltage, typically to step up voltage levels from generators. Power can then be transmitted at a low current (with less loss). At the end of the transmission line, a step-down transformer reduces the voltage to a usable level.

A transformer consists of a ferromagnetic core wrapped with multiple coils, or windings, of wire. The input line is connected to the primary coil, and the output line is connected to the secondary coil. Alternating current I_1 in the primary coil induces an alternating magnetic flux ϕ that flows through the ferromagnetic core, changing direction during each electrical cycle. This flux in turn induces alternating current I_2 in the secondary coil. The voltage V_2 at the secondary coil is directly related to the primary voltage by the turns ratio (i.e., the number of turns N_1 in the primary coil divided by the number turns N_2 in the secondary coil).

An **ideal transformer** with two windings wrapped around a magnetized core is shown in Figure 2. The ideal model for a transformer assumes I^2R losses, core losses, leakage flux, and core reluctance are insignificant. A practical model includes these losses.

Transformer **losses** can be divided into core (or iron) losses, copper losses, and stray losses. Core losses include hysteresis losses and eddy current losses. All ferromagnetic materials tend to retain some degree of magnetization after exposure to an external magnetic field. This tendency to stay magnetized is called hysteresis, and it takes energy to overcome this opposition to change every time the magnetic field produced by the primary winding changes polarity. Eddy current losses result from induced currents circulating in the

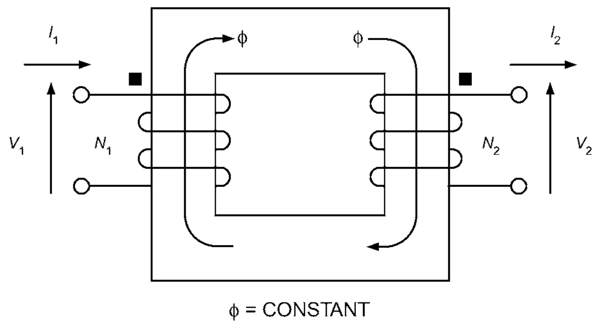

Fig. 2 Ideal Transformer

magnetic core perpendicular to the flux. Because iron conducts both electricity and magnetic flux, eddy currents are induced in the iron just as in the secondary windings from the alternating magnetic field.

Three identical single-phase, two-winding transformers may be connected to form a **three-phase bank**. The four possible connections are Y-Y, Y-Δ, Δ-Y, and Δ-Δ. The U.S. standard for marking three-phase transformers uses H_1, H_2, and H_3 on the high-voltage terminals and X_1, X_2, and X_3 on the low-voltage terminals; *A*, *B*, and *C* identify phases on the high-voltage side of the transformer, and *a*, *b*, and *c* identify phases on the low-voltage side. Typically, three-phase voltages present the higher voltage (phase-to-phase) first, followed by the lower voltage (phase-to-neutral). Single-phase voltages typically present the lower voltage (phase-to-neutral) first, followed by the higher voltage (phase-to-phase). For example, 208/120 V is three-phase and 120/240 V is single-phase.

Y-Y connections (Figure 3) are rarely used because of balancing and harmonics problems.

Y-Δ connections (Figure 4) are typically used for stepping down from high to medium voltage.

The Δ-Y transformer (Figure 5) is commonly used as a generator step-up transformer, where the Δ winding is connected to the generator terminals and the Y winding is connected to the transmission line. One advantage of the high-voltage Y winding is that a neutral point N is provided for grounding on the high-voltage side.

The Δ-Δ transformer (Figure 6) has the advantage that one phase can be removed for repair or maintenance while the remaining phases continue to operate as a three-phase bank. The open Δ connection allows balanced three-phase operation with the kVA rating reduced to 58% of the original bank. These Δ-Δ connections are typically used in distribution networks.

An **autotransformer** has two windings connected in series (Figure 7). Whereas a typical transformer's windings are only coupled magnetically via the mutual core flux, an autotransformer's windings are both electrically and magnetically coupled.

An autotransformer has smaller per-unit leakage impedances than a two-winding transformer; this results in both smaller series

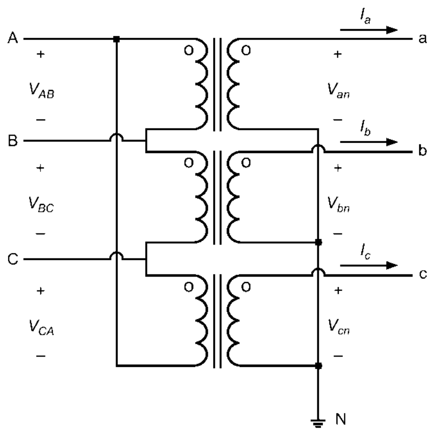

Fig. 5 Three-Phase Δ-Y Transformer

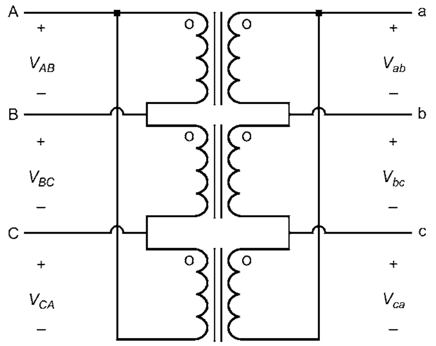

Fig. 6 Three-Phase Δ-Δ Transformer

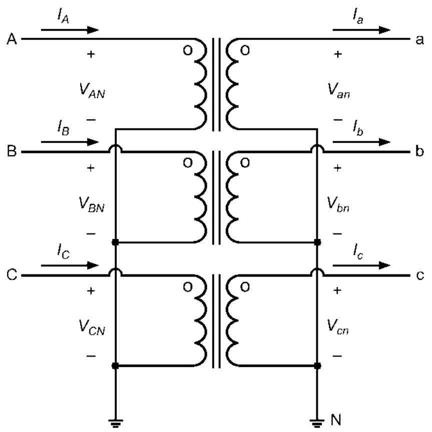

Fig. 3 Three-Phase Y-Y Transformer

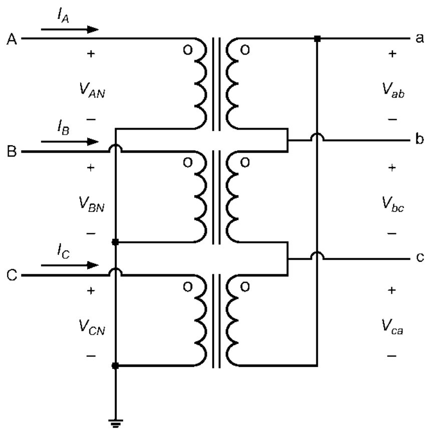

Fig. 4 Three-Phase Y-Δ Transformer

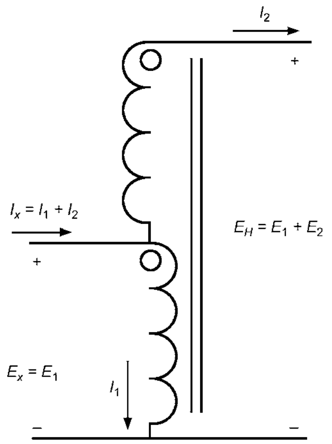

Fig. 7 Typical Autotransformer

voltage drops and higher short-circuit currents. It also has lower per-unit losses, lower excitation current, and lower cost, if the turns ratio is not large. An autotransformer is not isolated as well as a typical two-winding transformer; transient overvoltages pass through the autotransformer more easily because the windings are connected electrically.

Transformer Coolants and Insulators. Because heat is created by the flow of electrical current through the windings, a liquid (e.g., **oil** or **silicone**) is often used as a coolant inside the transformer. Such liquids are also good electrical insulators for the wire windings and iron core. **Dry transformers** do not require a liquid for cooling, instead using ambient air for cooling as well as insulation. Dust, dirt, moisture, and other contaminants in the air can reduce its insulating capabilities and deteriorate exposed parts, and may cause premature failure of the transformer.

Emergency and Standby Power Systems

Emergency Power Systems. IEEE *Standard* 446-1995 defines these systems as independent reserves of electrical power that automatically take over if the usual supply experiences an outage or failure, and sustain mission-critical systems (i.e., those that, if inoperable, could present a danger to health and safety, or to property). Local or national codes may also mandate specific systems as required emergency power systems.

Standby Power Systems. Generally, these systems provide power back-up for loads that may be critical to production or product preservation, but do not present a danger to life or safety. They allow facilities to carry on with satisfactory operation during failure or outage of the usual supply source. NFPA *Standard* 70 distinguishes between those that are legally required and those that are optional.

Emergency and Standby Power Supplies. Diesel **generators** are still the dominant source of emergency power, particularly for emergency loads such as fire pumps or elevators that require large starting currents and must meet the outage's full capacity at start-up. Some natural gas engines meet the start-up requirements for emergency systems, and are popular for smaller standby applications such as homes, communication towers, and other operations where diesel fuel is undesirable and/or impractical. Some turbines are also used for standby service, but most turbines are dedicated to combined heat and power (CHP) applications (see Chapter 7 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*).

The use and constraints of emergency and standby power systems must be understood to ensure proper safety and operation of the electrical equipment they support. This is especially true with emergency systems and with standby systems that are expanded to carry the full facility load, including HVAC&R systems. Starting and load step capabilities also must be understood when replacing diesel engines with natural gas engines and turbines, which have very different acceptable load step characteristics.

Most codes require emergency generators used for life-safety loads to be online within 10 s. However, age, battery wear, and even improper exercising of the engine can cause delays and even failures to start. Even if the engine does start within 10 s, some type of ride-through device may be required to support electronic loads (including computers and energy management systems) until the generator starts and picks up the load.

National mandates on emissions, and state and local implementation of those mandates, also influence the generator type specified. In the United States, Environmental Protection Agency (EPA) tier ratings are required for off-road engine permits, including for generators. U.S. EPA (2012) addresses emissions of oxides of nitrogen (NO_x), hydrocarbons (HC), particulate matter (PM), and carbon monoxide (CO). Earlier tier ratings limited diesel use to emergency applications in most cases, but the new tier 4 ratings allow their use for standby and CHP applications.

Another variable that must be considered with all generation equipment are the potential derates caused by elevation and weather. Combustion air has a direct effect, but of varying degrees, on the energy that can be generated during combustion. Ways to overcome theses derates include precooling or humidifying the combustion air. It is important to find out from a manufacturer what the derating characteristics are and the cost in equipment and consumables for any correction system selected.

Uninterruptible power supply (UPS) units are most commonly used to keep computers and controls running during the transition from outage to generator operation. Batteries are sized to meet the load requirement for a specified period of time (frequently about 15 min). The UPS provides power through the interruption and, if generators fail to start, provides enough time for orderly system shutdown.

Flywheel technology is gaining ground where larger (e.g., whole-building) loads are supported. The flywheels are also sized for time and load, but may be cost prohibitive for orderly shutdown and even for engines that do not start until the second or third try (20 to 30 s). They are only rarely used to support a natural gas engine that may take between 1 to 3 min to start.

Impedance of emergency and standby power supplies is usually higher than that of utility electric service. Thus, power quality of a circuit typically deteriorates when it is switched from regular utility power to emergency power.

A key component of the emergency generator system is the automatic transfer switch (ATS) used to switch from the primary source (usually the utility) to the secondary source (usually the generator). The type of switch selected has important ramifications to the overall electrical system. The types of automatic transfer switches are as follows:

Standard ATS (Figure 8)

- *Break-* (from one source) *before-make* (to another source) design.
- Mechanically interlocked electrical contactors move loads from one power source to another.
- Most can optionally be equipped for delayed transition (switch delays in the neutral position for a preset number of seconds). This allows larger (>37 kW) motors' residual voltage to decay before connection to the other source. Other timers are usually available to provide ride-through for one or two recloser operations (used by utilities to keep their system operational during momentary faults caused by falling limbs, high winds, etc.).
- An *in-phase monitor* can be preset and used in conjunction with or in place of the delayed transition to protect large motors during the transfer process.
- Can be two-, three- or four-pole, depending on phase and grounding scenario.
- Results in at least two momentary power outages: when utility service is lost and when the system switches back to the utility.

Closed-Transition ATS (Figure 9)

- Provides momentary (less than six cycles) connection of load to both power sources within acceptable phase angle for seamless transfer when both sources are available.

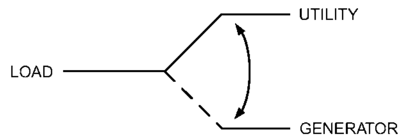

Fig. 8 Break-Before-Make Design for Standard ATS

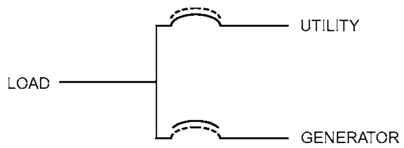

Fig. 9 Closed-Transition ATS

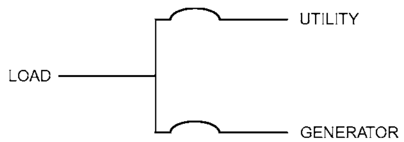

Fig. 10 Parallel-Transfer Switch

- Eliminates the second outage associated with a standard ATS and, in some cases, can be used to operate the generator as a peaking power source.

Bypass-Isolation ATS

- Same as a standard ATS except for its separate bypass mechanism to allow continuation of power to the load from either source while isolating the automatic switch device for maintenance or repair. Typically, the automatic portion of the switch can be mechanically isolated from the frame during this process.
- All other features of the standard ATS apply.
- Closed-transition and bypass-isolation can be combined to provide the capabilities of both.

Service-Entrance-Rated ATS

- Transfer switch includes a circuit breaker or fused device ahead of the transfer mechanism, allowing the device to act as the service-entrance point for building load.
- Fused protection can also be provided ahead of the secondary (generator) entrance point, but is normally omitted in lieu of locating the protection (circuit breaker) at the generator set.
- Can include any or all of the other ATS features listed in standard, closed-transition, or bypass-isolation types.

Parallel-Transfer (PT) Switch (Figure 10)

- Parallel switchgear in a simple one- or two-breaker design allows for parallel connection of the load to both power sources for an indefinite time period.
- Should include all protective relay devices as required by the local utility and generator supplier.
- Can include some of the features of a standard ATS, because most can also be operated as an open-transfer (break-before-make) switch.

Switch selection can profoundly affect the electrical system, especially if an existing back-up system is upgraded for an expanded role. For example, it may be necessary to completely replace the existing switchgear of a building if an original generator system with a small generator and a standard ATS is replaced with a larger generator and a closed-transition ATS.

If the emergency power system is being expanded to include large motor loads, such as chillers, then

- Set delay to account for chiller motor back current to dissipate.
- Size the generator set large enough to handle the motor loads' starting current requirements. The electrical engineer needs to know the starting requirements and maximum allowable voltage drop that the overall electrical system can handle, especially computer and control loads. Most major generator manufacturers can provide sizing software.

If a standard ATS is being replaced with a closed-transition or parallel-transfer switch,

- Verify that the existing switchgear can handle the added potential fault current of the generator set. For instance, if the available fault current from the utility is 65 000 A and the generator fault current is 30 000 A, then the system only has to be braced for 65 000 A with a standard ATS. It has to be braced for 95 000 A with either of the other two switches because fault current is additive with multiple sources connected at the same time.

If the emergency power system is being converted from diesel to natural gas, then

- Check the acceptable load steps of the new engine: the diesel likely accepted 100% load, but the natural gas engine may be limited to as low as 20% load. Chillers and other large loads frequently exceed the acceptable load increase.
- Determine whether large-motor-load starting systems can be changed to reduce starting requirements and meet acceptable load steps.

If the emergency system is being modified for peaking or curtailment uses, then

- Obtain the specific utilities' interconnection requirements; these tend to be utility-specific and may exceed normal NEC or local codes.
- Check the existing system for closed-transition or parallel-transfer switch issues and compatibility.
- Investigate emissions issues; standby emissions permit requirements are almost always less stringent than peaking requirements.

If the emergency system includes a UPS or flywheel system, then

- Size the UPS or flywheel for the maximum required load for a specific time; remember that capacity of these systems is *x* kW for *y* min.
- Avoid motor loads as much as possible.

Motors

Motor Control and Protection. Chapter 45 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* addresses motor control and protection in detail, but is summarized and simplified here. Motor control must be effective without damaging the motor or its associated equipment. Control must be designed to prevent inadvertent motor starting caused by a fault in the control device. The control should be able to sense motor conditions to keep the motor windings from getting too warm.

Motor protection involves sensing motor current and line voltage, and can include bearing vibration, winding temperature, bearing temperature, etc. Motor temperature increase has two basic sources. Heating occurs when dirt or debris blocks airflow over or through the motor, or it comes from the motor current and is commonly referred to as I^2R, where I is motor current and R is motor winding resistance. Because the current is squared, its contribution is exponential. R is quite small and contributes a linear function to heating (and therefore temperature rise) in the motor. Motor windings can withstand temperature rise, depending on the motor winding temperature rating. The second source of motor temperature increase is lack of motor cooling. The primary source of cooling is moving air, usually from a shaft-driven fan. As a motor slows down, the fan runs more slowly; therefore, the less air movement, the less cooling. Because fan loads are also exponential, a small decrease in motor speed greatly reduces airflow on the motor, reducing cooling. To compound the issue, the slower the motor runs, the greater the slip, and the greater the motor current. This then becomes a vicious circle.

Motor Starters and Thermal Overloads. Motor starters energize (start), deenergize (stop), protect, and control the motor. They sense motor current based on a time curve: the shorter the time, the more current they let through. They may also limit the number of motor starts in a given period of time so the motor does not exceed its ANSI rating. Another cause for concern is the starter's ambient temperature: if it is different from the ambient temperature around the motor controller, the thermal overloads need to be sized accordingly.

Several motor starter types are available, and they can function several different ways. The **across-the-line** starter is the simplest but may disturb electric service because of high motor-starting current requirements. Other starters reduce and may eliminate troublesome electrical disturbance; for instance, the **part-winding**, **reduced-voltage**, and **wye-delta** starters all act by reducing the starting voltage on the motor. Fan and pump loads can usually be started this way; this reduces starting current draw and demand, but sacrifices motor starting speed. **Soft-start** starters also reduce the voltage and limit demand during starting, thereby easing stress on the electric system during motor starting. **Variable-frequency drives (VFDs)** are also used to soft-start a motor, and are designed to control acceleration during starting as well as optimize motor speed to its load. See the section Motor-Starting Methods for more information.

A VFD converts ac to dc and then back to variable-frequency, variable-voltage ac. Motor speed is varied by varying the frequency of the ac output voltage, typically using pulse-width modulation (PWM). This power conversion process results in distorted input current and may contribute to building power system voltage distortion. When motors and other loads are supplied from a distorted voltage source, their operating temperatures may rise.

Phase Loss Protection. Phase loss can be detected by sensing either voltage loss or current loss on one of the phases. Motor overloads often are set based on the nameplate data of the motor, but the real motor current draw is less because the motor may not be fully loaded. If one of three phases is lost, the current increases in the other two phases, but not by enough to trip the overloads. However, it will overheat and possibly damage the motor. Some phase loss detectors also check phase current to be sure that it is balanced within 10%. This protects the motor and makes the operator aware of potential motor or line problems.

Motor-Starting Effects. The following effects do not occur with all motors. For instance, brushless dc and inverter-driven motors, which are electronically controlled, do not have inrush currents that cause light dimming or sags.

Light Dimming or Voltage Sags. Light dimming or voltage sag associated with motor starts can be more than a nuisance. Motors have the undesirable effect of drawing several times their full-load current while starting. This large current, by flowing through system impedances, may cause voltage sag that can dim lights, cause contactors to drop out, and disrupt sensitive equipment. The situation is worsened by an extremely poor starting displacement factor, usually in the range of 15 to 30%. If the motor-starting-induced voltage sag deepens, the time required for the motor to accelerate to rated speed increases. Excessive sag may prevent the motor from starting successfully. Motor-starting sags can persist for many seconds.

The Illuminating Engineering Society of North America (IESNA) is precise in describing lighting reactions. *Dimming* is an intentional technique to enhance the ambiance of surroundings by varying the perceived lighting levels. It is also used to reduce the electrical power used by lamps when adequate natural lighting is available; the controller electronically follows the natural variations in a way that will not be optically perceived. Similarly, *flicker* is deliberately selected in some lamps to resemble a candle's flame. In contrast, this chapter discusses possible causes of *undesirable, perceptible* reductions of a lamp's lumen output.

Momentary undesirable lighting reductions from voltage sags, often caused by motor starting, were common with incandescent lamps. More efficient lamps (especially fluorescent and electronic ballasts) are now the most common for most applications. For fluorescent lamps, electronic ballasts convert the 60 Hz electrical service to much higher frequencies, which eliminates perception of irritating flicker, and provides greater lumens per watt than the former magnetic ballasts. Similar improvements have occurred for mercury, metal halide, and sodium lamps, typically found in large stores, sports, and industrial applications. Including electronic circuitry in the lamps and lighting systems makes power quality even more important for building owners: electronic components are sensitive to both lower and upper threshold voltages, and the building's voltage may experience momentary voltage sag as large motors start. Specific product literature for lamps, lamp ballasts, and lighting controls should be reviewed to ensure client satisfaction with expected operations (starts, stops, and speed changes) of the HVAC system's motors and controls.

Motor-Starting Methods. The following motor-starting methods can reduce voltage sag from motor starts.

An **across-the-line start**, energizing the motor in a single step (full-voltage starting), provides low cost and allows the most rapid acceleration. It is the preferred method unless the resulting voltage sag or mechanical stress is excessive.

Autotransformer starters have two autotransformers connected to open delta (similar to a delta connection using three single-phase transformers, but with one transformer removed; carries 57.7% of a full delta load). Taps provide a motor voltage of 80, 65, or 50% of system voltage during start-up. Starting torque varies with the square of the voltage applied to the motor, so the 50% tap delivers only 25% of the full-voltage starting torque. The lowest tap that will supply the required starting torque is selected. Motor current varies as the voltage applied to the motor, but line current varies with the square of the tap used, plus transformer losses of ~3%.

Resistance and **reactance starts** initially insert impedance in series with the motor. After a time delay, this impedance is shorted out. Starting resistors may be shorted out over several steps; starting reactors are shorted out in a single step. Line current and starting torque vary directly with the voltage applied to the motor, so for a given starting voltage, these starters draw more current than the line with autotransformer starts, but provide higher starting torque. Reactors are typically provided with 50, 45, and 37.5% taps.

Part-winding starters are attractive for use with dual-rated motors (220/440 V or 230/460 V). The stator of a dual-rated motor consists of two windings connected in parallel at the lower voltage rating, or in series at the higher voltage rating. When operated with a part-winding starter at the lower voltage rating, only one winding is energized initially, limiting starting current and torque to 50% of the values seen when both windings are energized simultaneously.

Delta-wye starters connect the stator in wye for starting, then after a time delay, reconnect the windings in delta. The wye connection reduces the starting voltage to 57% of the system line-line voltage, starting current and starting torque are reduced to 33% of their values for full voltage start.

Utilization Equipment Voltage Ratings

Utilization equipment is electrical equipment that converts electric power into some other form of energy, such as light, heat, or mechanical motion. Every item of utilization equipment should have a nameplate listing, which includes, among other things, the rated voltage for which the equipment is designed. In some cases, the nameplate also indicates the maximum and minimum voltage for proper operation. With one major exception, most utilization equipment carries a nameplate rating that is the same as the voltage system on which it is to be used: that is, equipment to be used on 120 V systems is rated 120 V. The major exception is motors and equipment containing motors, where performance peaks in the middle of the

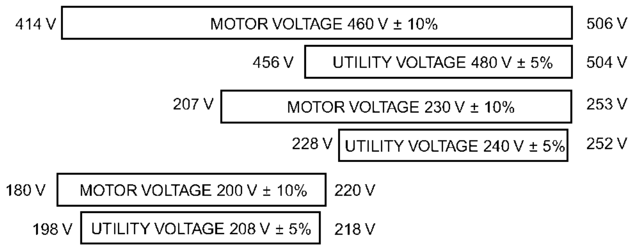

Fig. 11 Utilization Voltages Versus Nameplate Ratings

tolerance range of the equipment: better performance can be obtained over the tolerance range specified in ANSI *Standard* C84.1 by selecting a nameplate rating closer to the middle of this tolerance range. The difference between the nameplate rating of utilization equipment and the system nominal voltage is necessary because the performance guarantee for utilization equipment is based on the nameplate rating and not on the system nominal voltage.

The voltage tolerance limits in ANSI *Standard* C84.1 are based on ANSI/NEMA *Standard* MG 1, Motors and Generators edition, which establishes voltage tolerance limits of the standard low-voltage induction motor at ±10% of nameplate voltage ratings of 230 and 460 V. Because motors represent the major component of utilization equipment, they were given primary consideration in the establishment of this voltage standard. Figure 11 compares utilization voltages to nameplate ratings.

Voltage Level Variation Effects

Whenever voltage at the terminals of utilization equipment varies from its nameplate rating, equipment performance and life expectancy change. The effect may be minor or serious, depending on the equipment characteristics and the amount of voltage deviation from the nameplate rating. NEMA standards provide tolerance limits within which performance will normally be acceptable. In precise operations, however, closer voltage control may be required. In general, a change in the applied voltage causes a proportional change in the current. Because the effect on the load equipment is proportional to the product of the voltage and the current, and because the current is proportional to the voltage, the total effect is approximately proportional to the square of the voltage.

However, the change is only approximately proportional and not exact: the change in the current affects the operation of the equipment, so the current continues to change until a new equilibrium position is established. For example, when the load is a resistance heater, the increase in current increases the heater temperature, which increases its resistance and, in turn, reduces the current. This effect continues until a new equilibrium current and temperature are established. In the case of an induction motor, a voltage reduction reduces the current flowing to the motor, causing the motor to slow down. This reduces the impedance of the motor, increasing the current until a new equilibrium position is established between the current and motor speed.

Voltage Selection

Generally, the preferred utilization voltage for large commercial buildings is 480Y/277 V, three-phase. The three-phase power load is connected directly to the system at 480 V, and fluorescent ceiling lighting is connected phase-to-neutral at 277 V. Dry-type transformers rated 480 V/208Y/120 V are used to provide 120 V single phase for convenience outlets and 208 V three phase for other building equipment. Single-phase transformers with secondary ratings of 120/240 V may also be used to supply lighting and small office equipment. However, single-phase transformers should be connected in sequence on the primary phases to maintain balanced load on all phases of the primary system.

Where the supplying utility furnishes the distribution transformers, the choice of voltages is limited to those the utility provides. For tall buildings, space will be required on upper floors for transformer installations and the primary distribution cables supplying the transformers. Apartment buildings generally have the option of using either 208Y/120 V three-phase/four-wire systems, or 120/240 V single-phase systems, because the major load in residential occupancies consists of 120 V lighting fixtures and appliances. The 208Y/120 V systems are often more economical for large apartment buildings. Single-phase 120/240 V systems should be satisfactory for small apartment buildings and other small buildings.

However, large single-phase appliances, such as electric ranges and water heaters rated for use on 120/240 V single-phase systems, will not perform to the rated wattage on a 208Y/120 V systems, because the line-to-line voltage is appreciably below the rated voltage of the appliance.

5. POWER QUALITY VARIATIONS

Power quality refers to varied parameters that characterize the voltage and current for a given time and at a given point on the electric system. A power quality problem is usually any variation in the voltage or current that actually results in failure or misoperation of equipment in the facility. Therefore, power quality evaluations are a function of both the power system characteristics and the sensitivity of equipment connected to the power system.

This section defines the different kinds of power quality variations that may affect equipment operation. Important reasons for categorizing power anomalies include the following:

- Identifying the cause of the power anomalies. Understanding the characteristics of a power quality variation can often help identify the cause.
- Identifying the possible effects on equipment operation. A transient voltage can cause failure of equipment insulation; a sag in voltage may result in dropout of sensitive controls based on an undervoltage setting.
- Determining the requirements for measurement. Some power quality variations can be characterized with simple voltmeters, ammeters, or strip chart recorders. Other conditions require special-purpose disturbance monitors or harmonic analyzers.
- Identifying methods to improve the power quality. Solutions depend on the type of power quality variation. Transient disturbances can be controlled with surge arrestors, whereas momentary interruptions could require an uninterruptible power supply (UPS) system for equipment protection. Harmonic distortion may require special-purpose harmonic filters.

Power quality can be described in terms of *disturbances* and *steady-state variations*.

Disturbances. Disturbances are one-time, momentary events. Measurement equipment can characterize these events by using thresholds and triggering when disturbance characteristics exceed specified thresholds. Examples include transients, voltage sags and swells, and interruptions.

Steady-State Variations. Changes in long-term or steady-state conditions can also result in equipment misoperation. High harmonic distortion levels can cause equipment heating and failure, as can long-term overvoltages or unbalanced voltages. These are variations best characterized by monitoring over a longer period of time with periodic sampling of the voltages and currents. Steady-state variations are best analyzed by plotting trends of the important quantities (e.g., RMS voltages, currents, distortion levels).

These two types of power quality are further defined in seven major categories and numerous subcategories. There are three primary attributes used to differentiate among subcategories within a power quality category: frequency components, magnitude, and duration. These attributes are not equally applicable to all categories. For instance, it is difficult to assign a time duration to a voltage flicker, and it is not useful to assign a spectral frequency content to variations in the fundamental frequency magnitude (sags, swells, overvoltages, undervoltages, interruptions).

Each category is defined by its most important attributes for that particular power quality condition. These attributes are useful for evaluating measurement equipment requirements, system characteristics affecting power quality variations, and possible measures to correct problems. The terminology has been selected to agree as much as possible with existing terminology used in technical papers and standards.

The following descriptions focus on causes of the power quality variations, important parameters describing the variation, and effects on equipment.

Transients

Transients are probably the most common disturbance on distribution systems in buildings and can be the most damaging. Transients can be classified as impulsive or oscillatory. These terms reflect the waveshape of a current or voltage transient.

Impulsive Transient. An impulsive transient (spikes or notches) is considered unidirectional; that is, the transient voltage or current wave is primarily of a single polarity (Figures 12 and 13). Impulsive transients are often characterized simply by magnitude and duration. Another important component that strongly influences the effect on many types of electronic equipment is the **rate of rise**, or rise time of the impulse. This rate of rise can be quite steep, and can be as fast as several nanoseconds. Repetitive subtractive transients (Figure 13), often caused by thyristors such as silicon controlled rectifiers (SCRs), are referred to as voltage notches.

The high-frequency components and high rate of rise are important considerations for monitoring impulses. Very fast sampling rates are required to characterize impulses with actual waveforms. In many power quality monitors, simple circuits are used to detect the transient's peak magnitude and duration (or volt-seconds). If impulse waveshapes are recorded, they usually do not include the fundamental frequency (60 Hz) component. When evaluating these disturbances, it is important to remember that stress on equipment is based on the impulse magnitude plus the magnitude of the fundamental component at the instant of the impulse. The voltage, current available, and pulse width determine the amount of energy available in a transient.

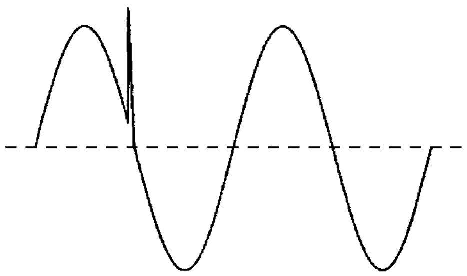

Fig. 12 Example of Spike

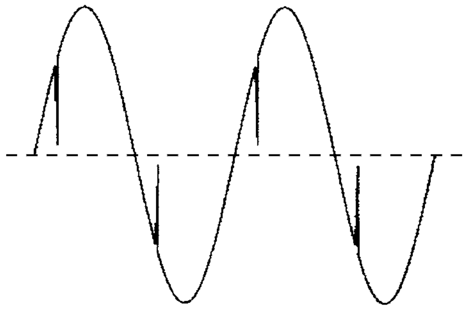

Fig. 13 Example of Notch

Oscillatory Transient. An oscillatory transient (Figure 14) is a voltage or current that changes polarity rapidly. Because the term "rapidly" is nebulous, the frequency content is used to divide oscillatory transients into three subcategories: high, medium, and low frequency. Frequency ranges from these classifications are chosen to coincide with common types of power system oscillatory transient phenomena.

As with impulsive transients, oscillatory transients can be measured with or without including the fundamental frequency. One way to trigger on transients is to continually test for deviation in the waveform from one cycle to the next. This method records any deviation exceeding the set threshold. When characterizing the transient, it is important to indicate the magnitude with and without the 60 Hz fundamental component.

Transients are generally caused by a switching event or by system response to a lightning strike or fault. The oscillations result from interactions between system capacitances and inductances, and occur at the natural frequencies of the system excited by the switching event or fault.

High-frequency transients can occur at locations very close to the initiating switching event. Rise times created by closing a switch can be as fast as a few tens of nanoseconds. Short lengths of circuit have very high natural oscillation frequencies that can be excited by a step change in system conditions (e.g., operating a switch). Power electronic devices such as transistors and thyristors/SCRs can cause high-frequency transients many times during each cycle of the fundamental frequency. The transients can be in the tens or hundreds of kilohertz, and occasionally higher.

Because of the high frequencies involved, circuit resistance typically damps transients out; thus, they only occur close (within tens to hundreds of metres) to the site of the switching event that generates them. Characterizing these transients with measurements is often difficult because high sampling rates are required.

Medium-frequency transients are associated with switching events with somewhat longer circuit lengths (resulting in lower natural frequencies). Switching events on most 480 V distribution systems in a facility cause transient oscillations within this frequency range, which can propagate over a significant portion of the low-voltage system. Motor interruption (definite interruption) is a good example of a common switching event that can excite transients in this frequency range.

Transients coupled from the primary power system (e.g., coupled through the step down transformer) can also cause medium-frequency transients. The most common cause of transients on the primary power system is capacitor switching.

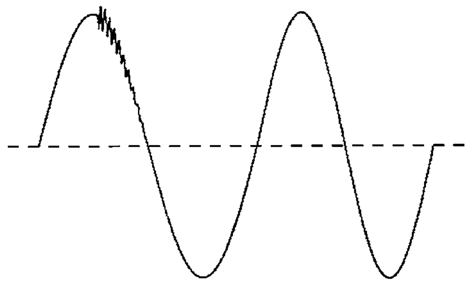

Fig. 14 Example of Oscillatory Transient

Capacitor energizing results in an initial step change in the voltage, which gets coupled through stepdown transformers by the transformer capacitance and then excites natural frequencies of the low-voltage system (typically 2 to 10 kHz). **Low-frequency transients** are usually caused by capacitor switching, either on the primary distribution system or within the customer facility. Lower-frequency transients result from capacitance of the switched capacitor bank oscillating with the inductance of the power system. The natural frequencies excited by these switching operations are much lower than those of the low-voltage system without the capacitor bank, because of the large capacitance of the capacitor bank itself.

Capacitor switching operations are common on most distribution systems and many transmission systems. Energizing a capacitor results in an oscillatory transient with a natural frequency in the range of 300 to 2000 Hz (depending on the capacitor size and the system inductance). The peak magnitude of the transient can approach twice the normal peak voltage (per unit), and lasts between 0.5 and 3 cycles, depending on system damping.

Isolation transformers, voltage arresters, and/or filters can reduce transients.

Short-Duration Variations

Short-duration voltage variations are momentary changes in the fundamental voltage magnitude. Common causes are faults on the power system (short circuits between phases or from phase to ground). Depending on the fault location and system conditions, the fault can cause either momentary voltage rises (swells) or momentary voltage drops (sags). The fault condition can be close to or remote from the point of interest.

Sags. Sags (Figure 15) are often associated with system faults but can also be caused by switching heavy loads or starting large motors (usually a longer-duration variation). Figure 15 shows a typical voltage sag that can be associated with a remote fault condition. For instance, a fault on a parallel feeder circuit (on the primary distribution system) results in a voltage drop at the substation bus that affects all of the other feeders until the fault is cleared by opening a fuse or circuit breaker.

The percent drop in the RMS voltage magnitude and duration of the low-voltage condition are used to characterize sags. Voltage sags are influenced by system characteristics, system protection practices, fault location, and system grounding. The most common problem caused by voltage sags is tripping sensitive controls (e.g., adjustable-speed drives or process controllers), relays or contactors dropping out, and failure of power supplies to ride through the sag. Many types of voltage regulators are not fast enough to provide voltage support during sags, but ferroresonant transformers and some other line conditioners can provide some ride-through capability or can quickly compensate for deep sags.

In practice, sags are the type of power quality variation that most frequently causes problems. Fault conditions remote from a particular customer can still cause voltage sags that can cause equipment problems. Because there are no easy ways to eliminate faults on the power system, it is always necessary for customers to consider the effects of sags.

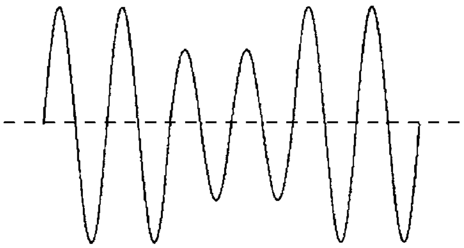

Fig. 15 Example of Sag

Swells. Swells or **surges** can also be associated with faults on the primary distribution system (Figure 16). They can occur on nonfaulted phases when there is a single-line-to-ground fault.

Swells are characterized by their magnitude (RMS value) and duration. The severity of a voltage swell is a function of fault location, system impedance, and grounding. On a three-phase ungrounded system (delta), the line-to-ground voltages on the ground phases are 1.73 per unit (i.e., 1.73 times the normal line-to-ground voltage) during a single-line-to-ground fault condition. Close to the substation on a grounded system, there is no voltage rise on the ground phases because the substation transformer is usually delta-wye, providing a low-impedance path for the fault current.

Long-Duration Variations

Long-duration RMS voltage deviations generally do not result from system faults. They are caused by load changes on the system and system switching operations. The duration of these voltage variations depends on the operation of voltage regulators and other types of voltage control on the power system (e.g., capacitor controls, generator exciter controls). The time required for these voltage controllers to respond to system changes ranges from large fractions of a second to seconds. Long-duration variations can be overvoltages or undervoltages, depending on the cause of the variation. Voltage unbalance should be considered when evaluating steady-state or long-duration voltage variations. Unbalanced voltages can be one of the major causes of motor overheating and failure. With increasing emphasis on energy-efficient motors, requirements for voltage balance (i.e., limitations on negative sequence voltage magnitudes) may become even more important.

Overvoltages. Overvoltages (Figure 17) can result from load switching (e.g., switching off a large load), variations in system generation, or variations in reactive compensation on the system (e.g., switching a capacitor bank on). These voltages must be evaluated against the long-duration voltage capability of loads and equipment on the system. For instance, most equipment on the power system is only rated to withstand a voltage 10% above nominal for any length of time. Many sensitive loads can have even more stringent voltage requirements.

Long-duration overvoltages must also be evaluated with respect to the long-time overvoltage capability of surge arresters. Metal oxide variation (MOV) arresters in particular can overheat and fail due to high voltages for long durations (e.g., seconds).

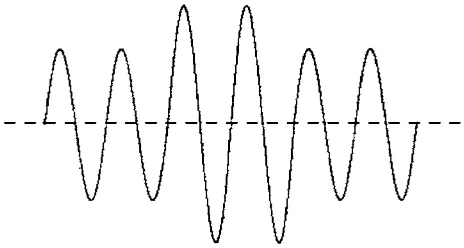

Fig. 16 Example of Swell (Surge)

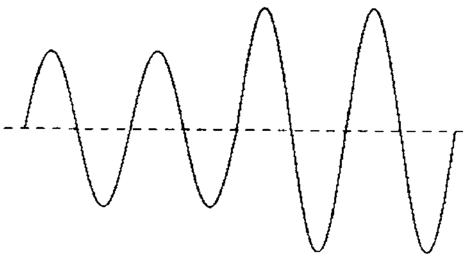

Fig. 17 Example of Overvoltage

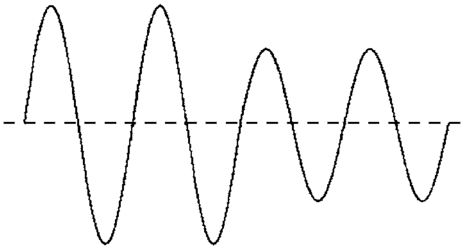

Fig. 18 Example of Undervoltage

Overvoltages can be controlled with voltage regulation equipment either on the power system or in a customer's facility. This can include various tap-changing regulators, ferroresonant regulators, line power conditioners, motor-generator sets, and uninterruptible power supplies.

Undervoltages. Undervoltages (Figure 18) have the opposite causes of overvoltages. Adding a load or removing a capacitor bank will cause an undervoltage until voltage regulation equipment on the system can bring the voltage back to within tolerances.

Motor starting is one of the most common causes of undervoltages. An induction motor draws 6 to 10 times its full load current during starting. This lagging current causes voltage drops in the system impedance. If the started motor is large relative to the system strength, these voltage drops can result in a significant system undervoltage. The magnitude of this starting current decreases over a period ranging from 1 s to minutes, depending on the inertia of the motor and the load, until the motor reaches full speed. This type of undervoltage can be mitigated by using various starting techniques to limit the starting current and is largely self-corrected when the starting is completed. For more information, see the section on Motor-Starting Effects.

Voltage Unbalance. Ideally, all phase-to-phase voltages to a three-phase motor should be equal or balanced. Unbalance between the individual phase voltages is caused by unbalanced loading on the system and by unbalances in the system impedances. Voltage unbalance is an important parameter for customers with motors because most three-phase motors have fairly stringent limitations on negative-sequence voltage (a measure of voltage unbalance), which is generated in the motor by unbalances in supplied voltages. Negative sequence currents heat the motor significantly. Voltage unbalance limitations (and steady-state voltage requirements in general) are discussed in ANSI *Standard* C84.1. The National Electrical Manufacturers Association (NEMA) developed standards and methods for evaluating and calculating voltage unbalance. Unbalance, as defined by NEMA, is calculated by the following equation:

$$\%\ \text{Voltage unbalance} = 100 \times \frac{\begin{array}{c}\text{Maximum deviation}\\ \text{from average voltage}\end{array}}{\text{Average voltage}}$$

The motor derating factor caused by the unbalanced voltage curve from NEMA *Standard* MG 1 shows the nonlinear relationship between the percent of voltage unbalance and the associated derating factor for motors (Figure 19). A balanced-voltage three-phase power supply to the motor is essential for efficient system operation. For example, a voltage unbalance of 3.5% can increase motor losses by approximately 15%.

Interruptions and Outages

Interruptions can result from power system faults, equipment failures, generation shortages, control malfunctions, or scheduled maintenance. They are measured by their duration (because the voltage magnitude is always zero), which is affected by utility protection system design and the particular event causing the interruption.

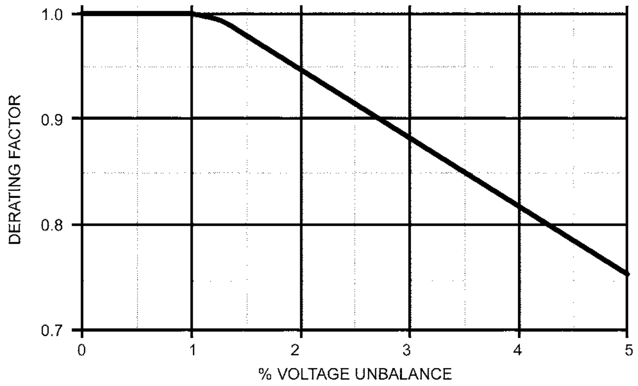

Fig. 19 Derating Factor Curve

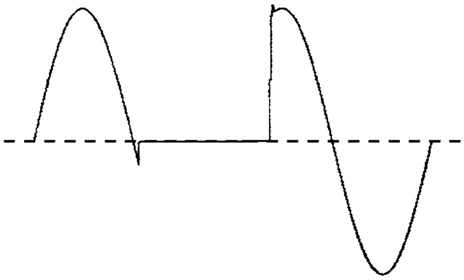

Fig. 20 Example of Momentary Interruption

Interruptions of any significant duration can potentially cause problems with a wide variety of different loads. Computers, controllers, relays, motors, and many other loads are sensitive to interruptions. The only protection for these loads during an interruption is a back-up power supply, a back-up generator (requires time to get started), or a UPS system (can constantly be online).

Momentary Interruption. A typical momentary interruption (Figure 20) lasts less than 3 s and occurs during a temporary fault, when a circuit breaker successfully recloses after the fault has been cleared. Lightning-induced faults usually fall into this category unless they cause a piece of equipment (e.g., transformer) to fail.

Temporary Interruption. Temporary interruptions that last between 3 s and 1 min result from faults that require multiple recloser operations to clear, or require time for back-up switching to reenergize portions of the interrupted circuit (e.g., automatic throwover switches).

Power Failure/Blackout. Outages lasting at least 1 min (Figure 21) are severe enough to be included in utility companies' reliability statistics. These failures are caused by fault conditions, maintenance operations that require repair crews, and emergency situations called blackouts.

Solutions involve using either UPS systems or back-up generators, depending on the critical nature of the load. UPS systems typically can provide uninterrupted supply for at least 15 min (based on battery capacity). This covers all momentary and temporary interruptions and provides sufficient time for an orderly shutdown. A UPS can be used in conjunction with a switching scheme involving multiple feeds from the utility to provide an even higher level of reliability. If back-up power is required beyond the capability of a UPS system, and multiple feeds are not realistic or adequate, then back-up generators are needed. On-site generators are typically used in these applications.

Brownout. A brownout is a long-term voltage reduction, usually of 3 to 5%. This is an intentional reduction to reduce load under emergency system conditions.

Harmonic Distortion

Harmonic distortion of the voltage waveform occurs because of the nonlinear characteristics of devices and loads on the power system. These nonlinear devices fall into one of three categories:

- Power electronics
- Ferromagnetic devices (e.g., transformers)
- Arcing devices

These devices usually generate harmonic currents, and voltage distortion on the system results from these harmonics interacting with the system impedance characteristics. Harmonic distortion is a growing concern for many customers and for the overall power system because of the increasing applications of power electronic equipment. In many commercial buildings, electronic (nonlinear), loads, such as variable-frequency drives, computers, and UPS systems, may be dominant in the facility, especially as more buildings switch to electronic ballasts for fluorescent lighting.

Harmonic distortion levels can be characterized by the complete harmonic spectrum with magnitudes and phase angles of each individual harmonic component. However, it is more common to use a single quantity, the **total harmonic distortion (THD)**, to characterize harmonic distortion of a particular waveform. It is important in general to distinguish between voltage distortion and current distortion because these quantities are handled differently in the standards and should be handled differently when performing measurements and interpreting data.

Voltage distortion is caused by the harmonic current emissions of nonlinear devices interacting with the impedance characteristics of the power system. Harmonic current distortion results in elevated true RMS current, which increases I^2R losses and elevated peak current. Because harmonics flow at frequencies higher than the fundamental frequency (e.g., 180 Hz, 300 Hz, 420 Hz), additional losses are experienced because of the reduction of conductor effective cross-sectional area, a phenomenon known as **skin effect**. These losses are attributed to I^2X_L at each harmonic frequency.

A particular concern is when resonance conditions on the power system magnify harmonic currents and high-voltage distortion levels. The natural resonance of the power system varies based on system inductance and capacitance and should be evaluated when adding nonlinear devices (equipment) or power factor capacitors to the system. Capacitors offer a low-impedance path to harmonic frequencies and can therefore attract harmonics, often resulting in reduced life, fuse blowing, or capacitor failure. Figure 22 illustrates the voltage waveform with harmonic content. Figures 23 and 24 illustrate distorted current waveforms.

Harmonic distortion can be reduced by adding an ac line reactor or harmonic filter at the input of individual nonlinear loads (Figure 25). A 5% impedance line reactor typically reduces harmonic distortion for three-phase nonlinear loads to about 35% of the fundamental current.

Harmonic current distortion can be reduced to levels of 5 to 8% total harmonic current distortion, at the individual load, using a typical low-pass harmonic filter (Figure 26). The benefit of reducing harmonics right at the contributing load is that the entire upstream power system benefits from reduced levels of current and voltage distortion.

Voltage Notches. A voltage waveform with notches (see Figure 13) caused by operating power electronics, especially where SCRs are involved [e.g., adjustable-speed drives (ASDs)], can be considered a special case that falls in between transients and harmonic distortion. Because notching occurs continuously (steady state), it can be characterized by the harmonic spectrum of the affected voltage. However, frequency components associated with the notching can be quite high, and it may not be possible to characterize them with measurement equipment normally used for harmonic analysis. It is usually easier to measure with an oscilloscope or transient disturbance monitor.

Three-phase SCR rectifiers (those typically in dc drives, UPS systems, ASDs, etc.) with continuous dc current are the most common cause of voltage notching. The notches occur when the current

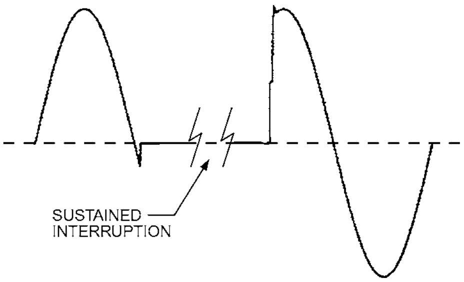

Fig. 21 Example of Blackout or Power Failure Waveform

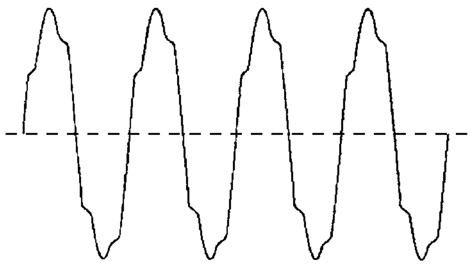

Fig. 22 Example of Harmonic Voltage Distortion

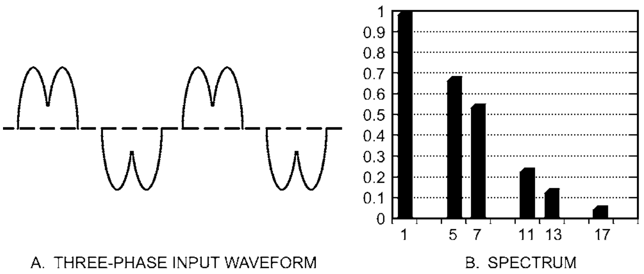

Fig. 23 Example of Harmonic Current Distortion for Six-Pulse Rectifier with 5% Impedance Reactor

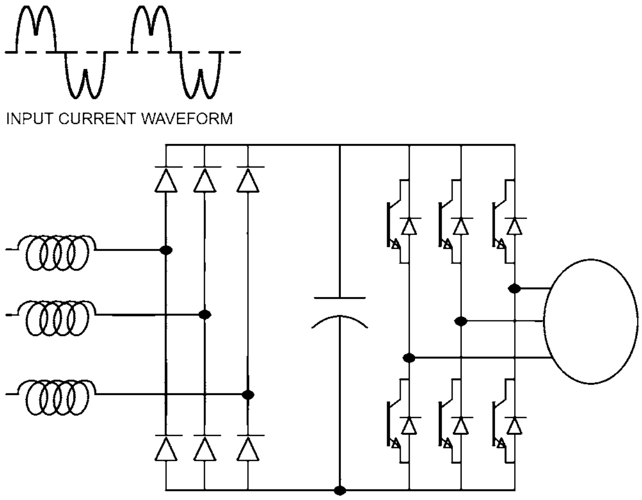

Fig. 25 Example of VFD with ac Line Reactor

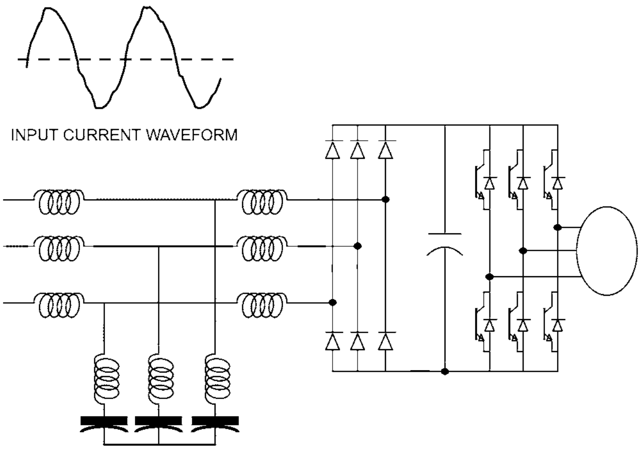

Fig. 26 Example of VFD with Low-Pass Harmonic Filter

commutates from one phase to another on the ac side of the rectifier. During this period, there is a momentary short circuit between two phases. The severity of the notch at any point in the system is determined by the source of inductance and the inductance between the rectifier and the point being monitored.

Often, an isolation transformer or 3% impedance ac line reactor (inductor) can be used in the circuit to reduce the effect of notching on the source side. The additional inductance increases the severity of voltage notches at the rectifier terminals (commutation time, or width of the notch, increases with increased commutation reactance); however, most of the notching voltage appears across the ac inductor and notching is less severe on the source side, where other equipment shares a common voltage source.

Steep voltage changes caused by notching can also result in ringing (oscillation) because of capacitances and inductances in the supply circuit. This oscillation can disturb sensitive controls connected to the affected circuit. The high frequencies involved can also cause noise be capacitively coupled to adjacent electrical or communication circuits.

Voltage Flicker

Loads that vary with time, especially in the reactive component, can cause voltage flicker; the varying voltage magnitudes can affect lighting intensity. Arc furnaces are the most common cause of

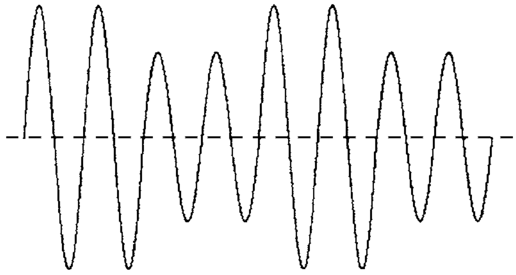

Fig. 27 Example of Flicker

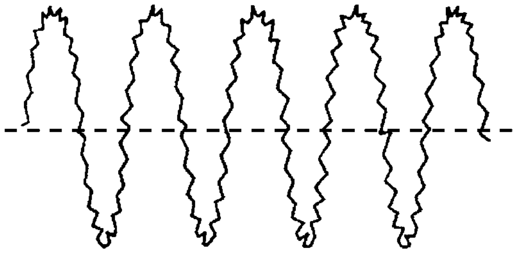

Fig. 28 Example of Electrical Noise

voltage flicker. The envelope of the 60 Hz variations is defined as the flicker signal V, and its RMS magnitude is expressed as a percentage of the fundamental. Voltage flicker is measured with respect to sensitivity of the human eye. A typical plot of the 60 Hz voltage envelope characterizing voltage flicker is shown in Figure 27.

The characteristics of voltage flicker are mainly determined by load characteristics and the system short-circuit capacity. For a critical load, it may be necessary to provide a dedicated feed so that it is not on the same circuit with a major load that causes voltage flicker. Using fast switching compensation, such as a static volt-ampere-reactive (VAR) system or dynamic VAR compensation system, can mitigate the problem. Another method is to effectively increase the short-circuit capacity at the point of common coupling with other loads by using a series capacitor. Protecting the series capacitor during fault conditions requires careful design.

Voltage flicker appears as a modulation of the fundamental frequency (similar to amplitude modulation of an AM radio signal). Therefore, it is easiest to define a magnitude for voltage flicker as the RMS magnitude of the modulation signal, which can be found by demodulating the waveform to remove the fundamental frequency and then measuring the magnitude of the modulation. Typically, magnitudes as low as 0.5% can result in perceptible light flicker if frequencies are in the range of 1 to 10 Hz. Flicker limitations are discussed in ANSI/IEEE *Standard* 146.

Light dimming, another type of light flicker, is caused by starting motors. Large single- or three-phase motors, as used in air conditioners, have the undesirable effect of drawing 6 to 10 times their full load current while starting. This large current, by flowing through system impedances, causes voltage sag that may dim lights.

Noise

Noise, a continuous, unwanted signal on the power circuits (Figure 28), can have a wide variety of different causes (e.g., switching, arcing, electric fields, magnetic fields, radio waves) and can be coupled onto the power circuit in a number of different ways. The noise source and susceptible circuit can be coupled by electric or magnetic fields or by electromagnetic interference (EMI).

The frequency range and magnitude of noise depend on the source that produces the noise. A typical magnitude of noise measured in the voltage is less than 1% of the RMS voltage magnitude.

Noise with enough amplitude disturbs electronic equipment such as microcomputers and programmable controllers. Some noise can be eliminated by using an isolation transformer with an electrostatic shield; other noise requires EMI filtering or line conditioners. Wiring and grounding practices also significantly affect the noise levels at particular loads. The appropriate method for controlling noise depends on the methods of coupling, frequency range of the noise, and susceptibility of the equipment being protected.

Inductive (Magnetic) Coupling. Magnetic fields induce currents in conductors. The magnetic fields are caused by current flowing in nearby power conductors, parts of circuits, data lines, or even building structure, and can be temporary or steady state. The actual coupled currents in power conductors and equipment conductors depend on exposure (length of conductor in the field), angle between conductor and field, and magnetic field strength. Conductors carrying large currents and/or with large spacing between conductors can create strong 60 Hz magnetic fields that do not decay quickly with distance from the source. These fields can cause distortion on CRT or TV screens, and may interfere with sensitive electronic (especially analog) devices such as radio-controlled equipment, energy and building automation systems, photoelectric sensors, test and measurement equipment, and data processing equipment. During building design, take steps to minimize generation of strong magnetic fields, and to keep sensitive equipment well separated from these areas.

Current flow in the power system ground can be an important cause of magnetic fields because the loop area between the supply conductor and the return path through the ground can be very large. Therefore, grounding techniques to minimize noise levels can help reduce magnetic field problems. To minimize interference, power conductors should always be physically separated from control circuit conductors. Magnetic shielding can also help.

Capacitive (Electrostatic) Coupling. Capacitive coupling between conductors results in coupling of transient voltage signals between circuits. Transient voltages with high-frequency components or high rates of rise are the most likely to be capacitively coupled between circuits (the coupling capability of a capacitor increases with frequency). Switch operations, arcing, lightning, or electrostatic discharge can cause these transients. Electric fields capacitively couple voltage between conductors. Strength is measured in volts per metre and may range from very slight to many kilovolts per metre.

High magnitudes of capacitively coupled voltages can affect normal operations of various types of electronic devices, or even cause discharges and damage. Possible solutions include applying shielding and coating, and improving design of power equipment to reduce the generation of high-transient-voltage conditions. To minimize interference, power conductors should always be physically separated from control circuit conductors.

Electromagnetic Interference (EMI). EMI refers to interference caused by electromagnetic waves over a wide range of frequencies. Many interference sources start out as either strongly magnetic or strongly electric, but within about half a wavelength the fields convert to a balanced ratio of electric and magnetic fields (an electromagnetic field). Transients such as electrostatic discharge, arcing, contacts, power electronic switching, fluorescent lighting, and lightning cause electromagnetic waves. Steady-state EMI can occur in the form of radio frequency interference (RFI) from microwave and radar transmissions, radio and TV broadcasts, corona of high-voltage transmission line, arc welding, and other sources that generate radio-frequency electromagnetic waves. Although RFI is not destructive, it can cause a variety of malfunctions of susceptible electronic equipment and can disturb microcomputers and programmable controllers; the level of disturbance depends on the amount of RFI. Solutions include using appropriate shielding or filtering techniques.

6. BILLING RATES

Equipment specifications state how much electricity is used, but the cost of that electricity is usually the determining factor in HVAC&R system design and equipment selection. Electricity tariffs or rates set prices for

- How much electricity is used; energy (MJ)
- Rate at which electricity is used; demand (kW)
- Quality of electricity used; power factor (VAR or kVAR)

Electric rates are contracts defining what the electricity user will pay for the amounts consumed. Rates may be based on cost, policy, market, or a combination of cost/policy and market. Additionally, rates may be based on either kW or kVA demand. Designers should not assume that the types of rates will remain the same over the life of a building, and owner/operators should review with their utility about potential rate changes that might lower cost or improve reliability.

Cost-Based Rates

Cost-based rates are designed to charge each class of consumer based on the utility's cost to serve that class. Costs depend on megajoules used, maximum demand, and time of day at which electricity is used. A customer class is a group of electricity consumers whose use characteristics are similar; each customer class has a different rate or tariff. Typical customer classes are residential, multifamily, small commercial, large commercial, small industrial, large industrial, electric water heating, electric space heating, street lighting, etc. Cost-based rates are usually predicated on the following assumptions:

- The more electricity a customer uses the less it costs, per megajoule, to serve that customer.
- The higher a customer's demand, the more it costs to serve that customer.
- It costs less per megajoule to serve a customer with a higher load factor. Load factor LF is defined as the customer's average demand divided by the peak demand, or the energy consumed in the billing period divided by the peak demand times the number of hours in the billing period. [LF = MJ used in the billing period/(peak demand × hours in billing period)]
- It costs less for a utility to deliver electricity at times of low system load than at times of high system load.

Energy Charge. The consumer pays the utility a fixed amount for every megajoule used. Small customers, especially residential, often simply pay for energy used. Certain loads may have usage profiles that allow the utility to provide electricity at times of low production costs (e.g., street lighting) or cost less per megajoule because the customer uses significantly more than a typical customer (e.g., electric space heating). These loads are often metered separately and are charged a lower cost per megajoule than general-service usage.

Fuel Adjustment Clause (FAC). A significant part of the cost of electricity is the fuel needed to generate it. In the 1970s, the price of primary energy sources (especially oil) became extremely volatile, and the fuel adjustment clause was designed to accommodate this without requiring frequent rate adjustments. Energy charges with FACs consist of two parts: a fixed charge per megajoule and a variable charge per megajoule that depends on the average price of fuel purchased by the power generator. During periods of low fossil fuel prices or high hydro runoff, for example, the FAC results in lower prices to the consumer. Many utilities embed part of the fuel cost in the rate tariffs and include the remaining variable portion in the FAC.

Demand Charge. "Demand" is the maximum rate of use of electricity. It is expressed in kilowatts (kW) or kilovolt-amps (kVA) and is typically measured over 15, 30, or 60 min periods. For example, 1 kWh used in 15 min is equal to 4 kW demand (1 kWh/0.25 h). Demand charges are designed to cover the system capacity cost to deliver energy to a customer and/or the marginal generation cost to produce electricity at time of highest usage. To deliver electricity to a consumer, a utility must install wires, transformers, and meters; the higher the customer's projected demand, the larger the capacity of wires and transformers serving the customer must be. From a system-wide perspective, the utility must also build enough generation and transmission capacity to serve the system load at its highest peak level. A **noncoincident demand (NCD) charge** is a charge per kilowatt for the customer's maximum demand for electricity (in any 15, 30, or 60 min period) during the billing cycle. Noncoincident demand charges are generally imposed to cover the cost to transform and deliver energy to the consumer. A **coincident demand (CD) charge** (also known as a **peak** or **on-peak demand charge**) is a charge per kilowatt for the customer's maximum demand for electricity in any 15, 30, or 60 min period occurring during times of high system load. For example, in a summer-peaking utility, the demand charge may be applied only to the maximum demand occurring between 11:30 AM and 6:00 PM on weekdays from May to September. CD charges are designed to pay for additional generation and other system reinforcement costs needed to meet peak demands.

Ratcheted Demand Charge. Demand charges may be calculated based on the customer's maximum demand during each billing cycle, or the maximum demand during the current or previous 11 months preceding the electricity bill. A high demand in one month "ratchets" the demand charge up for some or all of the following 11 months.

Seasonal Rate. Some utilities' generation costs vary significantly from one season to another. For example, spring runoff may yield more low-cost hydroelectric energy, or high summer air-conditioning loads may result in more power generation by less efficient peaking plants. A seasonally adjusted rate reflects this by setting different kilowatt and/or megajoule charges for different seasons.

Time of Use (TOU) Rate. A utility's average production cost for electricity usually varies with the total system load. As demand increases, less efficient (i.e., more costly) generators are used. Increasing peak loads also require that a utility invest in greater generation, transmission, and distribution capacity to meet the peak. A TOU rate is designed to recover the increased production or capacity costs during times of system peak. Electricity use is recorded by multiregister meters and priced at different levels, depending on whether the peak/off-peak or peak/shoulder/off-peak model is used. TOU rates are usually designed not only to "recover" time-differentiated production costs, but also to induce consumers to shift their electricity usage from peak periods to times of lower system load. In this way, TOU rates are both cost-based and policy-based. Thermal energy storage (TES) systems are one method for consumers to reduce their on-peak demand or energy charges and to consume electricity during lower-cost, off-peak times. With TES, a consumer may use the same or more total electricity but will pay less for it.

Declining Block Rate. In designing cost-based rates, the cost to serve is usually inversely proportional to the amount consumed. To reflect this, energy may be priced according to a declining block rate, where the cost per megajoule decreases as usage increases. For example, a residential customer may pay $0.033/MJ for the first 3000 MJ used in a month, $0.028/MJ for the next 2000 MJ, and $0.022/MJ for all electricity above 5000 MJ.

Demand-Dependent Block Rate. For larger customers, the size of the blocks of a block rate may depend on the measured demand. For example, a commercial consumer may pay $0.033/MJ for the first 300 MJ per kilowatt of billing demand, $0.028/MJ for the next 550 MJ per kilowatt of billing demand, and $0.022/MJ for every MJ above 850 MJ per kilowatt of billing demand.

Load Factor Penalty. Utilities recover their fixed costs (e.g., capital cost of a transformer) as well as production costs through energy (MJ) charges as well as demand charges. If a consumer's load factor is less than expected, then the utility's megajoule revenues may not be sufficient to recover its fixed costs. This may occur for a customer with self-owned on-site generation who relies on the utility mainly when the on-site generator is being maintained. In this case, the utility may impose a load factor penalty or surcharge.

Power Factor Penalty. A power system is more efficient and stable when all three phases are equally loaded (balanced) and serving pure resistive load (100% power factor). Some inductive loads, such as most lighting and motors, require reactive power, which may be more difficult and expensive for the utility to supply. Moreover, reactive power (kVAR) is not always measured, and therefore not billed, by typical megajoule meters. Therefore, utilities often impose a power factor penalty or surcharge on customers with very reactive or inductive loads (power factor not close to 100%) to pay for the VARs that it must supply.

Customer Charge. This is a monthly, usually fixed charge that a consumer must pay, regardless of whether any electricity is used, for being a customer of a utility. This charge typically covers customer services such as the costs of billing, metering, and customer support services, such as call centers.

Connection Fee. When electric service is initiated, especially when construction (additional distribution lines, substations, distribution transformers, etc.) is required, the utility may charge a connection fee. For example, a utility may charge a residential customer a fixed cost per metre of distribution line that must be constructed beyond an initial 150 m of line. Some customers may require redundant facilities to ensure reliable service (e.g., a second feeder and load transfer switch for a hospital). The utility would probably include such costs in its connection fee.

Policy-Based Rates

Policy-based rates are designed to encourage consumers to modify their energy use to better conform with the objectives of the utility or legislative or regulatory body (e.g., using nonpolluting or renewable energy sources, deferring grid expansion or generator construction by shifting electricity demand from peak periods, better using waste heat from industrial processes, etc.). It can be argued that some policy-based rates are in fact cost-based, but they incorporate "externalities," or external costs that cannot be directly allocated to a consumer's electricity use. The time of use rate could fall under either category.

Inverted Block Rate. The marginal cost to provide an existing customer with additional energy decreases as energy use per kilowatt of connected load increases. However, additional energy use often hastens the need to construct new generation facilities. An inverted block rate motivates the consumer to reduce energy use by charging less for the first megajoule used. For example, a residential consumer may pay $0.022 for the first 3000 MJ per month, $0.028 for the next 1800 MJ, and $0.033 for all usage above 5000 MJ. As with the declining block rate, the break points between "blocks" may be based on demand for that billing cycle.

Lifeline Rate. Lifeline rates are designed so lower-income consumers will still be able to afford necessary electricity (e.g., enough for refrigeration, lights, adequate heat in winter, etc.). For example, a consumer pays a subsidized price per megajoule for a minimal amount of electricity and the market rate for any usage above the minimum (e.g., $0.01/MJ for the first 2500 MJ and $0.03/MJ for usage above 2500 MJ/month).

Net Metering. This is applicable for consumers who own their own on-site generation, still buy electricity from the grid, but sometimes can generate more electricity than is needed in their facility. Net metering is a contract in which the customer pays the utility for the net electricity purchased (i.e., excess on-site generation is sold to the grid and offsets what the customer owes the utility for purchases from the grid).

Green Power Rate. Customers may sign up for blocks of electricity produced by renewable sources, such as solar photovoltaic (PV) or wind turbines. Because electricity from such sources usually costs more than electricity produced by conventional generation, the green energy is sold at a premium.

Surcharges. Government agencies may add special surcharges to electric bills to provide funding for specific energy-related or general-purpose programs. For example, in the United States, many state governments collect public benefit funds through electric bills to provide money for energy efficiency, renewable energy, low-income weatherization, and research programs. Other surcharges may be for power plant upgrades or putting electric distribution lines underground. Surcharges can be fixed or charged on a per-kWh basis. Some surcharges may be capped at a specific dollar amount per type of customer.

Taxes. Government agencies may collect sales and other specific taxes through utility bills. The taxes may be calculated as a percentage total of the entire bill, or on a per-kWh basis (such as $0.001 per kWh). For some customers, taxes and surcharges may comprise a significant portion of the total bill.

Market-Based Rates

Electric utilities are restructuring to disaggregate electricity production, transmission, and distribution and open the market to competition. The theory is that a competitive electricity sector, governed by market rules, is more efficient, lower cost, and more congruent with consumer needs than regulated electric utilities. Market-based rates are not new, but they are becoming more prevalent. Rates tend to be volatile, and are structured as a contract between the consumer and energy supplier, rather than as a traditional tariff. As a result, they tend to be more customer specific than uniform over a customer class.

Real-Time Pricing (RTP). Under this scheme, the cost of electricity varies with each hour. The supplier sets a price for electricity based on its forecasted cost to produce or provide the electricity. Hour-by-hour prices are communicated to the customer from 1 to 24 h in advance, and the consumer decides what, if any, action to take in response to the forecasted prices. The most common RTP programs send prices to consumers each evening, to cover the next day. Some programs send prices 4 h in advance, and several also allow 1 h alerts for "surprise" prices during system emergencies or forced outages. Consumers who were on a demand (kilowatt) and energy (MJ) rate often are billed only for energy use (MJ) on RTP, because the hourly energy cost incorporates the demand charge. The RTP may only apply to the generation portion of the electric bill if transmission and distribution charges are still regulated.

Fixed Pricing. Some consumers in a deregulated market may opt for fixed prices for their electric supply. In these situations, the consumer may pay a price that is higher or lower than the RTP or spot prices. With this type of pricing, the burden of price risk goes to the supplier, who may charge a risk premium to the customer.

Spot Pricing. Consumers in some regions may purchase some or all of their electricity on the spot market, based on the current marginal cost of electricity. This is done through a power exchange, with the consumer either contracting directly with the exchange or going through a third-party electricity broker. Consumers may also purchase electricity through a combination of long-term contracts and spot market purchases.

Interruptible Rates and Responsive Loads. At times of high marginal electricity costs, it may be more cost effective for a utility to pay its customers to reduce electricity consumption than to contract for additional electricity supplies. With interruptible rates, a consumer agrees to reduce power consumption to or below an agreed-upon level (or go off-line) when requested to do so by the utility, in return for a lower price. The utility's requests may be limited in number of times per year (or month) the consumer can be asked to reduce load, maximum duration of the load reduction, and minimum notice required (typically 1 to 4 h) before electric load is reduced. In other cases, there is no limit to the number or length of utility requests.

Direct Load Control. This is similar to interruptible load, but instead of the consumer's complying with the utility's request, the utility can exercise direct control over the consumer's appliances. Appliances commonly contracted for load control programs are water heaters, swimming pool pumps, air conditioners, heat pumps, resistance space heat, and controllable thermostats for HVAC&R systems. The tariff usually is in the form of a monthly rebate or fixed bill credit for each controllable appliance.

Performance-Based Rates. These are designed to ensure that the consumer receives acceptable quality and reliability of electric supply. The utility and consumer agree on a minimum standard for service quality in terms of number and duration of outages, voltage sags and swells, harmonic levels, or other transient phenomena. If these minimum service quality levels are not met, the utility must rebate money to the consumer; the amount rapidly increases as performance or service quality declines. In some cases, the rate, or type of rate charged, may not change, but customers receive bill credits or rebates based on a reduction in the electric company's rate of return.

Performance Contracting. In performance contracting, a consumer contracts with a third party to pay for the end-use applications of electricity. This usually involves an agreement where the performance contractor [often called an energy service company (ESCO)] installs and sometimes operates and maintains improved equipment for HVAC&R systems, lighting, building or process energy management, etc. The consumer's payments are indexed to successful equipment performance, which is often evaluated in terms of the facility's utility bills and calculated cost savings comparing the actual energy costs with estimates of what the costs would have been without the ESCO's intervention. A more detailed explanation of performance contracting is presented in ASHRAE *Guideline* 14-2002.

7. CODES AND STANDARDS

NEC®

The *National Electrical Code*® (NEC; NFPA *Standard* 70) is devised and published by the National Fire Protection Association, a consensus standards writing industry group. It is revised every three years. The code exists in several versions: the full text, an abridged edition, and the NEC Handbook (which contains the authorized commentary on the code, as well as the full text). It sets minimum electrical safety standards, and is widely adopted.

UL Listing

Underwriters Laboratories (UL), formerly an insurance industry organization, is now independent and nonprofit. It tests electrical components and equipment for potential hazards. When a device is UL-listed, UL has tested the device, and it meets their requirements for safety (i.e., fire or shock hazard). It does not necessarily mean that the device actually does what it is supposed to do. The UL does not have power of law in the United States; non-UL-listed devices are legal to install. However, insurance policies may have clauses that limit their liability in a claim related to failure of a non-UL-listed device. The NEC requires that a wiring component used for a specific purpose is UL-listed for that purpose. Thus, certain components must be UL-listed before inspector approval and/or issuance of occupancy permits.

CSA Approved

The Canadian Standards Association (CSA) is made up of various government agencies, power utilities, insurance companies, electrical manufacturers, and other organizations. They update CSA *Standard* C22.1, the *Canadian Electrical Code* (CEC), every two or three years.

The Canadian Standards Association (or recognized equivalent) must certify every electrical device or component before it can be sold in Canada. Implicit in this is that all wiring must be done with CSA-approved materials. Testing is similar to UL testing (a bit more stringent), except that CSA approval is required by law. Like the UL, if a fire is caused by non-CSA-approved equipment, the insurance company may not pay the claim.

ULC

Underwriters Laboratory of Canada (ULC) is an independent organization that undertakes the quarterly inspection of manufacturers to ensure continued compliance of UL listed/recognized products to agency reports and safety standards. This work is done under contract to UL, Inc.; they are not a branch or subsidiary of UL.

NAFTA Wiring Standards

Since the North America Free Trade Agreement (NAFTA) came into effect on January 1, 1994, CSA approval of a device is legally considered equivalent to UL approval in the United States, and UL listing is accepted as equivalent to CSA approval in Canada. Devices marked only with UL approval are acceptable in the CEC, and CSA approval by itself of a device is accepted by the NEC. This allows much freer trade in electrical materials between the two countries. This does not affect the electrical codes themselves, so differences in practice between the NEC and CEC remain.

IEEE

The Institute of Electrical and Electronic Engineers' *Standard* 519 suggests limits for both harmonic current and voltage distortion, based on electrical system conditions.

CHAPTER 58

ROOM AIR DISTRIBUTION

Application Guidelines 58.1
Fully Mixed Air Distribution 58.2
Fully Stratified Air Distribution 58.9
Partially Mixed Air Distribution 58.13
Air Dispersion Systems 58.15
Air Terminal Units (ATUs) 58.19
Room Fan-Coil Units 58.26
Heating and Cooling Coil Selection 58.30
Chilled Beams 58.31
Air Curtain Units 58.34

ROOM air distribution systems, like other HVAC systems, are intended to achieve required thermal comfort and ventilation for space occupants and processes. Although air terminals (inlets and outlets), terminal units, local ducts, and the rooms themselves may affect room air distribution, this chapter addresses only air terminals and their effect on occupant comfort. This chapter is intended to help HVAC designers apply air distribution systems to occupied spaces, providing information on characteristics of various air distribution strategies, and tools and guidelines for applications and system design. Naturally ventilated spaces are not addressed; see Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals* for details. Also see Chapter 20 of the 2017 *ASHRAE Handbook—Fundamentals* for more information on space air diffusion; Chapter 19 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for information on room air distribution equipment; and Chapter 49 of this volume for sound and vibration control guidance.

Room air distribution systems can be classified by (1) their primary objective and (2) the method by which they attempt to accomplish that objective. The objective of any air distribution system can be classified as one of the following:

- Conditioning and/or ventilation of the space for occupant thermal comfort
- Conditioning and/or ventilation to support processes within the space
- A combination of these

As a general guideline, the **occupied zone** of a space is any location where occupants normally reside, and may differ from project to project; it is application-specific, and should be carefully defined by the designer. The occupied zone is generally considered to be the room volume between the floor level and 1.8 m above the floor. Standards and guidelines, such as ASHRAE *Standards* 55 and 62.1, further define the occupied zone (e.g., *Standard* 55 exempts areas near walls).

Occupant comfort is defined in detail in ASHRAE *Standard* 55-2017. Figure 5.3.1 of the standard shows acceptable ranges of temperature and humidity for spaces. As a general guide, a majority of occupants in typical office spaces can be satisfied with thermal environments over a wide range of temperatures and relative humidities. Designers often target indoor dry-bulb temperatures between 73 and 22 and 25°C, relative humidities between 25 and 60%, and occupied zone air velocities below 0.25 m/s.

ASHRAE *Standard* 113 describes a method for evaluating effectiveness of various room air distribution systems in achieving thermal comfort.

Room air distribution methods can be classified as one of the following:

- **Fully mixed systems** (e.g., overhead distribution) have little or no thermal stratification of air in the occupied and/or process space.
- **Full thermal stratification systems** (e.g., thermal displacement ventilation) have little or no air mixing in the occupied and/or process space.
- **Partially mixed systems** (e.g., most underfloor air distribution designs) provide limited air mixing in the occupied and/or process space.
- **Task/ambient air distribution** (e.g., personally controlled desk outlets, spot conditioning systems) focuses on conditioning only part of the space for thermal comfort and/or process control.

Because task/ambient design requires a high degree of individual control, it is not covered in this chapter; see Chapter 20 of the 2017 *ASHRAE Handbook—Fundamentals* for details. Guidance is also provided by ASHRAE (2013).

Figure 1 shows the spectrum between the two extremes (full mixing and full stratification) of room air distribution strategies.

1. APPLICATION GUIDELINES

Design Considerations

Architectural and Spatial Constraints. Air distribution products must fulfill both the functional requirement of conditioning space and the visual aesthetic determined by the architect. Architectural constraints may limit placement of air outlets and ductwork.

Heat Gain and Loss Characteristics. Large sensible heat loads can drive air movement in a space. Warm air is more buoyant and rises; cooler air is denser and descends to the ground. A zone may experience different heat loads depending on the season or time of day. The air distribution system must meet the varying heating and cooling needs throughout the building's operation. Care should be taken to ensure cool surfaces, such as exterior windows, do not reach temperatures below dew point, or condensation will occur.

Thermal Comfort. Occupant thermal comfort depends on several variables, including air velocity, air temperature, thermal radiation, humidity, occupant metabolic rate, and occupant clothing. Air distribution systems that use higher air velocities and temperature differentials may create a greater risk of draft. Likewise, exterior windows with warm or cold surfaces can produce undesired thermal radiation to nearby occupants. For more information, see ASHRAE *Standard* 55-2017 and its user's manual (ASHRAE 2016).

Acoustical Requirements. Sound emitted from inlets and outlets is directly related to the airflow quantity and free area velocity. The airflow sound intensity in a space also depends on the room's acoustical absorption and the observer's distance from air distribution devices. For more information, see Chapter 49 of this volume and Chapter 8 in the 2017 *ASHRAE Handbook—Fundamentals*.

Available Locations for Air Inlets and Outlets. Inlet and outlet characteristics are discussed in Chapter 20 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. This chapter discusses more specific application considerations for air inlets and outlets.

Code Requirements. Some applications (e.g., operating rooms) may require compliance with special or local codes that limit the selection and placement of certain types of air outlets.

The preparation of this chapter is assigned to TC 5.3, Room Air Distribution.

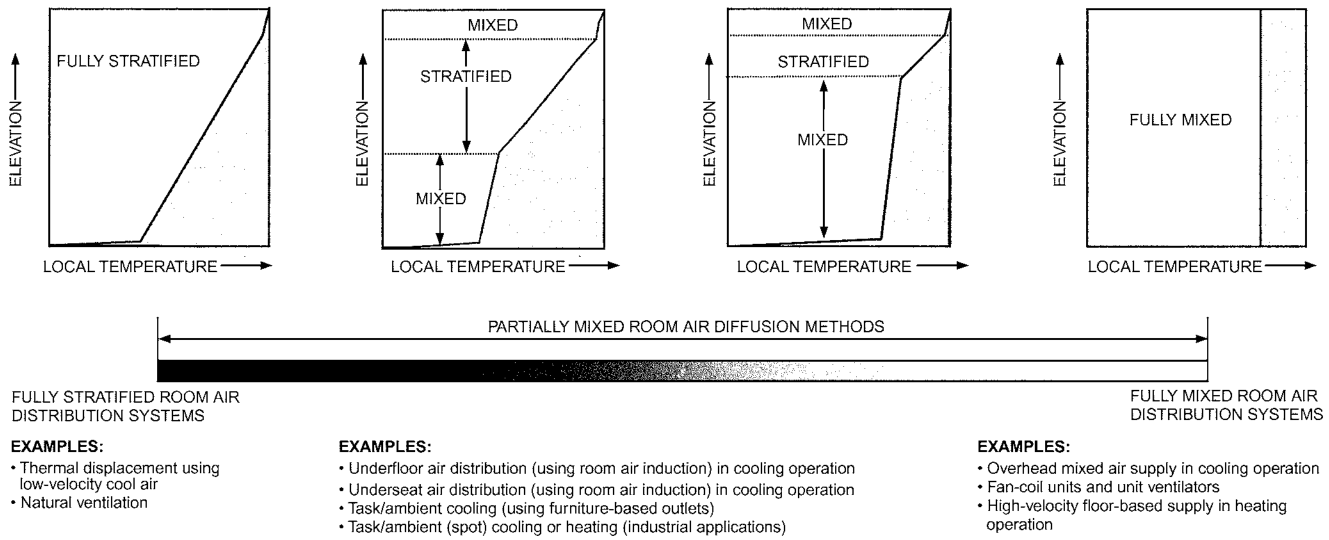

Fig. 1 Classification of Air Distribution Strategies

Indoor Air Quality and Sustainability

Air distribution systems affect not only indoor air quality (IAQ) and thermal comfort, but also energy consumption over the entire life of the project. Choices made early in the design process are important. ASHRAE *Standard* 90.1 provides energy efficiency requirements that affect supply air characteristics.

U.S. Green Building Council's (USGBC) Leadership in Energy and Environmental Design (LEED®) Green Building Rating System™ was originally created in response to indoor air quality concerns, and has evolved to include prerequisites and credits for increasing ventilation effectiveness and improving thermal comfort (new.usgbc.org/leed). These requirements and optional points are relatively easy to achieve if good room air distribution design principles, methods, and standards are followed.

Environmental tobacco smoke (ETS) control is a LEED prerequisite. Banning indoor smoking is a common approach, but if indoor smoking is to be allowed, ASHRAE *Standard* 62.1 requires that more than the base non-ETS ventilation air be provided where ETS is present in all or part of a building. Rock (2006) provides additional advice on dealing with ETS.

Ventilation effectiveness is affected directly by the room air distribution system's design, construction, and operation, but is very difficult to predict. Many attempts have been made to quantify ventilation effectiveness, including ASHRAE *Standard* 129. However, this standard is only for experimental tests in well-controlled laboratories and should not be applied directly to real buildings.

Because of the difficulty in predicting ventilation effectiveness, ASHRAE *Standard* 62.1 provides a table of typical values that were determined through the experiences of its Standard Project Committee and reviewers or extracted from research literature; for example, well-designed ceiling-based air diffusion systems produce near-perfect air mixing in cooling mode, and yield an air change effectiveness of almost 1.0. More information on ASHRAE *Standard* 62.1 is available in its user's manual (ASHRAE 2011).

Displacement and underfloor air distribution (UFAD) systems have the potential for values greater than 1.0. More information on ceiling- and wall-mounted air inlets and outlets can be found in Rock and Zhu (2002). Performance of displacement systems is described by Chen and Glicksman (2003), and UFAD is discussed in detail by ASHRAE (2013).

Table 1 Recommended Return Inlet Face Velocities

Inlet Location	Velocity Across Gross Area, m/s
Above occupied zone	>4
In occupied zone, not near sedentary occupants	3 to 4
near sedentary occupants	2 to 3
Door or wall louvers	1 to 1.5
Through undercut area of doors	1 to 1.5

Air terminals, such as diffusers or grilles, may become unsightly over time because of accumulation of dirt on their faces (smudging). Instead of replacing air terminals, and thus requiring new materials and energy for manufacturing, they can often be cleaned in place to restore their appearance. Those that cannot be cleaned and must be replaced should be recycled, not discarded, to recover the various metals and other desirable materials of construction.

Return Air Inlets

The success of a mixed air distribution system depends primarily on supply diffuser location. Return grille location is far less critical than the location of air outlets. In fact, the return air intake affects room air motion only in the area immediately around the grille. Measurements of velocity near a return air grille show a rapid decrease in magnitude as the measuring device is moved away from the grille face. Table 1 shows recommended maximum (to avoid excessive noise) return inlet face velocities as a function of grille location. Every enclosed space should have return/transfer inlets of adequate size per this table.

For stratified and partially mixed air distribution systems, it can be advantageous to place the return air inlet in the ceiling. ASHRAE *Standard* 62.1 allows ventilation effectiveness greater than 1.0 for some stratified and partially mixed air distribution systems in cooling mode if the return air inlet is located in the ceiling.

Supply air short circuiting is normally not a problem if the outlet is selected to provide adequate throw and directed away from returns or exhausts. The success of this practice is confirmed by the availability and use of combination supply and return diffusers.

2. FULLY MIXED AIR DISTRIBUTION

In mixed air systems, high-velocity supply jets from air outlets maintain comfort by mixing room air with supply air. This air mixing, heat transfer, and resultant velocity reduction should occur outside the occupied zone. Occupant comfort is maintained not directly by motion of air from outlets, but from secondary air motion from mixing in the unoccupied zone. Comfort is maximized when uniform temperature distribution and average room air velocities of less than 0.25 m/s are maintained in the occupied zone.

Maintaining average velocities less than 0.25 m/s in the occupied zone is often overlooked by designers, but is critical to maintaining comfort. The outlet's selection, location, supply air volume, discharge velocity, and air temperature differential determine the resulting air motion in the occupied zone.

Principles of Operation

Mixed systems generally provide comfort by entraining room air into discharge jets located outside occupied zones, mixing supply and room air. Ideally, these systems generate low-velocity air motion (less than 0.25 m/s) throughout the occupied zone to provide uniform temperature gradients and velocities. Proper selection of an air outlet is critical for proper air distribution; improper selection can result in room air stagnation, unacceptable temperature gradients, and unacceptable velocities in the occupied zone, possibly leading to occupant discomfort or poor air quality.

The location of a discharge jet relative to surrounding surfaces is important. Discharge jets attach to parallel surfaces, given sufficient velocity and proximity. When a jet is attached, the throw increases by about 30% over a jet discharged in an open area. This difference is important when selecting an air outlet. For detailed discussion of the surface effect on discharge jets, see Chapter 20 of the 2017 *ASHRAE Handbook—Fundamentals*.

Space Ventilation and Contaminant Removal

These systems are intended to maintain acceptable indoor air quality by mixing supply and room air (dilution ventilation). Supply air is typically a conditioned mixture of ventilation and recirculated air. Outlet type and discharge velocity determine the mixing rate of the space and should be a design consideration. The room's return or exhaust air carries away diluted air contaminants. Space air ventilation rates are mandated under ASHRAE *Standard* 62.1, but supply airflow rates are often higher because of thermal loads.

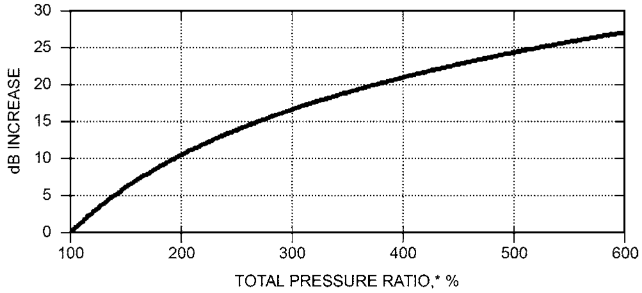
Benefits and Limitations

Benefits of fully mixed systems include the following:

- Most office applications can use lower supply dry-bulb temperatures, for smaller ductwork and lower supply air quantities.
- Air can be supplied at a lower moisture content, possibly eliminating the need for a more complex humidity control system.
- Vertical temperature gradients are lower for cooling applications with high internal heat gains, which may improve thermal comfort.
- Mixed systems are the most common design for air distribution systems, because designers and installers are familiar with the required system components and installation.

Limitations of mixed systems include the following:

- Partial-load operation in variable-air-volume (VAV) systems may reduce outlet velocities, reducing room air mixing and compromising thermal comfort. Designers should consider this when selecting outlets.
- Cooling and heating with the same ceiling or high-sidewall diffuser may cause inadequate performance in heating mode and/or excessive velocity in cooling mode.
- Ceilings more than 4 m high may require special design considerations to provide acceptable comfort in the occupied zone. Care should be taken to select the proper outlet for these applications.
- Because mixed systems typically use high-velocity jets of air, any obstructions in the space (e.g., bookshelves, wall partitions, furniture) can reduce comfort.



*Ratio of air pressure before and after damper.

Fig. 2 Effects of Neck-Mounted Damper on Air Outlet

- Lighter-than-air contaminants are uniformly mixed in the space and typically result in higher contaminant concentrations, which may compromise indoor air quality.

Mixed air systems typically use either ceiling or sidewall outlets discharging air horizontally, or floor- or sill-mounted outlets discharging air vertically. They are the most common method of air distribution in North America.

Inlet Conditions to Air Outlets

The way an airstream approaches an outlet is important. For good air diffusion, the inlet configuration should create a uniform discharge velocity profile from the outlet, or the outlet may not perform as intended.

The outlet usually cannot correct effects of improper duct approach. Many sidewall outlets are installed either at the end of vertical ducts or in the side of horizontal ducts, and most ceiling outlets are attached either directly to the bottom of horizontal ducts or to special vertical takeoff ducts that connect the outlet with the horizontal duct. In all these cases, devices for directing and equalizing the airflow may be necessary for proper direction and diffusion of the air.

ASHRAE research project RP-1335 (Landsberger et al. 2011) determined that a wide-open damper installed in the neck of a diffuser could add up to 8 NC to the cataloged NC value, depending on diffuser and damper types. Significantly closed balancing dampers can add more than 10 NC, depending on duct pressure and how far upstream it is installed. Table 2 gives forward throw asymmetries for various diffuser types, and Figure 2 compares the total pressure ratio of a diffuser with no damper versus a neck-mounted damper that is increasingly throttled.

Effects of Typical Field Installations on Common Ceiling Diffusers.

Ceiling air outlets are tested using ideal installation conditions described in ASHRAE *Standard* 70: a minimum of three vertical, straight duct diameters before the diffuser inlet.

Field installations are often not ideal because of ceiling plenum limitations, architectural design, structural supports of the building, etc. ASHRAE research project RP-1335 (Landsberger et al. 2011) developed some useful application data that can be used by design engineers to predict throw, pressure drop, and sound caused by nonideal installations. Tables 2, 3, and 4 give a general summary of application data from RP-1335. The multipliers provided in these tables may be applied to diffuser performance data measured from tests compliant with ASHRAE *Standard* 70-2006.

Space Temperature Gradients and Airflow Rates

A fully mixed system creates homogeneous thermal conditions throughout the space. As such, thermal gradients should not exist in the occupied zone. Improper selection, sizing, or placement may

prevent full mixing and can result in stagnant areas, or having high-velocity air entering the occupied zone.

Supply airflow requirements to satisfy space sensible heat gains or losses are inversely proportional to the temperature difference between supply and return air. The following equation can be used to calculate space airflow requirements (at standard conditions):

$$Q = \frac{q_s}{1.2(t_r - t_s)} \quad (1)$$

where

Q = required supply airflow rate to meet sensible load, L/s
q_s = net sensible heat gain in the space, W
t_r = return or exhaust air temperature, °C
t_s = supply air temperature, °C

For fully mixed systems with conventional ceiling heights, the return (or exhaust) and room air temperatures are the same; for example, a room with a set-point temperature of 24°C has, on average, a 24°C return or exhaust air temperature.

Methods for Evaluation

The objective of air diffusion is to create the proper combination of room air temperature, humidity, and air motion to provide thermal comfort and acceptable indoor environmental quality in the occupied zone. There are three recommended methods of selecting outlets for mixed air systems using manufacturers' data:

- By appearance, flow rate, and sound data
- By isovels (lines of constant velocity) and mapping
- By comfort criteria

These selection methods are not meant to be independent. It is the designer's choice as to which to start with, but it is recommended that at least two methods be used for any design.

Variation from accepted thermal limits (ASHRAE *Standard* 55), lack of uniform thermal conditions in the space, or excessive fluctuation of conditions in one part of the space may produce discomfort. Thermal discomfort can also arise from any of the following conditions:

- Excessive air motion (draft)
- Excessive room air temperature stratification (horizontal, vertical, or both)
- Failure to deliver or distribute air according to load requirements at different locations
- Rapid fluctuation of room temperature

Design Procedures

By Appearance, Flow Rate, and Sound Data. For a given appearance, flow rate, pressure drop, and sound level criteria, designers can select outlets from manufacturers' catalogs, using the following steps:

1. Determine air volumetric flow requirements based on load and room size. For VAV systems, evaluation should include the range of flow rates from minimum occupied to design load. Consider both cooling and heating mode requirements.
2. Determine acceptable outlet noise criterion (NC); consult Chapter 49 of this volume, or Chapter 8 in the 2017 *ASHRAE Handbook—Fundamentals*.
3. Locate a range of products from manufacturers' catalogs that meet the airflow and NC requirements. Multiple outlets in a space at the same cataloged NC, and other design considerations, may result in actual sound levels greater than cataloged values. Manufacturers' data are obtained using ideal inlet conditions, and may vary from field installations. From experience,
   - For identical outlets 3 m or more apart, the cataloged NC rating applies.
   - Identical outlets within 3 m of each other add no more than 3 dB to the sound pressure level.
   - For continuous linear outlets, only the sound produced by the closest 3 m need be considered.
4. Select air terminals from manufacturers' catalogs that meet aesthetic and physical needs.

Although these selections may meet the sound requirements for a project, the results do not fully address occupant comfort. Without evaluating the throw of the outlets or room air mixing, this selection method may result in excessive air velocities in the occupied zone, or limited mixing and resultant stagnation. It is recommended that the designer consider selection by isovel mapping or by comfort criteria in addition to selection by appearance, flow rate, and sound

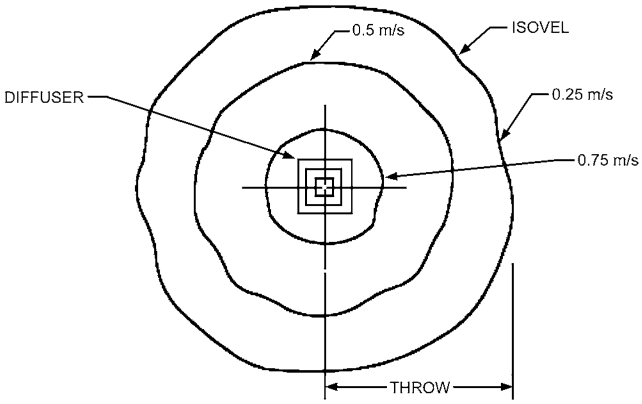

Fig. 3 Throw Isovels at Different Terminal Velocities
(Adapted from ASHRAE *Standard* 70-2006)

data. Either of these methods addresses resulting air motion in the occupied zone and occupant comfort.

Selection by Isovels and Mapping. Using manufacturers' catalog throw data, a designer can predict the path of an outlet's discharge jet. Most manufacturers' catalogs list the distance a jet travels to reach a terminal velocity of 0.75 to 0.25 m/s. With this information, the designer can map the path of the discharge jet for a given outlet. This evaluation can prevent problems such as excessively high air velocities in the occupied zone, or stagnation in a given area. Note that most manufacturers' throw data are based on isothermal supply air; the supply jet temperature is equal to the room air temperature. When using this mapping method, consider the positive or negative buoyancy of nonisothermal (heated or cooled) supply air. In both heating and cooling, a discharge jet should travel the distance shown in the catalog to a terminal velocity of 0.75 m/s without much influence from buoyancy. When evaluating a jet at lower terminal velocities (e.g., 0.5 to 0.25 m/s), consider buoyancy's effect on the distance the jet will travel.

Horizontal Throw. A cooled confined air jet projecting along a horizontal surface travels a shorter distance than the equivalent volumetric isothermal air jet traveling the same path. If an outlet is selected so that the cooled horizontal jet does not have enough velocity to reach a vertical surface, the jet can separate from the horizontal surface and project down into the occupied zone, causing drafts and discomfort.

A heated confined air jet projecting along a horizontal surface travels farther than the equivalent volumetric isothermal jet traveling the same path. If an outlet is selected so that the heated, horizontal jet does not have enough velocity to reach a vertical surface, the jet can pool at the ceiling level, causing stagnation (no mixing) within the occupied space and resulting in high levels of contaminants, thermal stratification, and discomfort.

In a free jet scenario, expect similar results as for a confined jet, but if isothermal performance is based on confined jet installation, a 30% reduction in throw length from isothermal performance will occur, along with buoyancy effects.

Vertical Throw. A cooled air jet projecting vertically upward travels a shorter distance than the equivalent volumetric isothermal air jet traveling the same path. A heated air jet projecting upward travels farther than the equivalent volumetric isothermal air jet traveling the same path. For both cooled and heated air jets, the opposite is true for downward projection.

Combining selection by isovels and mapping with acoustical selection allows discharge jet location and intensity in a space to be predicted. Outlet selection should be evaluated at the space's typical

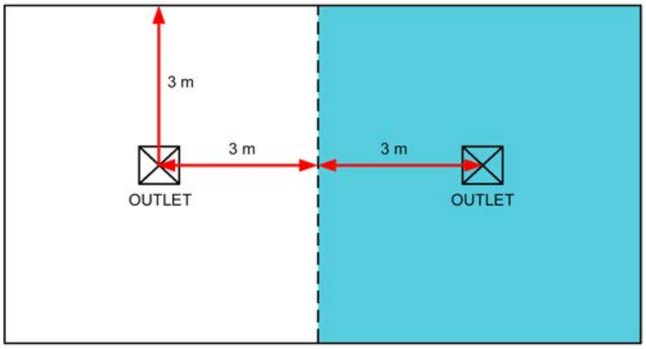

Fig. 4 Schematic for Example 1

operating points (i.e., maximum heating and cooling, and minimum heating and cooling).

The following steps may be used:

1. Identify the occupied zone for the space, as defined by ASHRAE *Standard* 55-2017.
2. Select outlet(s) that meet design NC, pressure drop, and flow rate requirements. Identify the supply jet location using cataloged throw data.
3. Evaluate air jet mapping to ensure terminal velocities in the occupied zone do not exceed 0.25 m/s.
4. For overhead heating applications, $\Delta t \times 8.5$ K (see Chapter 20 of the 2017 *ASHRAE Handbook—Fundamentals*), evaluate the diagram to ensure that jet velocities 1.4 m from the floor are at least 0.75 m/s.

Other design considerations include the following:

- In multiple-outlet applications, jets should not collide to cause a downward projection of air resulting in velocities greater than 0.25 m/s in the occupied zone.
- For VAV applications, consider both minimum and maximum flow conditions.

Example 1. For a 6 by 12 m zone, with a 2.7 m ceiling, with uniform loading of 31.5 W/m^2 or 700 W, and air volumetric flow of 5 L/s per square metre or 378 L/s for a dual-outlet configuration, use isovel mapping to select an appropriate diffuser option that meets a sound criteria of NC 35.

Solution:

1. The occupied zone is defined as a height of 1.8 m off the floor, 0.3 m from interior walls, and 1 m from exterior walls.
   See ASHRAE *Standard* 55 for the most current definition of occupied zone.
2. One manufacturer suggests that a single 0.6 × 0.6 m plaque diffuser with a 0.2 m inlet at 189 L/s yields an NC 30 and an isothermal throw of 3.6 m at a terminal velocity of 0.25 m/s.
3. With an air jet characteristic length of 3 m, and 0.9 m between ceiling and start of the occupied zone, the velocity of the colliding jets can be assumed to not exceed 0.25 m/s in the occupied zone. Verify that resulting diffuser pressure drop and aesthetics meet requirements.
4. If one or more of the walls are exterior in this example, even with additional throw length due to warmer supply air, additional air volume may be required to meet 1.4 m above the floor at 0.75 m/s.

Evaluate other diffuser types for similar or better performance criteria.

Selection by Comfort Criteria $T_{0.25}/L$. Selection by isovels and mapping is effective at predicting the path of the discharge jet from an outlet and evaluating resultant occupant comfort. However, there is an established method to quantify occupant comfort for both cooling and heating conditions, based on space dimensions and isothermal catalog throw data. This method can be used to predict a space's resulting air diffusion performance index (ADPI).

The comfort criteria $T_{0.25}/L$ method was developed to predict occupant comfort using manufacturers' isothermal catalog throw data (T, usually for 0.25 m/s terminal velocity) and the dimensions available for throw L on the plan view of a mechanical drawing. By using the ratio of $T_{0.25}/L$, the designer can predict the level of comfort with a single rating number, ADPI, which can provide further information about the comfort level in a space for results obtained from the NC and mapping selection methods.

Air Distribution Performance Index (ADPI). The air distribution performance index was developed as a way to quantify the comfort level in heating and cooling for a space conditioned by a mixed air system. ADPI uses the effective draft temperature collected at an array of points taken within the occupied zone to predict comfort. ADPI is the percentage of points in a space where the effective draft temperature is between –1.7 and +1.1 K for cooling and –2.2 and +2 K for heating. The acceptable air velocity is less than 0.36 m/s for heating and cooling. In addition, the acceptable vertical temperature gradient should be less than 3 K/m. High ADPI values generally correlate to high space thermal comfort levels with the maximum obtainable value of 100. Selecting outlets to provide a minimum ADPI value of 80 generally results in a well-mixed space.

The effective draft temperature provides a quantifiable indication of comfort at a discrete point in a space by combining the physiological effects of air temperature and air motion on a human body. The effective draft temperature t_{ed} (the difference in temperature between any point in the occupied zone and the control condition) can be calculated using the following equation for the cooling condition, proposed by Rydberg and Norback (1949) and modified by Straub (Straub and Chen 1957; Straub et al. 1956) in discussion of a paper by Koestel and Tuve (1955):

$$t_{ed} = (t_x - t_c) - 8.0(V_x - 0.15) \text{ [Cooling Only]} \qquad (2)$$

where

t_{ed} = effective draft temperature, K
t_x = local airstream dry-bulb temperature, °C
t_c = average (control) room dry-bulb temperature, °C
V_x = local airstream centerline velocity, m/s

Liu and Novoselac (2015) developed an effective draft temperature t_{ed} for the heating condition based on predicted mean vote (PMV) model specified in ASHRAE *Standard* 55. A high vertical temperature gradient occurs during heating when throws are insufficient, resulting in stagnation of supply air and unacceptable ventilation to the breathing zone.

$$t_{ed} = (t_x - t_c) - 9.1(V_x - 0.15) \text{ [Heating Only]} \qquad (3)$$

where

t_{ed} = effective draft temperature, K
t_x = local airstream dry-bulb temperature, °C
t_c = average (control) room dry-bulb temperature, °C
V_x = local airstream centerline velocity, m/s

$T_{0.25}$/L *Selection Method*. This method uses the ratio of cataloged isothermal throw data at 0.25 m/s to the characteristic length for a given device (Table 5).

Each type of diffuser has different performance characteristics and therefore may provide a different ADPI value for the same conditions. Calculating $T_{0.25}/L$ for a given outlet can predict the level of comfort for a space. Using Tables 6A and 6B, the designer can optimize not only the type of diffuser to select but also the size and capacity for both cooling and heating.

Using $T_{0.25}/L$ helps designers maximize space cooling comfort; however, this method is not meant to, nor may it be practical to, evaluate $T_{0.25}/L$ values for each outlet on a project. The design guidelines in Tables 6A and 6B were developed from laboratory experiments in chambers lower than 3 m, with test diffusers symmetrically distributed (Liu and Novoselac 2014; Liu et al. 2016; Miller and Nash 1971). Therefore, attention should be paid to ceiling height of buildings (e.g., airport terminals) or highly asymmetric diffuser layouts. Previously published $T_{0.25}/L$ values at higher cooling loads (60 to 250 W/m^2) are available in previous versions of this chapter and available in the ASHRAE Handbook Online version of this chapter.

Table 5 Characteristic Room Length for Several Diffusers (Measured from Center of Air Outlet)

Diffuser Type	Characteristic Length L
High sidewall grille Adjustable blade Fixed blade Linear bar Nozzle	Distance to wall perpendicular to jet
Horizontal-throw ceiling diffuser Round Square Perforated Louvered Plaque Swirl	Distance to closest wall, midplane between outlets or intersecting air jet
Sill grille	Length of room in direction of jet flow
Ceiling slot diffuser	Distance to wall perpendicular to jet or midplane between outlets
Light troffer diffusers	Distance to midplane between outlets plus distance from ceiling to top of occupied zone

Design Procedures. $T_{0.25}/L$ can be used as a general tool to evaluate cooling comfort levels in a space, at the beginning of design to optimize outlet selection (as shown in the following steps), or at the end of the process to predict comfort levels in spaces designed using NC and mapping methods:

1. Determine air volumetric flow requirements based on load and room size. For VAV systems, evaluation should include both minimum occupied and maximum design flow rates.
2. Select tentative diffuser type and location in room.
3. Determine room's characteristic length L (Table 5).
4. Select recommended $T_{0.25}/L$ ratio from Tables 6A and 6B.
5. Calculate throw distance $T_{0.25}$ by multiplying recommended $T_{0.25}/L$ ratio from Tables 6A and 6B by available length L.
6. Locate appropriate outlet size from manufacturer's catalog.
7. Ensure that this outlet meets other imposed specifications (e.g., noise, static pressure loss).

Example 2. For a 6 by 3.7 m room, with 2.7 m ceiling, with uniform loading of 31.5 W/m^2 or 700 W and air volumetric flow of 5 L/s per square metre or 110 L/s for one outlet, find the size for a 0° deflection horizontal blade, high sidewall grille located at center of 3.7 m end wall, 225 mm from ceiling.

Solution:

1. Constant-volume system, 110 L/s**,** high sidewall grille, located at center of 3.7 m end wall, 225 mm from ceiling
2. Characteristic length L = 6 m (length of room: Table 5)
3. Recommended maximum,

$$T_{0.25}/L = 1.8 \text{ in cooling mode (Table 6A)}$$

$$T_{0.25}/L = 1.6 \text{ in heating mode (Table 6B)}$$

4. Throw to 0.25 m/s,

$$T_{0.25} = 1.8 \times 6 = 10.8 \text{ m in cooling mode}$$

$$T_{0.25} = 1.6 \times 6 = 9.6 \text{ m in heating mode}$$

To satisfy both modes of operation, choose one or find a common throw distance that resides within the overall ADPI range of both modes and base product selection off chosen criteria. Further

evaluation may be required if air volumetric flow changes based on mode of operation.

5. Refer to the manufacturer's catalog for a size that gives this isothermal throw to 0.25 m/s. One manufacturer recommends the following sizes, when vanes are straight, discharging at 110 L/s: 400 by 100 mm, 300 by 125 mm, or 250 by 150 mm.

There are many considerations to be made when designing a fully mixed system. For more information, see Rock and Zhu (2002).

Typical Applications

Horizontal Discharge Cooling with Ceiling-Mounted Outlets. Ceiling-mounted outlets typically use the surface effect to transport supply air in the unoccupied zone. The supply air projects across the ceiling and, with sufficient velocity, can continue down wall surfaces and across floors, as shown in Figure 5. In this application, supply air should remain outside the occupied zone until it is adequately mixed and tempered with room air. Air motion in the occupied zone is generated by room air entrainment into the supply air (Nevins 1976).

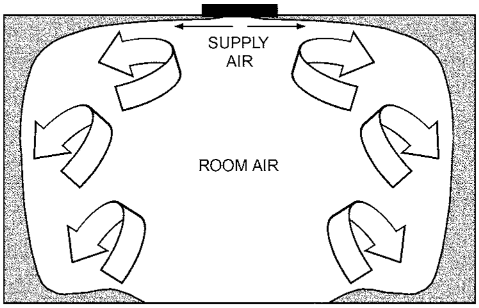

Fig. 5 Air Supplied at Ceiling Induces Room Air into Supply Jet

Overhead outlets may also be installed on exposed ducts, in which case the surface effect does not apply. Typically, if the outlet is mounted 300 mm or more below a ceiling surface, discharge air will not attach to the surface. The unattached supply air has a shorter throw and can project downward, resulting in high air velocities in

Additional data point used to create new regressions for ADPI curves to better represent current diffusers/grilles. Table applies to spaces with maximum 3.7 m ceiling.

the occupied zone. Some outlets are designed for use in exposed duct applications. Typical outlet performance data presented by manufacturers are for outlets with surface effect; consult manufacturers for information on exposed duct applications.

Vertical-Discharge Cooling or Heating with Ceiling-Mounted Outlets. Vertically projected outlets are typically selected for high-ceiling applications that require forcing supply air down to the occupied zone. It is important to keep cooling supply air velocity below 0.25 m/s in the occupied zone. For heating, supply air should reach the floor.

There are outlets specifically designed for vertical projection, and it is important to review the manufacturer's performance data notes to understand how to apply catalog data. Throws for heating and cooling differ and also vary depending on the difference between supply and room air temperatures.

Cooling with Sidewall Outlets. Sidewall outlets are usually selected when access to the ceiling plenum is restricted. Sidewall outlets that are within 300 mm of a ceiling and set for horizontal or a slightly upward projection provide a discharge pattern that attaches to the ceiling and travels in the unoccupied zone. This pattern entrains air from the occupied zone to provide mixing.

In some applications, the outlet must be located 0.5 to 1.25 m below the ceiling. When set for horizontal projection, the discharge at some distance from the outlet may drop into the occupied zone. Most devices used for sidewall application can be adjusted to project the air pattern upwards toward the ceiling. This allows the discharge air to attach to the ceiling, increasing throw distance and minimizing drop. This application provides occupant comfort by inducing air from the occupied zone into the supply air.

Some outlets may be more than 1.25 m below the ceiling (e.g., in high-ceiling applications, the outlet may be located closer to the occupied zone to minimize the volume of the conditioned space). Most devices used for sidewall applications can be adjusted to project the air pattern upward or downward, which allows the device's throw distance to be adjusted to maximize performance.

When selecting sidewall outlets, it is important to understand the manufacturer's data. Most manufacturers offer data for outlets tested with surface effect, so they only apply if the device is set to direct supply air toward the ceiling. When the device is 1.25 m or more below a ceiling, or supply air is directed horizontally or downward, the actual throw distance of the device is typically shorter. Many sidewall outlets can be adjusted to change the spread of supply air, which can significantly change throw distance. Manufacturers usually publish throw distances based on specific spread angles.

Cooling with Floor-Mounted Air Outlets. Although not typically selected for nonresidential buildings, floor-mounted outlets can be used for mixed-system cooling applications. In this configuration, room air from the occupied zone is induced into the supply air, providing mixing. When cooling, the device should be selected to discharge vertically along windows, walls, or other vertical surfaces. Typical nonresidential applications include lobbies, long corridors, and houses of worship.

It is important to select a device that is specially designed for floor applications. It must be able to withstand both the required dynamic and static structural loads (e.g., people walking, loaded carts rolling across). Also, many manufacturers offer devices designed to reduce the possibility of objects falling into the device. It is strongly recommended that obstructions are not located above these in-floor air terminals, to avoid restricting their air jets.

Long floor-mounted grilles generally have both functioning and nonfunctioning segments. When selecting air outlets for floor mounting, it is important to note that the throw distance and sound generated depend on the length of the active section. Most manufacturers' catalog data include correction factors for length's effects on both throw and sound. These corrections can be significant and should be evaluated. Understanding manufacturers' performance data and corresponding notes is imperative.

Cooling with Sill-Mounted Air Outlets. Sill-mounted air outlets are commonly used in applications that include unit ventilators and fan-coil units. The outlet should be selected to discharge vertically along windows, walls, or other vertical surfaces, and project supply air above the occupied zone.

As with floor-mounted grilles, when selecting and locating sill grilles, consider selecting devices designed to reduce the nuisance of objects falling inside them. It is also recommended that sills be designed in a way that prevents their use as shelves.

Perimeter Control Techniques. In many cases, it is advantageous to decouple perimeter and interior supply air sources, especially as new buildings trend toward full glazing exteriors. Often, interior spaces require cooling all year round due to personnel, electronic equipment, and lighting load requirements. Perimeter spaces, however, are more susceptible to the outside environmental conditions and can have major effects on interior space loads if not properly managed.

Heating and Cooling with Perimeter Ceiling-Mounted Outlets. When air outlets are used at the perimeter with vertical projection for heating and/or cooling, they should be located near the perimeter surface, and selected so that the published 0.75 m/s isothermal throw extends at least halfway down the surface or 1.4 m above the floor, whichever is lower. In this manner, during heating, warm air mixes with the cool downdraft on the perimeter surface, to reduce or even eliminate drafts in the occupied space.

If a ceiling-mounted air outlet is located away from the perimeter wall, in cooling mode, the high-velocity cool air reduces or overcomes the thermal updrafts on the perimeter surface. To accomplish this, the outlet should be selected for horizontal discharge toward the wall. Outlet selection should be such that isothermal throw with terminal velocity of 0.75 m/s should include the distance from the outlet to the perimeter surface. For heating, the supply air temperature should not exceed 8.5 K above the room air temperature.

Be conscious of room design. If there are shelves or desks against or near the perimeter surface the high velocity air jet could disturb items on the surfaces or result in drafts.

Perimeter Heating with Floor/Sill-Mounted Outlets. The outlets used in this configuration must be located near the perimeter surface. In heating mode, it is important to select a vertical throws such that it overcomes the down draft produced by a cold perimeter surface. The amount of heat generated from the outlet must be enough to overcome or mix with this down draft airstream to avoid ankle-level draft issues in the occupied space.

3. FULLY STRATIFIED AIR DISTRIBUTION

Fully stratified air distribution systems are characterized by a vertical temperature gradient throughout the space, where the coolest temperature is at the floor level, and the warmest temperature is at the ceiling height. Displacement ventilation (DV) systems are the most common example of a fully stratified air distribution system. DV systems typically use floor or low sidewall (sometimes ceiling-mounted) diffusers delivering low-velocity, cool air across the floor. The low-velocity air, in conjunction with room loads and buoyancy effects, creates the characteristic vertical thermal stratification.

Principles of Operation

DV systems (Figure 6) use very low discharge velocities, with diffusers typically sized to provide outlet velocities between 0.20 and 0.35 m/s. In addition to the low velocity discharge, the temperature of the supply air is also different from a fully mixed system, with temperatures generally above 16°C; lower temperatures may be used in industrial applications, exercise or sports facilities, and transient areas where comfort concerns are minimal. This cool supply air is more dense than the ambient air and drops to the floor after discharge, whether from floor, low sidewall, or ceiling mounted locations, spreading across the lower level of the space (typically less than 0.2 m in height).

As convective heat sources (Figure 6) in the space transfer heat to the cooler air around them, natural convection currents form and rise along the heat transfer boundary. Without significant room air movement, these currents rise to form a convective heat plume (thermal plume) around and above the heat source; as the plume rises, it expands by entraining surrounding air. Its growth and velocity are proportional to the heat source's size and sensible load, as well as the temperature of the ambient air above it. As the plume rises, ambient air from below and around the heat source fills the void. An occupant in a DV system entrains the cool, conditioned air directly into their breathing zone. As the occupant exhales, the spent air, being warmer and more humid than the ambient air, is pulled out of the breathing zone by the rising plume. Convective heat from sources located above the occupied zone has little effect on occupied-zone air temperature.

At a certain height, where plume temperature equals ambient temperature, the plume dissipates and spills horizontally. Two distinct zones are thus formed in the room: a lower occupied zone with little or no recirculation flow (close to displacement flow), and an upper zone with recirculation flow. The boundary between these two zones is often called the **shift zone** (or **stratification height**). The height of this boundary layer between the upper and lower zones is determined based on the convection flow rates of the thermal plumes in relation to the airflow rate supplied by the diffusers. In a DV system, increasing the airflow rate limits stratification and lowers the boundary layer height, with a decrease in airflow providing the opposite effect Actual and simplified representations of the temperature gradient in the space are shown in Figure 6.

DV systems can be modeled as shown in Figure 7. A thin layer of conditioned supply air (typically between 100 and 200 mm) lies adjacent to the floor. Directly above this layer of conditioned air is the lower zone, in which both ambient air temperature and contaminant concentration levels increase with height; this relationship is mostly linear. As the air transitions through the boundary layer, the upper, unoccupied zone contains a pool of warm, used, and/or contaminated air. This upper zone may or may not form, depending on the supplied airflow rate in proportion to the volume of thermal plumes rising through the space.

Space Ventilation and Contaminant Removal

Thermal plumes created by heat sources, in conjunction with thermal stratification within the space, allow DV to be very effective at removing airborne contaminants that are equal to or lighter than the ambient air (e.g., respiratory-produced contaminants, tobacco smoke). The upward momentum of room air created by thermal plumes from heat sources drive an overall upward momentum of air, which displace contaminants out of the breathing zone. This typically results in a concentration of contaminants above the occupied

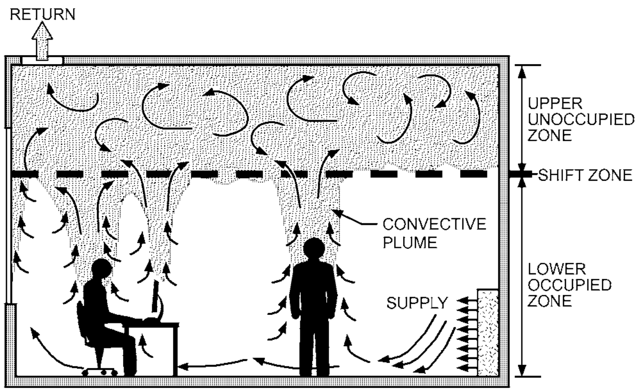

Fig. 6 Displacement Ventilation System

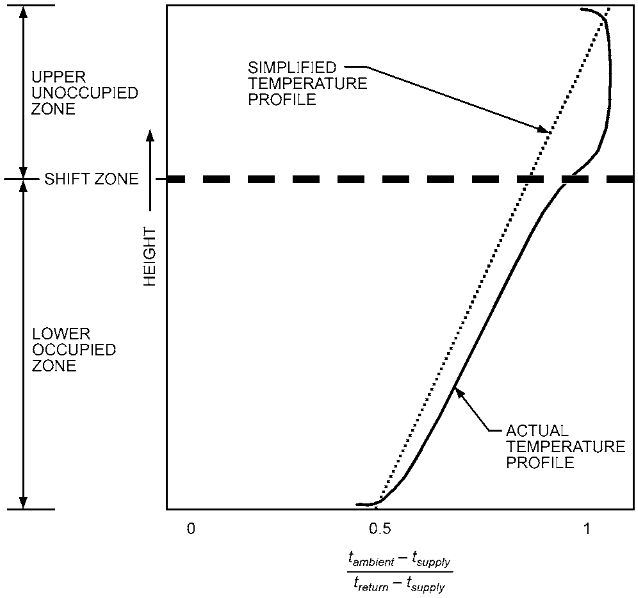

Fig. 7 Temperature Profile of Displacement Ventilation System

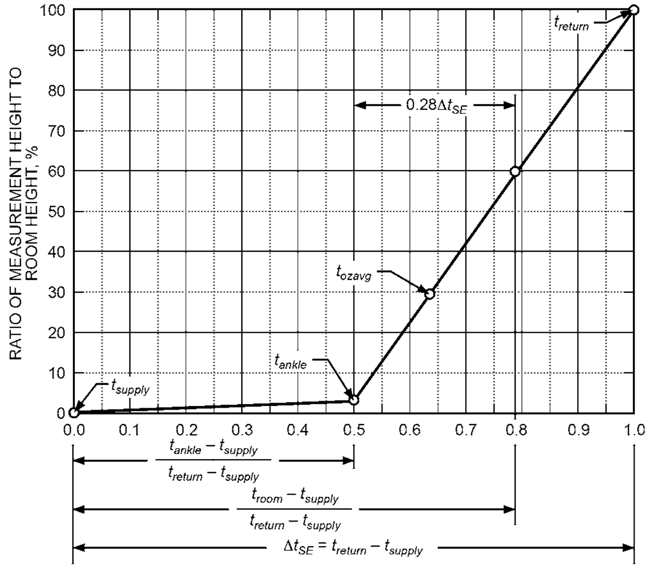

Fig. 8 Temperature Gradient Relationships for Thermal Displacement Ventilation System in Typical Classroom or Office with 3 m Ceiling

zone greater than that in the breathing zone. This has been recognized in ASHRAE *Standard* 62.1-2016, which allows DV systems to have a zone air distribution effectiveness E_Z value of 1.2, compared to maximum values of 1.0 for mixed air systems. Thus, the designer can decrease the required outdoor air by 17% when using a DV system, which may result in energy savings for the system. Care should be taken when selecting DV systems when it is known that there will be airborne contaminants that are heavier than the ambient air. In these systems, a fully mixed system is typically recommended.

Figure 8 shows thermal temperature gradients that might be expected for a classroom with a 3 m ceiling, served by DV. If loads are typical to the application and proper space airflow is supplied, Skistad et al. (2002) indicate that approximately 50% of the total temperature difference between supply air and return or exhaust air is dissipated in clear zone(s) next to the outlet(s). The other half of the temperature gradient is the **space temperature gradient (STG)**, assumed to be linear with air temperature, increasing gradually from floor to ceiling.

For stationary, low-activity occupants, keep supply air temperatures above 16°C. When occupants are very near outlets (e.g., in underseat delivery), it is recommended to keep supply air temperatures at or above 18°C.

Outlet Characteristics

Displacement outlets are designed for average outlet velocities between 0.20 to 0.35 m/s, and are typically mounted in a low sidewall or floor location. Yuan et al. (1999) recommend 0.2 m/s to maintain thermal comfort in the space. Returns or exhausts should be located at a minimum height of 2.75 m to ensure temperature stratification control. Returns or exhausts should be located as high as possible in the space to promote upward momentum of the air, and should efficiently remove as much of the stratified zone as possible; they also should be equally distributed throughout the space to encourage equal air movement and discourage cross flow in the stratified zone. Intensive heat sources may benefit from having returns located directly above them to quickly remove generated heat from the room.

Displacement outlets are available in a number of configurations and sizes. Some models are designed to fit in corners or along sidewalls, or stand freely as columns. It is important to consider the degree of flow equalization the outlet achieves, because use of the entire outlet surface for air discharge is paramount to minimizing clear zones and maintaining acceptable temperatures at the lower levels of the space.

Stationary occupants should not be subjected to discharge velocities exceeding around 0.25 m/s because air at the ankle level within this velocity envelope tends to be quite cool. As such, most outlet manufacturers define an **adjacent zone** (also called a **clear zone**) in which locating stationary, low-activity occupants is strongly discouraged, but transient occupancy, such as in corridors or aisles, is allowed. Occupants with high activity levels may also find the clear zone acceptable.

For a typical space, a single displacement diffuser can penetrate around 8 to 9 m. Spaces that are wider than this or have high load densities should look at providing displacement diffusers on multiple walls, or free standing (e.g., around columns) for even airflow distribution. A computational fluid analysis (CFD) may be warranted for more complex spaces to validate the design. Contact the diffuser manufacturer for further diffuser selection assistance.

Benefits and Limitations

Benefits of displacement ventilation systems include the following:

- **Flexibility:** as load distribution changes in the space, the buoyancy forces drive/pull where the conditioned air will go. Thus, a DV system can work effectively in an evenly distributed load space, as well as a space with concentrated loads. A mixing system may cause drafts, or have stagnant zones in similar loading circumstances.
- **Low noise:** due to the low velocities associated with DV diffusers, the generated noise is typically very low (<20 NC for most applications).
- **Fewer drafts:** lower turbulence intensity can reduce draft-related complaints.
- **Indoor air quality improvements:** properly designed DV systems displace higher concentrations of contaminants above the occupied zone than in the breathing zone.
- **Energy savings:** due to a supply air temperature typically above 16°C (more typically 18°C), significantly less energy may be used

in certain climates due to an increase in free cooling hours. Less outdoor air is required to meet ASHRAE *Standard* 62.1 requirements, meaning less outdoor air needs to be conditioned.

Some applications do not favor use of DV systems. Small offices, especially with perimeter exposures, often do not have room for the large outlets that may be required. The following types of areas may be better served by a mixed system:

- Spaces with ceiling heights less than 2.7 m
- Some spaces with exceptionally high occupied zone heat loads.
- Spaces in hot and humid climates that may result in higher dehumidification and reheat energy usage
- Spaces with ceiling heights below 3 m that are subjected to significant room air disturbances
- Applications where contaminants are heavier and/or colder than ambient air.

Methods of Evaluation

Unlike mixed systems, outlets in thermal displacement systems discharge air at very low velocities, resulting in very little mixing. As such, design of these systems primarily involves determining a supply airflow rate to manage the thermal gradients in the space in accordance with ASHRAE comfort guidelines. ASHRAE *Standard* 55 recommends that the vertical temperature difference between the ankle and head levels of standing occupants be no more than 3 K to maintain a high degree (>95%) of occupant satisfaction.

Inlet Conditions

Similar to mixing system diffusers, inlet conditions (including presence of dampers, elbows, flex duct, etc.) can have a negative effect on performance, primarily noise (NC) and pressure drop. Inlet conditions should match ASHRAE *Standard* 70 testing conditions as closely as possible to mimic catalogue performance data. DV diffusers are typically designed with internal baffles or nozzles, which should not be affected by inlet conditions at relatively low plenum velocities.

Design Procedures

DV system design is somewhat different than for mixing ventilation. For mixing ventilation systems, where air is mixed relatively evenly throughout the space, the return/exhaust air temperature is assumed to equal the space temperature. In displacement ventilation systems, the space is divided into two vertical zones. The desired space air temperature is maintained only in the lower zone and is always higher in the upper zone because of the temperature stratification created by natural convection.

ASHRAE research project RP-949 (Chen et al. 1999) developed a calculation method for determining supply air volume, air temperature, and other design parameters specifically for DV systems. Using these calculations, the maximum temperature stratification, as outlined in ASHRAE *Standard* 55, is not exceeded. Example 4 uses the calculations outlined in RP-949 and the procedure presented by Chen & Glicksman (2003). This research project is intended for use with typical office and classroom spaces; for larger spaces such as atriums and theaters, careful consideration is necessary, and a computational fluid dynamic (CFD) analysis is recommended to verify design. The Federation of European Heating and Air Conditioning Associations (REHVA) also developed two procedures for calculation of air volume in DV systems; see the REHVA design guide for further information on these methods.

Example 4. Determine the supply air temperature, supply air flow rate, and face area for a displacement diffuser for a small office room (3 × 4 × 3 m) with the following characteristics:

q_o = occupant load, 150 W
q_e = computer/equipment load, 90 W
q_{oe} = $q_o + q_e$ = 240 W
q_l = lighting load, 250 W
q_{ex} = exterior load, 130 W
$t_{set\ point}$ = 22°C

Step 1. Determine total cooling load:

$$q_t = q_{oe} + q_l + q_{ex} = 240 + 250 + 130 = 620 \text{ W}$$

Step 2. Determine airflow rate to meet cooling load. ASHRAE RP-949 (Chen et al. 1999) allows applying factors to each heat load based on how much they contribute to room stratification:

$$Q_{DV} = \frac{0.295q_{oe} + 0.132q_l + 0.185q_{ex}}{1000\rho c_p \Delta t_{hf}} \tag{4}$$

$$Q_{DV} = \frac{0.295(240) + 0.132(250) + 0.185(130)}{1000(1.005)(1.225)(3)} = 0.035 \text{ m}^3\text{/s} = 35 \text{ L/s}$$

where

c_p = specific heat, 1.005 kJ/kg·K
ρ = density of air, 1.225 kg/m³
Δt_{hf} = maximum head-to-foot temperature differential for a standing occupant, 3 °C (per ASHRAE *Standard* 55-2017)

Step 3. Determine minimum outdoor air requirement per ASHRAE *Standard* 62.1-2013:

$$Q_{oz} = \frac{R_p P_z + R_A A_z}{E_z} \tag{5}$$

$$Q_{oz} = \frac{(2.5)(2) + (0.3)(3 \times 4)}{1.2} = 7.2 \text{ L/s}$$

where

R_p = outdoor air rate per person, 2.5 L/s-person per ASHRAE *Standard* 62.1-2013
P_z = zone population (number of people in zone during typical usage), 2
R_a = area outdoor air rate, 0.3 (L/s)·m² per *Standard* 62.1
A_z = zone floor area, 12 m²
E_z = ventilation effectiveness, 1.2 (per *Standard* 62.1 for DV systems)

Therefore, the total supply air volume Q_s for cooling is determined by the cooling load and is 35 L/s.

Step 4. Calculate supply air temperature. The following formula assumes thermostat is located 1 m from the floor:

$$t_s = t_{sp} - \Delta t_{hf} - \frac{A_z q_T}{0.584Q_{DV}^2 + 1.208AQ_s} \tag{6}$$

$$t_s = 22 - 3 - \frac{(12)(620)}{(0.584)(35)^2 + (1.208)(12)(35)} + 12.9°\text{C}$$

Step 5. Determine return air temperature:

$$t_r = t_s + \frac{q_T}{1.208Q_s} \tag{7}$$

$$t_r = 12.9°\text{C} + \frac{620}{(1.208)(35)} + 27.6°\text{C}$$

Step 6. Adjust airflow for new supply temperature. DV systems typically use warmer supply air temperatures than mixing systems. The supply air temperature should be at least 17°C, or 5.5 K less than the room set point, whichever is higher. Supply airflow should maintain the same return temperature:

$$t_s = 17°\text{C}$$

$$Q_S = \frac{q_t}{60\rho c_p(t_r - t_s)} \tag{8}$$

$$Q_s = \frac{620}{1000(1.005)(1.225)(27.6 - 12.9)} = 0.0343 \text{ m}^3/\text{s} = 34 \text{ L/s}$$

Therefore, in order to condition this particular office using a DV system, it is necessary to deliver 17°C, air at an airflow rate of 34 L/s.

Step 7. Size diffuser. Yuan et al. (1999) recommend a maximum diffuser face velocity of 0.2 m/s to obtain acceptable thermal comfort. This recommendation is based on the nominal diffuser size.

$$A_{diffuser} = \frac{Q_s}{0.2} \tag{9}$$

$$A_{diffuser} = \frac{34}{0.2 \times 1000} = 0.170 \text{ m}^2$$

A single diffuser that is 300 × 600 mm will meet this minimum area requirement to maintain comfort. Check with the manufacturer's performance data to ensure diffuser selection meets noise and comfort requirements.

Space temperature gradient (STG) is affected by the strength and location of heat sources in the space, heat exchange by radiation between surfaces in the space, and supply airflow. The design procedure presented in this section is based on Skistad et al.'s (2002) simplified method of estimating temperature gradient (Figure 8). This method is applicable for typical spaces with a ceiling height up to 3.7 m, such as classrooms, office spaces, and meeting rooms. When designing more complex spaces, computational fluid dynamics (CFD) software programs may be used (see Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals* for more information).

The thermal gradient relationships illustrated in Figure 8 can be used to establish an acceptable supply-to-return air temperature differential Δt_{SR} from which the supply airflow rate is calculated. Because the space temperature gradient is assumed to be linear, the occupied gradient in the occupied zone is proportional to the volume of the space it represents. For example, if return height is 3 m and the occupied zone is 1.5 m high, its gradient comprises 50% of the space temperature gradient, or 25% of Δt_{SR}. The temperature difference between room air at the top of the occupied zone and the supply air is therefore 75% of Δt_{SR}.

Determining an acceptable Δt_{SR} should consider both the room-to-supply temperature differential and the occupied zone temperature gradient (as limited to 3 K by ASHRAE *Standard* 55).

In general, high-ceiling applications allow larger supply-to-return air temperature differentials, because the occupied zone is a smaller percentage of total room air volume. However, the differential may be reduced by limitations on supply air temperature, as shown in Example 5.

The supply airflow rate Q to achieve Δt_{SR} is calculated from Equation (1).

Example 5. A classroom with a 3 m ceiling is to be cooled by displacement ventilation. The supply air temperature is 16.5°C and room temperature is maintained at 24°C at 1.5 m level. The total sensible heat gain of the space is 8200 W.

Calculate the (1) overall temperature differential between supply and return airflow and (2) required space airflow. Identify return air temperature and temperature at occupants' ankle level.

Solution: Using the relationships in Figure 8, the supply-to-return temperature differential Δt_{SR} and return air temperature can be predicted as follows:

$$\Delta t_{SR} = (t_{room} - t_{supply})/0.75 = (24 - 16.5)/0.75 = 10 \text{ K} \tag{10}$$

$$t_{return} = t_{supply} + \Delta t_{SR} = 16.5 + 10 = 26.5°\text{C} \tag{11}$$

To ensure a high level of thermal comfort, the occupied-zone temperature gradient Δt_{oz} should not exceed 3 K. For this application, the occupied zone gradient is acceptable:

$$\Delta t_{oz} = \Delta t_{SR} \times 0.25 = 10 \times 0.25 = 2.5°\text{C}$$

From Equation (1), the airflow required to maintain this gradient is

$$Q = 8200/(1.2 \times 10) = 683 \text{ L/s}$$

Typical Applications

Thermal displacement ventilation systems typically have higher return air temperatures than mixed systems. Thus, they may allow extended periods of air- or water-side economizer operation, especially in mild, relatively dry climates.

Thermal displacement ventilation systems are commonly used in applications such as

- Restaurants
- Casinos
- Classrooms/education facilities
- Large open-plan offices, classrooms, lecture halls, and meeting rooms
- Theaters and auditoriums
- Industrial spaces
- Hospitals and cleanrooms
- Other spaces with high ceilings

Perimeter Control

DV systems rely on buoyancy of the cool supply air and thermal plumes of the heat sources to drive stratification in the space. Due to this, DV is typically a cooling-only method of room air distribution. When heating is required, the warmer (more buoyant) air, in conjunction with the low discharge velocity, can mean that the air may not effectively condition the occupied zone, or may completely bypass the occupied zone to the returns. This can have a negative effect on both the thermal comfort and indoor air quality in the space. Limited heating differentials may be acceptable depending on a number of factors. ASHRAE research project RP-1373 (Jiang and Chen 2009) explores the ventilation effectiveness of DV systems in heating and cooling scenarios.

For heating, either a displacement diffuser with integrated heating or a separate system is generally recommended. Displacement ventilation can be used successfully in combination with perimeter fan coils, hydronic systems, or radiators and convectors installed at exterior walls to offset space heat losses. Radiant heating panels and heated floors can also be used. Using this hybrid approach, the DV diffusers can provide isothermal ventilation air, with the auxiliary devices handling the heating load.

Displacement diffusers with integrated heat typically have a separate heating plenum featuring a heating coil and are often used for perimeter applications. Heat/cool changeover diffusers can also be used. For this design, the heating portion of the diffuser may not provide a displacement pattern, so care should be taken to ensure proper ventilation effectiveness.

Care is also needed when using DV systems in high perimeter cooling load applications. DV diffuser mounting locations should be carefully considered to minimize the risk of conditioned air being drawn toward the strong thermal plume of the exterior surface. It may be better to place diffusers along an interior surface to ensure that the conditioned air reaches interior occupants before conditioning the exterior envelope loads.

Considerations Unique to Displacement Ventilation Systems

It is often beneficial to couple DV systems with hydronic products. As Yuan et al. (1999) state, a maximum of 120 W/m² hydronic products can be used to increase capacity of the system. Another common application is to use DV systems to only provide ventilation air, while the hydronic system satisfies the cooling load. It is important that the hydronic product used be passive, and not active: an active product will disrupt the natural stratification of the DV system.

When thermal displacement systems are used in humid climates, it may be necessary to dehumidify and possibly reheat supply air to maintain desired space conditions. As with all HVAC air systems' design, a psychrometric analysis is advised.

Thermal displacement ventilation systems can be either constant or variable air volume. A thermostat in a representative location in the space or return plenum should determine the delivered air volume or temperature. If the time-averaged requirements of ASHRAE *Standard* 62.1 are met, intermittent on/off airflow control can be used.

Avoid using DV and mixed air systems in the same space, as mixing destroys the natural stratification that drives the thermal displacement ventilation system. DV systems can be complemented by hydronic systems such as chilled floors. Use caution when combining chilled ceilings, beams, or panels with fully stratified systems, because cold surfaces in the upper zone of the space may recirculate contaminants stratified in the upper zone back into the occupied zone.

Chen and Glicksman (2003) provide additional information on fully stratified air distribution systems.

4. PARTIALLY MIXED AIR DISTRIBUTION

A partially mixed system's characteristics fall between a fully mixed system and a fully stratified system. It includes both a high-velocity mixed air zone and a low-velocity stratified zone where room air motion is caused by thermal forces. For example, floor-based outlets, when operating in a cooling mode with relatively high discharge velocities (>0.75 m/s), create mixing, thus affecting the amount of stratification in the lower portions of the room. In the upper portions of the room, away from the influence of floor outlets, room air often remains thermally stratified in much the same way as displacement ventilation systems.

Principles of Operation

Supply air is discharged, usually vertically, at relatively high velocities and entrains room air in a similar fashion to outlets used in mixed air systems. This entrainment, as shown in Figure 9, reduces the temperature and velocity differentials between supply and ambient room air. This discharge results in a vertical plume that rises until its velocity is reduced to about 0.25 m/s. At this point, its kinetic energy is insufficient to entrain much more room air, so mixing stops. Because air in the plume is still cooler than the surrounding air, the supply air spreads horizontally across the space, where it is entrained by rising thermal plumes generated by nearby heat sources.

Research and experience have shown that the amount of room air stratification varies depending on design, commissioning, and

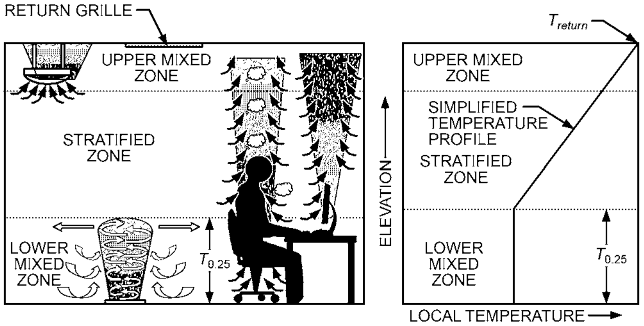

Fig. 9 UFAD System in Partially Stratified Application

operation. Control of stratification includes the following considerations:

- By reducing airflow and mixing in the occupied zone, fan energy can be reduced and stratification can be increased, approaching a reasonable target at 1.5 to 2.5 K temperature difference from head level to ankle level, which satisfies ASHRAE *Standard* 55-2017.
- By increasing airflow and mixing in the occupied zone, excessive stratification can be avoided, thereby improving thermal comfort.

In practice, successful installation requires an optimal balance of these issues (Webster and Bauman 2006).

Figure 9 shows one example of the resulting room air distribution in which the room air is mixed in the **lower mixed zone**, which is bounded by the floor and the elevation (**throw height**) at which the 0.25 m/s terminal velocity occurs. At this elevation, stratification begins to occur and a linear temperature gradient, similar to that found in thermal displacement systems, forms and extends through the **stratified zone**. As with thermal displacement ventilation, convective heat plumes from space heat sources draw conditioned air from the lower (mixed) level through the stratified zone and to the overhead return location. A third zone, referred to as the **upper mixed zone**, may exist where the volume of rising heat plumes terminate. Although velocities in this area are quite low, the air tends to be mixed.

Space Ventilation and Contaminant Removal

Partially mixed systems' ventilation and contaminant removal efficiencies vary considerably. Restricting mixed conditions to below the breathing level results in most respiratory-associated contaminants being conveyed directly to the overhead return by heat plumes rising from occupants. If the lower mixed zone extends above the breathing level, contaminants are entrained and horizontally transmitted across occupied levels of the space, as occurs in mixed air (dilution ventilation) systems.

According to ASHRAE *Standard* 62.1, these systems may have zone air distribution effectiveness E_Z values that exceed those of fully mixed systems.

Outlet Characteristics

One outlet type is a **swirl diffuser** with a high-induction core, which induces large amounts of room air to quickly reduce supply to ambient air velocity and temperature differentials. Supply air is injected into the room as a swirling vertical plume close to the outlet. Properly selected, these outlets produce a limited vertical projection of the supply air plume, restricting mixing to the lower portions of the space. Most of these outlets allow occupants to adjust the outlet airflow rate easily. Other versions incorporate automatically controlled dampers that are repositioned by a signal from the space thermostat and/or central control system.

Another category includes more conventional **floor grilles** designed for directional discharge of supplied airflow. These grilles may be either linear or modular in design, and may allow occupants to adjust the discharge air pattern by repositioning the core of the outlet. Most floor grilles include an integral actuated damper or other means to automatically throttle the volume of air in response to the zone conditioning requirements.

Room air induction allows UFAD diffusers to comfortably deliver supply air a few degrees cooler than possible with outlets used for thermal displacement ventilation outlets. Keeping clear or adjacent zones above and around the diffusers, where stationary occupants should not reside, is recommended. Outlet manufacturers typically identify such restrictive areas in their product literature.

Typical Applications

Partially mixed systems are commonly used in applications such as the following:

- Office buildings with raised floors
- Call centers
- Libraries
- Casinos
- Other spaces with open or high ceilings

Many UFAD systems can be classified as partially mixed systems. These systems are popular because of their relocation flexibility when used in conjunction with raised-access flooring systems. Outlet accessibility also allows easy occupant adjustment of space airflow delivery. The cavity beneath the access floor tiles is generally pressurized and used as a supply air plenum. Supply outlets placed in access floor tiles are commonly tapped directly into the pressurized plenum, but may be ducted from a fan-assisted terminal unit mounted beneath the floor.

Benefits and Limitations

Benefits of UFAD systems include the following:

- Using a raised floor system may substantially reduce air distribution ductwork and terminal requirements.
- Possibility of lowering deck-to-deck dimensions.
- Central fan energy consumption may be lower.
- The space service flexibility of the access floor platform is extended to include HVAC services as well. Nonducted outlets can be easily added or relocated.
- Because most outlets are sized to handle loads typical to an interior single-occupant office or workstation, they can be placed within the workstation to give occupants thermal control over their individual work environment. This makes higher individual occupant comfort levels possible.
- Air- and water-side economizer opportunities are extended, especially in mild and relatively dry climates.

Limitations to consider are

- Applications where contaminants are heavier and/or colder than ambient air may be better served by a mixed air system.
- As with thermal displacement systems, partially stratified systems in humid climates require that outdoor air be sufficiently dehumidified to satisfy space latent requirements. The temperature of dehumidified air must often be increased before introduction to the occupied space.
- Uncontrolled air can leak from pressurized underfloor plenums. Proper design and installation can minimize or eliminate this.
- Plenum air temperature can degrade in relation to distance traveled from the supply air source.

Methods of Evaluation

As with thermal displacement systems, design involves determining a supply airflow rate that limits thermal gradients in the occupied zone in accordance with ASHRAE *Standard* 55 guidelines; that is, the vertical temperature difference between the ankle and head level of space occupants should be no more than 3 K if a high degree (>95%) of occupant comfort is to be maintained.

Inlet Conditions

UFAD systems usually pressurize the open plenum space under the access floor, this way the diffusers do not need to have an inlet. If linear floor diffusers with plenum boxes are utilized, they are usually made with very large rectangular inlets that are the same size as the linear length of those plenums. For ducted installations, use the same inlet criteria as the other air distribution systems.

Design Procedures

The design of partially mixed air distribution systems requires identifying both thermal and contaminant removal objectives:

- The desired space temperature, the elevation to which it applies, and an appropriate supply air temperature must be identified.
- The supply air temperature for UFAD systems served by a pressurized or neutral pressure floor plenum should be limited to that which results in a relative humidity level below 80% in the floor cavity, to minimize the threat of mold or fungus growth.
- Supply air temperatures tend to rise as air moves through the floor cavity; therefore, supply air temperature varies with its distance traveled. When determining space airflow requirements, supply temperatures should be modified accordingly to avoid undercooling the occupied space. This subject is discussed further in ASHRAE's *UFAD Guide* (2013).
- If the objective is to provide displacement ventilation of respiratory contaminants in the stratified zone, mixing must be limited to below the breathing level of most space occupants.
- Outlets should be located far enough from stationary occupants to ensure that they are not subjected to drafts that might cause thermal discomfort. Outlet manufacturers generally prescribe clear zones that quantify this separation distance.

Perimeter Control

There are several ways to provide perimeter air distribution using a partially mixed air system. Air distribution in the perimeter zone is highly influenced by weather and solar loads at the building envelope; this means that different amounts of cooling or heating may be needed at different times, independent of interior zone load needs. The most common scenario is when cooling is needed at the interior zone and heating is needed at the perimeter zone; both internal and perimeter loads can be met using a zone divider or a dedicated plenum system. See ASHRAE (2013) for more information on how to handle perimeter zone applications.

Space Temperature Gradients and Airflow Rates

The objective of partially mixed systems is to condition the air in the occupied zone while allowing stratification to naturally occur. By allowing this stratification, some of the space heat gain can be removed by return or exhaust instead of by supply air delivery to the space. If the supply airflow rate and sensible heat gains affecting the lower zone are balanced, an acceptable temperature gradient (<3 K) can be achieved in the occupied zone. Supply airflow beyond that required by these heat gains reduces the degree of stratification shown in Figure 9. If the supply airflow rate is insufficient, excessive vertical space temperature gradients may occur.

Accurate calculation of the space design supply airflow rate requires analysis of all space sensible heat gains to determine their contribution to the lower zone. Although there is not yet a single recognized procedure for calculating these airflow rates, most UFAD equipment manufacturers offer guidance.

Considerations Unique to Underfloor Air Distribution Systems

The ASHRAE *UFAD Guide* (2013) includes a thorough discussion of issues involved in the design, application, and commissioning of UFAD systems. Some considerations include the following:

- Supply temperatures in the access floor cavity should be kept at 16°C or above, to minimize the risk of condensation and subsequent mold growth.
- Most UFAD outlets can be adjusted automatically by a space thermostat or other control system, or manually by the occupant. In the latter case, outlets should be located within the workstation they serve.
- Use of manually adjusted outlets should be restricted to open office areas where cooling loads do not tend to vary considerably or frequently. Perimeter areas and conference rooms require

automatic control of supply air temperatures and/or flow rates because their thermal loads are highly transient.

- Heat transfer to and from the floor slab affects discharge air temperature and should be considered when calculating space airflow requirements. Floor plenums should be well sealed to minimize air leakage, and exterior walls should be well insulated and have good vapor retarders. Night and holiday temperature setbacks should likely be avoided, or at least reduced, to minimize plenum condensation and thermal mass effect problems. With air-side economizers, using enthalpy control rather than dry-bulb control can help reduce hours of admitting high-moisture-content air, thus also reducing the potential for condensation in the floor plenums.
- Avoid using stratified and mixed air systems in the same space, because mixing destroys the natural stratification that drives the stratified system.
- Return static pressure drop should be relatively equal throughout the spaces being served by a common UFAD plenum. This reduces the chance of unequal pressurization in the UFAD plenum.

5. AIR DISPERSION SYSTEMS

Principles of Operation

The design methodologies provided in this section cover textile air dispersion systems, though the same principles can be applied to systems constructed with metal. Textile air dispersion systems are low pressure extended plenum systems with pressurized tubing and air distributed along the path of least resistance. Suggestions are provided for material selection and dispersion style, support and structure of the textile air dispersion system, and sizing/venting locations of the system. Consult with the manufacturer and specific product data and performance information when designing and specifying textile air dispersion systems.

These systems can also be found designed into the plenum space of raised floor applications. In these applications, the designer must consider that the system is exposed in the space that it is conditioning and delivering air to. Air outlet throws of the textile air dispersion system must be designed for the plenum space in which they are located.

Air Dispersion System Supply Air Outlet Styles

Various supply air outlet styles are available: porous fabric weave used as an outlet, microperforations, linear vents, orifices, and nozzles. Many of these air outlet styles can be used together to achieve specific results.

Porous Fabric Weave (Figure 10). Air is delivered through the weave of the fabric. This can result in air velocities of less than 0.15 m/s at the material surface. The ability to achieve such a low face velocity makes this the preferred dispersion style where displacement ventilation is needed. This dispersion style is ideal for food processing, cleanrooms, and laboratory environments where elimination of drafts and uniform air distribution is required, and can be used in combination with other types of air outlets to achieve the specified room airflow. Cool air drops to the floor and then spreads across the lower level of the space.

Porous fabric ducts can be used in combination with most linear vents and orifice applications. Air throw distance is generally lower than with linear vents, and may not be appropriate for heated supply air applications.

Microperforation Outlets (Figure 11). Air is delivered through laser-cut microperforations, generally smaller than 0.4 mm. As with porous fabric, air velocities of less than 0.15 m/s can be realized 0.61 m from the duct. Microperforations offer low-velocity distribution in the occupied zone without forcing the majority of the air through the weave of the material. Further, the microperforations can be uniformly located along 360°, or within a specific area or side of the air dispersion device, allowing designers to disperse air exactly where it is needed. This method can be used for displacement ventilation and isothermal/makeup air, but is limited for heating applications (when using directed microperforations for heating, consult manufacturer for throw data). This dispersion style is also ideal for food processing, cleanrooms, and laboratory environments where elimination of drafts and lower-velocity air is required. Cool air can be more evenly distributed in the space using directed microperforations rather than dropping or "dumping" due to buoyancy, directly below the diffuser. Microperforations can be used in combination with most other flow models to modify throw and velocity to meet design requirements.

Linear Vent Outlet (Figure 12). Air is delivered through a linear vent outlet, which generally consists of many small outlets in a linear pattern. This provides uniform airflow with throw suitable for commercial and retail spaces, schools, and theaters. Generally, medium air throw distance can be achieved.

Orifice and Nozzle Outlets (Figure 13). Air is delivered through orifices or venturi-shaped nozzles providing jet-type air distribution for applications such as gymnasiums, pools and manufacturing facilities. This style generally has a higher air throw distance than other outlet styles. Nozzles can direct air perpendicularly away from the surface of the duct. Adjustable nozzles allow for changing the direction and/or flow rate and throw. Nozzles generally have the least entrainment of longer-throw outlets. Manufacturers have many specific options for this style of air outlet, and the manufacturer's data must be consulted.

Air Dispersion System Shapes

Three shapes are commonly available: cylindrical, half circle (D-shape), and the quarter circle, as shown in Figure 14. Cylindrical

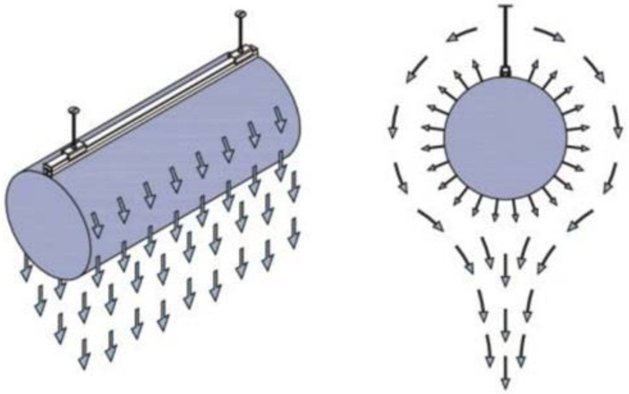

Fig. 10 Porous Fabric Weave Used as Outlet

Fig. 11 Microperforations Used as Outlet

systems are typical for open ceiling spaces and are mounted using a tension cable or suspended aluminum track suspension system. The half circle can be installed against a ceiling or wall. Manufacturers also have many custom shapes that can be used to solve installation challenges.

Material Selection

Air dispersion system ducts, classified by Underwriters Laboratories as an air distribution device, should have a Class 1 rating per UL *Standard* 723. The maximum flame spread/smoke developed index is currently 25/50.

Additional important properties in selecting a material for air dispersion systems are durability and aesthetics. Durability includes not only the environment, but the design. Supports and static pressure must hold fabric air dispersion system materials in tension to prevent fabric wear and tear. The maximum velocity in a system should not exceed the manufacturer's rated velocity; excessive air velocities cause fabrics to fail prematurely. The *International Mechanical Code*® (ICC 2018) and the *Uniform Mechanical Code* (IAPMO 2018) require that air dispersion systems be listed and labeled in compliance to UL *Standard* 2518.

The use of a slightly permeable material allows dispersion of air below dew point without the risk of condensation forming on the fabric air dispersion system. The duct is pressurized, and air is forced through the surface of the material, forming an insulating barrier of cooler air around the duct, preventing warm moist air from contacting the cold surface of the air dispersion system and thereby preventing water droplets from forming on the surface. The permeated air is often induced by outlets on the system and entrained into the supply air exiting the outlets.

Nonpermeable materials can be used where risk of condensation is low and applied in a way similar to uninsulated single wall metal ducts. These are often used in dryer climates or for extensive systems.

Polyester is typically the preferred material for fabric air dispersion systems because it has very low hygroscopic properties, is a

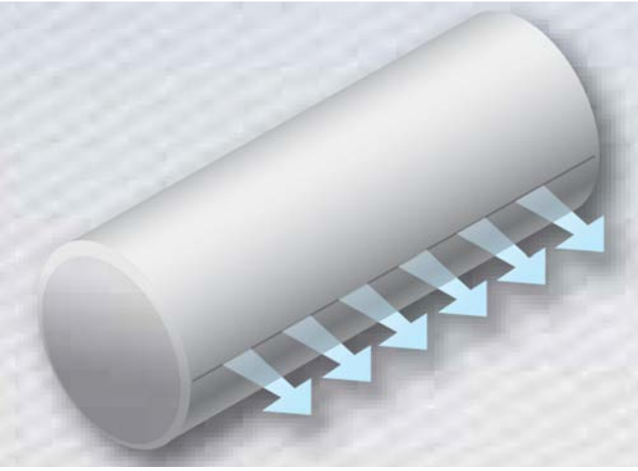

Fig. 12 Fabric with Linear Vent Outlet

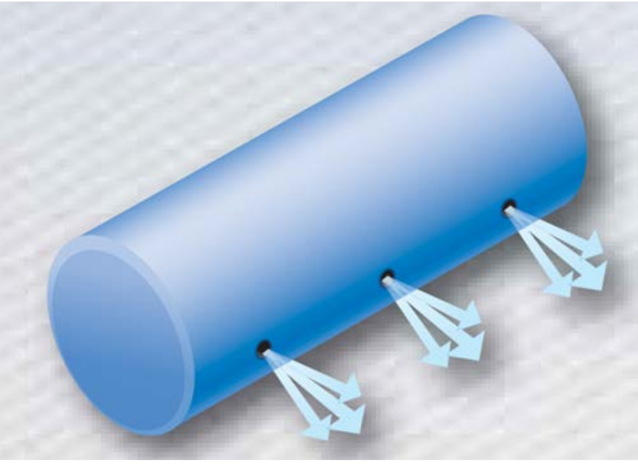

Fig. 13 Fabric with Orifice Outlets

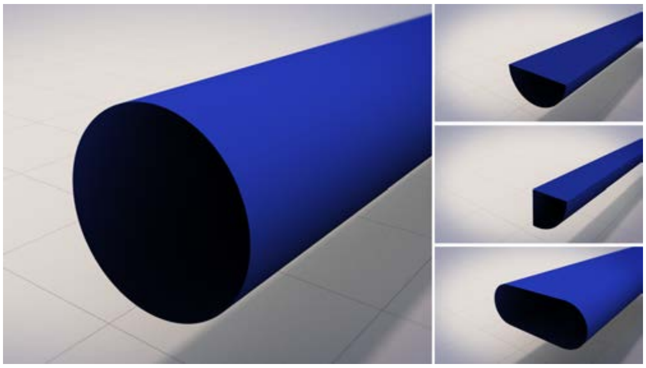

Fig. 14 Common Shapes of Air Dispersion Systems

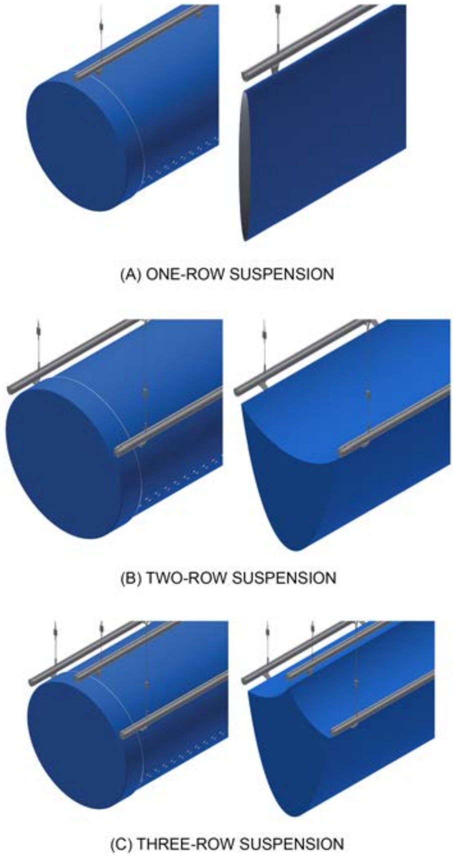

Fig. 15 Inflated and Deflated Suspension System

synthetic material that is not a food source for organisms, and is easy to launder. Several manufacturers offer materials with complementary properties, such as antimicrobial treatment (to prevent microbial growth), antistatic for use around sensitive electronics and in explosion proof facilities, and fabrics that do not "shed" filament particles for use in cleanrooms and critical laboratories.

Suspension Systems

Textile air dispersion system manufacturers offer many different types of suspension systems to address the various applications in which they are used (Figure 15). Typical types include

- Clips sewn to the top of the air dispersion system and clipped onto a tensioned horizontal cable
- Sliders or continuous keder cord sewn to the top of the air dispersion system and slid into a metal track (the track could be mounted directly to the ceiling or suspended a distance below it)
- Sliders or continuous keder cord sewn to the top corners of a half or quarter circle air dispersion system and slid into a metal track (the track could be mounted directly to the ceiling or suspended a distance below it)
- Direct suspension from an internal frame system

Hold-Open and Fabric Retension Systems (Figure 16). Textile air dispersion systems can also be held open (restricting their potential to collapse onto themselves when the HVAC unit is not providing airflow) with rings, hoops, and arcs.

Fabric Tension Systems (Figure 17). Fabric tensioning systems hold the fabric in place regardless of whether the system is pressurized. These systems increase fabric longevity by reducing movement of the fabric. Some hold the fabric in such a way that air velocities in the product can be increased to a higher maximum (which results in smaller diameter sizes) without the fabric wall being unstable and fluttering, which could lead to premature failure.

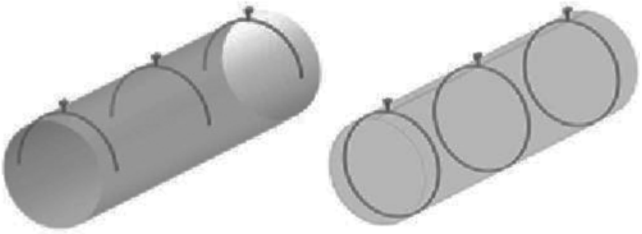

Fig. 16 Ring and Arc Style Hold-Open Retension

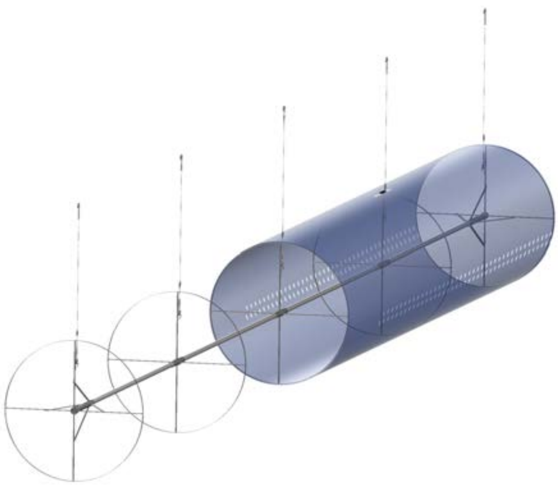

Fig. 17 Direct Suspension from Fabric Tensioning

Layout

A fabric air dispersion system performs as both a duct and a diffuser. When designing a textile air dispersion system, keep the layout as simple as possible, preferably with straight runs. Because porous fabric duct, linear vents, and orifice outlets can be integrated into all sections, system design may vary significantly while providing adequate air dispersion.

Metal ductwork before the fabric inlet should have the same air velocity as the fabric duct, and, when possible, it is recommended to use 3× the diameter of straight metal duct. If there is a transition preceding the fabric inlet, it is recommended to use 1.5× the diameter radius elbows and turning vanes in sheet metal transitions before fabric. High velocity (8 m/s) and turbulent conditions immediately before the system can cause excessive fabric movement and premature wear.

There is little need to reduce diameters because air dispersion systems are essentially extended plenums that can maintain static pressure due to continuously occurring static regain. Custom fittings should be coordinated with the manufacturer. It is recommended that end caps be one diameter from a wall to maintain clearance for systems and allow for movement and ease of installation.

Fittings. Straight duct lengths and fittings are connected together using a circumference zipper, which is affixed with its start/stop typically located at the top center, and includes a circumferential fabric overlap to conceal the zipper. Typical lengths of zippered sections are sized for easy laundering and installation. Longer sections are broken into multiple lengths.

Elbows. The typical centerline radius of an elbow is figured by multiplying the cross-sectional diameter by 1.5. For example, a 610 mm diameter air dispersion system elbow would have a centerline radius of 914 mm. The number of gores depends on the angle of the turn, as shown by Figure 18.

Transitions. Reducing transitions are available in concentric, top flat, or bottom flat configurations (Figure 19). Transition length varies and is based on the change in diameter, such that the total angle does not exceed 30°.

Tees. Tees are saddle type, and the branch requires a zipper for attachment. Typical tee arrangement is shown in Figure 20. It is recommended that tees be located at least 1.5× the outlet diameter from end caps (Figure 21).

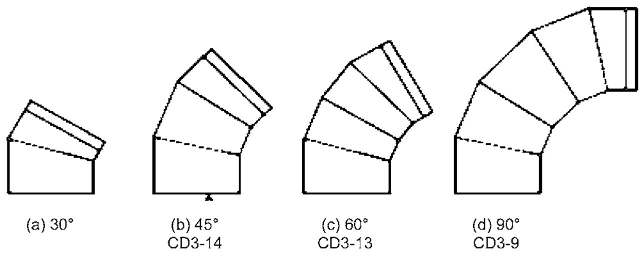

Fig. 18 Number of Elbow Gores Based on Turn Angle

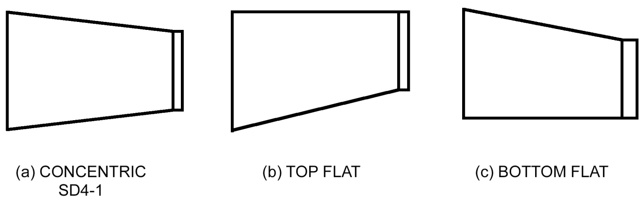

Fig. 19 Styles of Fabric Duct Transitions

Cross, Capped. See Figure 22 for the capped cross, which is SD5-20 in the ASHRAE (2017a) *Duct Fitting Database* (DFDB).

Dampers and Static Regain Devices. These fittings are used to address multiple objectives. The fittings offer engineered resistance to balance airflow in multiple runs and branches, reduce turbulence, reduce inflation pop, reduce noise, reduce movement from abrupt start-ups, and balance static regain. Locate flow devices at (1) inlet collars, (2) one-third point of a straight section, and (3) after take-offs and elbows. A flow device at the inlet collar reduces fluttering due to turbulent airflow entering the air dispersion system. At the first zipper, the flow device reduces the force of initial inflation and reduces "pop;" a fabric tensioning system can also eliminate any movement, deflation, or noise due to the HVAC system cycling on and off. Straightening out velocity profiles also reduces wear in a fabric duct system. Examples of dampers and static regain devices are shown in Figure 23.

Sizing

Cylindrical Air Dispersion Systems. The recommended design velocity is 8.1 m/s for a system without fittings, and 7.1 m/s for a system with fittings. Use lower velocity (5.1 to 6.1 m/s) for noise sensitive areas. If the diameter is too large, design the system for multiple runs.

Half Circle (D-Shape) Air Dispersion Systems.

D-shape air dispersion systems should be sized so that the fabric duct velocity does not exceed the rigid supply duct velocity. The maximum velocity for a straight run is 5.1 m/s. For a system with a fitting, the recommended velocity is 4.1 m/s. A lower inlet velocity to the fabric duct reduces stress and noise.

Flow can be any split (e.g., for a top inlet in the middle, split is 50/50; for a top inlet a third of the distance from one end, split is 33/67), including flow from the end. The D-shape diameters and the duct diameters are good for a split to 38 to 62%. For a greater split, the inlet duct diameter needs to be reduced so the branch duct velocity does not exceed the design inlet duct velocity (4.1 or 5.1 m/s).

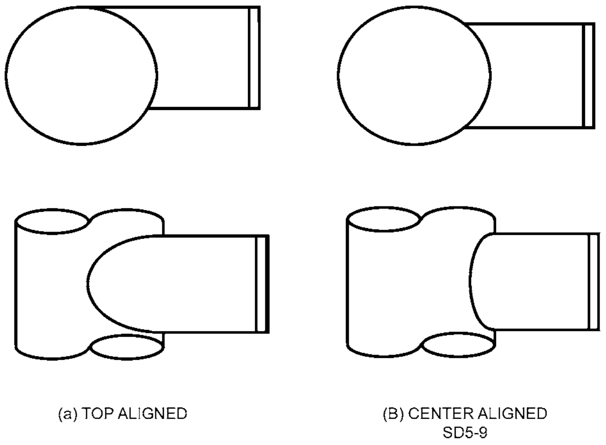

Fig. 20 Common Tee Types for Fabric Duct

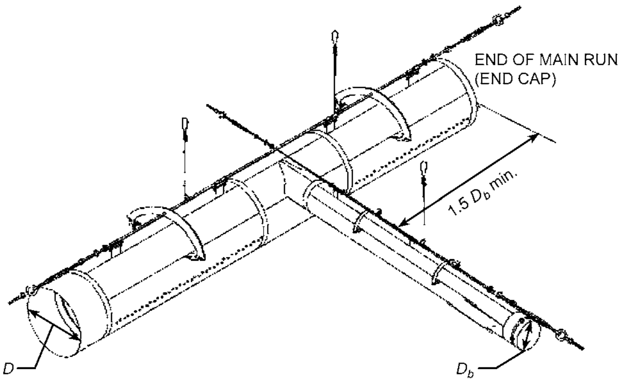

Fig. 21 Relationship of End Caps to Tees

Design Procedure

To design air dispersion systems follow the steps below:

Step 1. Lay out the system. Keep as simple as possible.

Step 2. Given the system airflow requirement, determine the fabric duct size.

Step 3. Assuming an inlet static pressure (ISP) to each section of the air dispersion system, calculate the average static pressure.

Step 4. In each section, use Equation (12), and use the DFDB (ASHRAE 2017a) to calculate Δp_{tx}. Equation (12) is an empirical equation based on experience gained by air dispersion system designers. Leverette et al. (2014) state that this equation is approximately correct. Most often, the ISP to the air dispersion system is approximately 125 Pa.

$$p_{sx,avg} = p_{sx} + 0.65(p_{vx} - \Delta p_{tx}) \tag{12}$$

where

$p_{sx,avg}$ = average static pressure in section x, Pa
p_{sx} = ISP to section x, Pa
p_{vx} = inlet velocity pressure to section x, Pa
Δp_{tx} = total pressure loss of section x, Pa

The component of total pressure drop Δp_{tx} of a fabric duct that is dispersing air equally along its length can be estimated using the DFDB (ASHRAE 2017a; fitting CD11-1) and 35% of the duct length, where 35% is an approximation (because typical systems have a constant diameter from inlet to endcap). The absolute roughness for a system with an internal support frame is 1.69 mm, and for an unsupported system (no internal frame) is 0.11 mm (Kulkarni et al. 2012). These values are based on a 368 mm nonporous polyester fabric duct with an acrylic/urethane coating.

Step 5. Airflow through porous material of length L is calculated by Equation (13):

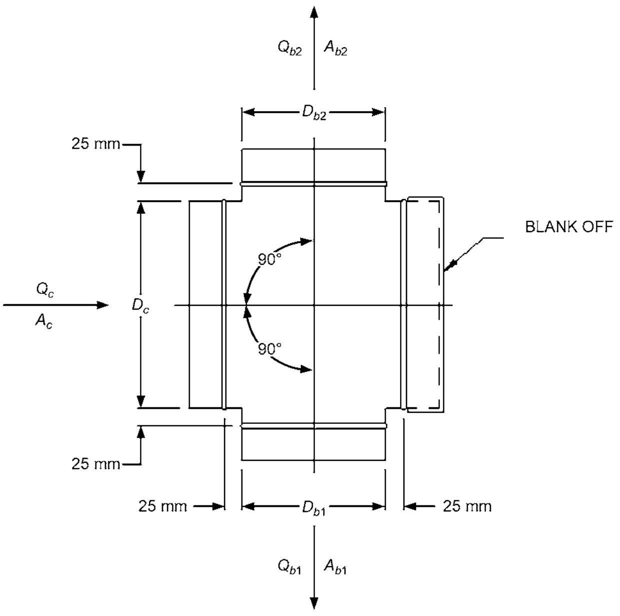

Fig. 22 Capped Cross, Fabric (SD5-20)

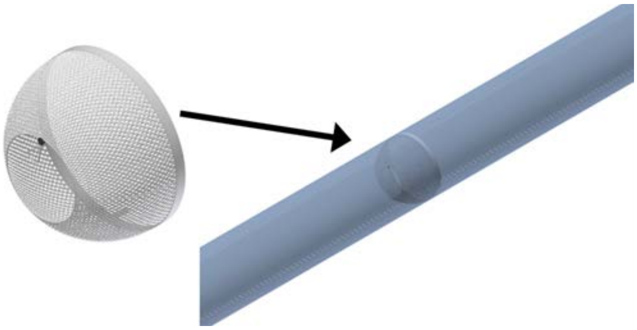

Fig. 23 Fabric Adjustable Flow Devices

$$Q_{material} = \bar{P}\left[\pi\left(\frac{D}{K_1}\right)L\right]\left[\frac{p_{sx,avg}}{K_2}\right] \quad (13)$$

where

$Q_{material}$ = airflow diffused through porous material, L/s
D = system duct diameter, mm
$\bar{P}$ = material porosity, L/s per m^2 at 125 Pa
L = length of system duct, m
$p_{sx,avg}$ = average static pressure in section x, Pa
K_1 = 1000
K_2 = reference SP, 125

Step 6. Calculate the airflow required though the fabric duct outlets (vents or orifices):

$$Q_{outlet} = Q_{system} - Q_{material} \quad (14)$$

where

Q_{outlet} = total outlet airflow, L/s
Q_{system} = system airflow, L/s
$Q_{material}$ = airflow through material, L/s

Step 7. Determine the length of vent or number of orifices, orientation of outlets (Figure 24), and throw. Typically there is a 1.2 m void (no outlets) near the inlet or after any fitting within a system to reduce wear. This is manufacturer dependent. Consider the following when selecting the orientation of air outlets:

- 11 and 1, 10 and 2, and 3 and 9 o'clock (Figure 24): Primarily chosen for cooling or ventilating, these locations direct the exiting air upward and/or outward from the air dispersion system. Throw should reach the exterior walls or fill the gaps between parallel air dispersion ducts.
- 4 and 8, 5 and 7, and 6 o'clock (Figure 24): Primarily chosen for applications with heating, but can also be used for cooling or ventilating, these location direct the exiting air downward and/or outward from the air dispersion system. Throw requirements can be critical in these locations because the air is directed towards the occupied space.

Determine throw:

$$T = K_5(H - K_T) \quad (15)$$

where

T = required throw, m
H = distance between bottom of duct and floor, m
K_T = 1.8
K_5 = 2.0 for 4 and 8 o'clock
1.15 for 5 and 7 o'clock
1.0 for 6 o'clock

For linear vent outlets, select vent size using manufacturer data. Terminal velocity is the maximum airstream velocity at end of throw.

For orifice outlets, select orifice diameter using manufacturer data. Terminal velocity is the maximum airstream velocity at end of throw.

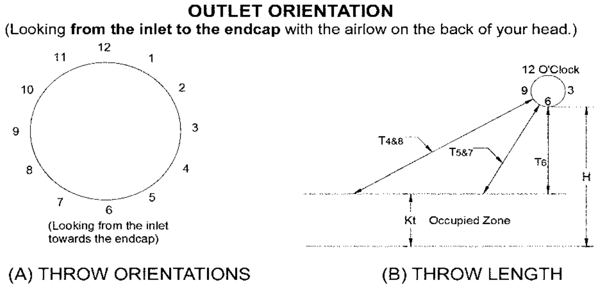

Fig. 24 Throw: Directional Airflow/Distance

Operation

Filtration. It is essential to filter incoming air before it reaches the textile air dispersion system. An efficient filtration system means less cleaning, resulting in a longer product life. Higher filtration (MERV 5) is recommended for low velocity outlets (porous fabric and microperforations). Textile air distribution systems are launderable.

Pressure Required for Inflation. For proper inflation, the static pressure at the inlet to a fabric air distribution system should be no less than 1.3× the inlet velocity pressure.

6. AIR TERMINAL UNITS (ATUS)

Principles of Operation

Single-Duct ATUs. Single-duct ATUs are used to regulate airflow to a conditioned space. Primary air is ducted from an air handler. The basic single-duct unit consists of an airflow regulator and may also include an actuator, an airflow-measuring device, selected controls, and heating coils.

Single-duct ATUs can be applied to pressure-dependent or -independent systems. **Pressure-dependent** units consist, at minimum, of an airflow regulator, thermostat, and actuator. The thermostat dictates the damper position based on room demand, which is independent of system pressure. Using pressure-dependent ATUs can cause system pressure fluctuation, which must be considered. Current ventilation requirements may preclude the use of pressure-dependent ATUs.

Pressure-independent units consist of, at minimum, an airflow regulator, airflow measuring device, controller, room sensor, and actuator. This is a closed-loop control system that measures and regulates airflow based on room demand. Pressure-independent ATUs allow a minimum airflow set point to be established to enable proper ventilation to the zone.

Pressure-independent single-duct ATUs can be used for constant- or variable-volume applications. Variable-volume applications often include controls that limit maximum and minimum airflow set points determined by load, acoustical, and zone ventilation requirements.

Dual-Duct ATUs. Dual-duct ATUs function similarly to single-duct terminals but are composed of two sets of airflow regulators merging two airstreams into a single mixed airstream. These are typically used to mix cold and hot primary air ducts to a single warm discharge air duct.

Fan-Powered ATUs. Series fan-powered ATUs have a continuously operating fan during occupied mode, supplying either a constant or variable volume of air to the space, and they are typically installed in the ceiling plenum. Primary air is ducted from an air handler. Induction air is either from the ceiling plenum or ducted from the space. The fan and damper are aligned so that all primary air and all induced air independently enter the mixing section and go through the fan to be delivered to the space. The mixing space is between the VAV air valve and the fan.

Parallel ATUs have an intermittently operating fan and are typically installed in the ceiling plenum. Primary air is ducted from an air handler and flows directly to the zone in a variable-volume cooling mode. Fan air is induced from the ceiling plenum or may be ducted from the space. The fan should run in heating and dead-band mode. In dead band and heating mode, the supply air is a combination of primary and induced air. The fan and damper are arranged so that all induced air enters the fan, and primary air bypasses the fan. Any mixing of primary air with the induced plenum air occurs on the discharge side of the fan. A backdraft damper inhibits air from exiting the unit through the fan when it is not running.

Fan-powered ATUs applied with underfloor air distribution systems differ from conventional overhead systems in that the ATUs are mounted in a supply air plenum rather than a return air plenum. The ASHRAE UFAD Guide (2013) addresses these ATUs in detail.

DOAS ATUs. Sometimes ATUs may be used in conjunction with dedicated outdoor air systems (DOAS) to provide ventilation air to individual zones. The ATUs could be single-duct VAV, dual-duct, or fan-powered. Single ATUs can work in parallel with sensible cooling devices (e.g., passive chilled beams) to handle latent loads and meet ventilation requirements. Dual-duct ATUs can blend ventilation air with conditioned building air to meet ventilation requirements. Series fan-powered ATUs with a ventilation air inlet can blend ventilation air, conditioned building air, and plenum return air to meet ventilation requirements. Series-fan-powered ATUs designed with chilled-water coils at the induction inlets are specifically designed to work with DOAS applications. These are called fan-powered chilled-water terminal units. The entering chilled-water temperature should be warm enough to preclude latent work at the ATU. The entire latent load is typically satisfied by an outdoor air handler providing preconditioned air to the fan-powered chilled-water ATU.

Benefits and Limitations

Single-Duct ATUs. *Benefits*: Typically produce very low sound levels and can be used for both VAV and CV applications. With the addition of an inlet-mounted thermistor, these units can also provide VAV heating and cooling from a central air handler.

Limitations: The central air handler must provide adequate inlet static pressure to supply air to the box, overcome any pressure drop of the unit and any integral coils, and move air to the zone. Any heating coils integral to the unit must be treated as reheat. Only remote heating devices located in the occupied space such as finned-tube elements or radiant panels that could be operated by unit controls would be treated as heat.

Dual-Duct ATUs. *Benefits*: Allow centralized heating and cooling in the facility. They can provide very high comfort at relatively low sound levels.

Limitations: Dual-duct systems generally have higher initial costs and operating costs.

Series Fan-Powered ATUs. *Benefits*: Make use of free heat in the form of return air for reduced heating requirement. Typically provide constant air motion and low noise levels in the zone for improved air circulation and occupant comfort. The constant fan operation recirculates return air from the plenum, returning unvitiated air and reducing outdoor air requirements. Low inlet static pressure requirements can reduce fan energy at the air handler. Energy savings can be maximized with electronically commutated motor (ECM), reducing the amount of plenum air sent to the occupied space during cooling and nearly eliminating motor heat in the supply air stream. Unit fan allows night setback heating capability on a zone-by-zone basis without need too operate the air handler during unoccupied mode.

Limitations: Some states still allow PSC motors to be used. Such applications send excess plenum heat to the space in cooling. PSC motors are not efficiently modulated and are difficult to control when attempting to track part-load conditions.

Parallel Fan-Powered ATUs. *Benefits*. Make use of free heat in the form of return air for reduced heating requirement. Fan only runs during heating and dead band modes, and fan is sized to only handle heating airflow. Unit fan allows night setback heating capability on a zone-by-zone basis without need to operate the air handler during unoccupied mode.

Limitations: VAV turndown must be considered when selecting diffusers. Sudden changes in airflow cause noticeable changes in sound levels in the space, which is generally annoying to occupants. Casing air leakage during cooling severely affects overall efficiency of these units and measurably limits the amount of heat to be reclaimed in the ceiling plenum.

Fan-Powered Chilled-Water ATUs with Sensible Cooling Coils. *Benefits*: Make use of free heat in the form of return air for reduced heating requirement. Typically provides constant air motion and sound level in the zone for improved air circulation and occupant comfort. Low inlet static pressure requirements can reduce fan energy at the air handler or DOAS. DOAS allows for reduced ventilation air volumes. Energy savings can be maximized with ECMs. Unit fan allows night setback heating and cooling capability on a zone-by-zone basis without need to operate the air handler or DOAS during unoccupied mode. These units control ventilation, temperature, humidity levels, and sound; replace interior air handlers; and provide metered dry outdoor air, sensible cooling, plenum air, and sensible heat as needed as occupied-space loads change.

Limitations: Units must be selected and operated to keep local cooling 100% sensible. Units should not be allowed to condense water on the coils.

Selection Considerations

Sizing ATUs. For primary air inlets, select an inlet size that meets the minimum and maximum airflows desired from the recommended primary airflow range table in the manufacturer's catalog. Selecting terminals near the top of their range increases velocity, sound, and air handler fan energy. Oversizing single-duct terminals reduces control accuracy and stability, and may result in higher sound levels. Transducer fidelity at the low end varies by manufacturer and must be considered in combination with the airflow sensor signal at the minimum airflow rate when selecting an inlet size. To maximize performance, size the terminal's maximum airflow limit for 70 to 85% of its rated capacity (approximately 10 m/s) in accordance with the catalog recommendations. For accurate control, the minimum setting guideline should not be lower than 2 m/s inlet neck velocity for units using inlet velocity sensors. Other minimum guidelines may apply for units with specialty controls.

Select terminals based on recommended air volume ranges. A pressure-independent terminal's main feature is its ability to accept factory-recommended minimum and maximum airflow limits that correspond to the designer's space load and ventilation requirements for a given zone. A common misconception is that oversizing a terminal makes the unit's operation quieter. In reality, the oversized terminal damper must operate in a near-closed condition most of the time, which may actually increase noise levels to the space. Control accuracy may suffer because the terminal is only using a fraction of its total damper travel or stroke. In addition, the low inlet velocities may be insufficient to produce a reliable signal for the velocity pressure measuring device and reset controller. This means minimum settings may not hold, with a resultant loss of control accuracy and undesirable hunting.

Oversizing the discharge duct may create low static conditions, requiring the fan to operate outside its recommended operating range.

Oversizing terminals with electric heat can lead to insufficient total pressure, which can occasionally trip the airflow safety switch.

Environmental Factors. Environmental factors play an important role in system selection. They include the climate and air conditions both indoors and outdoors. They also include legislative requirements such as outdoor air ventilation rates and local building codes. When high ventilation rates are required, such as in critical hospital spaces and clean rooms, reheat is often required to maintain human comfort. Fan-powered ATUs are usually used in noncritical spaces where the thermal load changes significantly and heating is required. Single-duct ATUs are frequently applied in the interior, where the thermal load is normally stable.

Building Use. Before specifying equipment types, the designer must consider the building's intended use. Office buildings with daily operational schedules frequently use fan-powered ATUs. Usually, fan-powered ATUs with auxiliary heaters (supplementary heat) are used in perimeter zones; these units allow the greatest flexibility for individual zones while also allowing the central system to be turned off during unoccupied periods. During unoccupied periods, the fan-powered ATUs maintain the minimum or setback temperature levels without the help of the central air-conditioning equipment.

In institutional, medical, or campus buildings, systems that provide pressurization differences between interior areas may be required.

Buildings with centralized heating and cooling plants sometimes use dual-duct ATUs.

Building Size. In large buildings, central air handlers deliver large quantities of air to many zones with different needs. Interior zones may not require heat; therefore, they may be served either by single duct ATUs with no heat, or with reheat or fan-powered ATUs with no heat or with supplemental heat. Unless the building is located in a tropical climate, the perimeter zones require heat, typically electric or hot water. These are usually included with the ATUs, but sometimes separate heating systems are used (such as baseboard heat). The static pressure in the ducts should be lowered to the minimum pressure in accordance with ASHRAE *Standard* 90.1, which sets at least one VAV damper to near full open. Interior zones in these buildings can use fan-powered ATUs to keep the static pressure low. Buildings with parallel-type fan-powered ATUs usually use single-duct ATUs in the interior zones and require higher system static pressures.

In small buildings, such as shopping malls and other low-rise buildings where each tenant area is small, it is common to use small packaged air conditioners. If ATUs are used on these systems, single-duct or bypass units are usually selected. A variation of this system, variable-volume variable-temperature (VVT), uses pressure-dependent single-duct units with a main bypass air valve in the supply duct. The bypass damper is regulated by static pressure in the supply duct. A near constant pressure can be maintained, allowing the packaged units to operate at constant volume and the individual zones to be pressure-dependent VAV.

Building Controls. The type of control system depends somewhat on the size and type of building.

- **Electric** controls are pressure dependent where the air valve responds to a single control input. For example, the thermostat sends a signal to the air valve to open or close based solely on room sensible temperature.
- **Pneumatic** controls are usually used for building renovation or expansion where the base building already has a pneumatic system installed. They can be pressure dependent or independent. They require regular system maintenance and may need to be periodically rebalanced.
- **Analog** controls are often applied to smaller buildings that do not have a building automation system. Typically, these controls do not communicate with other zones or other equipment in the building.
- **Digital** controls are typically used on buildings that have a building automation system. These controls provide individual zone control and communication to the building management system.

Cost Factors. Consider costs before finalizing system selection. Installation, operation, and maintenance all contribute to total cost. Often, one of these costs overrides the others. Electric heaters usually have a lower installed cost than hot-water coils, but they may have a higher operating cost. Research local utility rates and building codes to arrive at the correct decision before making the final selection.

Acoustical Considerations. ATUs and room air distribution devices are typical sound sources. However, they are not the only equipment affecting room acoustics. See Chapter 49 of this volume, Chapter 4 of ASHRAE (2017b), AHRI *Standard* 885, and other standards for guidance on space acoustics. Broadcast studios, theaters, libraries, and other acoustically sensitive applications require careful consideration, because equipment selection and location are important. Radio-frequency interference (RFI) and electromagnetic interference (EMI) should also be considered when designing broadcast studios.

Sound levels are affected by primary air valve and/or fan-generated sound. The maximum sound generated by a given primary air valve size is determined by the difference between the highest inlet static pressure and external static pressure at the design cooling airflow for a non-fan-powered ATU and parallel fan-powered ATUs. For series fan-powered ATUs, the highest air valve sound level usually occurs at the highest inlet static pressure; however, the fan usually sets the room noise levels for series ATUs. To determine fan noise levels, fan airflow (adjusted within its range by the speed controller) and external static pressure conditions are required.

Acoustical performance data are presented in formats for both the parallel and series ATUs, because their sequence of operation differs. With a parallel ATU, air valve and fan operation are evaluated separately. With a series ATU, air valve and fan are evaluated together. Series fan-powered ATU sound levels are more consistent compared to ambient background sound levels than those of the parallel fan-powered ATU, which has a cycling fan.

From the performance data, determine the sound power levels and predicted room noise criteria for discharge and radiated paths under the appropriate operating conditions. Use care, because some published room noise criteria are based on certain path attenuation assumptions that may not correspond to specific applications. To minimize these differences, AHRI *Standard* 885, Appendix E, provides specific values to apply to sound power levels for NC calculations. These may not match any specific space, but yield comparable NC values between different manufacturers. For a complete description of these processes, see AHRI *Standard* 885 and Chapter 4 in ASHRAE (2017). Both of these sources provide guides to apply specific attenuation values for a specific space to predict actual room noise criteria. However, the attenuation values depend on the room furnishing and finish, as well as the sound power levels generated by the ATU.

It is necessary for the architect and the engineer to recognize all factors in the building specifications that affect sound attenuation. This is necessary to properly evaluate the room noise criteria and ensure the finished levels do not exceed the design goal in the occupied space. An ideal specification identifies maximum allowed discharge and radiated sound power by octave band, rather than just catalog based NC values.

A sound-sensitive occupied space (e.g., conference room, private office, music studio, concert hall, classroom) may require more discharge sound attenuation than less sound-sensitive spaces. Usually some internal lining in the discharge duct can accomplish this. Occasionally, a discharge attenuator or silencer may be attached to the ATU. Care must be taken to not increase the discharge pressure enough to increase fan speed, generating additional noise that may be greater than the attenuated value.

Installation and Operational Considerations

Space Restrictions. During design, try to ensure that terminals are located for ease of installation, optimum performance, and maintenance accessibility.

Optimizing Inlet Conditions.

- The type of duct and its approach may have a large and adverse impact on both pressure drop and control accuracy. Although multipoint velocity pressure measuring devices can compensate to a large degree, good design practice should always prevail. Wherever possible, a straight duct inlet connection with a minimum length of three duct diameters and the same internal diameter as the inlet should be provided. Flex duct runouts at the ATU inlets are generally good attenuators.
- Terminal collars are undersized to suit nominal ductwork dimensions. The inlet duct slips over the terminal inlet collar and is fastened and sealed in accordance with job specifications. Never insert a duct inside the inlet collar, or control calibration will be adversely affected.
- Sometimes space restrictions make it impossible to provide an ideal inlet condition. In this case, field adjustment of the airflow settings may be required to compensate for error in the flow measurement. Using flow-straightening or velocity equalizing devices (equalizing grids) is recommended after short-radius elbows that are immediately ahead of the terminal and where terminals are unavoidably tapped directly off the main duct. Use of these devices typically increases sound levels.
- The balancing contractor should validate flow rates as best as possible. See ASHRAE *Standard* 111.

Zoning Requirements. Correctly sizing terminals with regard to the physical conditions of the occupied space is vital to ensure acceptable performance. One large terminal serving a space with divided work areas may result in the single thermostat only providing acceptable temperature control for the area where the thermostat is located. The other area(s) served may be too cold or too hot if they have differing space load requirements.

Optimizing Discharge Conditions. Poor discharge duct connections may have an adverse effect on pressure drop. Try to avoid installing tees, transitions, and elbows close to the unit discharge. Avoid long runs of flex, and keep short flex runs as straight as possible. Make curves as shallow as possible, and ensure that the entrance condition to diffuser outlet is straight. Discharge ducts should be designed for a maximum velocity of 5 m/s. Flex duct runouts at the diffuser inlets are generally a good attenuator.

Noncompliance with Local Electrical Codes. Some local jurisdictions have more exacting codes than the minimum requirements of national codes and standards such as the International Code Council's (ICC) *International Building Code*® (IBC). One example is the primary fusing required of the power circuit in some areas.

Power Source Compatibility. Terminals with an electrical power supply (e.g., fan-powered terminals, single-duct terminals with electric heat) should be checked for compatibility with source. Voltage, phase, and frequency must match. Where motor voltage differs, the single-phase voltage requirement may have to be tapped from a three-phase power source.

Fan Interlocks. Typically, series fan-powered ATUs are designed to run continuously. Usually, they are energized only during occupied periods or when needed for emergency heating during unoccupied periods. Use care to interlock the unit fan with building's air handlers to ensure that the ATU fans start during occupied periods. Series-unit fans should be started prior to the air handler to prevent backflow into the plenum and backward rotation of the fan.

Fan Shift in Fan-Powered ATUs. Before adjusting the fan, the possibility of fan shift must be considered. This occurs when the blower is subjected to variations in pressure or airflow patterns. As the primary airflow changes, pressure drop and changes in local jets may cause the fan to shift its performance as it rides the fan curve. Consequences vary from building to building and zone to zone. Noise levels may change greatly as the volume changes, and this may be annoying. Design ventilation rates can also vary, sometimes by more than 20%. This can be aggravated by undersizing the ATU.

Avoiding Excessive Air Temperature Rise. ATUs with electric or hot-water reheat coils should be designed to satisfy load conditions, but attention should be paid to the temperature differential Δt between the supply air temperature and room air temperature. Hart and Int-Hoyt (1980) and Lorch and Straub (1983) recommend a maximum Δt of 8.5 K to avoid possible stratification when heating from overhead caused by the excessive buoyancy of the warm air. This ensures good room mixing and temperature equalization. Exceeding a Δt of 8.5 K requires an increase of 25% in the ventilation air per ASHRAE *Standard* 62.1. Absolute maximum discharge air temperature is 49°C. Although this temperature will probably keep the equipment on line, it will not provide comfortable temperatures in the space.

Correctly Supporting Terminals. Although the basic single-duct terminal is light enough that it usually can be supported by the ductwork in which it is installed, these units should be independently supported. When accessory modules such as heating coils, attenuators, or multiple-outlet plenums are included, the assembly must be supported independently. Larger terminals such as fan-powered ATUs should always be independently supported, secured to building structure, and may require isolation mounting. Be careful not to block access panels with straps, thread rods, or trapeze supports. Be sure to comply with all building and local codes regarding seismic restraints (see Chapter 56).

Minimizing Duct Leakage. To prevent excess air leakage and minimize energy waste, all joints should be sealed with a UL-approved duct sealer. Most leakage can be avoided by practicing good fabrication and installation techniques, particularly upstream of the terminal, which may be required to hold significantly higher pressures than downstream of the terminal.

Acoustic Design and Installation. To help ensure an acceptable room noise level in the occupied space, engineers can minimize the sound contribution of air terminals by taking into account the following precautions:

- Avoid locating terminals near return air openings or light fixtures to decrease the potential of direct paths for radiated sound to enter the space without the benefit of ceiling attenuation.
- To avoid possible aerodynamic noise, keep airflow velocities below 5 m/s in branch ducts, and below 4 m/s in runouts to air outlet devices.
- Design systems to operate at low (minimum) supply static pressure at the primary air inlet. This reduces the generated sound level, provides more energy-efficient operation, and allows the central fan to be downsized. Excessive static pressure generates noise.
- Use of metal ducts before the inlet can reduce breakout noise from the air valve. Between the ATU and the air outlet, flexible duct can be more effective than lined duct at reducing ATU noise. Flexible duct can also generate sound if bends or sagging are present. Sometimes, flexible couplers can reduce vibration passed from the ATU to the duct connections.

- Select air valves in ATUs to operate at or below 10 m/s or less. Larger inlets reduce velocity (and therefore noise) in low-pressure applications, but may increase noise in higher-pressure applications. For fan-powered ATUs, lower fan speeds generally produce lower sound levels, but care must be taken to ensure that the minimum airflows are met. Sound emissions are sometimes lower when fan-speed controllers are used to reduce fan rotational speed rather than using mechanical dampers to restrict airflow. AC induction motors can generate pure tones that are unacceptable when thyristor controls are used. Mechanical dampers will not reduce fan rotational speeds or sound levels when applied to ECMs.
- When required, locate terminals above noncritical areas that are less sensitive to noise, such as corridors, copy rooms, or storage/file rooms. This isolates critical areas from potential radiated noise. Locating fan-powered series ATUs closer to the mechanical room increases the amount of heat and unvitiated air that can be reclaimed.
- Locate terminals in the largest ceiling plenum space available to maximize radiated noise reduction. Install ATUs at the highest practical point above ceiling to optimize radiated sound dissipation.
- When required, locate ATUs to allow use of lined discharge ductwork to help attenuate discharge sound.
- In large spaces, consider using a larger number of smaller air outlets to minimize outlet-generated sound.
- Insulated flexible duct on diffuser runouts reduces room noise levels.
- Using ceilings with a high sound transmission loss classification helps reduce radiated sound.

Maintenance and Accessibility.

Typical Applications. Terminal units are typically not easily accessible after building occupation; they should be selected and located with consideration for required maintenance. Review the applicable building codes (e.g., ICC [2009]) for required access. Fan-powered ATUs do not require filters, per section 307.2 of International Code Council's (ICC) *International Mechanical Code*® (ICC 2018) and ASHRAE *Standard* 62.1. Many fan-powered terminals are manufactured with construction filters that must be removed after construction is complete and are not suggested to be replaced.

Critical Environments. Some applications, such as cleanrooms and operating theaters, require high levels of reliability from ATUs because of the difficulty and cost associated with servicing or maintaining the equipment. In a cleanroom, for example, if the ceiling must be opened, the space may require disinfection before it can be used again. Associated costs might include lost production time as well as the cost for wipedown and/or disinfecting the room and/or equipment. In cases like these, consider locating the equipment outside of the clean space or using highly reliable, very-low-maintenance, very basic equipment and controls. ATUs may require access to internal components for cleaning in the case of contamination.

Control of Fan-Powered ATUs

Fan Airflow Control of Fan-Powered Terminal Units

Fan-powered ATUs nearly always use single-phase motors, either electronically commutated motors (ECMs), permanent split capacitor (PSC) motors with electronic fan speed control (sometimes called **wave choppers**, **thyristor controllers**, or **silicon-controlled rectifiers [SCRs]**), or PSC motors with three-speed switches combined with electronic fan speed control.

Electronically Commutated Motor (ECM). Currently, ASHRAE *Standard* 90.1 and ICC's 2018 *International Energy Conservation Code*® (IECC) require ECMs in fan-powered ATUs. ECMs provide superior controllability. They can be pressure-independent devices that calculate airflow, and can respond to a signal from a local controller or a remote signal from the building management system (BMS).

Electronic Fan Speed Control (PSC Motors). Electronic fan speed controls use a thyristor to adjust the fan's electrical input ac voltage. This is called **phase proportioning** or **wave chopping**. Some units may suffer from large changes in amp draw that significantly affect the motor efficiency and operating characteristics. The PSC motor is a pressure-dependent device with a single setting.

ECM versus PSC in Parallel and Series Fan-Powered ATUs

ECMs provide significant energy savings over PSC motors, especially in part-load conditions (Edmondson et al. 2011). The part-load savings are primarily achieved by reducing airflow and taking advantage of the increased fan efficiency at below-design airflows. PSC motors have a limited amount of turndown available, but they also lose efficiency at or sometimes above the savings that can be achieved by the blowers. ECMs have a very small decrease in efficiency when they are operating at reduced speeds, and consequently they allow for nearly all of the improved blower efficiency to be captured in the operating system costs. PSC motor inefficiency manifests itself in the motor heat that is added to the supply air. Generally, PSC motors in fan-powered VAV ATUs can add 0.6 to 1.7 K to the airstream (Davis et al. 2007).

Nameplate Ratings. UL *Standard* 1995 covers fan-powered ATU nameplate ratings. This standard relates to equipment manufacturers and not field issues (which are covered in international and local codes). Nameplate ratings on the unit usually do not match the nameplate ratings on the motor. Amperage can be above or below the motor nameplate. Differences between the motor label and the unit label may be significant in some cases. Refer to the unit nameplate ratings and not the motor nameplate ratings when determining supply circuit requirements. These ratings are set at the safest possible condition. Static pressure and set points vary on each unit, so performance may not match what is on the unit nameplate.

Series. At typical design airflows, the ECM uses about 70% less energy than the PSC (Edmondson et al. 2011). At reduced airflows during part-load conditions, the overall energy savings is greater. Additionally, the reduced plenum air during cooling saves as much or more energy than the motor due to reduced cooling requirements.

Parallel. Default programming in digital controllers run the fan in the parallel ATU during dead band and heating. Because both conditions can suffer from overcooling in the occupied zone due to cold air supplying the required outdoor airflows, the PSC motor heat is used to augment the heat in the induced air to the zone. If ECMs are used, heat may need to be supplied from some other source to offset the overcooling potential during dead band and short cycling during heating. The heat source may be more efficient than the PSC motor heat generation, but overall energy savings is nearly negated by the motor heat loss.

Control Strategy

Series. Most direct digital controllers (DDCs) provide an optional output that may be used for controlling fan airflow by the BMS if an ECM is used. This allows dynamic fan volume control, which may be either modulating or multiple-speed operation from a single-speed motor. The fan must be sized to match the maximum airflow to be supplied to the zone.

The sequence for **series constant volume** is as follows: the fan runs constantly at maximum design fan airflow during all occupied periods. On a call for cooling, the controls modulate the primary air valve toward maximum airflow, delivering primary air to the mixing chamber. If the fan is set at the same airflow as the primary air at maximum cooling, no air is induced from the plenum. If the fan is at a higher airflow than the primary air (e.g., as in a low-temperature application), air is constantly induced from the plenum.

As cooling demand decreases, the primary air valve modulates toward minimum airflow, reducing the flow of primary air into the mixing chamber. This increases the volume of warmer induced air into the mixing chamber. The increased percentage of induced plenum air causes the discharge temperature to rise to approach the plenum temperature, taking advantage of recaptured heat.

On a call for heating, the controls automatically energize the supplemental heat (optional equipment), which can be either electric or hot-water coils. The discharge temperature increases as heat is applied. As the temperature increases in the zone, the sequence reverses.

For **series variable volume**, the sequence is the same, except that the fan modulates.

As cooling demand decreases, the primary air valve and the fan modulate toward minimum airflow with the primary air valve reducing airflow more quickly than the fan.

On a call for heating, the fan modulates toward maximum heating airflow set point. On a further increase in heating demand, the controls energize the supplemental heat (optional equipment), which can be either electric or hot-water coils.

Parallel. In the heating and dead-band modes, the fan supplies a relatively constant volume of induced air to the space. The fan must be sized to supply the required heating airflow to the zone, which requires overcoming the pressure created in the mixing chamber caused by the inclusion of primary air.

Parallel Variable-Volume Sequence. On a call for cooling, the controls modulate the air valve toward maximum airflow while the fan is off. Variable-volume, constant-temperature air is then discharged into the space. On a decreasing call for cooling, the sequence reverses.

In dead band, the controls energize the fan. Fan air and primary air are blended in the mixing chamber on the fan's discharge side. The increased plenum air causes the discharge temperature to rise. Constant-volume, constant-temperature air is delivered to the space.

On a call for heating, the controls automatically energize the supplemental heat (optional equipment), which can be either electric or hot-water coils.

Energy Consumption

Fan-powered VAV ATUs take advantage of typical VAV savings at the air handler and chiller during cooling periods, and even more savings are realized when heating is required. Fan-powered terminals induce warm plenum air from the ceiling and blend it with the primary air at minimum ventilation requirements. This recaptures much of the heat created in the zone and plenum. If additional heating is required, supplemental heat is added to the sequence, thereby complying with ASHRAE *Standard* 90.1 during the heating sequence. The unit saves energy by warming blended air, for example, at 22°C rather than reheating primary cooled air at 13°C, saving the cost of 9 K at the heating airflow. According to ASHRAE research project RP-1292 (Davis et al. 2007; Furr et al. 2007), there is very little difference in total building energy use between series and parallel units when both are equipped with permanent split-capacitor (PSC) motors. However, each type of unit consumes that energy in different ways. ASHRAE (2017b) explains these differences in greater detail.

Series. Series units are designed for very low inlet static pressures. This saves energy at the air handler compared to a parallel unit for a similar zone. RP-1292 identified the PSC motor as the biggest energy user in a series unit (Davis et al. 2007; Furr et al. 2007). The fan energy raises the air temperature across the motor by 0.6 to 1.7 K. When modeling energy consumption for this unit, it is important to model the energy consumption and heat generated by the fan motor for both unoccupied and occupied periods (Davis et al. 2007; Furr et al. 2007). This means that total energy use can be reduced if the fan energy is reduced. Using ECMs can significantly increase motor lifetimes and provide significant energy savings. Warm air induced from the plenum at part load conditions increases the cooling requirement because of the increased air temperature in the mixing chamber of the ATU. The combination of motor and plenum heat can equal or exceed the energy consumed by the PSC motor.

Because the fan cabinet is neutral or negative during operation, the casing leakage does not affect energy consumption of series units. All the primary air injected into the unit is delivered to the occupied zone. This causes ceiling plenum temperatures to be warmer for installations with series units than those with parallel units, and more heat can be reclaimed from the ceiling plenum when the unit is in heating mode.

Parallel. More energy is required at the air handler in a parallel ATU system due to the higher inlet static pressure requirement. When just one duct path is designated as the critical path for static pressure set point, system pressure (and thus energy usage) can increase compared to a building with series units. However, ASHRAE *Standard* 90.1 procedures reset the system static pressure to always drive at least one VAV air valve to its nearly full-open position, making the increased static pressure required for parallel units lesser.

According to RP-1292, the largest single energy usage is leakage in the parallel unit even with dynamic reset at the air handler (Davis et al. 2007; Furr et al. 2007). Leakage is typically between 5 and 12% of the total primary airflow through the parallel unit, and it is highest at full cooling. This does not account for other casing leakage like seams and penetrations. Thus, parallel units may need to be oversized to cover the total load to the occupied zone. Due to the leakage, ceiling plenums are cooler with parallel units than with series units, reducing or eliminating the amount of free heat that can be reclaimed in heating mode. Per ASHRAE (2017b), casing leakage has been calculated at $1.84/cfm per year. When modeling energy consumption for this unit, it is important to model casing and backdraft damper leakage as well as fan energy consumption for both the ATU and the air handler during operation. Motor heat should also be included in heating mode.

Because the motor runs in dead band and heating modes, any heat generated by the motor is delivered to the occupied space. Consequently, the motor heat does not significantly affect the total energy consumed by the parallel unit. Because of this, using more efficient motors will not measurably improve the unit's energy consumption.

Inlet Static Pressure Requirements

Series. The inlet static pressure is the pressure required to push the conditioned air across the air valve into the mixing section.

Parallel. The inlet static pressure is the pressure required to push the conditioned air across the damper, through the mixing section, through the discharge duct, and across the diffuser(s) into the space.

Sizing Fan-Powered Terminals

Selection of fan-powered ATUs involves three elements: primary inlet, fan size, and heating coil. Selection of these elements and their interactive effects determine the overall performance of the units.

Primary Air Inlet Selection. See the section on Single-Duct Primary Air Inlet Selection. *Note*: casing leakage is an important issue for parallel fan-powered ATUs and must be taken into account when determining actual airflow supplied to and from the ATU.

Fan Size. Series fan-powered ATUs require the fan to be sized to handle the maximum design airflow. Fan airflow must be at least equal to primary airflow to ensure the mixing chamber in the terminal does not become positively pressurized, resulting in primary air short-circuiting into the ceiling plenum through the induction port(s). The external static pressure requirements are the sum of the ductwork and diffusers at design airflow plus an applicable hot-water coil or electric heater and optional filter, if required. When fan airflow and external static pressure have been determined, select the fan size from the fan curves provided by the manufacturer. Upsizing the fan and operating it at a reduced speed can result in quieter operation, but pay attention to fan stability at very low airflows.

Parallel fan airflow is determined by calculating the difference between the total discharge design heating airflow and minimum primary airflow. If minimum airflow is zero, then fan airflow is the heating airflow. In most applications of a parallel ATU, a minimum primary airflow is required to meet ventilation requirements. This primary airflow contributes to the total external static pressure experienced by the fan and should be accounted for along with all components, such as heaters, ductwork, diffusers, and optional filters.

Heating Coils

Heating coils on ATUs are generally either electric or hot water coils. Sometimes steam may be used. Electric heaters are always encased for safety. Water coils may or may not be encased.

Heating coils on single-duct ATUs are located on the discharge where the duct is attached. They are almost always not encased on single duct units and are generally sized to be the same size as the discharge duct. If the ATU is internally lined, the internal diameter of the ATU will be smaller than the coil face area. Multiple outlet plenums or silencers may be mounted downstream of the coil. Sometimes the coils are mounted at the discharge end of the silencers. Access doors may be located upstream and/or downstream of the coils. Heating coils on single-duct ATUs are always reheat coils and must be designed to heat the air from the leaving air temperature at the air handler to the desired entering air temperature at the occupied space. Heating coils are usually either electric or hot water finned tube type.

Heating coils on series fan-powered ATUs are mounted on the discharge where the duct is attached. If the ATU is properly controlled, these coils provide supplemental heat and not reheat. Water coils may or may not be encased. Discharge ducts may have access doors to allow access to the coil. Coils should be designed to heat the mixed air in the ATU mixing chamber. The mixed air is a blend of the minimum primary airflow and the induced plenum air at the point where the heater is energized.

Heating coils on parallel fan-powered ATUs may be mounted on the discharge of the unit or at the induction inlet upstream of the fan. Heating coils on the induction port must be sized to heat the fan airflow to a temperature high enough to mix with colder primary air, achieving the required entering air temperature for the occupied space. Coils mounted on the ATU discharge must be sized to heat the blended air from the mixing chamber to the required leaving air temperature. On ATUs with coils on their discharge, discharge ducts may have access doors to allow access to the coil. Coils may or may not be encased.

Use manufacturers' catalog data or ASHRAE (2017b) for details on sizing coils.

Additional Fan Guidelines

When selecting a unit for a particular set of conditions, ensure that the air delivery is designed to meet the room's sound criteria and the system's static requirements. Specific sound data are provided by manufacturers for various airflow deliveries for each unit and should be the guiding factor in selecting unit sizes. Avoid selecting equipment near the maximum or minimum of the fan curves. Selecting fans at these points may limit flexibility for future changes. When designing air systems and using fan-powered ATUs, it is important to match the fan air and primary air capacities to the space requirements. Series units require precise adjustment of fan airflow in relation to the primary air to ensure proper discharge air temperatures and to protect against short circuiting of primary air into the plenum.

Special Applications

ATUs for Cold-Air Systems. These systems often involve ice storage and can provide supply air typically colder than 9°C, below that supplied by conventional systems. To reduce the chances of condensation on outer surfaces, keep the following in mind:

- Select insulating materials to provide adequate thermal protection throughout the cold-air path. Internal and external insulation must be sufficient to prevent any outer exposed surfaces from dropping below the dew-point temperature of the surrounding environment.
- Single-duct, dual-duct, and parallel fan-powered ATUs have a higher potential for condensation because they handle the coldest air during cooling operation.
- Series fan-powered ATUs have the lowest potential for condensation because, in most operations, they mix warmer return air with primary air (i.e., air delivered to the ATU through supply duct to satisfy all or part of ventilation, latent, and sensible load). Fan-powered series flow ATUs are sometimes used to mix return air during occupied mode to deliver supply air at a more conventional temperatures to the occupied space. This may help to avoid occupant comfort issues caused by excessive vertical drop from air outlets, and possible condensation at outlet devices.

Several other design and operational considerations can also minimize the possibility of condensation and related issues:

- Ceiling plenum returns are recommended for cold-air systems. Return air circulating throughout the ceiling plenum can prevent uncontrolled humidity or temperature extremes that can occur in attic spaces of fully ducted systems.
- To control humidity and prevent condensation problems, it is always good practice to limit outdoor air infiltration. Design and construct buildings to operate under positive pressure, and limit the amount of uncontrolled outdoor air that infiltrates occupied and unoccupied spaces.
- Cold-air systems should follow start-up procedures that gradually reduce the supply air temperature. This prevents moisture trapped in new construction or previously unoccupied buildings from condensing and possibly causing damage to ceilings and other finished surfaces.

ATU Contamination Considerations. Hospitals, cleanrooms, and laboratories pose special challenges. Protective isolation spaces such as operating rooms, bone marrow transplant patient rooms, AIDS patient areas, and cleanrooms require positively pressurized environments. Infectious isolation spaces such as tuberculosis patient rooms require negatively pressurized environments. See ASHRAE *Standard* 170 for details on room pressurization, Chapter 9 for specifics on health care requirements, and Chapter 19 for details on clean spaces. Hospital rooms and cleanrooms frequently also require constant high ventilation rates, which tend to favor single- or dual-duct ATUs. Pressure-independent, variable-speed motor technology has led to the development of fan-powered pressurization units.

To minimize entrainment of fibers into the airstream, either do not use internal insulation or use nonfibrous liners in the ATUs and duct systems. Insulations can be isolated from the airstream by metal, foil, or polymer liners inside silencers and ATUs. All of these liners have different thermal, acoustic, and other physical properties and should be evaluated for each job.

See Chapter 12 of ASHRAE (2017b) for more information on health care facilities.

System Selection

Designers have various systems (ATUs and their associated controls) to choose from when designing a building. The owner's needs

[b]Special consideration should be given to selecting very quiet operating equipment and use of attenuators or silencers.

must be met for installation, application, and cost of operation. The designer must consider performance, capacity, reliability, energy consumption, sustainability, and spatial requirements and restrictions. The following guidelines describe different types of equipment and their general uses, restrictions, and limitations. Table 7 summarizes the different types of ATUs and their suitability for particular commercial building applications.

7. ROOM FAN-COIL UNITS

Designers have various fan-coil systems to choose from when designing a building. Choosing which one to use depends on meeting the owner's needs for installation, application considerations, first cost, and cost of operation. The designer must consider performance, capacity, reliability and spatial requirements and restrictions. The following guidelines describe different types of fan-coil equipment and their general uses, restrictions, and limitations.

Principles of Operation

Fan-Coil Types. *Vertical Stack*: A vertical stack fan-coil uses a fan and a water coil to condition air within a space by regulating tempered water flow through the coil. Designed for free-blow or ducted, concealed, or painted cabinet applications. This fan-coil model usually uses a riser piping system to deliver the chilled and hot water to the coil. This type of unit is typically used in high-rise hotels, condominiums, dormitories, and residential buildings.

Vertical: A standard vertical fan-coil uses a fan and a water coil to condition air within a space by regulating tempered water flow through the coil. These units either are concealed in the wall or have a painted metal cabinet built around them. This type of fan-coil is commonly used in hallways, dormitories, small apartments, etc.

Horizontal (Blow-Through): A horizontal unit is normally mounted overhead and contains a fan and a water coil to condition air in a space by regulating tempered water flow through the coil. The fan blows air into the coil and then discharges into the space. These units may be built in or have decorative housings installed.

Horizontal (Draw-Through): A horizontal unit is normally mounted overhead and contains a fan and a water coil to condition air in a space by regulating tempered water flow through the coil. The fan draws air across the coil and then discharges into the space. These units may be built in or have decorative housings installed.

Water Piping Distribution Systems. For fan-coil units requiring chilled and/or hot water, the piping arrangement determines the performance quality, ease of operation, operating cost, and initial cost of the system.

Four-Pipe Distribution of Chilled and Hot Water: This system has dedicated supply and return pipes for chilled and hot water. It generally has a high initial cost compared to a two-pipe system. Four-pipe systems have better performance because of all-season availability of heating and cooling at each unit, no summer/winter changeover requirement, and simpler operation. It can be controlled to maintain a dead band between heating and cooling during shoulder season.

Two-Pipe Changeover Without Electric Heat: In this system, either hot or cold water is supplied through the same piping. The fan-coil unit has a single coil. The most common system changeover scheme with the lowest initial cost is the two-pipe changeover scheduled by outdoor temperatures. The outdoor changeover temperature is set at some predetermined set point. If a thermostat is used to control water flow, it must reverse its action depending on whether hot or cold water is available.

The two-pipe system cannot simultaneously heat and cool, which is required for most projects during intermediate seasons when the morning hours may need heat and the afternoon hours likely require cooling. In intermediate seasons when the boiler is not on, two-pipe systems without supplemental electric heat cannot meet heating demands.

Two-Pipe Changeover with Partial Electric Strip Heat: This arrangement can provide electric heating in some zones and cooling in other zones in intermediate seasons by using a small electric strip heater in the fan-coil unit. The unit can handle heating requirements in mild weather while continuing to circulate chilled water to handle any cooling requirements. When the outdoor temperature drops sufficiently to require heating beyond the electric strip heater capacity, the water system must be changed over to hot water. The designer should consider the disadvantages of the two-pipe system carefully; many installations of this type increase operational cost, and can be unsatisfactory if climates temperatures vary widely from morning to afternoon.

Two-Pipe Nonchangeover with Full Electric Strip Heat: This system should be closely evaluated due to the escalated operational cost of electric heat compared to hot-water heat. It may be practical in areas with small heating requirements.

Three-Pipe Distribution: Three-pipe distribution uses separate hot- and cold-water supply pipes. A common return pipe carries both hot and cold water back to the central plant. The fan-coil unit control introduces hot or cold water to the common unit coil based on the need for heating or cooling. This type of distribution is not recommended because of its energy inefficiency from constantly reheating and recooling water, and it does not comply with most recognized energy codes.

Benefits and Limitations

Vertical Stack. *Benefits*: These units take advantage of the multi-story feature to plumb the water piping vertically floor to floor to conserve space.

Limitations: These units occupy floor space in the room. Because the units are traditionally located in the space, noise can be a problem if the fan and motor are not sized properly or if noise is not considered during design.

Vertical. *Benefits*: These units traditionally condition air directly in the space. Return air is typically drawn in the bottom and discharged out the top, directly back into the space.

Limitations: These units occupy floor space in the room. Because the units are traditionally located in the space, noise can be a problem if the fan and motor are not sized properly or if noise is not considered during design.

Horizontal (Blow-Through). *Benefits*: These units do not occupy floor space in the room, and can be manufactured with a lower profile.

Limitations: The velocity profile may not be evenly distributed across the cooling coil.

Horizontal (Draw-Through). *Benefits*: These units do not occupy floor space in the room, and generally have evenly distributed airflow across the cooling coil, resulting in greater heat transfer and lower noise.

Limitations: Any condensate blow-off caused by airflow over the coil has the potential to land on electrical components, including the fan motor.

Selection Considerations

Sizing Fan-Coil Units. How fan-coil units are selected and how they interact with the rest of the system determine the overall performance of the units.

General Sizing Guidelines: Select fan-coil based on recommended air volume ranges. A common misconception is that oversizing a fan-coil makes the unit operate more efficiently. On the contrary, an oversized fan-coil reduces run times, making the room air stratified and humidity more difficult to maintain at comfortable levels.

The recommended selection for maximizing performance is to size the fan-coil maximum airflow limit for 70 to 85% of its rated capacity in accordance with the catalog recommendations.

Do not exceed 2.5 m/s air velocity through the coil section of a chilled-water fan-coil. Exceeding this limit could cause condensate blow-off from the fin material, potentially causing damage to surrounding materials.

Select water flow rates that will not exceed a velocity of 2.4 m/s in the coil tubing, because this velocity can erode the copper and cause pinholes, which could result in water leakage and potential damage to material and property.

Fan Size Selection: Fan-coil units require the fan to be sized to handle the maximum design airflow. The external static pressure requirements are the sum of the ductwork, diffusers, and filters at design airflow. When fan airflow and external static pressure have been determined, select the fan size from the fan curves or the selection software provided by the manufacturer. Vertical fan-coils with one return and one supply grille integral to the cabinet have no appreciable external static pressure requirements. This style of vertical fan-coil must deliver the design airflow for the application between 0 and 124 Pa. Oversizing the fan and operating it at a reduced speed can result in quieter operation, but pay attention to fan stability at very low airflows.

ASHRAE research project RP-1741, Understanding Fan Coil Components and How They Relate to Energy Consumption and Energy Modeling, is currently analyzing energy modeling of fan-coils.

Environmental Factors: Environmental factors include the climate and air conditions, indoors as well as outdoors. They also include legislative requirements such as outdoor air ventilation rates and local building codes. Fan-coil units receive ventilation air from a penetration in the outer wall or from a central air handler. Units that have outdoor air ducted to them from an aperture in the building envelope are not suitable for commercial buildings because wind pressure allows no control over the amount of outdoor air admitted. Ventilation rates can be affected by stack effect and by wind direction and speed. Also, freeze protection may be required in cold climates.

Fan-coils are, however, often used in residential construction because of their simple operation and low first cost, and because residential rooms are often ventilated by opening windows or by outer wall apertures, if not handled by a central system. Operable windows can cause imbalance in a ducted ventilation air system.

When outdoor air is introduced from a central ventilation system, it may be connected to the inlet plenum of the fan-coil or introduced directly into the space. If introduced directly, ensure that this air is pretreated, dehumidified, filtered, and held at the room's temperature so as not to cause occupant discomfort when the fan-coil unit is off. One way to prevent air leakage is to provide a spring-loaded motorized damper that closes off ventilation air when the unit's fan is off.

Building Size: In large buildings, where a central air handler(s) is not practical and where individual power costs are the responsibility of each space owner, a fan-coil is generally the system of choice for temperature and humidity control. These systems require a central water supply and a water transport system. If the initial cost and cost of operation of central chilled- and hot-water-generating equipment make more economical sense, the hydronic fan-coil comfort system is a good choice.

Cost Factors: Costs should be considered before the final system selection is made. Installation, operation, and maintenance all contribute to total cost. Sometimes one of these costs is more important than others. Electric heaters usually have a lower installed cost than hot-water coils, but may have a higher operating cost. Local rates and codes should be researched to arrive at the correct decision before making the final selection. See Chapters 13 and 46 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, Chapter 22 of the 2017 *ASHRAE Handbook—Fundamentals*, and Chapter 51 of this volume for more information on piping systems.

Acoustical Considerations. Since fan coils are often located within the occupied space, extra consideration should be given to avoid generating noise near occupants. For fan coils located outside the occupied space, the acoustical considerations are very similar to those of terminal units. Refer to the Acoustical Considerations portion of the section on Terminal Units for more information.

Installation and Operational Considerations. *Space Restrictions.* During the design phase, ensure the fan-coils are located for ease of installation, optimum performance, and maintenance accessibility.

Optimizing Inlet Conditions. Fan-coils should be located to optimize the inlet return air and discharge grilles or duct work. Proper location and size of grille and duct contribute to the overall effectiveness of air mixing and efficiency.

Locating a return grille in an area that does not properly serve the entire conditioned space can lead to poor performance of the coil and hot or cold spots within the occupied space.

Zoning Requirements. Correctly sizing fan-coils with regard to the physical conditions of the occupied space is vital to ensure acceptable performance. One large fan-coil serving a space with divided work areas may result in the single thermostat only providing acceptable temperature control where the thermostat is located. The other space(s) served may be too cold or too hot if they have differing space load requirements.

Optimizing Discharge Conditions. Poor discharge duct connections may have an adverse effect on pressure drop. Avoid installing tees, transitions, or elbows close to the unit discharge. Avoid long runs of flex duct, and keep short flex runs as straight as possible. Make curves as shallow as possible, and ensure entrance condition to diffuser outlet is straight. Discharge ducts should be designed for a maximum velocity of 5 m/s.

Noncompliance with Local Electric Codes. Some local jurisdictions have more exacting codes than the minimum requirements of national codes and standards such as IBC, the National Fire Protection Association's *National Electrical Code*® (NEC®; NFPA *Standard* 70), UL, and Canadian Standards Association (CSA) standards. One example is the primary fusing required of the power circuit in some areas.

Power Source Compatibility. Fan-coils with electric heat should be checked for compatibility with source. Voltage, phase, and frequency must match. Where motor voltage differs, the single-phase voltage requirement may have to be tapped from a three-phase (4 wire wye) power source.

Fan Interlocks. When an electric heat source is used, a fan interlock is required to ensure the fan is on during the call for heat.

Avoiding Excessive Air Temperature Rise. Fan-coils with electric heaters or hot-water coils should be designed to satisfy load conditions, but attention should be paid to the temperature differential Δt between the supply air and room air. Exceeding Δt of 8.5 K requires an increase of 25% in the ventilation air per ASHRAE *Standard* 62.1. Absolute maximum discharge air temperature is 48.9°C per UL standards. Although this temperature will probably keep the equipment on line, it will probably not provide comfortable temperatures in the space.

Correctly Supporting Fan Coils. Fan-coil units should always be independently supported and secured to building structure, using the proper isolation mounting. Be careful not to block access panels with straps, thread rods, or trapeze supports. Where codes require seismic restraints, be sure to comply with all building and local codes.

Minimize Duct Leakage. To prevent excess air leakage and minimize energy waste, all joints should be sealed with a UL approved duct sealer. Most leakage can be avoided by practicing good fabrication and installation techniques

Acoustic Design and Installation. To help ensure an acceptable room noise level in the occupied space, engineers can minimize the sound contribution of a fan-coil by taking into account several design considerations and by using the following guidelines for good design practice:

- Design systems to operate at low (minimum) external static pressure. This reduces the generated sound level and provides more energy-efficient operation. Excessive static pressure generates noise.
- Between the fan-coil unit and the air outlets of a ducted system, flexible duct can be more effective than lined duct at reducing unit noise. Flexible duct can also generate sound if bends or sagging is present. Sometimes, flexible couplers can reduce vibration passed from the fan-coil unit to the duct connections.
- Select fan-coils to operate toward the middle area of their operating range. Larger return air inlets reduce velocity across coils and hence, noise. Lower fan speeds produce lower sound levels. Sound emissions can be lower when using an ECM motor blower combination.
- Whenever possible, locate horizontal fan-coils above noncritical areas that are less sensitive to noise, such as corridors, copy rooms, or storage/file rooms. This isolates critical areas from potential radiated noise.
- Locate fan-coils in the largest ceiling plenum space available to maximize radiated noise reduction. Install fan-coils at highest practical point above ceiling to optimize radiated sound dissipation.
- Avoid locating fan-coils near return air openings or light fixtures. This decreases the potential for direct paths for radiated sound to enter the space without the benefit of ceiling attenuation.
- Locate fan-coils to allow the use of lined discharge ductwork to help attenuate discharge sound.
- In large spaces, consider using a larger number of smaller air outlets to minimize outlet generated sound. Insulated flexible duct on diffuser run-outs provides excellent attenuation performance.
- Using ceilings with a high sound transmission loss classification will help reduce radiated sound.

Control of Fan Coil Units

Fan Airflow Control of Fan-Coil Units. Three-speed permanent split capacitor (PSC) motors are the standard motor option for most fan-coils. These motors have high, medium, and low speeds. These motors are likely be phased out because of minimum efficiency requirements in ASHRAE *Standard* 90.1.

The availability of **electronically commutated motors (ECMs)** for fan-coil units is rapidly growing, and most manufacturers offer a model. These motors often provide significant energy savings, improved controllability, and wider operating range in fan-coil units.

ECM versus PSC Motors in Fan-Coil Units. *Three-Speed PSC*: When a PSC motor is used in a fan-coil, the fan motor is switched on and off by a thermostat. This control scheme does not allow precise control of temperature and humidity levels in the conditioned space, and can cause comfort issues and increased energy cost.

Multispeed ECM: When a multispeed ECM is used in a fan-coil, the fan motor is switched on and off by a thermostat. The control scheme can be identical to that of a PSC but with the added benefit of a higher-efficiency motor, thus lower operating cost. Generally, an ECM is a 24 V control, and the motor can be energized directly from the thermostat or through a specially designed ECM fan control board, which could offer additional features.

Fully Modulating ECM: When used in the fan-coil with a more sophisticated control (e.g., analog control or DDC), this sequence of operation can provide a higher level of comfort and energy savings.

Table 8 Applications for Fan-Coil Configurations

P = Preferred for this application.
• = Used for this application.
N = Not recommended for this application

Typically, an analog signal (0 to 10 V DC) from a controller is used to remotely vary the speed of the ECM. The dead-band differential between no call for heating/cooling and the energized state is generally much smaller in this type of control scheme. This approach provides minimal swings in temperature and humidity levels in the conditioned space, which can provide superior comfort and reduced energy costs.

Basic Control Types. *Electric Thermostat*: Traditionally, the most common control type for fan-coils is a room thermostat. These thermostats come in both line voltage (i.e., same voltage as motor) and 24 V, which require a Class 2 step-down transformer (typically provided with the fan-coil).

When using a line voltage thermostat, the blower motor speed taps (three-speed) are connected directly to the thermostat. In this configuration, the water control valve is also line voltage. This type of thermostat is limited, and is generally used only on smaller motors because of ampacity limitations and thermostat ratings. In much of the United States, these thermostat leads must be run in a conduit between the fan-coil and thermostat.

When using a 24 V thermostat, fan relays, rated for the current of the motor, are used to switch each speed of the motor on and off. In this configuration, the water control valve is also typically 24 V. In most of the United States, these thermostat leads are not required to be run in a conduit between the fan-coil and thermostat.

Analog Stand-Alone: Another control type for fan-coils is an analog control combined with a room sensor. This control type is powered with 24 V thermostats, which require a Class 2 step-down transformer (typically provided with the fan-coil).

An analog controller is used when the fan-coil has modulating components such as an ECM and modulating water valves. The analog controller provides the appropriate outputs, based on room demand, to modulate the fan and water valves, if equipped.

This type of control can provide improved comfort over a simple electric thermostat. Depending on the features of the analog controller, the cost is generally higher than a room thermostat without set back features.

Direct Digital Control (DDC): This control type, paired with a room sensor, is powered with 24 V; these thermostats require a Class 2 stepdown transformer (typically provided with the fan-coil).

A DDC controller can be used for both types of fan-coil sequences described previously.

A DDC has both digital and analog inputs and outputs. The controller is programmable to provide many operation sequences, depending on the application. Generally, these controls can provide anything from a simple control sequence to a more sophisticated application. In some cases, DDC can control features and components outside the fan-coil, such as humidifiers, baseboard heat, bathroom ventilators, or lights, and can be programmed for occupied and unoccupied modes for energy savings.

Some DDCs can communicate through building automation systems (BASs) in several different protocols, such as BACnet™, Lonworks™, and Modbus®.

This type of control can provide improved comfort over a simple electric thermostat or stand-alone analog controls. Depending on the features, cost for a DDC is typically higher than for a room thermostat or analog controls

Basic Control Sequences. *Three-Speed Motor with Two-Position Valves*: Thermostats are available with many features beyond the purview of this explanation, but the simplest sequence is as follows.

On a call for cooling, the fan is energized at the speed (high, medium, or low) selected by the occupant or by the thermostat. The chilled-water control valve opens fully. On reaching the room set point, the fan de-energizes and the chilled-water control valve closes.

On a call for heating, the fan is energized at the speed (high, medium, or low) selected by the occupant or by the thermostat. The hot-water control valve opens fully. On reaching the room set-point, the fan de-energizes and the hot-water control valve closes. For a fan-coil with electric resistance heat, a heater control, like a contactor or heater sequencer, is energized on and off by the thermostat based on room demand for heating.

Consult the manufacturers' catalog or installation and operating instructions for specific applications.

Modulating Motor with Modulating Valves: Controllers for fan-coils with modulating components are available with many additional features, but a basic sequence is as follows.

On a call for cooling, the chilled-water valve opens to a position consistent with the controls algorithm based on room demand, and the fan modulates toward the maximum cooling airflow set point. At a full call for cooling, the chilled-water valve is wide open and the fan is at the maximum cooling airflow set point. When approaching the room set point, the fan airflow reduces and the chilled-water control valve modulates toward the closed position. On reaching the room temperature setting, the valve closes completely and the fan modulates to the dead-band fan airflow set point.

Dead Band: Fan is off or running at a minimum airflow to circulate air through the space. On a call for heat, the hot-water valve opens to a position based on room demand, and the fan modulates toward the maximum heating airflow set point. At a full call for heating, the hot-water valve is wide open and the fan is at the maximum heating airflow set point. When approaching the room set point, the fan airflow reduces and the hot-water control valve modulates toward the closed position. Similar to the case of a fan-coil with electric resistance heat, a heater control, like a contactor or heater sequencer, is energized on and off by the room demand for heating. An SCR heater control can modulate the resistance heater by an analog output from the controller similar to the hot-water valve operation described above.

Consult the manufacturers' catalog or installation and operating instructions for specific needs.

Building Type

The designer must consider the intended building use when determining the type of fan-coil equipment to be used. Fan-coil systems are best applied where individual space temperature control or cross-contamination prevention is needed. Suitable applications are shown in Table 8.

8. HEATING AND COOLING COIL SELECTION

Sensible Cooling and Heating Coil Selection

First, determine the air temperature rise by calculation using the heat transfer equation:

$$q = 1.206Q\,\Delta t \tag{16}$$

where

q = sensible coil capacity, kJ
Q = coil airflow rate, L/s
Δt = supply air temperature (SAT) – coil entering air temperature (EAT), °C

$$\text{EAT} = (T_1Q_1 + T_2Q_2)/Q_T \tag{17}$$

where

EAT = entering air temperature of coil, °C
T_1 = return air temperature, °C
T_2 = primary or ventilation air temperature, °C
Q_1 = return airflow rate, L/s
Q_2 = primary or ventilation airflow rate, L/s
Q_T = total airflow rate moved by fan, m/s

$$\text{LAT} = (T_1Q_1 + T_2Q_2)/Q_T \tag{18}$$

where

LAT = leaving air temperature of unit, °C
T_1 = coil leaving air temperature, °C
T_2 = primary or ventilation air temperature, °C
Q_1 = coil airflow rate, L/s
Q_2 = primary or ventilation airflow rate, L/s
QT = total airflow rate moved by fan, m/s

The supply air temperature (SAT) to the space equals the leaving air temperature (LAT) for the terminal unit or fan-coil. The terminal unit or fan-coil LAT and airflow rate should be known based on the load calculation. The coil EAT can be calculated using Equation (17) for all units mixing air upstream of the coil, or it should be equal to the return air temperature for all units mixing air downstream of the coil.

Once the coil EAT has been determined, the coil capacity can be calculated using Equation (16).

In applications for units mixing air downstream of the coil, the LAT of the unit can be calculated using Equation (18).

The required kilowatts and number of steps/stages desired should be checked with the manufacturer.

For hot-water coils, refer to the capacity charts in the manufacturer's performance data or selection software to select the appropriate coil.

In heating applications, it is good practice to limit supply air temperature to 9.4°C above room temperature.

In applications in which mixing occurs downstream of the coil, heat generated by the water coil shortens the motor life and may cause nuisance tripping of the motor thermal overload.

At part-load conditions, it may be desirable to modulate airflow through the terminal unit or fan-coil as well as the heat output to maintain an acceptable discharge air temperature. This can be done with modulating valves on coils or proportional control on electric heaters. Staging the electric heaters can create similar results at a lower equipment cost. Modulating the heat causes the heaters to run longer, but at lower energy consumption. This can make the room more comfortable without increasing energy costs.

Example 3. Parallel Terminal with Discharge Hot-Water Heat. Select a unit inlet for a maximum/minimum primary airflow at 0.472/0.118 m^3/s with 249 Pa inlet static pressure.

The heating airflow required is 0.283 m^3/s at 39.4°C. Downstream resistance at 0.472 m^3/s is 99.5 Pa. Zone design heat loss is 5.9 kW, design room temperature is 22.2°C, return air temperature is 23.9°C, and primary/ventilation air temperature is 12.8°C.

Solution:

Air Valve Selection. Based on a good design inlet velocity of 10.6 m/s, choose a 250 mm inlet.

Fan Selection. Fan heating airflow = Total heating airflow (0.283 m^3/s) – Primary airflow (0.118 m^3/s) = 0.165 m^3/s. The downstream static pressure the fan must overcome is the fan airflow plus primary airflow (0.283 m^3/s), and because this is less than maximum design airflow (0.472 m^3/s), fan downstream static pressure = $((0.283/0.472)^2 \times 99.5 = 38$ Pa. Refer to fan curves to select the proper unit. The correct unit will handle 0.165 m^3/s at 38 Pa static pressure with correct setting of the speed controller, and allows for the selection of a one- or two-row hot-water coil.

Heating Coil Selection. The heating coil is on the unit discharge in this example, so the unit supply temperature equals the coil LAT. Coil entering air temperature (EAT) is a mixture of return and minimum primary air. Using Equation (16), calculate the coil EAT.

$$\text{EAT} = [(0.165\text{ m}^3\text{/s} \times 23.9°\text{C}) + (0.118\text{ m}^3\text{/s} \times 12.8°\text{C})]/0.283\text{ m}^3\text{/s}$$
$$= 19.4°\text{C}$$

The coil capacity can be calculated using Equation (1),

$$q = 1.026 \times 0.283\text{ m}^3\text{/s} \times (39.4°\text{C} - 19.4°\text{C}) = 6.9\text{ kW}$$

From the hot-water coil data, select a two-row coil at 0.283 m^3/s to provide 6.9 kW at about 0.063 L/s.

Note 1: The coil selection in this example produces a discharge air temperature that is too high for normal applications. A discharge air temperature limit of 30.6°C should be used. If additional heat is required, airflow should be increased.

Note 2: The mixed-air condition does not bring the EAT to room temperature. Additional induction or plenum air should be considered to increase the mixed-air temperature.

Note 3: Using a PSC motor adds 0.6 to 1.7 K to the airstream.

Example 4. Series Terminal with Electric Heat. Select a unit to supply a constant 0.708 m^3/s with 124 Pa inlet static pressure. Minimum primary airflow is 0.177 m^3/s and downstream resistance caused by ductwork and diffusers is 100 Pa. Zone design heat loss is 13.19 kW, design room temperature is 22.2°C, return air temperature is 23.9°C, primary air temperature is 12.8°C, and supply air temperature is 37.8°C.

Solution:

Air Valve Selection. Based on a good design inlet velocity of 10.16 m/s, choose a 300 mm inlet.

Fan Selection. Fan airflow equals design airflow with a series unit. Fan external static pressure equals downstream static pressure (ductwork and diffusers). The resistance of electric and hot-water heating coils and their associated additional pressure drop may or may not be taken into account on the fan curves. Be sure it is included in the final static needs. From the fan curves, select a unit that will handle 0.708 m^3/s at 124 Pa and falls in the middle of the fan range as recommended in the section on Fan Size.

Heating Coil Selection. The heating coil is on the unit discharge, so the unit supply temperature equals the coil LAT. Coil entering air temperature (EAT) is a mixture of return and minimum primary air. Using Equation (16), calculate the coil EAT.

$$EAT = [(0.530\ m^3/s \times 23.9°C) + (0.177\ m^3/s \times 12.8°C)]/0.708\ m^3/s = 21.1°C$$

Coil capacity can be calculated using Equation (1).

$$q = 1.026 \times 0.708\ m^3/s \times (37.8°C - 21.1°C) = 14.3\ kW$$

From the manufacturer's catalog, select an electric heater with the proper input voltage (120, 208, 240, 277 or 480 V electric coil) that could be available with a variety of stages.

Note 1: Although there are air-side pressure drop data for electric heaters in the catalog, it is only necessary to calculate the drop if it is not included in the fan curves.

Note 2: The coil selection in this example produces a discharge air temperature that is too high for normal applications. A discharge air temperature limit of 30.6°C should be used. Airflow should be increased if SAT is above the recommended 8.5 K Δt.

Note 3: The mixed-air condition did not bring the EAT to room temperature. Additional induction or plenum air should be added to increase the mixed-air temperature.

Note 4: Using a PSC motor adds 0.6 to 1.6 K to the airstream.

Note 5: Reference manufacturer's recommendations for maximum temperature on electric heat to reduce the likelihood of nuisance tripping.

Total Cooling Coil Selection

Most manufacturers provide coil performance data and/or selection software. Coil capacity depends on coil design characteristics and the properties of the entering air and water. The enthalpy increase or decrease of the water through the coil multiplied by the airflow is the resultant capacity. The water temperature and the flow rate determine the inlet enthalpy; the airflow and coil characteristics determine the outlet enthalpy. The sensible to latent ratio is important to maintain occupant comfort. In the cooling mode, the resultant capacity should be the appropriate combination of sensible capacity for dry-bulb temperature control and latent capacity for humidity control. When these two components of capacity are met, the space being conditioned can stay in control and provide comfort for the occupants.

Do not exceed 2.5 m/s through the coil section. Exceeding this limit could cause condensate blow-off, potentially causing damage to surrounding materials.

Select water flow rates that will not exceed a velocity of 2.4 m/s within the coil tubing; this velocity can erode the copper and cause pin holes, resulting in water leakage and potential damage to material and property.

Example 5. Vertical Fan-Coil (Cooling Only). Select a unit at 189 L/s with a total capacity of 3.5 kW, with 2.6 kW sensible capacity and 0.88 kW latent capacity. The entering air is 23.9°C db and 17.22°C wb. Consulting the manufacturer's coil capacity data, a three-row coil is adequate to provide the capacity at 0.252 L/s. The resultant sensible and latent capacities are met as follows:

Rating Conditions:

Entering air db: 23.9°C	Entering air wb: 17.22°C
Airflow rate: 189 L/s	Water flow rate: 0.252 L/s
Fluid temp. EWT: 7.22°C	

Performance:

Total capacity: 3.67 kW	Sensible capacity: 2.77 kW
Latent capacity: 0.9 kW	
Leaving db: 11.78°C	Leaving wb: 11.33°C
Fluid pressure drop: 26.3 kPa	
Face velocity: 1.39 m/s	Air pressure drop: 39.8 Pa
Fluid temperature out: 10.67°C	Fluid velocity: 1.04 m/s

9. CHILLED BEAMS

Principles of Operation

An **active chilled beam** is an air diffusion device that introduces conditioned air to the space for ventilation and temperature control purposes. Primary air, conditioned at the air handling unit to meet the ventilation and latent requirements of the space, is delivered through a series of nozzles, creating induction of room air through a unit-mounted sensible heat transfer coil. This primary air often also contributes to sensible cooling of the space and drives the induction function through the coil. Depending on their nozzle size and configuration, active beams typically induce two to five parts of room air for every part of primary air they deliver to the space. When heating is required, warm water can be circulated through the coil.

Passive chilled beams rely on the natural buoyancy of air currents associated with convective heat sources to transport warm air to the upper portion of the space. On contact with the beam's integral sensible heat transfer coil, this air is cooled and falls back into the space. Primary air must be delivered to the space via a separate system for the purposes of ventilation and dehumidification.

Application Considerations

Chilled-beam systems must be designed to treat sensible and latent space heat loads, provide adequate space ventilation, conform to space acoustical requirements, and maintain occupant comfort in conformance with ASHRAE *Standard* 55 and other applicable codes.

In general, chilled beams offer the opportunity to capitalize on the benefits of decoupled ventilation systems with beam coils being responsible for most of the sensible load in the zone and the primary air satisfying ventilation and latent load.

Benefits and Limitations

Benefits. Heat extraction or addition by the coil often allows for significant reduction in primary airflow requirements over all-air systems. Energy to transport cooling and/or heating media can be significantly reduced because of water's high specific heat and density. As a result, chilled-beam systems require less space for the mechanical services, because of smaller ductwork and air-handling unit sizes. This reduction in mechanical service space requirements may make it possible to reduce the floor-to-floor height of a multistory building.

Water-side economizer opportunities may be extended as a result of the higher beam chilled-water temperatures, and provide an improved selection of available system options (e.g., geothermal, dry coolers, closed-circuit fluid coolers). Chilled-beam systems may offer opportunities to enhance chiller efficiencies and provide broader evaporator ranges.

Chilled beams require minimal maintenance. Vacuuming the beam coils is occasionally required and is typically guided by the needs of the space. Often, it is expected that service intervals could extend to three to five years. The lack of moving parts in chilled beams produces an inherently highly reliable system.

Chilled beams may be considered beneficial for the following applications/spaces:

- Environments with moderate to high sensible heat ratios, such as offices, hotels, and other spaces with significant imbalances between sensible loads and ventilation requirements
- Heat-driven laboratories where ventilation (100% outdoor air) requirements are relatively low (4 to 8 ach) but sensible gains are often 125 to 190 W/m^2, resulting in supply airflow rates in all-air systems that are significantly higher (12 to 18 ach).
- Hospital patient rooms where ventilation requirements severely limit the turndown ratio with all-air (VAV) systems, and thus require significant amounts of parasitic reheat to balance the

cooling delivery with the actual room cooling demand. See ASHRAE *Standard* 170 for additional detail.
- Classrooms where outdoor air ventilation rates are significantly lower than the space sensible cooling requirements. Chilled beams typically provide at least half of the space sensible heat removal by way of their chilled-water coil, thus allowing ducted airflow rates to be reduced to a level near the classroom ventilation rate. This facilitates the use of dedicated outdoor air (DOAS) units for classroom applications.
- Retrofits, because of minimal mechanical space requirements, and in cases of suitable envelope construction.
- Passive chilled beams can provide a very efficient means of perimeter-area temperature control when coupled with underfloor air distribution (UFAD) systems.

Limitations. Space humidity levels must be managed closely because of the limited dehumidification capability of the primary air. This is particularly important where operable windows are used or high infiltration levels are encountered in a humid climate.

Chilled beams may be inappropriate for the following applications/spaces:

- Environments with high latent gains such as kitchens, bathrooms, or locker rooms
- Natatoriums and sauna areas
- Poor building envelopes or buildings with unmanageable latent loads
- Mixed-mode ventilation (operable windows) without proper condensation safeguards

Design Considerations

The objective of chilled-beam system design is to minimize primary airflow rates. When chilled-beam systems are applied, the minimum primary airflow rate is typically the greater of that required for ventilation and for space dehumidification. In cases where these values are similar (differing by no more than about 25%), consider using a dedicated outdoor air system (DOAS). Laboratories and health care may require or benefit from the use of a DOAS, which uses chilled beams efficiently.

In cases where the sensible cooling requirements require significantly more than the minimum primary airflow rate, air-handling units that mix return and outdoor air volumes may be considered for use with chilled beams.

Chilled beams are generally intended to operate without condensation. Consequently, active chilled-beam supply water temperatures should be maintained at or above the room dew-point temperature to prevent condensation on the coil and its supply water piping. Passive chilled-beam water supply temperatures should be kept slightly (1.2 to 1.7 K) above the room dew-point temperature. In both cases, the chilled-water piping must be adequately insulated to prevent condensation on the pipe itself. Where adequate control of space humidity levels cannot be ensured, higher supply water temperatures and/or condensation controls should be considered. This is discussed in the following sections.

Terminal filtration and condensate pans are not required with a properly designed and operated primary air system with chilled-water temperatures maintained above the room dew point. Heating coils provide sensible heat only, and thus filtration and condensate capture devices are not necessary. Chilled-beam systems designed with noncondensing (dry) coils should be treated similarly. Beams with sensible-only cooling coils do not require filters per ASHRAE *Standard* 170 and section 307.2 of the International Code Council's *International Mechanical Code®* (ICC 2018).

Heating

Heating is limited to active chilled-beam systems; heating with overhead passive chilled beams is not effective.

The hot water serving the active beam's coil must be chosen to limit the discharge air temperature to less than 8.5 K above the room design set point. Additionally, to ensure proper room air distribution, the discharge velocity should be selected in accordance with guidance presented previously.

Alternatively, resetting the primary air temperature with a duct-mounted heating coil allows the primary air serving the interior spaces to continue to provide cooling, while the perimeter duct adds heating capability through this reset. Assuming the active chilled beams are the primary heating system, the beams should be located parallel to the curtain wall, to ensure air movement across these surfaces in order to promote a comfortable environment.

Six-port zone control valves may be used to eliminate a significant amount of zone runout piping and allow more efficient heating across active chilled beam coils.

When ceiling-based active beams are the primary space heating source, their primary air supply must be maintained to project the warm air into the space.

Thermal Comfort

Chilled-beam systems are designed to optimize delivery of cooling to the space, but the paramount consideration in sizing and locating beams in the room should focus on occupant thermal comfort. ASHRAE *Standard* 55 defines limits on local air temperatures and velocities that maintain acceptable levels of occupant thermal comfort.

Properly applied passive chilled beams have a limited effect on occupant thermal comfort; however, their complementary primary air supply system often does. Stratified or partially mixed air diffusion strategies are commonly used with passive beams because of their minimal influence on the natural buoyancy-driven air patterns associated with the chilled-beam operation. The secondary air circulation through the passive beam transports upper-level air back to the occupied zone, possibly altering the level of stratification in the space.

Active chilled beams directly supply a mixture of primary and secondary air to the space and should therefore be treated like the other air distribution devices used in fully mixed air distribution systems. Because the temperature of the chilled water supplying the coil must be at (or above) the space dew-point temperature, it is typically 13 to 16°C; thus, reconditioned air leaving the coil is typically several degrees warmer than the primary air with which it is subsequently mixed. This results in beam design discharge air temperatures that are above 16°C, thus warmer than those normally used by conventional all-air systems. Because of warmer discharge temperatures, larger active beam discharge air volumes are required.

Control and Zoning

Chilled-beam system primary airflow rates are much closer to the space ventilation rates than those of all-air systems, so primary control of the space temperature is normally accomplished by throttling the chilled-water flow. Simple on/off operation of two-position water valves provides adequate control of active chilled beams. Proportional valves are recommended for passive beams and active beams in applications where more precise space temperature control is required.

In applications where primary air is supplied at conventional temperatures (13 to 16°C) to spaces with significant sensible load variations, it may also be necessary to reset the primary airflow rate or temperature during low-load conditions. One approach is to vary the primary airflow rate in reaction to thermal demands and/or occupancy of the space.

Although many chilled-beam applications involve a constant-volume supply of primary air, chilled beams can also be served by varying primary airflow rates. For example, classrooms and conference rooms where occupancy levels may vary considerably can be

Table 9 Applications for Chilled Beams

	Commercial Buildings						Educational Facilities		Laboratories and Health Care					Domiciliary

fitted with demand control ventilation (DCV) provisions. In such cases, the primary air supply to the beams can be varied according to occupancy, while a space dew point override ensures that the primary air volume reduction does not compromise room humidity levels. Water flow through the coil remains controlled by the space thermostat, resulting in the ability to control space temperature levels independent of the primary airflow rate.

When chilled-beam systems are used to condition spaces with widely varying sensible cooling requirements (e.g. perimeter spaces), consider using a variable-air-volume (VAV) terminal to vary the primary airflow rate to beams in the zone. This allows the primary airflow rate to be throttled in response to the zone's sensible cooling requirements. The minimum flow limit on the VAV terminal is set at the minimum primary airflow rate required to ensure proper space ventilation, adequate room air induction, and humidity control.

Thermal zoning of chilled-beam systems should be performed in a manner generally consistent with other HVAC systems. Each thermal zone consists of a space thermostat, a chilled- (and, where applicable, hot-) water control valve, and multiple chilled beams.

Selection and Location

Chilled beams may be exposed or integrated with an acoustical ceiling system. Active chilled beams may be of either open or closed design. **Closed beams** induce secondary air from below, whereas **open beams** induce through their top or sides within a ceiling plenum. When passive or open active beams are applied, an adequate air path must be provided for secondary air to enter the beam.

For sizing and selection purposes, secondary air entering an active chilled beam should generally be considered at an equal temperature to that maintained within the occupied zone, unless solid evidence indicates otherwise. For passive beams, the entering air temperature is higher than that in the occupied zone due to room air stratification. The actual placement of the beam with respect to space heat sources often affects the entering air temperature.

Most active chilled beam suppliers offer various nozzle sizes and configurations. Nozzle configuration affects the beam's primary air pressure requirement and acoustical performance as well as its induction rate. Active beams with adjustable discharge or nozzle patterns may also allow for field alteration of the beam's air distribution characteristics. This may also affect the beam's cooling capacity, so changes should be made with caution.

Beam sizing and location must consider cooling capacity, acoustics, thermal comfort, and integration with other equipment and services. Active beams use a horizontal discharge of their supply air mixture through linear openings along their perimeter, and thus display room air diffusion characteristics similar to those of linear slot diffusers. As such, active beams should be selected and located such that velocities within the occupied zone are limited to 0.25 m/s or less if compliance with ASHRAE *Standard* 55 is the design intent. Mapping techniques (see the sections on Fully and Partially Mixed Air Distribution) and/or selecting active beam throw values from Table 6 may be used to estimate compliance with these comfort recommendations.

Locating stationary occupants directly below passive beams can result in thermal discomfort. Care must be taken to ensure that the velocity and temperature of the descending airstream entering the occupied zone comply with the thermal comfort requirements of ASHRAE *Standard* 55.

Operational Considerations

Water supply service to active and passive beams should not be activated until space dew-point temperatures are at or below the chilled water's supply temperature.

Where maintenance of adequate space dew-point temperatures cannot be ensured, some type of condensation detection and mitigation strategy should be used. There are various methods of accomplishing this, including the following:

- Sensors may be attached to the supply water pipe to detect formation of surface moisture and discontinue chilled-water flow until the moisture has evaporated. This method is relatively inexpensive but also reactive, and halts induced air cooling through the sensible water coil while conditions favoring the possibility of condensation formation exist.
- Dew-point calculation and reset of the chilled-water supply temperature is a proactive strategy that does not fully suspend secondary cooling. This method can be applied on a room-by-room basis, but calculation on a floor-by-floor basis is usually sufficient and less costly.
- In spaces with operable windows or doors, occupants and staff should be educated on the effect these have on their thermal environment.
- In some applications, condensate trays may be used to collect temporary and infrequent condensation. When used, trays must have adequate condensate removal and/or water flow modification provisions.

Building Type

The designer must consider the intended building use when determining the type of chilled beams to be used. General recommendations for chilled beam applications are shown in Table 9.

10. AIR CURTAIN UNITS

An air curtain unit acts as a controlled barrier for environmental and thermal separation and wind resistance when a building's doors or windows are opened. As an environmental separation barrier, it repels airborne dust, dirt, fumes, odors, and flying insects from entering a building or a protected indoor area. As a thermal barrier, it reduces cross migration of warm, lighter air flowing through the upper part of the opening and cold, heavier air flowing through the lower part of the opening. As a wind resistance barrier, it minimizes the effect of outdoor wind blowing into a building's openings.

A properly applied air curtain can maintain environmental integrity between two distinct areas while allowing unobstructed access between the areas. Energy savings are possible when the air curtain separates areas of different temperatures.

Principles of Operation

An air curtain unit operates on the principles of air entrainment, velocity vector, and pressure. Because the airstream entrains a volume of air as it travels across an opening, it can maintain separation of environments by returning these air volumes back to their respective areas when the airstream splits, thereby minimizing losses.

Air curtain unit energy effectiveness is defined by the amount of energy saved (i.e., the energy loss prevented through an opening with an air curtain), divided by the amount of energy that would have been lost without an air curtain. It is represented as a percentage, and the amount of energy saved is reduced by the energy consumed by the unit. Research (e.g., Pappas and Tassou [2003]) shows that air curtains have a range of effectiveness from 60 to 90%, depending on the type and application.

To fully realize benefits of using an air curtain unit, make sure that equipment is properly sized, installed, adjusted, and maintained.

Application Considerations

Air curtain unit selection depends on the opening's width and height. To maximize effectiveness, the air curtain unit must at least cover or slightly overlap the entire opening, and have a minimum velocity projection of 2 m/s at the target surface (Wang and Zhong 2014). The unit is usually mounted above or beside a door or window opening. When mounted above the opening, the horizontal air curtain unit discharges its air vertically down across the opening. When mounted next to the opening, the vertical air curtain unit discharges air horizontally across the opening. On wide openings, two vertically mounted, lower-air-velocity units can be used as an alternative to a single horizontally mounted, higher-air-velocity unit. The air curtain unit discharge must have a free and clear path to the entire opening for optimum performance. AMCA (2012) is an application manual for air curtains that provides detailed considerations for unit selection, installation, and construction.

Air curtain units are classified into two different types of construction: non-recirculating and recirculating. A non-recirculating system draws air into the unit directly from the surrounding environment in both horizontal and vertical applications (see Figures 25, 26, 27, and 28). An air curtain equipped with inlet ductwork, which draws air from outside the surrounding environment, is also considered to be non-recirculating (Figure 29). A recirculating system draws air from ductwork that primarily collects and returns the discharge air back to the inlet. Applications often use a plenum with a floor return connected to the inlet with ductwork (Figure 30). An alternative construction includes horizontal flow that discharges and returns from side to side (Figure 31).

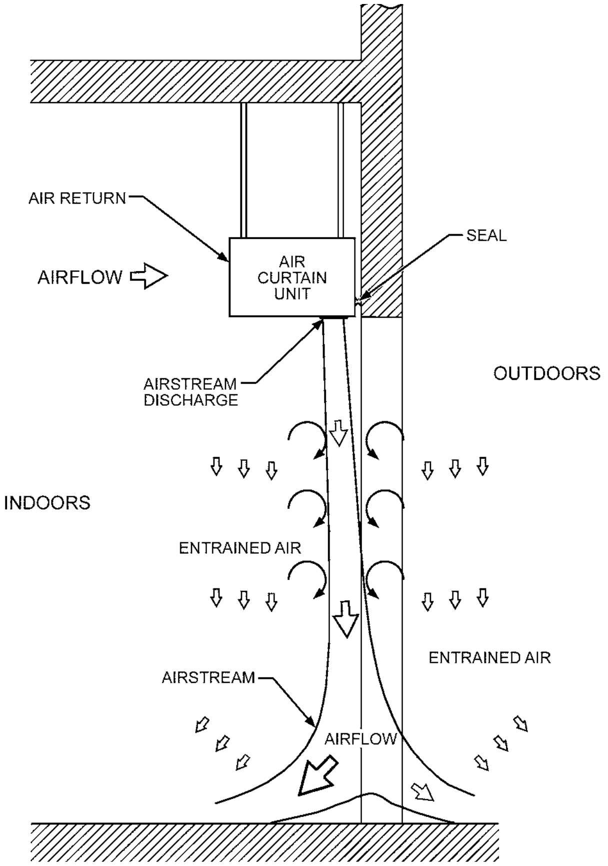

Fig. 25 Non-Recirculating, Horizontal-Mount High-Velocity Air Curtain Unit
(AMCA *Standard* 222)

Building Design Considerations

Non-recirculating air curtain units comprise the majority of systems built today. There are few limitations to where they can be installed, they have little effect on the construction or design of the building opening, and they are less expensive to install and maintain. In buildings with high ceilings, they can aid in destratification.

Recirculating air curtain systems have a higher effectiveness and are more expensive than non-recirculating systems. They are typically limited to commercial or cold storage applications where doorways have high traffic or are open for extended periods of time. They require careful integration into the building's construction and design and have door height limitations.

Types of Applications

Air curtain units use various electrical and mechanical means to control airflow rate and temperature to achieve environmental separation, mitigate wind conditions, and repel flying insects.

General applications of air curtain units include the following:

- **Exterior environmental separation:** protects an exterior opening from unwanted infiltration of outdoor air and the escape of indoor air caused by effects of natural wind and/or temperature differences.

- **Interior environmental separation:** provides protection between interior rooms connected by a common opening. This application is intended to prevent the unwanted infiltration of unconditioned air or the loss of conditioned air from one room to another caused by temperature differential. Typically, this can be controlled by an air curtain unit that has an air performance requirement much smaller than the air performance requirement for exterior applications.

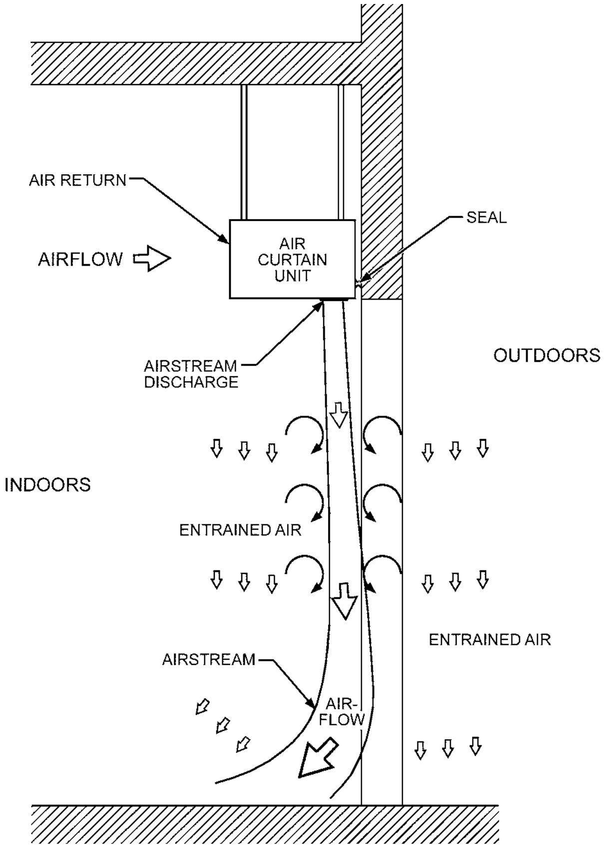

Fig. 26 Non-Recirculating, Horizontal Mount Low-Velocity Air Curtain Unit
(AMCA *Standard* 222)

- **Flying insect control:** protects an opening or doorway, usually exterior, from the unwanted entry of flying insects. This is a common requirement in facilities that produce, process, or serve foods (e.g., kitchens, cafeterias). This application typically requires an air curtain unit with a higher airstream velocity to repel flying insects. When units are selected with a higher airstream velocity to improve resistance against insect penetration, the energy effectiveness will be reduced.
- **Coolers/chill rooms and freezers/cold stores:** prevents loss of refrigerated air through openings and/or doorways in coolers and freezers. Three types of applications exist: cooler to freezer, ambient to cooler, and ambient to freezer. These types of installations are generally (but not limited to) indoor applications; therefore, the air curtain unit is only required to overcome airflow caused by temperature differential and not wind pressure. Air curtain units are typically horizontally mounted on the warm side of the doorway, so that the airstream split created can balance against the air trying to leave the cold room. Cold storage installations can be difficult to balance and may require a vertical or cold-side mount, dampers, and/or multispeed motors to effectively protect the opening.
- **Ovens:** protects against loss of heated air through openings and/or doorways in ovens. Air curtain units are normally mounted horizontally over the oven opening and angled slightly inward toward the oven to prevent hot air from escaping through the top of the opening. These types of installations are generally indoor applications; thus, the air curtain unit is only required to overcome airflow caused by temperature differential and not wind pressure. The heating process in ovens is typically designed to maintain a neutral pressure with the surrounding environment. The air curtain unit should be adjusted to only entrain and “turn back” the heated air to avoid creating an unbalanced condition by forcing air into the oven. The mounting location of the air curtain unit should also provide adequate protection from exposure to hot air that would escape the oven in the event the air curtain unit is shut down.
- **Negative building pressure:** Air curtain units installed on an opening where a negative pressure exists require special consideration. When the building is underpressurized, standard air curtain airflow rate will not be able to overcome the artificial deflection created by the negative condition. In special cases, airflow may be increased to overcome a slight negative condition. For proper operation of the air curtain, the building should be neutral or positively pressurized.

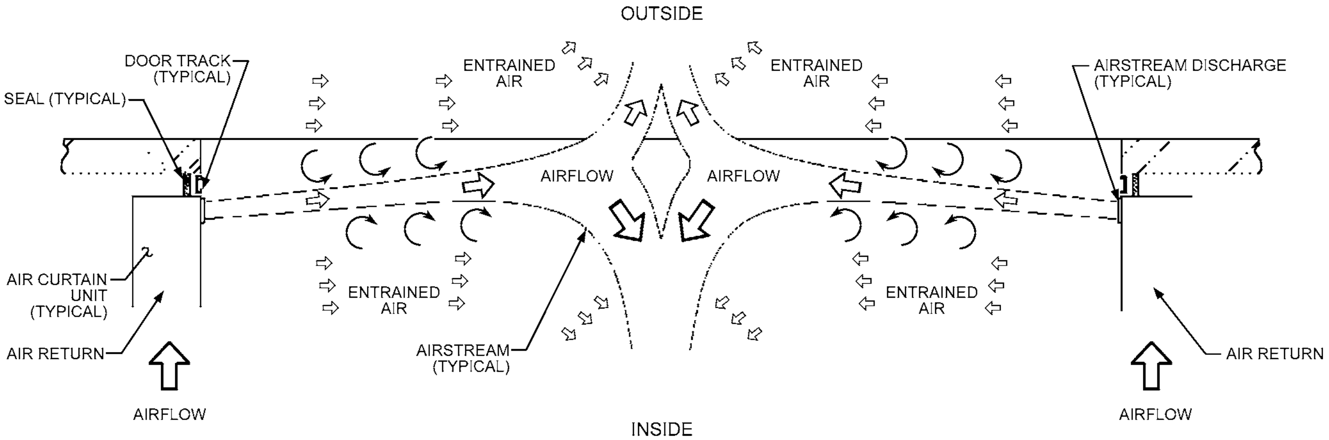

Fig. 27 Two Non-Recirculating, Vertical-Mount Air Curtain Units
(AMCA *Standard* 222)

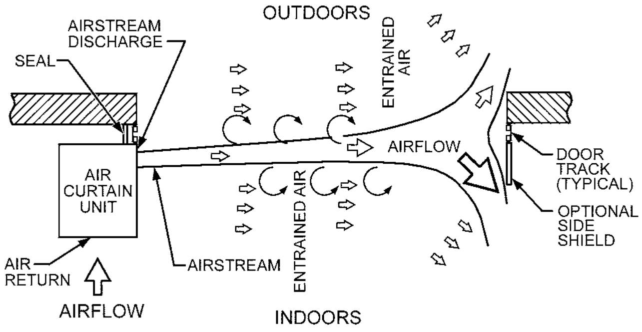

Fig. 28 Non-Recirculating, Vertical-Mount Air Curtain Unit
(AMCA *Standard* 222)

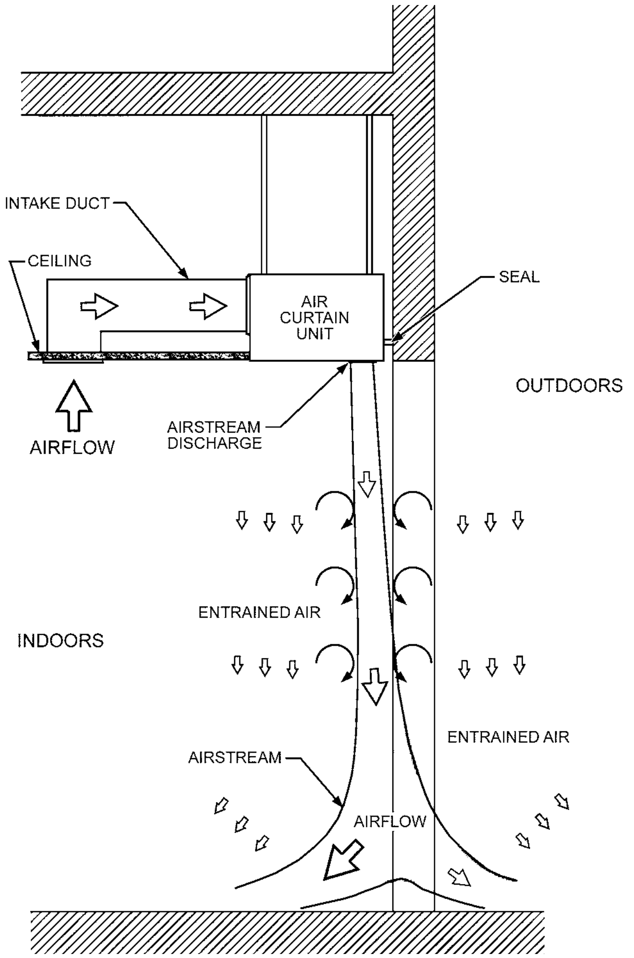

Fig. 29 Non-Recirculating, Horizontal-Mount Air Curtain Unit with Ducted Inlet
(AMCA *Standard* 222)

- **Special/custom:** other applications include protection against dust infiltration, water removal in drying processes, smoke and odor containment, and defrosting doorways. In these cases, effectiveness is defined by the application criteria.

Optional Features and Controls

Optional features for air curtain units include heating, cooling, filters, and special controls. A combination of special components, casing materials, and casing coatings may be required for outdoor mounting, hazardous locations, or harsh environmental applications. Supplemental heating/cooling can be provided by an air curtain unit to reduce the zone load on unitary HVAC equipment, but it should not be seen as the primary source for conditioning internal areas. The energy effectiveness of an air curtain unit is not enhanced when it provides conditioned air. Heating methods can include steam, hot water, electricity, and fuel gas. Cooling methods can include chilled water or direct expansion.

Applications in dusty or dirty areas may benefit from air curtain units equipped with inlet air filters to reduce maintenance and maintain optimal performance. Note that the aerodynamic performance of an air curtain unit will be reduced if filters are not properly sized, cleaned, or changed. Air curtain unit electrical controls that monitor door position and temperature, or BMS interfaces are required to provide the design velocity, temperature, and operation of the air curtain. They are also used to minimize unnecessary energy usage and overconditioning of the building opening.

The discharge of an air curtain unit adjusts the direction of the air curtain for proper protection. This adjustment may include (but is not limited to) the following types:

- **Pivot mount:** the ACU cabinet is capable of pivoting on its mounting so that it may direct the air curtain at the proper angle to protect the opening.
- **Adjustable nozzle:** the ACU discharge nozzle is capable of pivoting within the ACU so that it may direct the air curtain at the proper angle to protect the opening.
- **Adjustable nozzle vane(s):** the ACU discharge nozzle employs a vane, or vanes, that are capable of pivoting within the nozzle so that it may direct the air curtain at the proper angle to protect the opening.
- **Both adjustable nozzle and vanes:** the ACU employs a combination of the adjustable nozzle and adjustable nozzle vanes.
- **Diverter nozzle:** the ACU employs an apparatus within the nozzle that is capable of diverting the air curtain at the proper angle to protect the opening.

Performance and Safety Standards

Air curtain unit performance data can be used to select and/or compare different products. ANSI/AMCA *Standard* 220 defines the test methods that can be used to generate data for the typical types of non-recirculating air curtain aerodynamic performance.

ANSI/AMCA *Standards* 300, 301, and 320 are sound standards that can be used to rate air curtains units are.

For insect control applications, use ANSI/NSF *Standard* 37 to determine criteria for air curtain unit air performance, construction, design, and material type. An air curtain unit that complies with this standard is considered by the food service industry to provide effective flying insect protection to an entryway by deterring flying insects from entering through the opening or nesting in the air curtain unit.

Safety standards that can be applied to air curtain units are UL *Standards* 507, 1995, and 2021.

Energy codes and standards such as ASHRAE *Standard* 189.1-2014 and the IECC define air curtain unit air performance and operation requirements for energy sustainable structures.

Maintenance and Accessibility

Whether the unit will be mounted horizontally or vertically, and inside or outside the opening, obstructions surrounding the opening will require special installation considerations. Typical obstructions may include beams, piping, ductwork, electrical conduit, door hardware, etc. Accessibility for maintenance should also be considered. Each manufacturer provides specific instructions for their products;

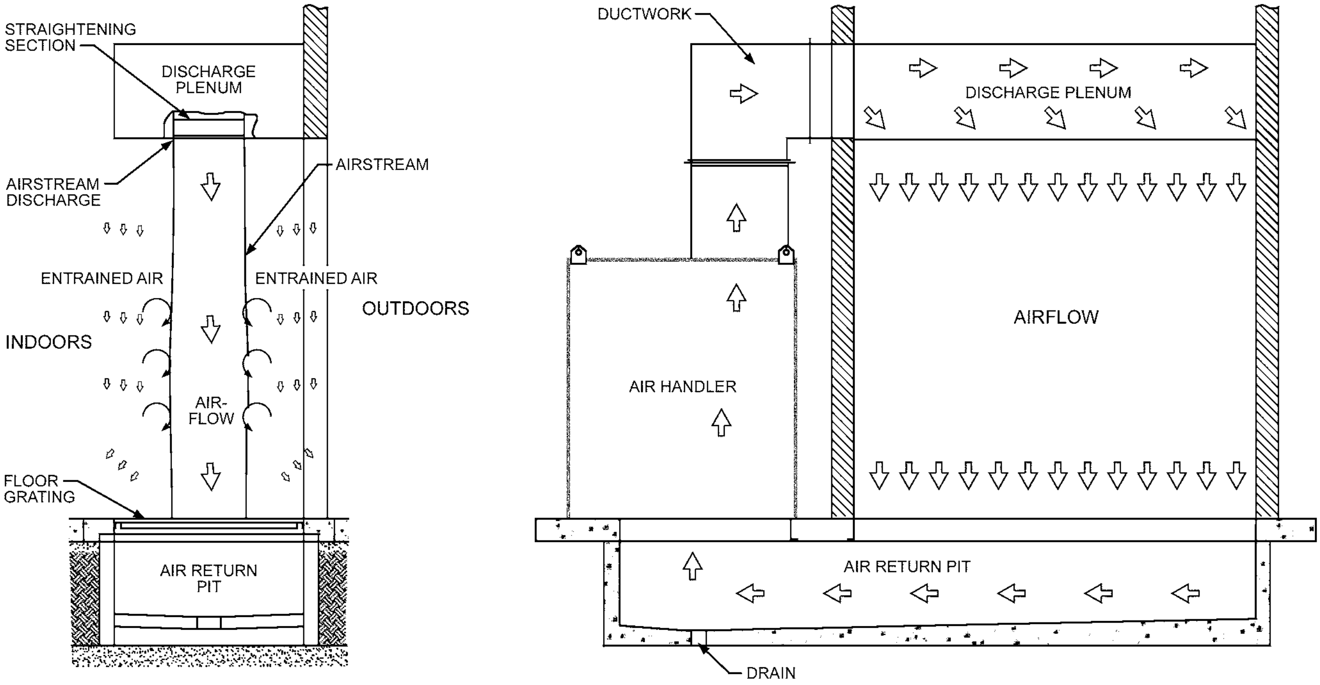

Fig. 30 Recirculating, Horizontal-Mount Air Curtain Unit
(AMCA *Standard* 222)

carefully follow the specific instructions regarding safety, installer qualifications and recommended work practices.

Multizone Simulation of a Typical Office Building 59.21

WHEN trying to determine best design practices for specific indoor spaces, building designers may encounter uncertainties regarding control of airflow, indoor air quality, thermal comfort, or heat transfer. A design may need to fulfill specialized requirements, such as reducing contaminant transport across building zones in a hospital or providing the most energy-efficient configuration for cooling in a cutting-edge data center. Evaluating performance of these complex and highly engineered designs is often beyond the ability of the tables, rules of thumb, and simple formulas given in the *ASHRAE Handbook*. In these situations, computer models allow designers to quantitatively evaluate multiple designs quickly and with a good degree of accuracy. This chapter expands on the general guidance of Chapter 13 in the 2017 *ASHRAE Handbook—Fundamentals*, with the addition of industry-specific advice and examples to aid designers in modeling indoor applications. Although this chapter is intended to be a fast-start guide for modeling indoor airflow, engineers should have a basic understanding of fluid mechanics and the modeling principles described in Chapter 13 of 2017 *ASHRAE Handbook—Fundamentals.*

1. PRELIMINARY CONSIDERATIONS

Although indoor airflow modeling provides engineers with unparalleled insights and visual design aids, the resulting model is only as good as the specified inputs and assumptions. An engineer must be cautious in selecting modeling parameters and carefully examine the simulation results before making any design decision. Circumspection is especially needed when simulation predictions do not conform to standard design practice.

First determine the scope of the domain (the physical extent of the simulated space) of a model; for most cases, this is a discrete indoor space, although it is possible to model a larger domain including multiple spaces or, conversely, a small domain containing only a subsection of a space. Next, determine the intent, or the desired output from the model. Local air velocities and temperatures or airflow rate into/out of a space are often the primary interests, but it is common to also include parameters such as relative humidity and pollutant concentration or application-specific derived data. With the modeling goals in mind, it is possible to provide appropriate inputs and select methodologies consistent with the desired quality of results.

The two methods featured in this chapter are computational fluid dynamics (CFD) and multizone (MZ) modeling, described in detail in Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*. CFD is typically used if a detailed airflow pattern/thermal comfort/indoor air quality analysis of a single space is desired. If only the aggregated zone information is important and determining the interaction between multiple spaces is desired (e.g., average airflow rates in individual rooms, spread of a contaminant through an entire building), the multizone method provides satisfactory results without the significant computational investment and complicated setup of CFD.

The preparation of this chapter is assigned to TC 4.10

2. COMPUTATIONAL FLUID DYNAMICS (CFD)

CFD methods simulate the detailed airflow distribution and related physical phenomena in a space and provide detailed information, such as temperature and relative humidity, at specific points. However, due to the relatively high computational cost, the size and geometric complexity of the space that can be modeled is limited by the computational resources available. Practitioners who plan to use CFD must weigh the computational requirements against the expected accuracy of the simulated results to determine the appropriate level of detail to implement in the CFD model. Detailed background and theoretical development can be found in Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*. This section provides only basic guidelines for modeling indoor airflow and associated attributes.

2.1 TERMINOLOGY

Terms and definitions in this section are neither comprehensive nor specific to any software packages. However, these terms should be easily recognized and applicable to any CFD software platform.

Domain. The specific space to be modeled in the CFD simulation. Typically, it is a single discrete space in a building, but it may be as large as several blocks of a street, or limited to only a specific region within a room.

Geometry. The physical geometry normally includes both the extent of the solution domain and the physical objects in it. The physical objects may form an integral part of the CFD model or may be excluded, depending on the intent of the computational model.

Mesh. Mesh, also called **grid**, is the discretized representation of the geometry. For CFD software to conduct its simulation, any geometry must be broken into a large number of small pieces or elements. The process of breaking up the geometry is called *meshing*, *gridding*, or *grid generation*.

Cell. This is the smallest individual unit of a mesh.

Mesh/cell type. Different cell geometries are used, and are typically basic geometric shapes. *Tetrahedral* (four faces) and *hexahedral* (six faces) are two common types. A *polyhedral* (shape-independent) mesh uses a collage of different shapes.

Mesh/cell organization. Structured grids are identified by regular connectivity. The simplest form is a single, block structured Cartesian mesh, where the cells form a hexahedral mesh containing only rectangular brick-shaped elements, with every face in a plane aligned with two of the Cartesian axes. The lines of such a mesh extend through the entire solution domain. An unstructured grid is identified by irregular connectivity. More complex meshing strategies often use unstructured meshes because the neighboring cell's data is no longer guaranteed to be the next cell in a three-dimensional matrix, and cell connectivity also has to be stored.

Aspect ratio. A measure of the stretching of a cell. This compares how similar in length a cell's sides are. Highly stretched cells are typically avoided, because this can distort simulation results.

Cell growth rate. A measure of how rapidly the size of cells changes for a given region. High growth rate is typically avoided because flow characteristic details might be lost.

Boundary conditions. A boundary condition is a surface or volume where known or estimated properties can be applied. These properties are the input parameter for CFD simulations.

Source/sink. Sources and sinks are specific boundary conditions that provide a net gain or a net loss of a specific quantity of mass, heat, or momentum.

Residual error. Residual is one of the fundamental measures of an iterative solution's convergence: it directly quantifies the error in the solution of the system of equations. In a CFD analysis, the residual measures the local imbalance of a conserved variable in each control volume.

2.2 OVERVIEW OF CFD SIMULATION

Following are the seven steps generally applicable to modeling indoor airflow in CFD.

1. **Geometry generation.** A physical model of the domain is generated from scratch or converted from an existing architectural model. Whether the geometry includes both the fluid and solid portions depends on the scope of the analysis. Generally, the fluid portion is sufficient for most types of analysis. (In this chapter, a **fluid** is defined as a substance that deforms continuously in response to shear stress, and a **solid** is a substance with a fixed shape.) The geometric model should capture all essential features of the space such as flow obstructions (e.g., furniture, equipment), air supply/return devices, and heat sources/sinks (e.g., exterior glazing, occupants, equipment). The geometric model should be kept as simple as possible, while still maintaining sufficient accuracy and satisfying the intent of the analysis.
2. **Mesh generation.** Mesh creation may occur in or outside of the CFD software package. Regardless of what tool is used, the meshing process should generally follow this outline:
   (a) Define desired outcome of simulation to reach meshing decisions.
   (b) Decide mesh/cell types. This selection usually follows the geometric shape of the 3D model. In buildings, due to the rectangular cubic nature of the space, the hexahedral mesh is often used. However, other types of mesh could be more suitable if geometry requirements exceed the nature of hexahedral mesh.
   (c) Determine cell size and number. Computational cost increases with number of cells. Though increasing the number of cells by decreasing cell size typically improves the accuracy of CFD simulation results, there is a practical limit on the number of cells for a given project due to both computational resources and time constraints.
   (d) Define the region of refinement. Given the practical limit on number of cells to be used, the engineer should focus on the optimal distribution of cell size for a given scenario, with finer cells used for regions of interest or near surfaces or regions where large gradients are expected.
   (e) Select an appropriate aspect ratio. An aspect ratio close to 1 ensures that the shape of the cells does not distort simulation results by ignoring the influence on details caused by the stretched dimension.
   (f) Transition/growth rate needs to be gradual. If the transition from small cell to large cell is abrupt, there could be loss in detail, impacting the resulting flow pattern.
   (g) Wall boundary layers often require additional mesh refinement due to the interaction between solid and fluid.

   Meshing is generally an iterative process, and the most suitable number and distribution of cells can sometimes only be identified after the simulation results have been verified. The included simulation examples provide some guidelines on the process for specific scenarios.
3. **Model/solver selection.** CFD is the process to iteratively solve the Navier-Stokes (NS) equations, which are the basic governing equations for a viscous, heat-conducting fluid. CFD software typically includes the option to select various physical/mathematical simulation models to help solve the NS equations. Some of the possible model parameters include the following:

   - *Steady-state and transient simulation.* Indoor environments are inherently unsteady, but a steady-state (SS) or a quasi-steady state (QSS) simplification can usually represent the bulk airflow pattern well. Hence, one of the very first decisions in a CFD simulation workflow is whether to conduct the simulation in SS or transient modes. An SS model simulates a snapshot of a moment in time. A transient model allows engineers to investigate flow characteristics that change over time.
   - *Fluid properties of air.* Although many fluid properties (e.g., density, pressure, viscosity) can be changed, usually the most important parameter is the fluid density, because it can alter the method of fluid movement calculation (see Buoyancy model).
   - *Buoyancy model.* When incompressible fluid is assumed (due to minimal change in pressure and temperature), density remains constant and buoyancy might be ignored or handled separately (through methods such as the Boussinesq approximation [Gray and Giorgini 1976]). Otherwise, an ideal-gas or real-gas model should be used.
   - *Energy model/equation.* The energy model accounts for the energy/heat transfer between the cells in CFD, and subsequently, the temperature for each cell. Some CFD software allows decoupling of energy model from the physical model for isothermal analysis. For most cases, due to local heat sources and higher/lower air temperature from the supply registers, the energy model should be enabled and coupled with a flow model.
   - *Thermal radiation model.* The indoor environment may include large surface-to-surface temperature difference or significant exposure to sunlight. In those cases, if forced-convection fluid transport is not dominant, a radiation model might provide a more accurate assessment of heat transfer in the domain, in addition to the conduction/convection-based transport in CFD.
   - *Turbulence model.* Because the typical cell size used in CFD is too large to directly simulate fluid-flow turbulence, turbulence models are used. Specific modeling techniques, including Reynolds-averaged Navier-Stokes (RANS) and large eddy simulation (LES), are discussed in Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*. The importance of selecting an appropriate turbulence model cannot be overstated. This has a significant impact on the modeled physics and the accuracy of the simulation. Due to their reasonable accuracy and low computational cost, RANS models (such as RANS k-ε RNG) are widely used. Relevant literature should be consulted for more guidance on choosing the appropriate turbulence model (e.g., Chen et al. [2010]). Examples of such selections can be found in the section on Multizone Simulation Method.
   - *Species model.* The species model is used when different types of fluids (in most cases, fluids other than air), each with

distinct fluid properties, are combined. One application of such a model is to track gaseous pollutants (e.g., volatile organic compounds, [VOCs]) in an indoor space.

4. **Boundary conditions.** Every surface in the CFD model provides a parameterized boundary to the fluid space that is simulated, and the conditions/inputs for these surfaces must be set. Several common boundaries typically encountered in indoor airflow simulations are as follows:
   - *Wall.* For most CFD software packages, any defined solid/surface has the default classification of wall, which usually indicates a solid, nonpermeable, no-slip surface. A wall can be slip or nonslip and/or have a roughness parameter associated with the surface, which can affect the turbulence simulation in the fluid region. In the case of the solid interacting with the fluid in a simulation, additional mechanisms may be introduced at the wall boundary. The interaction might include heat transfer, mass transfer, and chemical reactions.
   - *Inlet.* A surface set to inlet classification allows fluid flow into the simulation domain. The property of this flow can be defined by its velocity, direction, pressure, or flow rate. In the case of multiphase or multicomponent fluid simulation, the inlet definition might include the exact mixture of the fluid. The most common examples for an indoor inlet are the HVAC diffusers (as investigated by Srebric and Chen [2001]) or opened windows.
   - *Outlet.* This type of boundary allows fluid flow out of the simulation domain. Unlike an inlet, this boundary often does not require variables to be defined, because flow exiting the outflow boundary is outside of the simulation domain. In most cases, only hydrodynamic variables (pressure or velocity) need to be defined at an outlet. The most common example for an outlet in indoor airflow simulations is the return in an HVAC system.
   - *Source/sink.* Source and sink allow the specification of a flux of a specific quantity of interest. In most simulations, energy source/sink of the domain might be specified as a heat flux on a given surface or volume. In a multispecies simulation, injection or removal of gas or particles are treated as mass flux. When a mechanism that impacts the flow field is needed, artificial momentum flux might be applied.
5. **Solution convergence.** Because the CFD solution process is iterative, the solution must converge to a specified tolerance to be considered complete. If the solution has not met such criteria, the simulation results are usually considered inaccurate and insufficient for design purposes. Although some guidelines exist for when a solution is considered converged, there is no single definition. In general, convergence is usually judged by examining three solution parameters:
   - *Residuals of the equations being solved for the specific simulation* (e.g., momentum, mass, energy, species). These must fall below a certain tolerance before a solution is considered converged. The tolerance criteria are usually based on the physical property and the scale of defined problem.
   - *Global imbalance of the conserved quantities* (e.g., mass, momentum, energy). For steady-state simulations, the amount of mass, momentum, and heat going into a domain must be equal to that exiting the domain. The imbalance between the two must again fall below a specified tolerance for a solution to be considered converged.
   - A *specific variable in a region of interest.* Very roughly defined, when the variable of interest stops changing as the solution progresses, the simulation can be considered converged. For an indoor airflow simulation, examples are air temperature or velocity at specific monitor points. Guidelines on specific convergence criteria are discussed in the examples in the section on Multizone Simulation Method.
6. **Post processing.** Post processing takes the CFD solution at each cell and provides an easy-to-understand visualization in colorful and/or animated format. For example, a plane might be created in a simulation to bisect an entire simulation domain in order to display temperature profile/contour of the desired location. For reference, each of the cases in the section on CFD Examples includes specific visualization (i.e., post processing) unique to a given problem.
7. **Validation.** Even with simulations conducted with great care, results can still be incorrect due to unforeseen errors or poor assumptions. It is important to verify the results with domain knowledge or previous results that can be used as validation for the CFD simulation. Some sources of validation include published research articles, verified case studies, and previously designed projects.

3. CFD EXAMPLES

In this section, several real-world examples created by expert computational dynamics users demonstrate the use of simulations in buildings and indoor environments. Due to the diverse subject interests of contributors, the details vary. However, key information, including geometry and mesh construction, input parameters and boundary conditions, and solution convergence criteria, is included for all of the examples.

3.1 SIMPLE OFFICE WITH DIFFUSERS AND RETURNS

This example involves a typical office space with multiple cubicles, where supply air is delivered through ceiling diffusers, and return air enters through a grille on a wall. The purpose of this CFD simulation is to determine, under a steady-state (SS) assumption, the air characteristics (temperature and velocity) near the office workers seated in these cubicles. The SS assumption is used here because the workers often remain stationary for long periods of time, and the airflow characteristics do not vary significantly (flow rate and temperature of the air and surface remain steady). The following are specifications made for this simulation and the key parameters used, with a short discussion on the reasoning behind the decisions. Because this is the first example, some steps are explained in more detail with additional comments. This level of explanation is not repeated in the subsequent examples, but the considerations noted still apply.

Geometry Generation

As seen in Figure 1, the geometry is generated to represent the office with cubicles. Note that the furniture, desks, and workers are modeled with very simplified geometry. This is common in indoor CFD simulation, because the primary interest is often the bulk air movement and temperature, and the microenvironment near objects and human bodies is of less importance. Consequently, the small-scale features and curvatures of the room objects can be overlooked. This particular office space geometry is generated using a CAD tool included in a commercial CFD package. However, it might be simpler for a practitioner to generate 3D geometry in an external CAD tool, especially if complex shapes and curvatures are required.

Mesh Generation

Part B of Figure 1 displays the mesh generated for the office once the geometry is finalized. The base size of cells in the room might be relatively large depending on the complexity of the flow regime, but a grid independence test should be conducted to determine that a

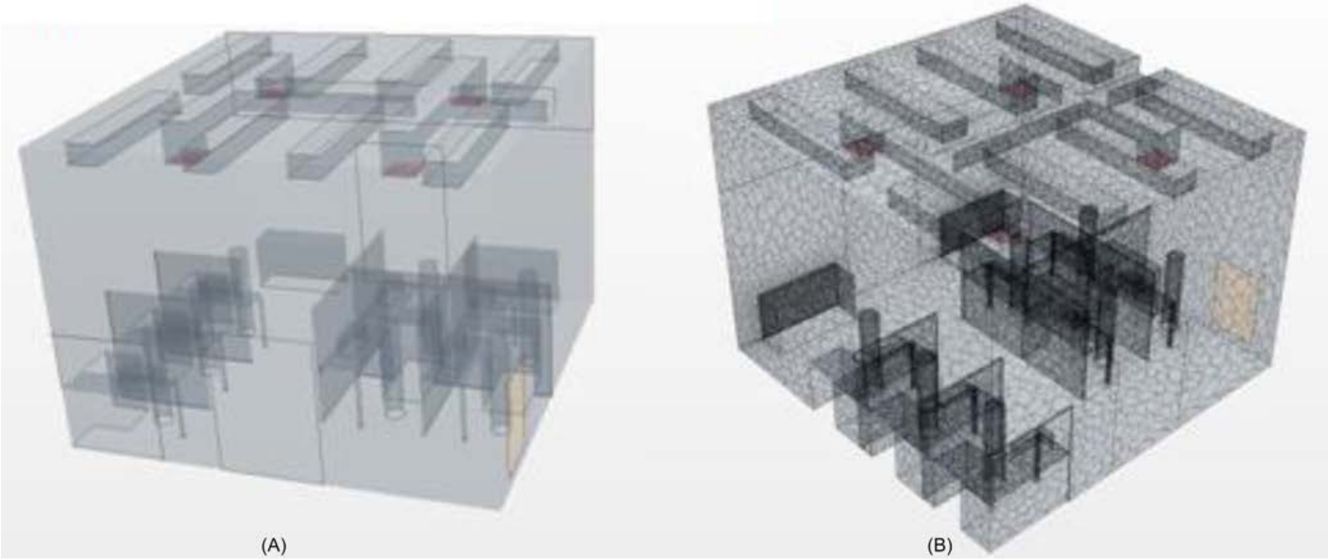

Fig. 1 (A) Geometry and (B) Mesh

balance between calculation time and accuracy has been achieved. In this case, a base cell size of 300 mm (roughly the size of the diffuser opening) is used for the automatic mesh generator. Polyhedral mesh is used here to reduce amount of mesh manipulation required (compared to hexahedral mesh). There are additional refinements near the region of interests, such as the inlet, the heat flux sources (lights, computers), and near the occupants. In this case, a 10% base cell size is used to refine the region near the occupants, in the interest of comfort level. The 300 mm base size was also checked for grid independence, where smaller base size did not yield a change in results in monitor points near the occupants (due to the refinement, the cell size is roughly 25 mm near the occupants, hence it is sufficient for the simulation). This cell size results in roughly 50,000 cells in the simulation domain, a number that can be accommodated by typical personal computers.

Solver and Models

RANS with a k-ε turbulence model (Chen et al. 2010) is selected because bulk flow near the occupants is the primary interest. Due to the heat flux in the room (see the section on Boundary Conditions), the flow energy coupled solver is used to determine the buoyancy aspect of the driving force in addition to the forced convection from the diffuser. For the same reason, the simulation assumes ideal gas (or real gas if a specific property is known) due to the small temperature and pressure variance in the domain.

Boundary Conditions

The specific boundary conditions for this example are the inlets, outlets, and heat sources in the room. The other boundary is a simple wall assumed to be no-slip. The outlet is a simple pressure outlet condition with a relative pressure of 0 Pa compared to the room pressure (just upstream of the outlet) This is due to the inlet already providing the flow driving force, and results in a negative pressure at the outlet. The heat sources (people, computers, and lights) are given specific heat fluxes on their corresponding surfaces (see Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*):

- Occupants: 50 W (sensible only)
- Lights: 30 W (single fluorescent tube)
- Computers: 50 W (nominal power consumption)

The supply diffuser model requires special consideration, because the inlet has a dominant influence on the room airflow

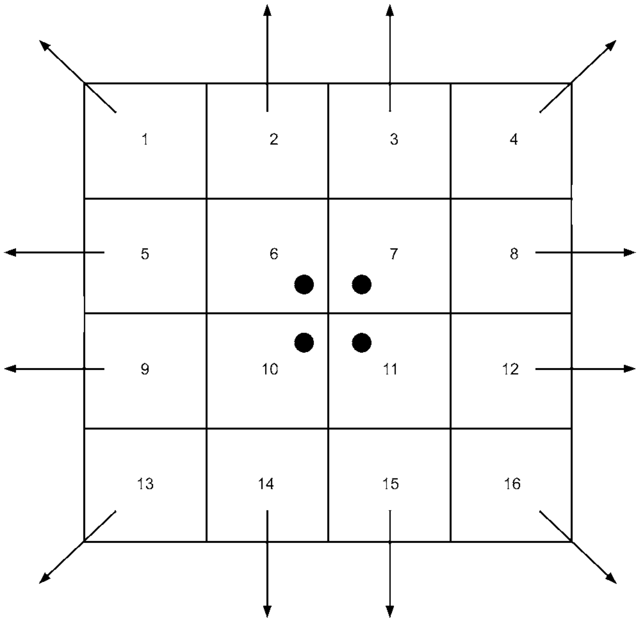

Fig. 2 Illustration of Momentum Method for Inlet Model

pattern and velocity. Unlike the return/outlet, the supply/inlet must have both direction and magnitude in order to establish a correct flow field for the simulation. Figure 2 shows an example of using the momentum method (Srebric and Chen 2002) to model the square louver diffuser in this problem.

The diffuser momentum method was chosen because, if the square diffuser supply for the office was left as a square hole without any additional information beyond the designed flow rate, this inlet boundary condition would be assigned to a specific pressure differential or velocity inlet normal to the opening. This normal assumption is correct in terms of providing airflow rate into the room, but the initial velocity direction and subsequent flow pattern are completely incorrect: a diffuser would spread out the supply air for good mixing, whereas a square-hole inlet model generates a column of air with downward velocity. In Figure 2, the square inlet is divided into

16 smaller inlets, each assigned with a different direction and velocity magnitude, in an attempt to replicate the dispersion airflow field from the diffuser. The resulting airflow pattern should follow the diffuser manufacturer data (throw/spread) or any experimental data available. Supply air temperature was set to 14°C, a typical value in U.S. office buildings.

In this method, because the air velocity and direction of multiple inlets are used, it is important to verify whether the total airflow rate from the inlets still represents the intended flow rate from the diffuser. If the momentum method is not applicable, Srebric and Chen (2011) also provide alternative diffuser modeling methods.

Convergence

Convergence of the CFD solution was achieved by monitoring the solution residuals as well as several temperature monitor points in various part of the room (Figure 3). In this case, the solution's mass and momentum equation residuals stabilized and dipped below 1×10^{-4} at roughly 450 iterations, and the temperatures stabilized at about 700 iterations. Selection of 1×10^{-4} in the continuity, momentum, and turbulence equation residuals is a typical rule of thumb for indoor CFD simulations, but 1×10^{-6} and 1×10^{-5} are recommended for the energy and species equations, respectively. These convergence tolerance metrics should be accompanied by stabilization of the solution variables. This stabilization indicates that a steady-state flow solution has emerged and the solution has been determined to be converged.

Post Processing and Results

To display the simulation results, two planes were used to show the solution contours near the occupants, displaying the air temperature and air velocity (Figure 4). A horizontal cut plane at head level of the sitting occupants demonstrates breathing zone quantities, and the vertical cut plane through the diffusers demonstrates inlet flow regime.

Results

The goal of the simulation was to determine whether the temperature and air velocity meet the ASHRAE comfort requirements. Per ASHRAE *Standard* 55, it is evident the velocity did not reach the level of a noticeable cold drift, and temperature near occupants is well within the ASHRAE comfort zone. Hence, this particular design fulfills the comfort criteria.

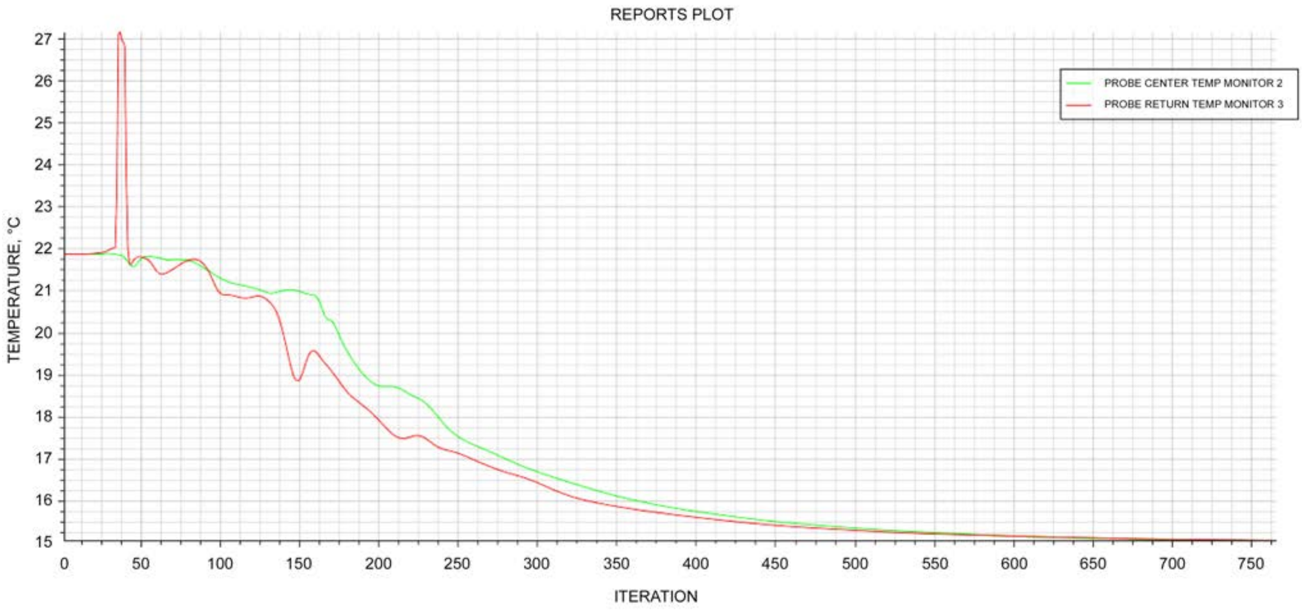

Fig. 3 Temperature over Iteration Indicates Steady-State Convergence

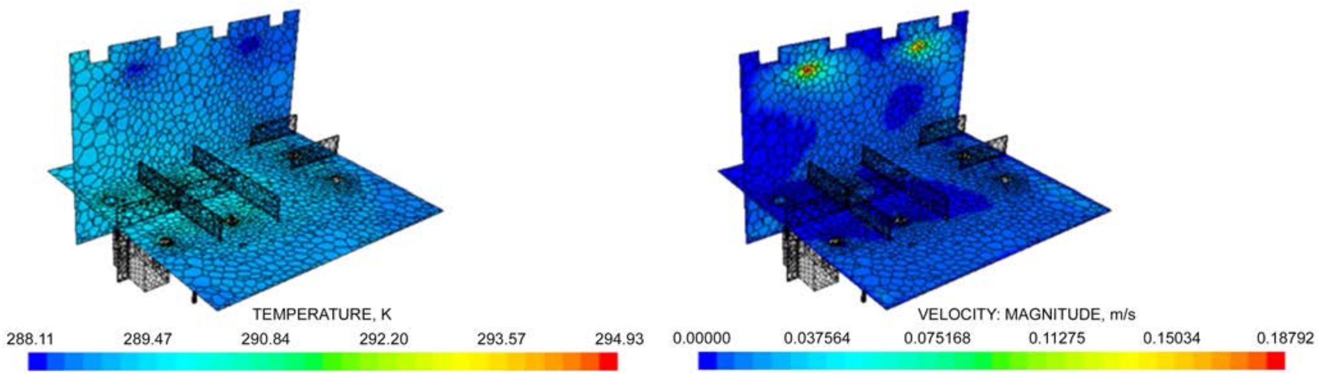

Fig. 4 Temperature and Velocity Results from Simulation Shown in Two Planes Bisecting Region of Interest

3.2 CHILLED BEAM

Use of passive (without fans) cooling applications in buildings has been on the rise. However, without a specific airflow rate from a HVAC fan system, it is difficult to design the system to satisfy specific thermal comfort and moisture control criteria. The purpose of this CFD model is to investigate the performance of the chilled-beam design by analyzing condensation risk on the windows as well as thermal comfort and ventilation effectiveness in the space in heating mode. The following is a discussion of the various modeling decisions made for this specific case and the reasoning behind them.

Geometry of Open Office with Chilled Beams

The modeled section of the open office is a 116 m^2 space with a 2.7 m high ceiling, and exterior windows. The office has cubicle desks with partitions and cabinets (as well as computers). This section of the office is conditioned with six two-way chilled beams in the ceiling, and return air is assumed to leave through an opening on the back wall (Figure 5).

Figure 5 is a simplified representation of the gross geometry of the office. The geometric features are

- Furniture (e.g., desks, cabinets, and cubicle partitions)
- Simplified occupants
- Computers, broken up into a monitor and a tower
- Windows, which include some details of the mullions
- Chilled beam discharge slots (inlet)
- Chilled beam induction face (outlet)
- Return opening on back wall (outlet)

Because the purpose of the model is to study bulk airflow and temperature distributions, simplicity is key when representing these features. Although box representations are used for all furniture and computers in the space, extra detail has been added to increase the fidelity of the simulation. For example, the spaces under the desks are included in the model, and the computers are split into parts (monitor and tower). This is not generally required, but was done to more accurately capture the thermal plumes from the occupants and the equipment in the space. Because there are only 12 occupants, more refined models of the occupants are used, although simplified models such as cylinders would have also been acceptable. These specific cuboid models include the arms, legs, and a head, while retaining the total surface area of an average-sized, seated adult male (see Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*). When modeling heat/contaminant sources (e.g., occupants), the surface area of the simplified representation is very important, because it determines the temperature of the surface when a heat flux boundary condition is specified and vice versa. The windows in the model include some details of the mullions, because one of the purposes of the CFD model is to study condensation risk. Geometric representations of the chilled beams and returns depend on the modeling approach as well as the desired level of accuracy. The chilled-beam model is described in detail in the section on Boundary Conditions.

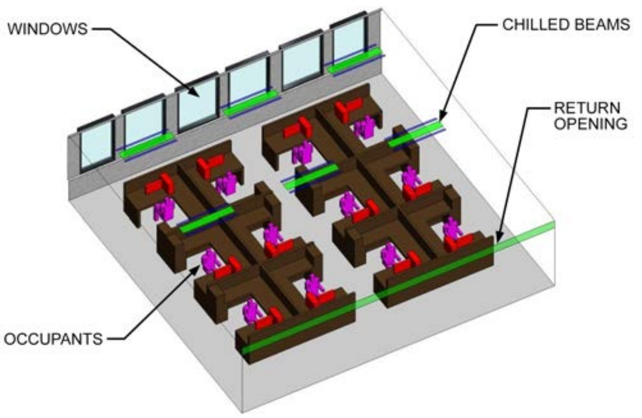

Fig. 5 Office CFD Model: Simplified Geometric Model

Mesh Generation

A snapshot of the computational mesh in a horizontal and vertical plane is shown in Figure 6. A tetrahedral mesh is used in this example; it can efficiently handle complex geometries and is less sensitive to random changes in flow direction like the hexahedral mesh. It is also less labor intensive to generate for the geometry used in this example. Local mesh refinement is used around the various geometric features mentioned in the Overview of CFD Simulation Process section, with particular attention paid to local refinement around the heat sources (to capture thermal plumes), as well as the discharge slots of the chilled beams (to capture the jets) and, to a lesser extent, the returns. Mesh refinement perpendicular to all surfaces in the model is used to capture the thermal and hydrodynamic boundary layers. For the current turbulence model, 12 layers of prismatic elements are used at the walls, with a dimensionless wall distance of $y^+ < 2$ for the first layer. In this simulation, a global mesh size of 127 mm is used, whereas mesh sizing of 50.8 mm is used around the computers, and 25.4 mm for the return/induction opening and the occupants. A mesh size of 25.4 mm is used on and around the discharge slots of the chilled beams to better capture the spread of the supply jet along the ceiling. A mesh growth ratio of 1:1 is used around the chilled-beam discharge slots, occupants, and computers, to ensure that this mesh refinement smoothly merges into the larger cell size of the room.

Boundary Conditions

The boundary conditions for this example are

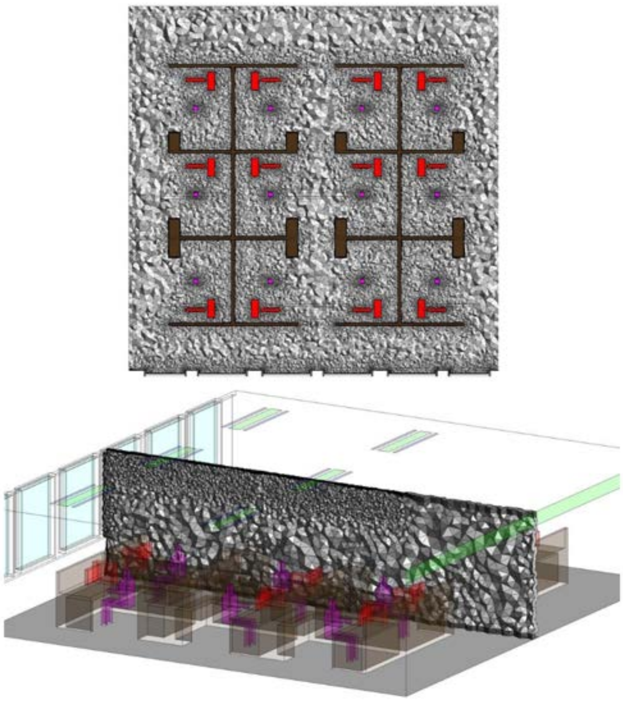

Fig. 6 Classroom CFD Model: Computational Mesh Resolution at Vertical and Horizontal Planes

- **Return opening** (back wall): No relative pressure, temperature, scalars, and turbulence quantities are extrapolated from the solution (do not need to be specified).
- **Windows:** Specified with a convective heat flux to model heat conduction through the glass.
- **Occupants:** Specified with radiant and convective heat flux, with 60% of the total heat gain being radiant and 40% being convective (see Table 1 in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*).
- **Lights:** Specified with radiant and convective heat flux (80/20% radiant/convective split) (see Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*); boundary condition applied to entire ceiling.
- **Computers:** Specified with a radiant and a convective heat flux, with 15% of the total heat gain being radiant and 85% being convective (see Tables 8 and 11 in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*).

All radiation heat fluxes are assumed to be isotropic (independent of direction). The chilled-beam model itself is worth discussing in more detail. Specification of this boundary condition is divided into two parts: the discharge opening and the induction opening. To specify both, the following performance metrics of the chilled beam are required:

- Induction ratio K_{in}
- Primary airflow rate q_p
- Primary supply air temperature T_p
- The sensible capacity of cooling coil Q_{coil} at the specified primary airflow rate
- Discharge angle (can be assumed if not available)

The induction opening is specified as an outlet boundary with a mass flow rate equal to the total volume of air induced by the chilled beam $q_p K_{in}$. Velocity measurements across the induction face of chilled beams show that the induction velocity varies very little, making a uniform velocity assumption reasonable. The discharge opening is specified as an inlet boundary with the total volume of air (induced + primary, $q_p[K_{in} + 1]$) set at the specified discharge angle. In the current case, the discharge angle is set to 15° and is based on smoke videos of the chilled beam from the manufacturer. The correct discharge is important; if it is set too low, it will cause the simulation to show throw (projection of discharge jet) as longer than in reality. Note that the velocity distribution along the length of the discharge slots is assumed to be uniform, which may not be realistic but is sufficient for the purposes of this simulation. Setting the appropriate discharge air temperature of the chilled beam requires some additional arithmetic to be implemented in the boundary condition. By applying a simple energy balance to the chilled beam, an equation for the discharge temperature T_m can be derived as a function of the preceding performance metrics:

$$T_m = \frac{T_p + K_{in}T_{in} + \dfrac{Q_{coil}}{\bar{\rho}C_p}}{1 + K_{in}} \qquad (1)$$

where T_{in} is the temperature of the induced air, which is calculated by the simulation from the induction opening boundary. The sign convention for coil capacity is a negative value in cooling and a positive value in heating. Because the specific heat capacity of air varies very little between 12.8 and 26.7°C, it can be taken at standard conditions. Air density, however, should be taken as an average between the induced air and primary air temperature. It is also assumed that the cooling capacity of the coil is fixed when, in reality, it is a function of the water flow rate and the temperature difference between the water and the induced air (as well as the primary airflow rate). Depending on how much information is available from the manufacturer, this dependence can be incorporated into Equation (1).

Solver and Models

A RANS approach is used with a finite-volume, fully coupled solver. The shear stress transport (SST) turbulence model is used to capture thermal effects near the walls with good accuracy for the velocity field as well (Zhang et al. 2011). A Monte Carlo model is used to capture the thermal radiation heat transfer in the space from all the heat sources. The buoyant force is computed directly from the density field and is important for modeling the cold downdraft from the windows, as well as accurately capturing the nonisothermal throw of the chilled beams.

Convergence

Convergence is judged by a combination of the normalized RMS residuals of mass and momentum, as well as the global energy balance in the domain. A solution is considered converged when the mass and momentum residuals fall below 1×10^{-4} and the global energy imbalance is less than 5%. The global energy imbalance (total energy coming in versus going out of domain) is a very important convergence parameter, and adding the mixed flow temperature equation generally tends to slow down convergence. The criterion of 1×10^{-4} for the normalized residuals is a frequently used rule of thumb that gives good convergence and sufficient accuracy for the purposes of this simulation. The 5% criterion for the global energy balance is based on experience and is a compromise between solution accuracy and the ability to converge the solution to a smaller tolerance.

Post Processing and Results

Figures 7 to 10 show results for one of the configurations in the example. Contour plots of temperature, velocity, predicted mean vote (PMV), and contaminant removal effectiveness are shown. PMV is a thermal comfort metric that correlates the thermal comfort response of a large group of occupants to various flow field variables such as velocity, temperature, humidity, and thermal radiation, as well as occupant properties (e.g., clothing insulation, activity level). This metric is based on the seven-point comfort scale described in detail in ASHRAE *Standard* 55. The band between 0.5 and –0.5 on the PMV scale is considered to be acceptable. Contaminant removal effectiveness is defined as a ratio of contaminant concentrations (see Chapter 15 of Zhang [2004]) from a chosen surrogate tracer gas. It is one way of measuring how efficiently the HVAC system distributes the ventilation air; for other approaches, see Etheridge and Sandberg (1996).

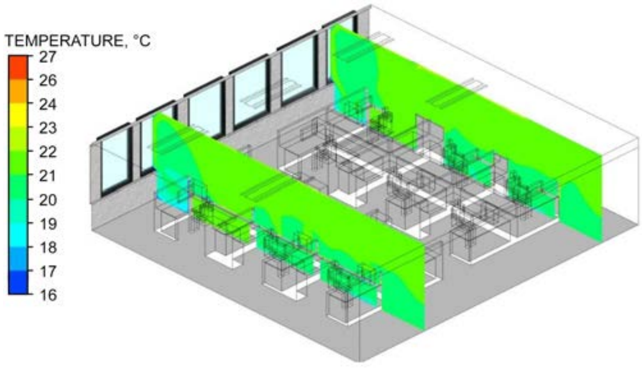

Fig. 7 Vertical Temperature Contour Showing Cold Downdraft near Windows

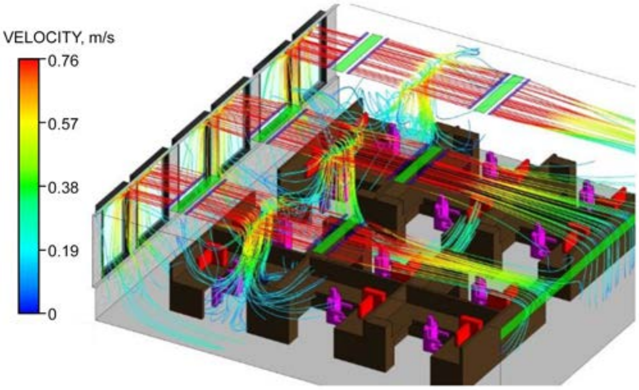

Fig. 8 Velocity Streamlines Showing Supply Air Velocity and Direction

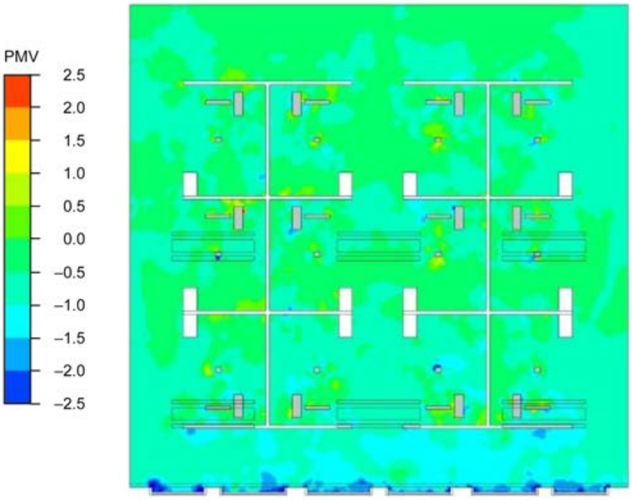

Fig. 9 PMV Contour Plot 1067 mm Above Floor

The results show some nonuniformities in the space temperatures, with a noticeable cold zone near the window, most likely caused by the downdraft of cold air. The thermal comfort varies throughout the space as well, with a cold zone near the windows due to the downdraft. The streamline plot shows that the chilled beams do a good job of washing the windows, as well as the collision zone above the occupants. The contaminant removal effectiveness (CRE) is reasonable, although some stagnant zones (CRE < 1) are evident in the back cubicles.

3.3 DISPLACEMENT VENTILATION

In some cases, displacement ventilation (DV) might be more appropriate than the common mixing HVAC solution. However, with the lack of mixing, controlling air stratification in the indoor environment becomes crucial. The purpose of this CFD example is to investigate the performance of a displacement ventilation system by analyzing the thermal comfort, stratification, and ventilation effectiveness in the space.

Model Geometry

The classroom is an 80 m^2 space with a 3 m high ceiling, an exterior window, and a radiant slab with two controlled zones (interior and exterior). The classroom has a projector and a teacher's desk, as well as other furniture, including multiple cabinets and tables. The

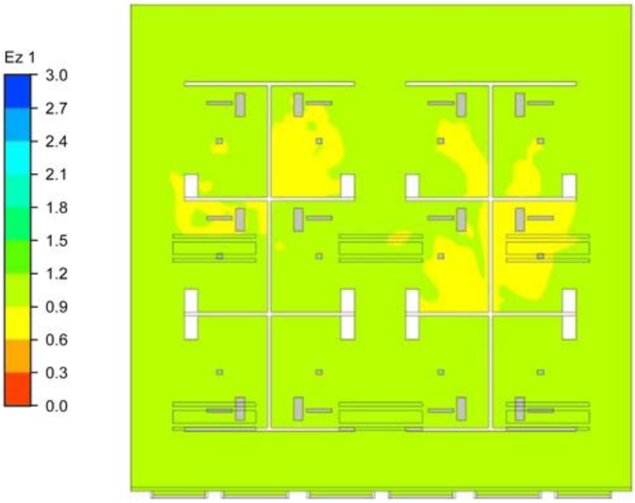

Fig. 10 Contaminant Removal Effectiveness (CRE) 1067 mm Above Floor (Seated Breathing Height)

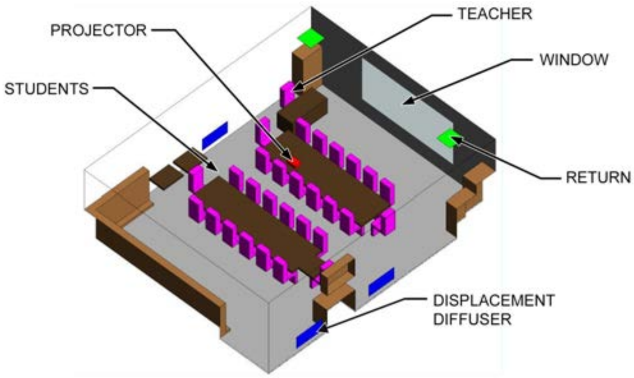

Fig. 11 Classroom CFD Model: Simplified Geometric Model

classroom is conditioned with three wall displacement diffusers on the side walls and two returns located on the ceiling near the exterior window. The various modeling decisions made for this specific case follow. Figure 11 shows a simplified representation of the gross geometry of the classroom. The geometric features in this CFD model are

- Furniture (e.g., tables and wall cabinets)
- Simplified occupants (seated students and a standing teacher)
- Projector
- Exterior window (surface, no mullions)
- Displacement diffusers (inlet)
- Returns in the ceiling (outlet)

The spaces under the tables are included in the model because airflow moves along the floor in a displacement system. It is therefore important to avoid flow obstructions that do not exist in the real space. In addition, the surface of the table affects the dynamics of the thermal plumes of the seated occupants. There are 35 occupants, so simplified models are used to represent them. They are meant to capture the rough geometric shape of a seated occupant while retaining the total surface area of an average-sized seated adult male (see Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*). It is acknowledged that there is some loss in accuracy, because the occupants are actually children. The standing teacher is modeled as a simple rectangular prism, with the appropriate surface area.

Mesh Generation

A snapshot of the computational mesh in a horizontal and vertical plane is shown in Figure 12. A tetrahedral mesh is used in this example; it can efficiently handle complex geometries and is less sensitive to random changes in flow direction like the hexahedral mesh. This is particularly important in displacement flows where thermal plumes (direction not known a priori) dominate the flow. It is also less labor intensive to generate for the geometry used in this example. Local mesh refinement is used around the various geometric features, with particular attention paid to local refinement around the heat sources (to capture thermal plumes), the displacement diffuser (to capture the three-dimensional floor jet), and, to a lesser extent, the returns. Mesh refinement perpendicular to all the surfaces in the model is used to capture the thermal and hydrodynamic boundary layers. For the current turbulence model, 12 layers of prismatic elements are used at the walls with a dimensionless wall distance of $y^+ < 2$ for the first layer. In this simulation, a global mesh size of 228.6 mm is used, and mesh sizing of 63.5 and 50.8 mm is used around the return and the occupants, respectively. A mesh size of 25.4 mm is used on the displacement diffuser to capture its waterfall flow pattern as well as the complex three-dimensional thermal wall jet. Refinement around a displacement diffuser is typically coarser than a mixing diffuser at the same flow rate, as a result of the shorter projection distance and the velocity of the jet. A mesh growth ratio of 1:15 is used around the displacement diffusers, the occupants, and the projector, to ensure that this mesh refinement smoothly merges into the larger cell size of the room.

Boundary Conditions

The boundary conditions for this example are

- **Returns:** No relative pressure, temperature, scalars, and turbulence quantities are extrapolated from the solution (do not need to be specified).
- **Window:** Specified with a convective heat flux to model heat conduction through the glass, and a directional radiant heat flux to model the solar heat gain. The direction is based on the position of the sun at the time the peak load occurs, and can be calculated using Chapter 15 of the 2017 *ASHRAE Handbook—Fundamentals*.
- **Occupants:** specified with radiant and convective heat flux, with 60% of the total heat gain being radiant and 40% being convective (see Table 1 in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*).
- **Lights:** specified with radiant and convective heat flux (80/20% radiant/convective split) (Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*). Boundary condition applied to entire ceiling.
- **Projector:** specified with a radiant and a convective heat flux, with 15% of the total heat gain being radiant and 85% being convective (see Tables 8 and 11 in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*).
- **Radiant slab:** beyond the scope of this example.

All radiation heat fluxes apart from the window are assumed to be isotropic (independent of direction). The displacement diffuser model is worth discussing in more detail. Although the face velocity of the diffuser is low and flow in the space is driven by the heat sources, it is important to accurately capture the velocity temperature distribution in front of the diffuser for an accurate assessment of thermal comfort. The model used in this example is a simplified version of the momentum method (Chen et al. 1999) that does not take the perforated face into account. In situ measurements have shown this to be a reasonable approximation for this type of diffuser. Note that better accuracy can be achieved with a more refined model.

Solver and Models

A RANS approach is used with a finite volume, fully coupled solver. The shear stress transport (SST) turbulence model is used to capture thermal effects near the walls with good accuracy for the velocity field as well (Zhang et al. 2011). A Monte Carlo model is used to capture the thermal radiation heat transfer in the space both from the short-wave (solar) and long-wave (e.g., people, lights) heat sources. Thermal radiation heat transfer from the ceiling to the cool floor also has a strong effect on the vertical temperature gradient in the space. The buoyant force is computed directly from the density

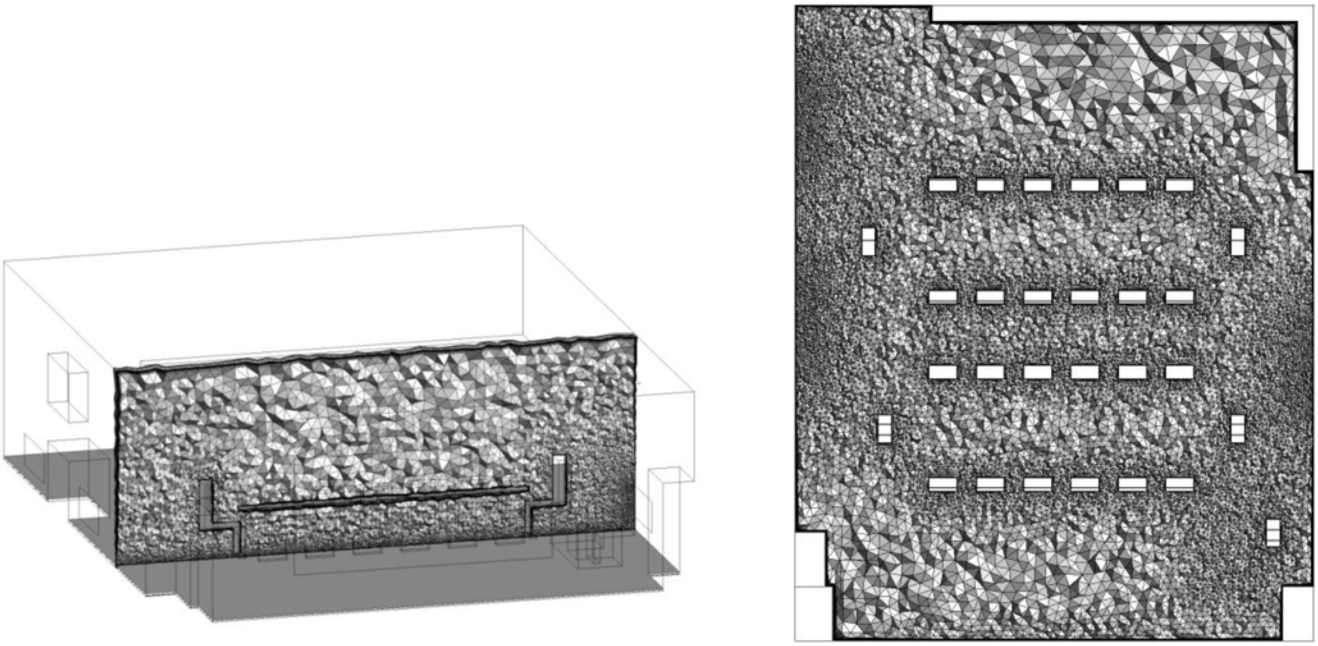

Fig. 12 Classroom CFD Model: Computational Mesh Resolution at Vertical and Horizontal Plane

field and is a crucial component of the simulation, because the dynamics of displacement ventilation systems are driven primarily by buoyancy.

Convergence

Convergence is judged by a combination of the normalized RMS residuals of mass and momentum as well as the global energy balance in the domain. A solution is considered converged when the mass and momentum residuals fall below 1×10^{-4} and the global energy imbalance is less than 5%. The criterion of 1×10^{-4} for the normalized residuals is a frequently used rule of thumb and gives good convergence and sufficient accuracy for the purposes of this simulation. The global energy imbalance (total energy coming in versus going out of domain) is a very important convergence parameter for displacement ventilation problems, because the thermal field takes much longer to stabilize than the hydrodynamic field. For example, the mass and momentum equation residuals can stabilize and converge before the global energy balance reaches its converged state, which yields the wrong solution (no thermal stratification).

Post Processing and Results

Figures 13 to 16 show results for one of the configurations investigated in the study. Contour plots of temperature, velocity, predicted mean vote (PMV), and contaminant removal effectiveness are shown. The contaminant removal effectiveness is defined as a ratio of contaminant concentrations (Zhang 2004) from a chosen surrogate tracer gas. It is one way of measuring how efficiently the HVAC system distributes the ventilation air. The results show good thermal stratification in the space with a layer of cold air spread across the floor. The streamline plots imply that the specific arrangement of diffusers does a good job distributing the cool supply air across the floor and around all of the flow obstructions in the space. The PMV plot shows a very distinct hot spot under the

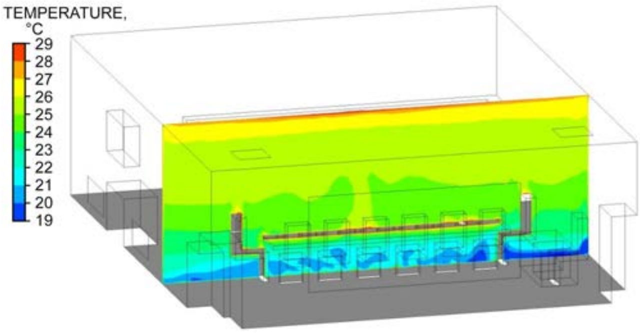

Fig. 13 Vertical Temperature Contour Showing Stratified Temperature Distribution Typical of DV Systems

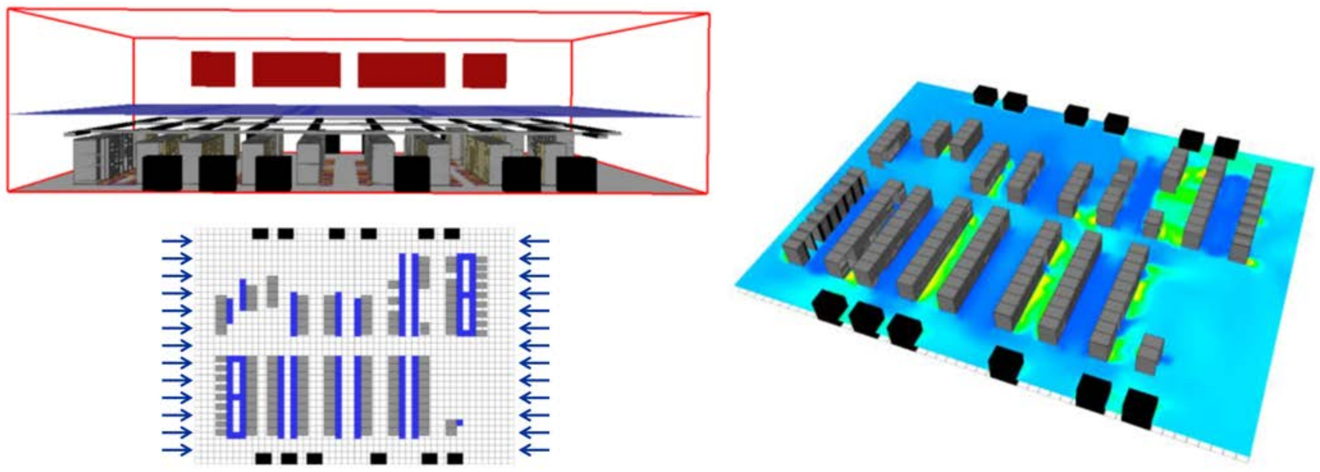

Fig. 17 Data Center Layout

window, which is a direct consequence of the magnitude and direction (pointed down) of the solar load. Overall, the thermal comfort in the space is slightly outside the desired comfort range (on the warm side). Contaminant removal effectiveness is also not very uniform, suggesting that some improvements can be made to the air distribution system to better distribute the supply air.

3.4 DATA CENTER DESIGN

Due to the intense cooling load of the computers (compared to human occupants), modeling of data centers is a drastically different challenge for HVAC design (ASHRAE *Standard* 90.4). The following example demonstrates use of CFD in design of this unique type of facility.

This example involves a 687 m^2 raised floor data center containing 138 information technology (IT) racks and 192 perforated floor tiles, as shown in Figure 17. The IT racks are arranged in rows, forming five cold aisles and four hot aisles. Twelve floor-mounted power distribution units are located along two opposing sides of the room. The IT and power distribution equipment collectively consume over 316 kW of power, and the floor tiles supply 48383 L/s of air to the room. Warm air returns to the cooling system through perforated ceiling tiles located above the hot aisles, which feed into a large open ceiling plenum. CFD is useful both to aid in the design of data centers and to optimize the performance of existing facilities (Healey et al. 2014; VanGilder and Seymour 2014); this example focuses on the latter.

Geometry Generation

In contrast with many general-purpose CFD tools, which require the user to assemble models using simple geometric primitives, data-center-specific CFD modeling tools and electronics-specific modeling tools typically provide high-level building-block objects that only need to be configured to represent the geometry and operating conditions of a given data center. For example, racks, coolers, or tiles can be selected from a library of objects and simply placed into the room.

To best capture the physics that govern a given data center's airflow patterns, it is recommended that the floor plenum be modeled together with the whitespace. However, it may be simpler to model the two spaces separately, and in cases where the floor tiles are fairly restrictive (in the range of 25% open area or less), doing so delivers reasonable accuracy.

Mesh Generation

The example data center was modeled using a rectangular Cartesian grid, which maps well to typical data center geometry. Generally, cells of side length 152.4 mm or smaller are recommended (Zhang 2008) for modeling data centers. In the example case, grid cells in the whitespace were set to have a maximum side length of 152.4 mm and a minimum side length of 25.4 mm below the dropped ceiling. The variation in grid cell dimensions allows for finer grid cells near objects and complex geometry, and larger grid cells in open space. However, the model uses grid cells of up to 609.6 mm on a side within the ceiling plenum, which is largely open space and far away from features of interest.

Solver and Models

The example case uses a RANS CFD solution methodology, assuming steady-state conditions, and the standard *k*-ε turbulence model was used.

Boundary Conditions/Object Modeling

Several specific modeling choices resulted in greater accuracy of the example model. Because the room is located inside a larger indoor enclosure and there is little heat transfer across the room walls, walls were modeled as adiabatic solid boundaries. Additionally, rather than modeling each rack as a monolithic box with uniform airflow into the front face and out of the rear (as per Zhai et al. [2012]), each rack was subdivided into a number of slices (Pardey et al. 2015), as shown in Figure 18. Each slice was assigned its own airflow rate and accordant temperature increase based on its power, with the assumption that servers draw 60 L/s per kW. Blanking panels were modeled as solid blocks, and open spaces were modeled as open. Rack doors were modeled as two-dimensional flow resistances coincident upon the front plane of the rack. A vertical momentum source was enforced inside a volume region over each tile extending to a height of 101.6 mm, in the method of Abdelmaksoud et al. (2010), to accurately model the jet-like tile airflow. Inside the floor plenum, care was taken to explicitly model the vertical stanchions that support the raised floor. However, stanchions can equally be modeled as a distributed resistance, as discussed in VanGilder et al. (2016).

Individual perforated floor tile airflow rates were measured using the anemometer scaling method described in VanGilder et al. (2016). The floor of the example facility is bolted and gasketed, preventing any significant air leakage, so the sum of floor tile airflows was considered to represent the total room airflow. To simulate airflow patterns inside the floor plenum, the total room airflow was divided among the 21 airflow inlet bays that feed the plenum, and each bay was modeled as a fixed-flow boundary condition. The portion of the total room airflow allocated to each bay was calculated based on measured air velocity through each given bay. It is important to note that total room airflow could also be estimated by summing the nameplate flow rates of all active computer room air-handler (CRAH) units, or by measuring airflow from CRAHs using an anemometer or a flow hood.

Convergence/Grid Independence

The model is considered converged when residual errors in the mass, momentum, energy, and turbulence-model equations reach a predefined level, which is usually set to a default value. Here, in accordance with best practices, a number of simulations were performed using computational grids with varying cell sizes. By comparing the predicted temperatures and airflow patterns produced by simulations with different cell sizes, grid independence was established.

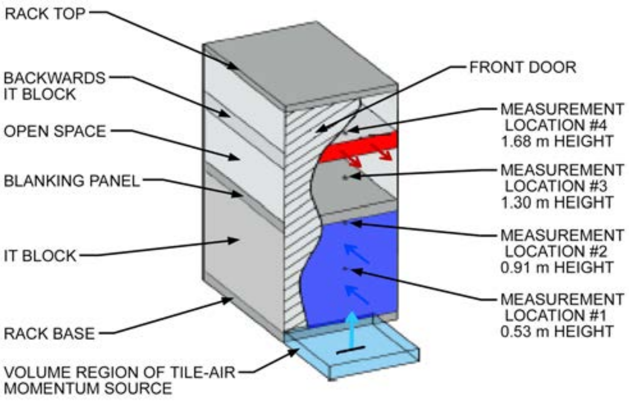

Fig. 18 Rack Model

Model Calibration

The CFD model was created to help optimize performance of an existing data center, so greater detail was required than would be necessary for preliminary design purposes. As such, the model was calibrated by iteratively increasing the detail and fidelity of its construction based on measurements and observations. Key parameters for accuracy were inlet rack temperature and tile airflow rate. Rack inlet temperatures were measured at four equally spaced points along a vertical line at the center of the face of each rack.

The accuracy of the model was enhanced by dividing each rack into 42 individual one-unit slices, each of which was either occupied by an active piece of IT equipment or blanking panel or was left open. Additionally, because IT equipment often generates jets of warm exhaust air, it was important to account for any IT equipment that produced such jets directed into a given cold aisle (either inadvertently or because of suboptimal equipment design). Including the doors of racks in the model as two-dimensional flow resistances also improved accuracy. In the floor plenum, accuracy was increased by modeling the vertical support stanchions, because it was discovered that if the stanchions were not included in the CFD model of the plenum, the model produced substantially different tile airflow predictions.

Capturing accurate input data is equally as important as making appropriate modeling choices, and to this end, it was crucial to account for the resistance of the flow hood on the measured perforated tile airflow rates. Methods for doing so have been evaluated at length in Zhang (2004). Note that CRAH return temperatures to the cooling system could also be used as a criterion by which to evaluate the accuracy of the CFD simulation or check the consistency of other assumptions.

Results

The model was created specifically for managing and optimizing an existing data center. Therefore, it was necessary to model in more

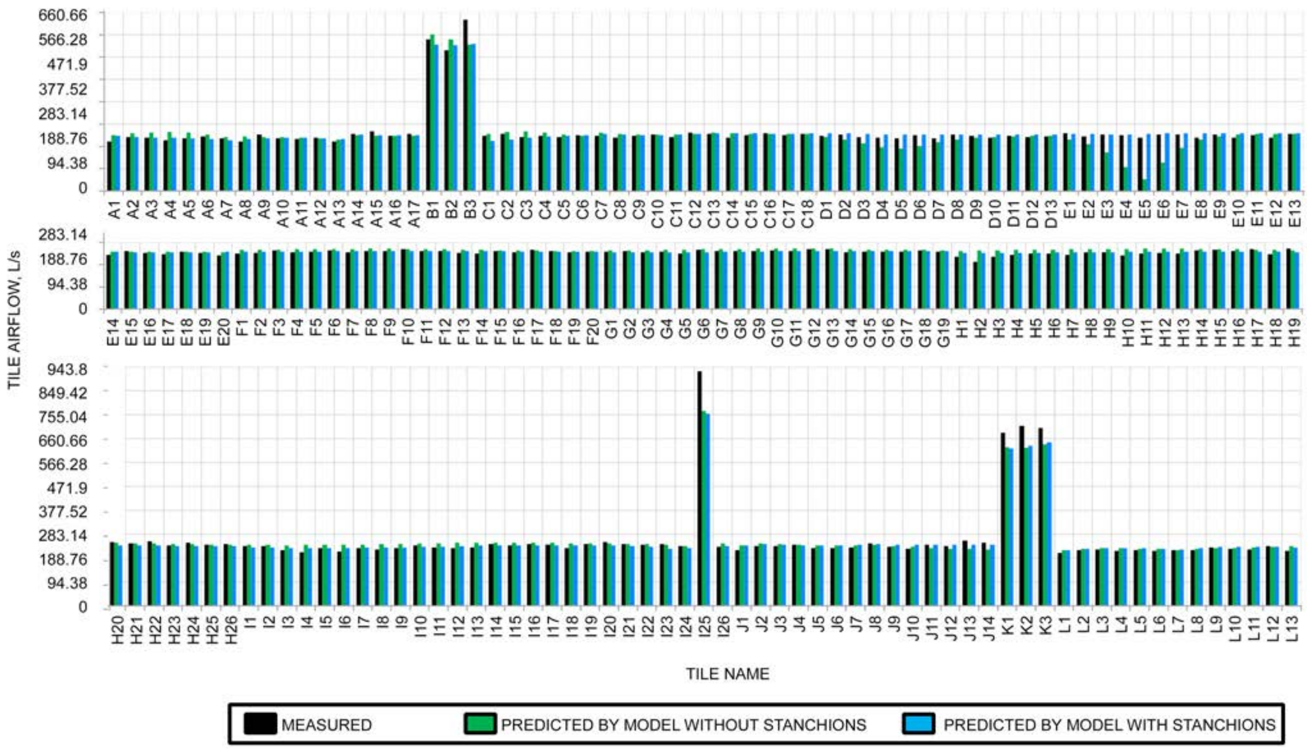

Fig. 19 Comparison of Measured and Predicted Tile Airflow Rates

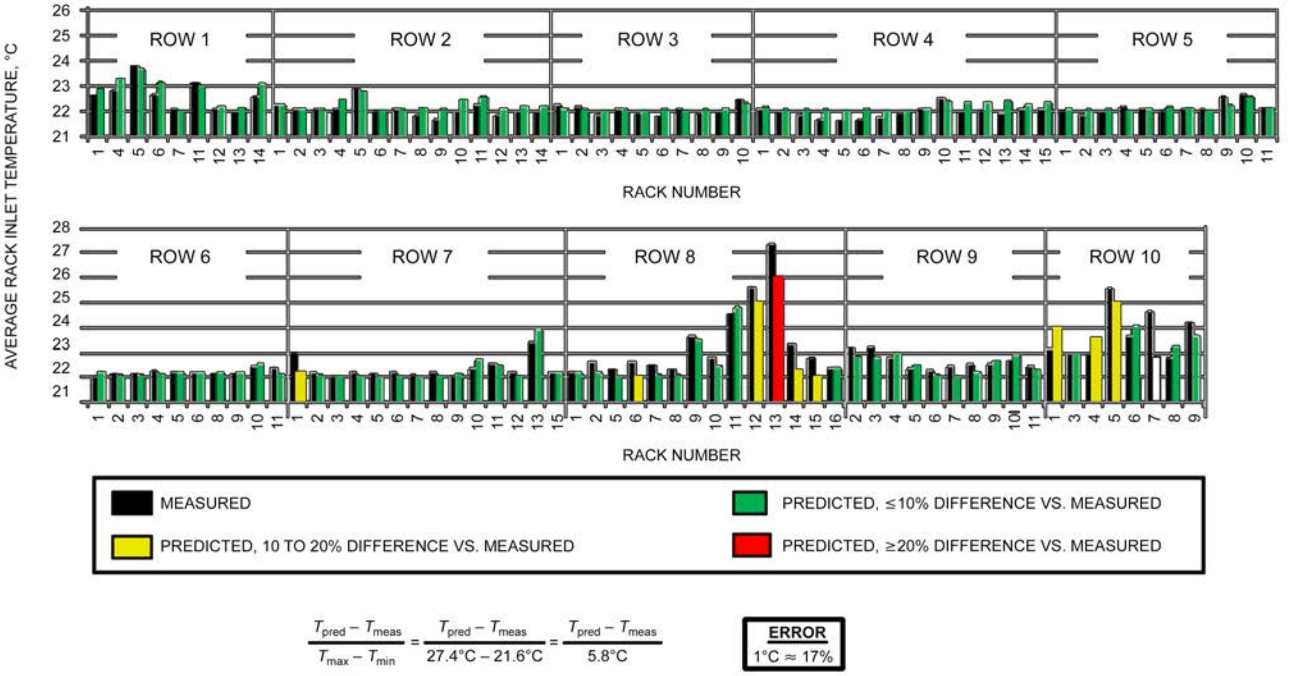

Fig. 20 Comparison of Measured and Predicted Rack Inlet Temperatures

detail than is required for preliminary design purposes. Figures 19 and 20 show the results of predicted versus measured perforated tile airflows and rack inlet temperatures, respectively. Figure 19 shows two variants of the plenum simulation: one that includes raised-floor support stanchions and one that does not. The model that includes stanchions predicts 186 of 192 tiles to within ±10% of the individual measured airflows and the remaining six tiles to within ±20%. Figure 20 depicts predicted rack inlet temperatures according to their accuracy and shows that the calibrated model predicts 105 of the 115 active racks with an error rate of less than 10% of the maximum temperature range observed in the data center. To achieve this level of accuracy, it was important to model the contents of each rack at the unit (U) level, rack doors as flow resistances, momentum sources above each perforated floor tile, and any backwards-oriented IT equipment. It will be necessary to recalibrate the model periodically to account for any changes to IT equipment population, room arrangement, or general operating conditions.

3.5 VIRAL CONTAINMENT IN HOSPITAL WARD

The goal of air distribution inside a hospital operating room (OR) is to protect the patient and staff from cross infection while maintaining occupant comfort and avoiding impediment of surgical tasks. In ORs, HEPA-filtered air and vertical (downward) laminar airflow are often used to achieve a unidirectional flow of fresh air from the ceiling, washing over the patient and flowing out of exhaust vents on the side walls, near the floor.

A CFD tool was used to predict the flow pattern and contaminant transport in a representative OR environment with standard airflow settings. The CFD model was first developed by Zhai et al. (2013) and validated against the full scale laboratory experiment; this example uses Zhai et al.'s diffuser specifications and air changes per hour (ach), as well as the same room, equipment, and occupant conditions (Table 1 and Figure 21). The equipment thermal loads (heat flux), as well as the temperature of the patient's wound and skin, can be seen in Table 2. Table 3 indicates the sizes of all of the objects in the room. These parameters provided crucial inputs for the following CFD model process.

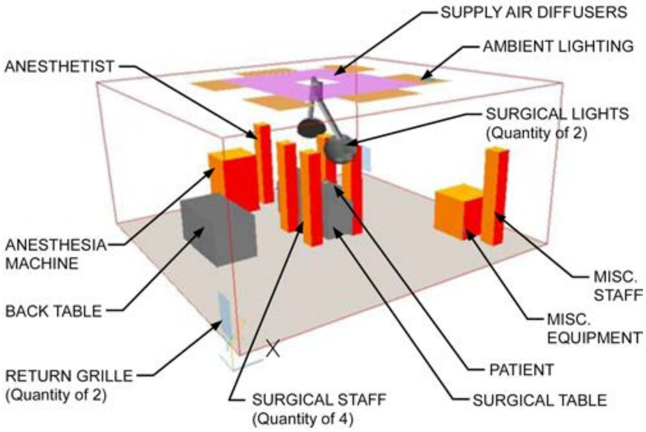

Fig. 21 Base CFD Model Setup

Table 1 Laboratory Experiment Specifications

Room dimensions	6.1 × 5.8 × 2.9 m
Diffuser dimensions	2.44 × 3.05 m

Geometry Generation

Melikov and Kaczmarczyk (2007) discuss the importance of detailed indoor objects such as a human body on indoor airflow characteristics, and indicate the local impacts of most details of indoor objects. Focusing on the general indoor airflow patterns and interactions between patient and medical staff, they simplified the simulation of indoor subjects such as human bodies and equipment

Table 2 Laboratory Thermal Boundaries

Object	Qty	Heat Gain W	Temperature °C

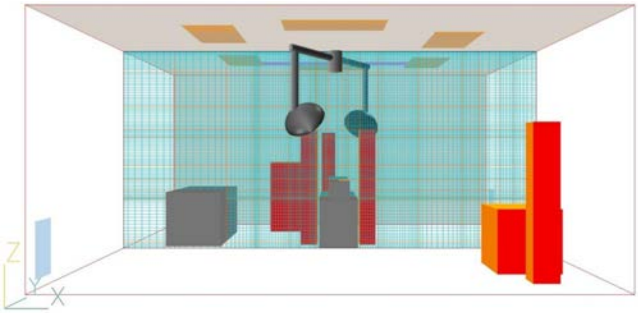

Fig. 22 Grid Refinement Case: 2.4 m Cells

(except for surgical lighting) as rectangular geometries with exact heat sources as tested. This practice facilitates the generation of high-quality meshes and therefore improves both speed and accuracy of the simulations.

Mesh Generation

A rectangular Cartesian grid, which maps well to typical OR geometry, was used. Local grid refinement was implemented near critical spaces and objects such as walls, inlets, and persons. The results of a CFD simulation are highly dependent on the quality of the computational grid. The grid refinement study was conducted on the following grids: 70 × 58 × 45 (180 k cells), 87 × 73 × 57 (362 k cells), 106 × 91 × 70 (675 k cells), 124 × 111 × 86 (1.2 million cells), and 155 × 142 × 108 (2.4 million cells). Figure 22 demonstrates the finest grid distribution.

Solver and Models

Both RANS and LES CFD methods were tested for this example case. Although advanced CFD modeling techniques such as LES provide substantial benefits, the currently available RANS technologies have proven to be adequate for modeling the steady-state characteristics of the hospital operating room air distribution. In the RANS CFD solution methodology, the RNG k-ε turbulence model (Yakhot and Orszag 1986) was used, as suggested by Zhang et al. (2007).

Boundary Conditions/Object Modeling

Most indoor objects such as persons and equipment were specified straightforwardly using the standard wall/block boundary

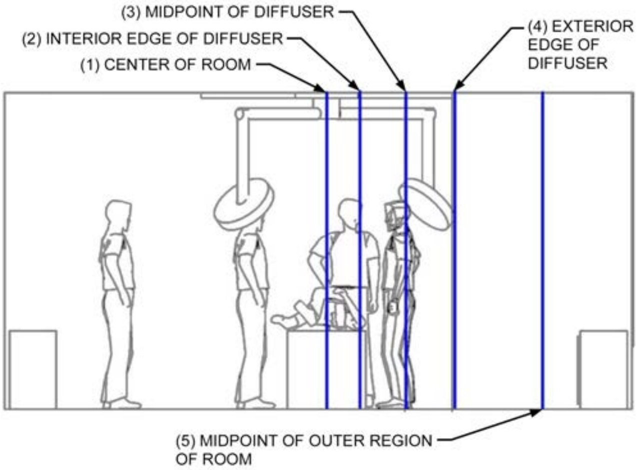

Fig. 23 CFD Grid Refinement Measurement Locations in Central Cross-Sectional Plane

condition methods. Inlet boundary condition is critical to accurate CFD modeling of indoor environments, because this is the primary source of momentum responsible for overall room air distribution pattern. Srebric and Chen (2002) performed a comprehensive analysis of diffuser boundary conditions to determine appropriate simplified boundary conditions, and found the box and momentum methods to be the most appropriate for the diffusers that were tested. The momentum method was used in this example, based on the recommendation of Chen and Srebric (2012) for the grille diffuser that is similar to the nonaspirating diffuser type.

Convergence/Grid Independence

The simulation was considered converged when the sums of residual errors in the mass, momentum, energy, and turbulence-model equations reached a predefined level (0.1%). The grids of different sizes were evaluated using the normalized root mean squared error (NRMSE) of the CFD model results with different grids (Wang and Zhai 2012). Figure 24 shows the NRMSE of the predicted x and y direction velocity at the four measure poles (1 to 4) across the center axis of the room, 2.88 m high (Figure 23), between the 180k and 362k meshes and the 675k mesh. It reveals that there is generally a great improvement in error with the 362k mesh; the computational error is typically below 10%, and absolutely below 30%. Based on this, and to minimize the simulation time, the 362k mesh was chosen for various parametric simulations.

Model Validation

The simulation replicates the airflow pattern as observed in the lab (see Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*): an inward curvature of the airflow to the center of the jet stream, as seen in Figure 25. This behavior reduces the overall coverage area and could pose a contamination risk to the patient.

The quantitative comparisons of simulation and experimental results were plotted in Figures 26 and 27, for x and y velocity components, respectively. Figures 26 and 27 show that the CFD simulations closely follow the experimental results, with a few exceptions. It also appears that there is, in general, a large difference between the experimental results and the 180k mesh, but a smaller difference between each of the latter meshes.

Results

This example demonstrates the applicability of CFD for modeling and analysis of airflow in the surgical environment. Although CFD can be accurately used for modeling indoor air distribution and

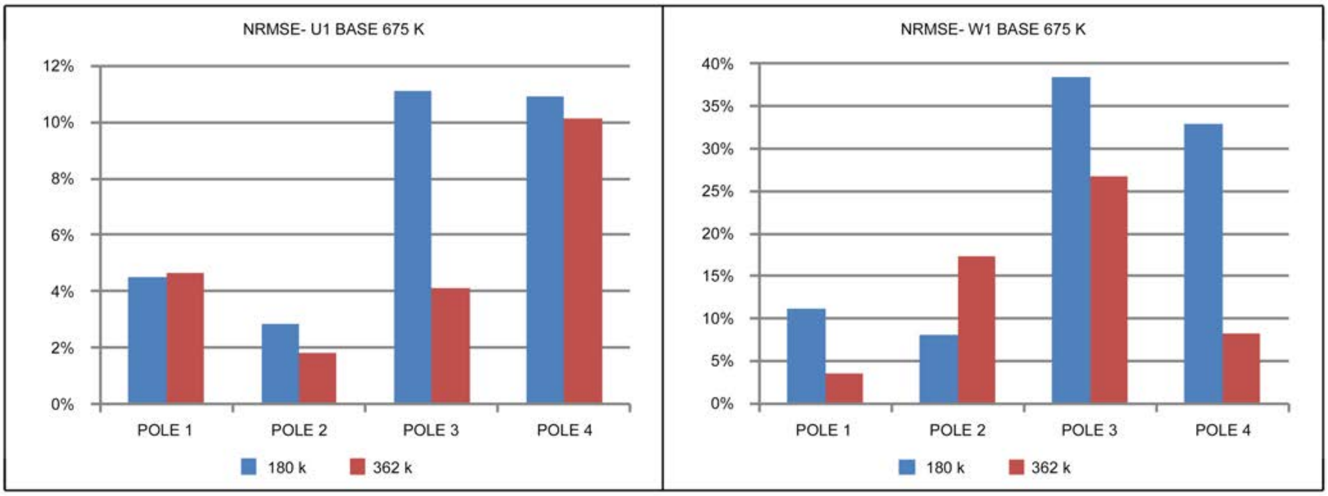

Fig. 24 NRMSE Comparison Between 180k and 362k Meshes and 675k Mesh

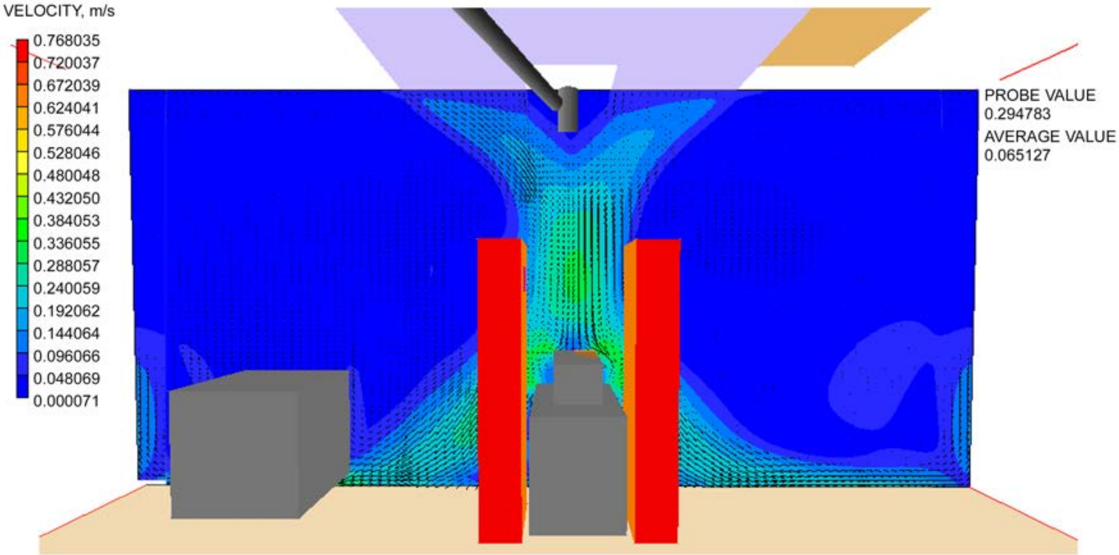

Fig. 25 Velocity Vectors and Contours at Central Cross Section with 675k Grid

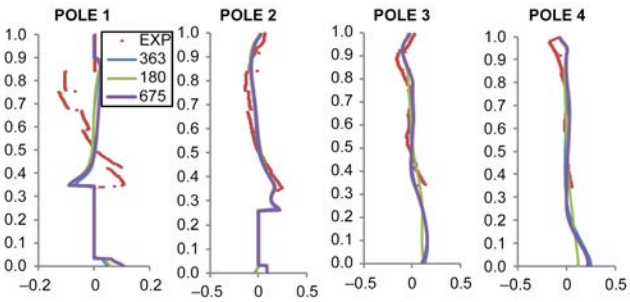

Fig. 26 Comparison of U-Velocity in X Direction

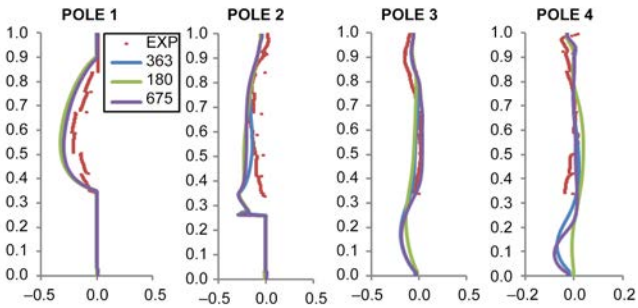

Fig. 27 Comparison of W-Velocity in Z Direction

contaminant transport in operating rooms, the CFD user must be extremely careful in implementing these models, to ensure accurate simulation of airflow. The sensitivity of airflow to thermal characteristics of the indoor environment makes the model sensitive to heat gain input parameters. The heat gain and inlet boundary conditions must be carefully selected to ensure that the resulting air distribution patterns are correct.

The following modeling methods were found to adequately model the represented physics identified in the operating room air distribution.

- Steady-state RANS
- RNG *k*-ε turbulence model
- Boussinesq approximation
- Hybrid differencing scheme
- Isothermal Lagrangian particle model

The general indoor environment conditions place the operating room indoor air distribution in the mixed convection category, but high cooling loads can lead to a strongly buoyancy-driven flow, verified by the parametric study of the Archimedes number of the supply air jet in the OR. The study reveals that the dependence of the room air distribution on the Archimedes number of supply air jets, rather than face velocity of supply diffuser, is of significant importance.

3.6 NATURAL VENTILATION

This example concerns a densely occupied, naturally ventilated auditorium, the key space at Lichfield Garrick, a performing and static arts center (Gorst 2003). This is one of several advanced naturally ventilated (ANV) buildings (Cook and Short 2005) that use low-energy design principles such as night cooling, thermal mass, buoyancy-driven stratification, and solar shading to enable natural ventilation to deliver thermal comfort in spaces with high heat gain. The Lichfield Garrick is comprised of foyer and bar areas surrounding a 500 seat auditorium and smaller studio space (Figure 28).

The large-volume space is ideally suited to buoyancy-driven natural ventilation, wherein the warm, stale air can be held above head height. The additional challenge in this space, however, was the presence of balcony areas, which meant careful concept design and computer modeling were required to ensure the stratification level was at the right level. These calculations rely on a knowledge of opening sizes and their aerodynamic performance. Buoyancy-driven natural ventilation is characterized by small driving pressures which lead to the need for large openings.

The ventilation strategy was designed to passively remove 110 kW. This required the provision of a total free area of 36 m^2 and was achieved using a plenum below each of the seating rakes, supplied with outdoor air from three sides of the building. A duct leading from above the rear stalls to the ceiling above the balcony seating avoids the build-up of warm, trapped air below the balcony that would diminish the effect of the thermal mass in that area. Outflow paths are provided by eight large stacks, mounted along two ridge lines on the roof (Figure 28).

Geometry and Mesh Generation

Both the geometry and the mesh were generated using the preprocessing tools available in the software package. When modeling natural ventilation in CFD, it is essential to accurately model the effects of flow through the openings. One approach is to model

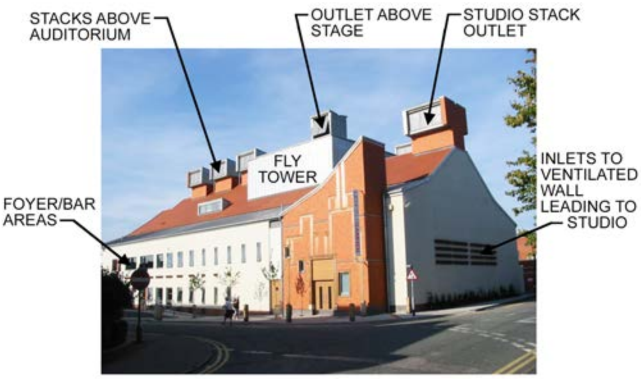

Fig. 28 View of Lichfield Garrick from South

some proportion of the external space, thus removing the need to specify boundary conditions at the opening boundaries. However, this requires more computation and detailed information about the geometry and components that comprise the inlets and outlets. As an alternative, the boundary here was defined at the point at which air enters and leaves the auditorium, and conditions specified to represent the effects of components such as louvers, dampers, attenuators, and heating elements at openings.

The mesh used in this simulation was a structured Cartesian grid. Such meshes can reduce the computational overhead required by unstructured meshes and avoid some of the numerical instabilities during the iterative solution procedure.

Boundary Conditions and Solver Techniques

Predicted pressure drops across components at inlets and outlets were used in the orifice flow equation (see Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals*) to determine a discharge coefficient C_d to represent resistance to flow at openings. For any openings where pressure loss data were unavailable, a discharge coefficient of 0.6 was used, representing the effect of a sharp-edged orifice. In these cases, it was necessary for the design team to ensure that the combination of free opening area and discharge coefficient in the final design provided at least as much airflow as the combination used in the CFD simulations.

Heat gains are generated by occupants (60 kW) and lighting (40 kW). These were modeled as convective gains into the domain. However, to account for the convective/radiative split, 50% and 10% of the occupant and lighting gains (respectively) were assumed to be radiated to the surrounding surfaces from where they were convected into the domain. Buoyancy was modeled using the Boussinesq approximation (Gray and Giorgini 1976), which assumes density to be constant everywhere except in the source term of the momentum equation.

Turbulence is modeled using the *k*-ε model with constants derived from renormalisation group theory (ASHRAE *Standard* 55). This model was used, because it was found to more accurately predict entrainment into the buoyant plumes, which are known to determine the key characteristics of these flows (e.g., interface height, temperature of stratified layer) (Cook and Lomas 1998). Validation of the CFD techniques described here was conducted using analytical and experimental models as described in Cook and Lomas (1998).

Convergence Criteria

Convergence was deemed to have been achieved when the residual in the enthalpy equation, in watts, was less than 1% of the total heat convected into the domain at the heat sources, and when the absolute values of variables at the user-defined monitoring point did not change by more than about 0.1% over approximately 20 iterations. The monitoring point used in this case was located just below the roof outlets in the auditorium. Convergence was successfully achieved according to these criteria, using under-relaxation in the form of false time steps. This type of convergence control uses the local cell size and a characteristic time scale for the flow evolution to define under-relaxation factors, which vary throughout the domain. False time step values of 0.1s were used for each of the three momentum equations.

Results

The simulation predicted a stable stratification in which the occupied zone is bathed in the air at, or just above, the ambient temperature (see Figure 29). This illustrates one of the key advantages of buoyancy-driven displacement ventilation, whereby the height of the stratified layer is determined by the ventilation opening sizes, not by the amount of heat gain in the space. The system can be thought of as self regulating because any increase in heat gain increases the temperature of air in the stratified layer, which increases the driving force, and hence the flow rate through the building, as required. In this case, the layer of stratified air drives a flow of 8.3 ach through the main auditorium, equivalent to about 21 L/s per person. This is typical for naturally ventilated buildings of this type and is necessary to provide thermal comfort, as well as an adequate supply of fresh air.

3.7 INDUSTRIAL WAREHOUSE

In large industrial warehouses, thermal stratification can be significant, resulting in buoyancy-dominant indoor airflows. A typical vertical temperature gradient was reported to be 1 K/m (Forrest and Owen 2010) to 1.4 K/m (Aynsley 2007). As a result, the accumulation of hotter air at higher sections elevates heat flux through surrounding walls and roofs, one of the major warehouse energy wastages. Severe thermal stratification is also a concern for temperature-sensitive goods and products (Li 2016). ASHRAE (2008) recommends thermal destratification for climate zones 5 to 8 of North America, using fans, high-velocity vertical-throw duct diffusers, and air-rotating devices. Examples of thermal destratification energy savings include 26.4% reduction in gas usage (Aynsley 2005) and 19.3% reduction of heating energy (Armstrong et al. 2009) in some cases. In recent years, warehouse thermal stratification and destratification have garnered more attention, mostly as a result of the booming e-commerce industries and their integration with conventional retailers, especially in China and other East Asian countries. CFD is an important technique for analysis of thermal stratification and destratification strategies in warehouses. One of the major challenges, however, is choosing the suitable CFD method for modeling air heating and mixing devices (e.g., ceiling rotating fans, wall-mounted bucket-type axial fans and forced air heaters). This example applies CFD to real-world, large industrial spaces, with the focus on heating and mixing devices, acquiring boundary conditions from the field, and analyzing the simulation results for the energy performance evaluations.

Geometry Generation

This example includes two actual warehouses: the QT and KS buildings. The QT building is a storage warehouse with a size of 12.0 × 9.3 × 6.62 m ($L \times W \times H$), with about half of the space divided horizontally into two sections (an upper section and a ground section) to maximize storage space, as shown in Figure 30A. The existing QT warehouse was equipped with a 15 kW electronic forced-air heater beneath the ceiling, and a 316 L/s ceiling bucket fan. The current analysis added a 2.67 Hz ceiling rotating mixing fan for the evaluation of potential destratification improvement.

The KS warehouse (Figure 30C) is a larger building, 41.1 × 17.5 × 6.9 m, heated by a mechanical duct diffuser system and six 1 kW baseboard heaters at the ground level under the windows. The conditioned air from every duct diffuser is projected horizontally into the space at 47 L/s per outlet, at a constant 40°C. Six 316 L/s bucket fans were installed above the baseboard heaters for destratification.

General geometrical information was collected, including the dimensions of the warehouses, the size of the doors and windows, connections to neighboring rooms or buildings, and storage rack layouts and dimensions. Here, a commercial CFD software package was used. Most of the storage racks and shelves were modeled by solid blockages, but the mixing devices and HVAC ducts were modeled as their original cylinder shapes. Internal partitions were modeled as zero-thickness blockages because no heat transfer calculation was needed for internal structures. The ceiling rotating fan was modeled in detail to reflect the real-world unit, considering the fan blade diameter of 1.3 m and a curve surface with a 0.35 m radius arc; the chord of each blade has a 15° angle with the horizontal plane (Momoi et al. 2004). Figure 30E shows the CFD model of the ceiling rotating fan, and Figure 30F, the bucket fan.

Mesh Generation

Both warehouse models are meshed mostly by Cartesian cut-cell grids first in the software. For regions with heaters and fans, more detailed localized meshes were created to provide enough resolutions considering the existences of strong gradients. Figures 30E and 30F show the local mesh examples for the ceiling rotating fan and the bucket fan models. To model the rotating fan, the whole model was divided into two parts: the cylindrical section encompassing the fan and rotating at a speed of 16.75 rad/s, and a stationary section, as

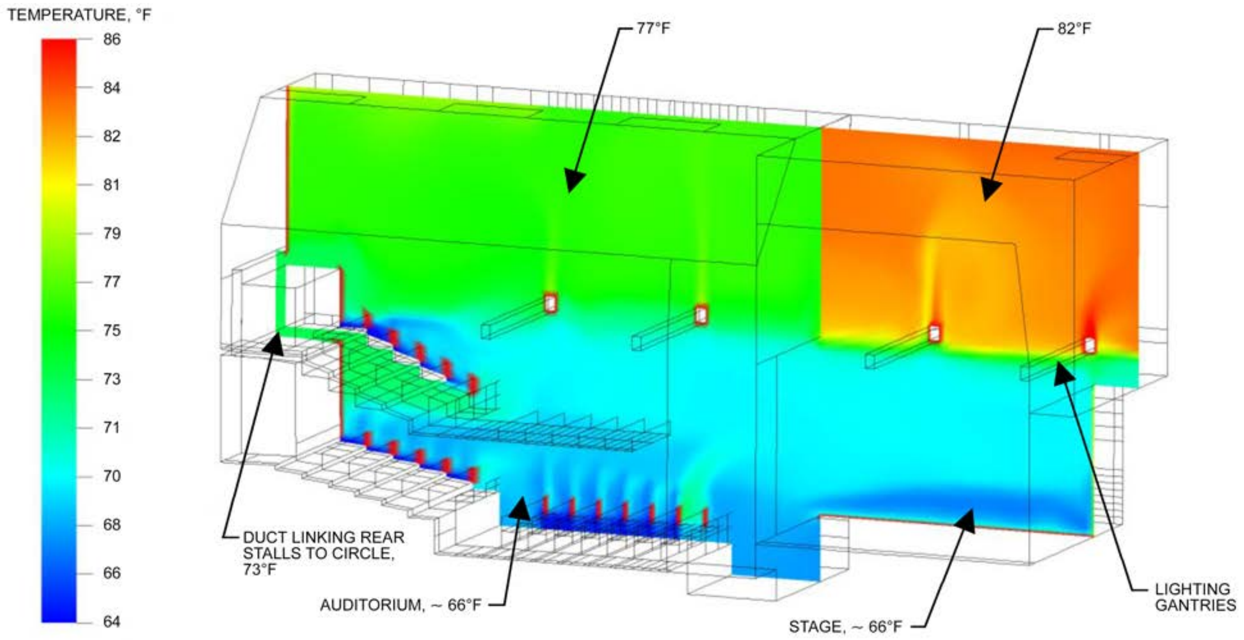

Fig. 29 Temperature Prediction over Vertical Plane in Auditorium

shown in part E of the figure. The bucket axial mixing fan was modeled by a constant-pressure jump fan model at a set volumetric flow rate (Figure 30F). The forced air heater (not shown) was also modeled by the pressure jump fan model with a constant heat source, following the method proposed by Forrest and Owen (2010). For more detailed CFD setups, see Wang and Li (2017). For the KS building, similar mesh refinement treatments were applied to the baseboard heaters and near the HVAC duct supplies, as shown in Figure 30D. As a result, a total mesh of 2.3 m was created for the QT and KS buildings.

Solvers and Models

To model buoyancy-driven flows in such large spaces, a real gas model with temperature varying density was used. For the turbulence effects, the standard k-ε two-equation turbulence model has

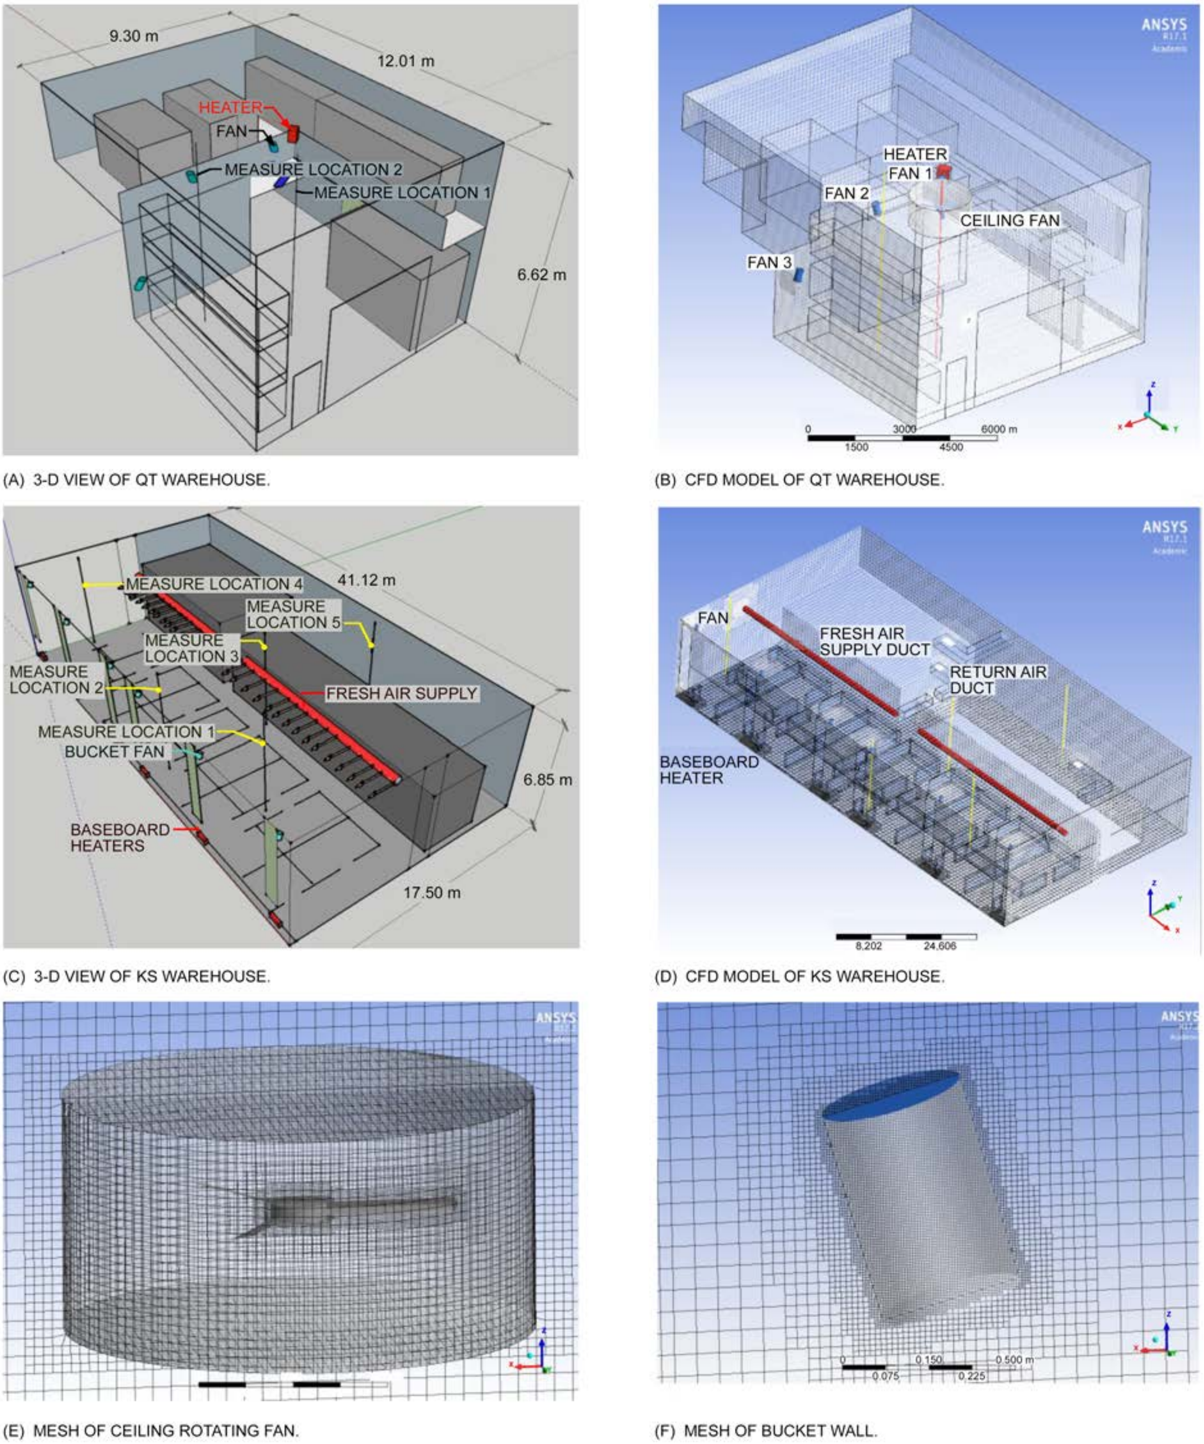

Fig. 30 View Models and CFD Models of Warehouses

been found effective (Li et al. 2009). Momoi et al. (2004) also found the standard k-ε model adequate for modeling ceiling rotating fans.

Boundary Conditions

The thermal resistance properties of building envelopes were collected from the owners or engineers. For CFD simulations of large spaces, various thermal boundary conditions are available for modeling solid surfaces: constant temperatures, heat transfer coefficients, and heat fluxes. For modeling actual warehouse envelopes, the constant heat transfer coefficient boundary conditions were more reasonable for modeling both interior and exterior surfaces. The estimation of the convective heat transfer coefficients h_c was based on the models suggested by Qi et al. (2013) as a function of temperature differences, surface orientations, and Reynolds and Prandtl numbers. For other surfaces (e.g., the ground), constant temperatures were applied. For the duct diffusers, constant velocity and temperature were modeled using the data available from the on-site HVAC monitoring systems. Table 4 provides the key boundary condition settings.

Convergence/Grid Independence

A grid sensitivity study was conducted for the QT warehouse using 2.3 m cells and 3.1 m cells. For the KS warehouse, the total grid number was also chosen to be 2.3 million.

Results

Different thermal destratification strategies were simulated, as shown in Table 5. For the QT warehouse, two more bucket fans were added: a second fan, to the left of the existing, first fan, and a third fan, close to the wall, with the supply air pointing upwards towards the ceiling. A ceiling rotating fan was also added, as shown in Figure 30B. Validation results of temperature and velocity profiles are shown in Figure 31. Including the existing system q_1, a total of six different combinations of fan operating strategies were simulated from q_1 to q_6. For the KS warehouse, different bucket fan operating speeds (all off, 30%, and 100%) and air supply directions from the duct diffusers (horizontal throw, vertically downward supply, and 45° downward supply) were simulated by a total of five cases from k_1 to k_5 (Table 5).

To quantify the level of thermal stratification, the non-uniformity coefficient θ is defined with Equation (2): a greater value of θ indicates a stronger stratification.

$$\theta = \frac{\sqrt{\sum_{i=1}^{n}(T_i - \overline{T})^2/(n-1)}}{\overline{T}} \qquad (2)$$

where

n = total number of temperature data measured vertically at specific location in space
T_i = temperature at location i
$\overline{T}$ = average temperature

Figure 32A compares the nonuniformity coefficients for all six cases of the QT warehouse. Comparing the cases with bucket fans running (q_1, q_4, q_5, and q_6) and off (q_2) demonstrated a clear

(A) NONUNIFORMITY COEFFICIENTS IN QT (B) HEAT LOSSES AND SAVINGS IN WAREHOUSES

Fig. 32 Comparison of Nonuniformity Coefficients, Heat Losses, and Savings in Warehouses

Table 4 CFD Simulation Thermal Properties and Boundary Conditions

CFD Settings	QT Warehouse	KS Warehouse
Ambient temperature, °C	–21.5	–6.7
Ground	Constant temperature 13°C	Constant temperature 21°C
Interior wall	R5	Constant temperature 24°C
Convective heat transfer h_c	Roof: 15.6 W/(m^2·K) Wall: 20.7 W/(m^2·K)	Roof: 3.4 W/(m^2·K) Wall: 9.6 W/(m^2·K)
Other surfaces	Constant temperature 20°C	Constant temperature 24.8°C
Air heater	Ceiling air heater: 15 kW	6 baseboard heaters: 1 kW/each
Ceiling rotating fan	Diameter: 1.3 m; 160 rpm0.02 Hz	N/A
Bucket fan	Diameter: 0.351 m; Height: 0.378 m; 316 L/s	
Diffuser	N/A	10.35 m/s of 40°C air

improvement in mixing when the fan was running. For the bucket fan flow direction, pushing air downwards (q_1) was better than sending air upward through the bucket fan (q_4): θ ≈ 0.23 in q_1, and θ = 0.38 in q_4. Therefore, it is more beneficial to use a bucket fan close to the roof heating source with downward air than a wall-mounted bucket fan blowing air upwards, which also causes a potential increase of ceiling heat transfer. The q_1 case was the worst thermal stratification case: the resultant roof heat loss was found to be about 2.9 kW, as shown in Figure 32B. Applying a destratification strategy (e.g., the best case of q_3), the energy saving can be 1.12 kW in q_3, a reduction of around 40% compared to q_1. Energy savings from other strategies also found that a lower θ result in a less heat loss through the roof.

The calculated nonuniformity coefficients of the KS warehouse are all less than 0.1, ranging from 0.006 to 0.096 (not shown here). This shows that, although the KS warehouse is about seven times larger than the QT, using ceiling duct diffusers and many wall-mounted bucket fans significantly overcomes the thermal stratification. The corresponding energy saving from ramping up fan speed is only 2% for k_1 and 5% for k_3 when using k_2 as the baseline, as shown in Figure 32B. Therefore, using duct diffusers already ensures a good mixing, and increasing mixing fan speed is unnecessary in this case. A more effective way to further reduce thermal destratification is to change the diffuser air supply angles (at zero extra energy

Table 5 Destratification Strategies in Warehouses

Warehouse Case		Destratification Strategy
QT	q_1 (existing system)	Bucket fan #1 on with air blowing downwards
	q_2	All fans off
	q_3	Only ceiling fan on, bucket fans off
	q_4	Bucket fan #3 on with air blowing towards roof
	q_5	Bucket fan #1 and #2 on
	q_6	Bucket fan #1, #2, and #3 on
KS	k_1 (existing system)	All bucket fans at 30% speed, horizontal diffuser air
	k_2	All fans off, horizontal diffuser air
	k_3	All fans at 100% speed, horizontal diffuser air
	k_4	All fans at 30% speed, 45° downward diffuser air
	k_5	All fans at 30% speed, vertical downward diffuser air

costs). When the diffuser supply air is changed from horizontal throw in k_1 (the existing system) to 45° downwards in k_4 and, further, to vertically downward (90°), the corresponding energy saving is 5% in k_4 and over 6% in k_5 (a similar scale as, or slightly better than, adjusting bucket fan speed). Therefore, for both warehouses, a preferred thermal destratification strategy is always to actively deliver warm conditioned air effectively to the lower portion of the building, rather than passively relying on local mixing devices (e.g., wall mounted bucket fans), which are often complicated by issues of location and number of units used. An exception is the ceiling-mounted rotating fan in the QT warehouse, which was found to be a superior destratification method. This example demonstrated that using CFD techniques can effectively aid the design and analysis of thermal stratification and destratification in warehouses.

4. MULTIZONE SIMULATION METHOD

Multizone modeling differs from CFD in that it considers a macro view of a building, as opposed to a micro view. CFD provides detailed transport characteristics in a given building volume, but multizone modeling provides building-wide characteristics of an entire building volume. Multizone airflow and contaminant transport models treat a building as (1) a system of interdependent nodes (or zones) that store air and (2) contaminant mass and transport elements (or links) that carry mass between the nodes. Zones in a model constitute by individual rooms, plenums, and duct junctions, and examples of links include windows, doors, envelope leaks, and duct segments. Nodes are considered to be well mixed (i.e., characterized by single, representative properties including temperature, pressure, and contaminant concentrations). However, pressure is allowed to vary within each zone hydrostatically.

Interzone and infiltration airflows are determined by calculating the interior zone pressures that satisfy mass balance in each zone, based on driving forces and boundary conditions that include HVAC system airflows, as well as wind and stack pressures exerted on the building envelope. Once the airflows are obtained, contaminant sources and removal mechanisms (e.g., deposition, filters) are accounted for in a contaminant mass balance to determine the time history of contaminant concentration over the simulation period. The fundamentals of multizone simulation are discussed in Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*.

4.1 MULTIZONE SIMULATION OF A TYPICAL OFFICE BUILDING

This example uses multizone modeling to evaluate indoor air quality (IAQ) and ventilation for a medium-sized office building. More specifically, this case demonstrates that multizone modeling can show the effects of building envelope leakage on ventilation system performance and average contaminant levels.

Building Description

The building (Figure 33) is based on a representation of a U.S. Department of Energy (DOE) Commercial Reference Building model developed by Ng et al. (2012). The building measures 50.29 by 32.92 m. Floor and plenum heights are 2.74 m and 1.257 m, respectively, for a total of 12 m. It consists of three floors, each served by a return air plenum located above the occupied level.

Multizone Representation of Building

The multizone representation of the building is shown in Figure 33. Each floor was subdivided to include five occupied zones: a core zone and four perimeter zones. This zoning strategy reflects that of the original DOE energy model upon which it is based, which treats the perimeter zones separately due to orientation-based solar loads and the core zone having a different energy load from the perimeter zones. This zone topology is also practical for the purposes of this example, because it captures the wind-related effects on the perimeter zones and the core/perimeter ventilation system layout. The core zone was slightly modified from the original model so that each floor includes a stairwell, elevator, and restroom. The stairwell and elevator span the entire height of the building to allow consideration of stack-driven flows through these vertical shafts.

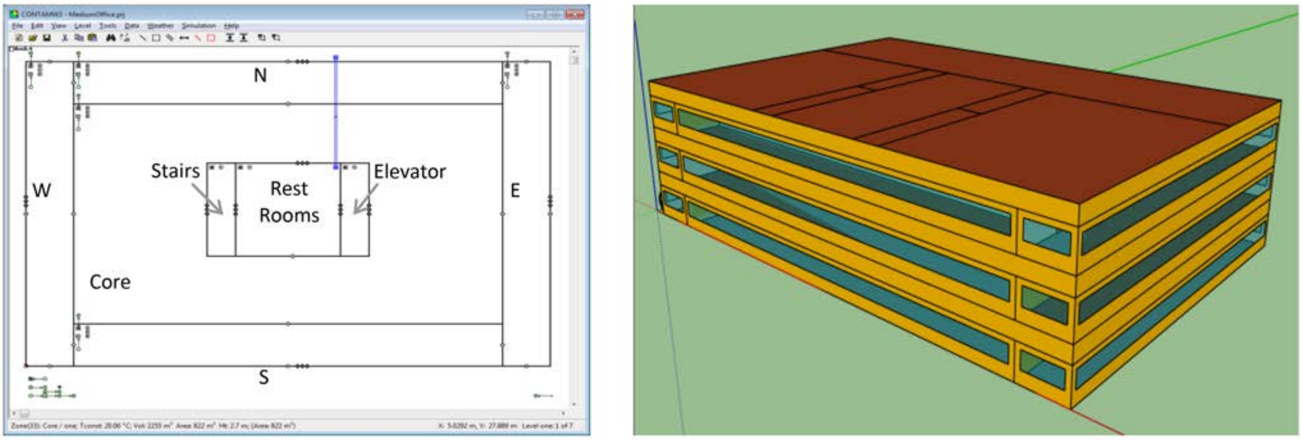
Airflow characteristics of the building envelope and interior partitions are based on the model described in Ng et al. (2012). Exterior envelope leakage is defined using an effective leakage area of 527 mm^2/m^2 at a reference pressure of 4 Pa, a discharge coefficient of 1.0, and a pressure exponent of 0.65. The leakage between the perimeter and core zones are defined as open office plans to reduce interzone resistance to airflows, and the ceiling plenum was connected to the occupied zones with orifice areas of 1.0 m^2 per 100 m^2 of ceiling area. Wind pressure coefficient profiles were specified based on low-rise buildings, as defined by Swami and Chandra (1988), and the building was situated in a suburban location to yield a surface-averaged wind speed modifier of 0.36 (Walton and Dols 2006). Simulations were run using a TMY3 weather file for Baltimore, MD.

Each floor of the building is served by a single air handler, and each restroom is served by a dedicated exhaust system. Two ventilation systems were modeled in this example: a constant-air-volume (CAV) mechanical ventilation system and a CAV system that also incorporates CO_2-based demand-controlled ventilation (DCV). The restrooms were exhausted at a constant rate of 100 L/s in both systems.

Source for Contaminant Model

Contaminants were simulated to represent both indoor and outdoor sources. The selected contaminants enable the investigation of the effects that various ventilation system and building leakage characteristics have on different types of sources. Occupant-generated carbon dioxide (CO_2) was included to model demand-controlled ventilation, because it can be used as an indicator of people being present in the building and thus as a controlled variable for establishing ventilation airflow rates. Volatile organic compounds (VOCs) were simulated to represent a generic indoor source associated with building materials and occupant activities. Particulates less than 2.5 µm in diameter ($PM_{2.5}$) were simulated to represent an outdoor source. The properties of these contaminants, sources, and sinks are based on those provided in Ng et al. (2012).

- CO_2
  - Outdoor concentration: 648 mg/m^3
  - Indoor generation rate: 0.3 L/min per person
- VOC
  - Outdoor concentration: $\mu g/m^3$
  - Indoor generation rate: 0.5 mg/h



(A) (B)

Fig. 33 Medium Office Building Model: (A) Schematic Floor Plan and (B) 3D Representation

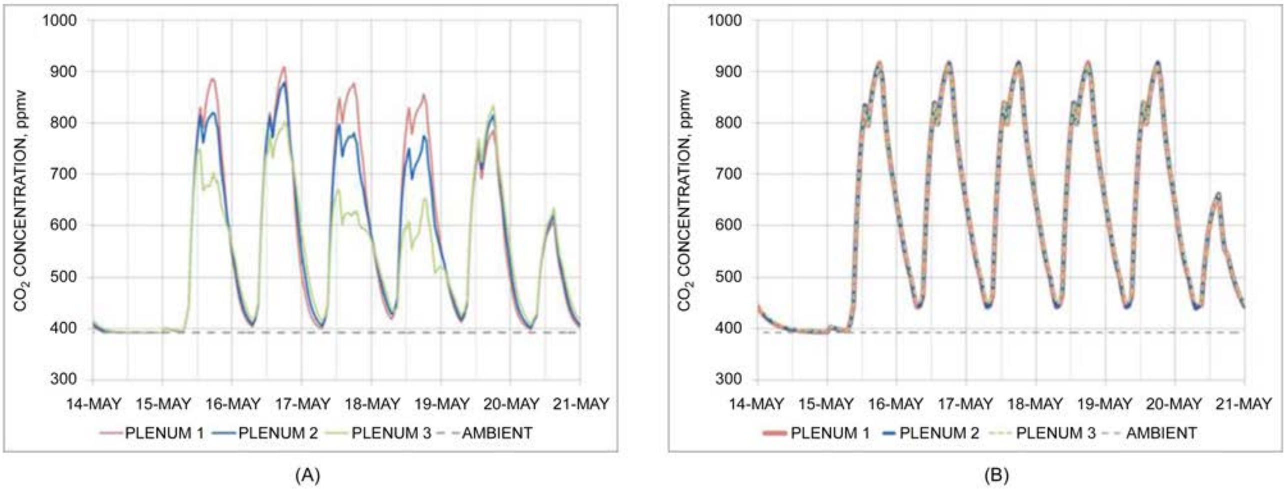


Fig. 34 CO_2 Concentration for DCV System in (A) Leaky and (B) Tight Buildings

- $PM_{2.5}$
  - Outdoor concentration: 18.0 μg/m^3
  - Indoor generation rate: N/A
  - Deposition rate: 0.5 h^{-1}

Simulation Results

Multizone modeling provides the ability to evaluate ventilation system designs with respect to building envelope tightness using pressure-based airflow network calculations as opposed to assumed and empirically determined air change rates (Ng et al. 2014). Figure 34 provides plots of the CO_2 concentration in the three return plenums. The plot on the left is for the base configuration with a building leakage rate of 527 mm^2/m^2, and that on the right is ten times tighter. As shown in Figure 34, there is less variation in the CO_2 concentrations among the three zones in the tighter building, enabling better control of the DCV system.

Calculating airflow and contaminants together allows comparisons between various ventilation systems that use contaminant-based control strategies, evaluating the controlled contaminant (here, CO_2) and the effect of different control schemes on uncontrolled contaminants (here, VOCs and $PM_{2.5}$). Figure 35 shows the building average VOC concentration for four different combinations of building envelope leakage and ventilation system type: leaky envelope with CAV system, tight envelope with CAV system, leaky envelope with CAV/DCV system, and tight envelope with CAV/DCV system. This plot reveals that the internal concentration is elevated by the lower outdoor air intake rates attributed to the DCV control system for both the leaky and tight envelopes. Thus, even though DCV and tighter building envelope may lead to energy savings by reducing outdoor air intake, this approach could lead to increased occupant exposure of internally generated, uncontrolled contaminants.

Further, as mentioned above, building energy measures such as ventilation strategies and envelope leakage rates can affect building energy usage. Multizone energy simulation tools could be used to evaluate the trade-offs between energy conservation strategies and IAQ. Multizone, whole-building energy analysis software can provide a wide range of building energy usage characteristics and has been coupled with various means, including cosimulation, to allow these analyses to be carried out in an integrated manner (Dols et al. 2016; Ng et al. 2018).

Phase 8: Use, Operation, and Maintenance 60.17
TERMINOLOGY 60.18

THIS chapter explains potential benefits of integration, implications for project management, and logistics of carrying out an integrated project. Resources in the References, Bibliography, and Resources sections, as well as other Handbook chapters and ASHRAE guidelines and standards, offer in-depth guidance on various integrated project delivery (IPD) application requirements.

Integrated work is done by a cross-functional team of people working together toward a common goal. This concept has been used formally in product manufacturing for at least 60 years and is growing in the building design and construction industry. This chapter discusses two levels of integration, integrated building design (IBD) and IPD, both of which use cross-functional team based project management to promote holistic collaboration by team members during the diverse phases of building project delivery. IBD is embedded within IPD, so the former is included within the scope of the latter. The distinction between these techniques is explained in the Terminology and Process sections.

1. WHY CHOOSE IPD?

Owners risk both money and reputation on new buildings. If the building costs too much, is put to beneficial use too late, or performs poorly (by not meeting the needs of occupants or costing too much to operate), the owner stands to lose a great deal. Integrated project delivery is a means to greatly reduce all these potential pitfalls. Integration promises to reduce the risk to the owner that a project will cost more than budgeted, be delivered later than planned, or fail to perform as intended.

There are two models of project development. In **sequential project delivery (SPD)**, designers work within their isolated functional area, as in a bureaucracy. Alternatively, in **integrated project delivery (IPD)**, designers work together with others from all functional areas, as a team. Benefits of integration are best explained by highlighting the distinction between these two ways of working.

The imagery most often used to describe sequential project organization is that of silos. Designers in each function work within their respective silos, isolated from others. Every function (e.g., architecture, HVAC engineering, plumbing engineering, fire suppression engineering, electrical engineering, structural engineering) has its own silo.

Silos exist to make the group efficient. People working in a functional silo are expected to stay busy doing the functional work assigned to them. They communicate with other functions only as necessary to do their work, endeavoring to complete their assignment as fast as possible, either by sending it back to the function that passed it to them, or finishing and passing it on to the next function. The piping designer does not get paid to help the duct designer, and the pipe fitter does not get paid to help the tin knocker or the piping designer.

When architecture decides plans are ready, they send them over the walls of their silo into that of HVAC engineering for HVAC design. If HVAC engineering likes what they receive, they get to work. If they do not, they send the architectural plans back with requests for rework (e.g., making more room for ductwork). Eventually, HVAC engineering passes their work on to others, like electrical and plumbing. Those disciplines may in turn send the HVAC work back for revision. When all the design functions are done, the plans and specification are sent to construction, which often returns them to the designers in the form of change orders because contractors cannot build, or do not understand the plans. Costs increase. Schedules lengthen.

An integrated project is very different. There is only one silo: the team silo. Every function is present and responsible for assisting the others. Architecture never gets a drawing back to make more room for ductwork because the HVAC engineer and the architect work together to size the ductwork and the architectural space it needs at the same time. Furthermore, there is construction expertise available to the design team. The mechanical contractor does not issue a mid-construction change order due to an unbuildable duct design because the contractors were there during design, ensuring the design can be built. Individuals are responsible for doing sound professional work and being good team members, and the whole team of designers and contractors is responsible for making the project efficient.

The work of design and construction gets done in both models. The difference is that a cross-functional team works together from the beginning of an integrated project. They agree on the objectives of their work and how the building will perform when it is done. Then they design the building and all its systems, front-loading collaboration efforts to optimize building system solutions in response to the defined project objectives. Integrated design identifies key issues and addresses them early in design and planning because the people who can see them and solve them are in the room doing the work.

An important point to remember is that integration does not necessarily mean getting more things done early; it means getting the right things done early, and maintaining focus on the required performance during key decisions. Another important point is that integration is not design by committee. Integration is design and construction professionals coordinating their work early in the project, when that coordination can be done most efficiently for the project. The professional work of the architects, engineers and contractors resides only with the professional responsible.

Costs early in the project rise because people are on the job that would have traditionally arrived later. However, because they are

The preparation of this chapter is assigned to TC 7.1, Integrated Building Design.

there, they can avert and rework problems that would have been more costly to fix later. Thus, costs of later phases (and overall) should be lower. Building performance should also be better because mid-construction design changes to solve problems or reduce cost are made by the whole team before a crisis develops.

1.1 COLLABORATION AND TEAMWORK

Collaborative design requires that all members of the design team possess demonstrated expertise, an ability to work collectively in a nonisolated setting, and a drive of stewardship to support IPD. Team members should share similar corporate philosophies, have compatible operating procedures, use common optimization tools, and be committed to adhering to consistent interdisciplinary quality assurance/quality control (QA/QC) procedures.

IPD extends the scope of design to construction tasks. With construction expertise available to inform the design process, planning can be more specific about materials and methods, more confident around estimating costs, and more accurate with setting schedules. Collaboration between design professionals is extended to constructors and subtrades, eliminating the oppositional relationship between design and construction that is commonly found with design-bid-build approaches. Disagreements may occur, but the IPD environment provides a structure to resolve them, through references to the owner's project requirements (OPR) and previously agreed-upon project values.

Each project requires a different set of disciplines, though certain roles, like the owner, architect, structural engineer and MEP engineers, are always needed. The selection of team members also depends on whether the project is an IBD or IPD project. These choices are described in the Process section.

1.2 TEAMWORK

Team members have two responsibilities:

- To perform their own professional design work developing the agreed basis of design (BOD), recognizing that their work is part of the team's design for the whole building
- To work for the benefit of the whole team, identifying conflicts that arise between their designs and any of the other disciplines, the OPR, or the BOD; promptly bringing issues to the attention of the other team members; and working toward successful resolutions

Working with a team requires that participants engage in joint decision making. Individual thinking and processes must be formally brought to the team and discussed in the context of project objectives and previous decisions. Having a space for discussing new ideas encourages a decision-making mentality that supports the team's direction. Individuals must keep in mind that their actions and reactions affect integrated system solutions. Design in isolation does not support team collaboration.

Team members must foster a professional level of respect for each other. When individuals suggest new strategies to improve the whole, dissenting views will occur. Emotions must be removed from these events. Evaluations must be made on objective application and support of project objectives. The project team leader should be trained to handle conflict management and dissenting views in a professional manner. Consensus agreement will not always be apparent, and the project team must avoid fracture of the collaborative effort when differences occur.

Effective, concise, and complete communication must be adopted to keep the team informed of all decisions across all design disciplines. Communications within the project team should be standardized as much as possible. Each form of communication should contain the origination date, any revision dates, project name, project number, and originator's contact information. In addition, a clear and concise subject line should be included to focus recipients on the subject matter at hand. For collaboration to work, all team members must be kept in the communication loop so that each understands where the collaboration process stands.

Team Formation

Unsurprisingly, integrated project team formation is more involved than in sequentially designed projects. To create a well established team, the owner needs to be prepared. Integration is not something that happens spontaneously, or that can be achieved at the last minute. Onus is on the owner to organize the team for the work at hand, building up the group as tasks approach. Often, this starts with hiring an integration specialist or design facilitator. As the team expands, it needs to create ground rules for working together and agree on who will be leader for the different phases of development. Often, leadership rotates, following the focus of the development phase. Team formation is discussed in the section on Phase 2: Project Initiation.

The team should consider **colocation** and use of shared development platforms. Colocation of designers and constructors facilitates speedy resolution of conflicts by increasing opportunities for timely collaboration, reducing rework. In a colocated environment, all disciplines get the same information at the same time, and it is easier to get all disciplines working on special conditions together. Colocation is helpful in avoiding conflicts between disciplines and trades, which are common and expensive to resolve. A colocated team has an opportunity to use shared documentation platforms that facilitate coordination and detect clashes between different disciplines. Common development platforms help keep the work of other disciplines visible and offer a common language for project development. Three-dimensional computer-aided design (CAD) systems and building information modeling (BIM) are excellent aids for this.

It is essential that the owner's team has a champion for the integrated project. Early investments are being made in the project that are not common, and without a champion, the focus of the project may drift and compromise the potential of those investments.

The importance of an experienced, integrated **design leader** cannot be overstressed. Systems thinking requires input from individuals who have design experience to match the project at hand. Decisions must be based on an understanding of how systems and components interact. The integration leader must ensure that those with limited cross-functional experience listen to other viewpoints and adapt their work for the best whole-building solutions.

IPD can succeed when key representatives learn as they go, but the work may take longer and require more iterations as the new participants are trained in the system. IPD provides an excellent opportunity to mentor and train supporting staff in system integration, and the opportunity should be fully exploited.

Participants should have a proactive attitude that supports the ups and downs of iterative system evaluation. Individuals who can see the big picture and appreciate that the whole will be better than the sum of the parts enhance the team's efforts.

They should also have experience with optimization techniques. True optimization expertise requires understanding how building systems interact, what elements can be revised for the benefit of the whole, and how to evaluate results in detailed financial models that consider all ownership costs.

Some projects may require adding **specialty consultants** to the project team to support activities such as smoke control, acoustics, seismic restraint, or food service. Only rarely can one firm meet all necessary needs on complex projects. Management of outside specialty consultants is an added responsibility that must be factored into the collaborative process.

Consensus in Decision Making

Typically, teams make decisions by consensus. That means that all share the responsibility for decisions, providing their expertise. Often, consensus is interpreted as "design by committee," which is not the approach used in either IBD or IPD. Rather, integrated design processes depend on sequential leadership, in which the professionals responsible for each of the building systems lead when their area of expertise is discussed, but also contribute their perspectives when other disciplines are in the leadership position. Project integration specialists are valuable in this process: their expertise is leading the team, ensuring that all decisions are made by teamwide consensus, and emphasizing compromises that accommodate valid concerns affecting other disciplines. Project integration specialists also have a strong technical understanding of how building systems work together and can capitalize on the expertise of all members.

2. PROCESS

This section describes methods that, based on the experience of the authoring ASHRAE subcommittee, are sound and may be followed for a successful project. The project overview (Table 1) outlines the basic framework and major milestones, listing the questions that must be answered by team members as they complete one phase of work and seek approval to move forward. It breaks down a typical building project into phases, and in each phase is a list of go/no-go questions to be answered *yes* or *no* by the owner. If all questions are answered *yes*, then the decision is to go forward and begin work in the next phase. If any question is answered *no*, then the decision is no-go; this does not stop the project but continues the team's work in the current phase until all answers are *yes*. Because each phase builds on those before it, the owner should require a *yes* answer to every question in a phase before approving work to begin in the next phase. If a phase is not done well, those that follow are at higher risk of producing an inferior project.

The phase descriptions explain what happens in each of the project phases and guide the reader. They are the how-to guides for completing the phases and delivering what is required for a *yes* answer to each question in the project overview.

This section is not intended to define the only way to carry out an integrated project but to provide guidance to a project team, and must be adapted to each specific project. Every team must establish its own methods through consensus of the team members. These descriptions provide guidance for a team new to integrated cross-functional team project management and inform a design team member about what to expect from others and what others will expect from them.

2.1 PHASE DESCRIPTIONS

This section explains the work to be done in each phase listed in Table 1. These descriptions explain methods that, based on the experience ASHRAE Technical Committee 4.10, are sound and may be followed for a successful integrated project. These sections are not intended to define the only way to carry out an integrated project: every team must establish its own methods through consensus of the team members. These descriptions are intended to provide guidance for a team new to integrated cross-functional project management and to inform a design team member who is assigned to an integrated project about what to expect.

- **Introduction:** In general, what happens during this phase?
- **Purpose:** Why is this phase important, what does the work in this phase contribute to the project?
- **Prerequisites:** What must be done before work begins in this phase?
- **Team:** Who are the project team members during this phase? How does membership change during this phase?
- **Work:** What work is done by the team?
- **Sequence of events:** What is the sequence of events, particularly as it pertains to meeting the requirements defined in the integrated building design checklist?
- **Role of design team member:** What is the role of each design team member; how is each person expected to serve as a team member; what must each member deliver as product to the project team?
- **Role of integration leader:** What is the integration leader/commissioning leader's role; how is this leader expected to serve as a team member; what must this person deliver as product to the project team?
- **Performance requirements:** What HVAC systems performance requirements can be affected by decisions made during this phase and require analysis and advice from the HVAC engineer?
- **Tools:** What tools are typically used?
- **Documentation:** What documents are produced?

2.2 PHASE 1: PROJECT JUSTIFICATION

Project justification is the owner's activity that determines whether constructing a building will satisfy a need for space and/or a specific return on financial investment. This process is commonly delivered by real estate or project management consultants, but for projects considering an integrated project delivery approach, it is better to develop the same information with a subset of the full IPD team. For speculative projects, this activity requires assumptions about potential end uses, expected revenue, development risks and costs, expected lifetime of the facility, and required return on the project investment.

For public sector or owner-occupied projects, a return on investment calculation may be secondary to long-term plans, staffing requirements, organizational image and communications, size of an organization's building portfolio, and funds commonly available for operations and maintenance. Public sector and owner-occupied projects may also be able to entertain longer payback periods than speculative developers. This fact creates an opportunity for IPD and improved building quality.

Project justification sets the conditions for all the work to follow, so it is best if the decision to use IPD is made before the justification work begins. Thus, the foundation for a sound IPD project can be built from the beginning, eliminating the need to convince people to change their minds later, particularly where the project budget is concerned.

Regardless of the state of an owner's initial project assumptions, IPD requires explicit discussion and acceptance of project goals by all participants on the design team. This provides an opportunity to confirm that facility programs and budgets are appropriate.

Purpose

- Financially justify the project for the owner's approval, before proceeding with the work and the cost of the next phase
- Clearly identify the need(s) for this built space
- Prepare a plan to complete second phase (project initiation), including key team members, objectives, funding required, and schedule

Prerequisites

For the project justification phase to begin, the owner must

- Have decided to use IPD practice to carry out the project
- Have hired an integrated project leader
- Be willing to actively engage with the design process more than is required by a standard "review and approve" structure

Table 1 Project Overview

Go/No-Go Question	No	Yes
Phase 1: Project Justification		
Has the project justification assessment been completed by a team of highly skilled people, assigned by the owner?	☐	☐
Has the team identified and clearly defined a need for this built space?	☐	☐
Has the team prepared a plan to complete phase 2, including key team members, objectives, funding required, and schedule?	☐	☐
Has the team demonstrated financial justification and secured funding to complete phase 2?	☐	☐
Phase 2: Project Initiation		
Is there a commitment to high performance?	☐	☐
Is integrated building design or integrated project delivery justified?	☐	☐
Have the owner's operation and maintenance (O&M) capabilities been documented?	☐	☐
Does the owner's O&M staff possess expertise that could contribute to successful outcome of the project?	☐	☐
Have these members been identified and included in the owner's team?	☐	☐
Has the commissioning agent prepared the first draft of the owner's project requirements (OPR)?	☐	☐
Has the project initiation team defined attributes of the concept development and design phases' cross-functional team members?	☐	☐
Have members of the concept development and design phases' cross-functional team been recruited?	☐	☐
Has a project integration specialist been recruited to join the team?	☐	☐
Has the team prepared a plan to complete phase 3, including key team members, objectives, funding required, and schedule?	☐	☐
Has the project initiation team demonstrated that there is financial justification and funding available to complete phase 3?	☐	☐
Phase 3: Concept Development		
Is the OPR complete, documenting clear and measurable targets for building performance, suitable for monitoring building operating performance?	☐	☐
Has the team agreed on one set of systems concepts that define the whole building?	☐	☐
Have the attributes of specialty resources been defined and are they available as needed?	☐	☐
Has the team prepared a plan to complete phase 4, including key team members, objectives, funding required, and schedule?	☐	☐
Has the project initiation team demonstrated that there is financial justification and funding available to complete phase 4?	☐	☐
Phase 4: Design		
Has the integrated team, including design professionals, construction contractors, and owner's O&M staff, worked together to perform design work?	☐	☐
Are schematic design documents complete and delivered to owner?	☐	☐
Are design development documents complete to the extent necessary for pricing and delivered to the owner?	☐	☐
Has the design team demonstrated that there is financial justification and funding available to complete phase 5?	☐	☐
Has the team prepared a plan to complete phase 5, including key team members, objectives, funding required, and schedule?	☐	☐
Phase 5: Construction Preparation		
Is the project price agreed between the owner and contractor(s)?	☐	☐
Do the construction documents include answers to all bid questions and scope of work change agreements?	☐	☐
Do the construction documents include all cost reduction design changes and related OPR changes?	☐	☐
Does the team agree that commissioning work completed in accordance with construction documents will prove that building performance meets the OPR?	☐	☐
Are contractors prepared to perform the commissioning tests and inspections required by construction documents?	☐	☐
Are the means and methods for project communication and decision making clearly defined?	☐	☐
Has the team prepared a plan to complete phase 6, including key team members, objectives, funding required, and schedule?	☐	☐
Phase 6: Construction		
Are all systems built and equipment installed in accordance with the construction documents and certified as such in accordance with commissioning requirements?	☐	☐
Has the owner's facility management/maintenance staff made regular visits during construction to ensure maintainability of installed equipment?	☐	☐
Are all systems and equipment operating as intended and certified as such in accordance with commissioning requirements?	☐	☐
Has the authority having jurisdiction (AHJ) approved the project for occupancy and agreed that all required inspections and tests are complete and satisfactory?		☐
Is the owner O&M training plan complete?	☐	☐
Has the team prepared a plan to complete phase 7, including key team members, objectives, funding required, and schedule?	☐	☐
Phase 7: Owner Acceptance		
Are all systems operating in accordance with the OPR?	☐	☐
Does the owner have all documentation required to operate and maintain the building?	☐	☐
Have all required documents and maintenance procedures been incorporated in the owner's maintenance management system?	☐	☐
Have the owner's O&M people been trained in the proper operation and maintenance of the integrated whole-building systems?	☐	☐
Is the owner prepared to operate and maintain building performance in accordance with the OPR?	☐	☐
Has the team prepared a plan to monitor the performance of building systems throughout the warranty period and tune or repair systems as necessary to make the building perform as required by the OPR?	☐	☐
Phase 8: Use, Operation, and maintenance		
Does operating performance, under normal use and occupancy, meet the OPR?	☐	☐
Are O&M personnel in place and prepared for ongoing operation?	☐	☐
Do all team members agree that the project is complete?	☐	☐
Is the owner prepared to operate and maintain building performance in accordance with the OPR?	☐	☐

- Be willing to explore alternative approaches to common building design and construction issues

Team

The project justification team is small and able to, quickly and at low cost, collect and analyze enough information to decide whether the project is worth pursuing further. The team must include

- Team leader (may be the integration specialist or owner)
- Owner (and/or an employee authorized to make decisions and able to obtain information)
- Integration specialist
- Financial analyst
- Expert in documenting occupant requirements (facility planning/commissioning basis of design fundamentals); could be the commissioning agent or integration specialist

The team may wish to augment their knowledge by consulting with other experts for information. Areas of expertise may include

- People with special knowledge of particular building types
- Local real estate conditions for various markets
- Details of local land use planning objectives and regulations
- Building commissioning
- Building operations and maintenance
- Building finances, including tax applications
- User groups varying with building type
- Knowledge of available government and utility incentives
- Construction cost estimating
- Structural design
- HVAC design
- Plumbing and fire protection systems design
- Electrical systems design
- Civil design
- Building science
- Natural lighting and acoustic design

Work

This phase begins when the owner believes that a building project is warranted. The project team first gains an understanding of the owner's hypothesis and determines either that it is valid enough to justify work in the next phase, or that it is not valid and no further effort is justified. The tasks include (but are not limited to)

- Collecting information on the market for the proposed building
- Identifying who would occupy the proposed space(s) and their needs
- Determining if and how their needs are being met now
- Determining what needs are not being met
- Defining what added space or existing space upgrades (adaptive reuse) would satisfy unmet needs
- Determining how the added space or existing space upgrades (adaptive reuse) could be used to satisfy unmet needs; evaluating if other spaces could meet the need by consolidation
- Estimating the cost of producing the new spaces or upgrades
- Estimating the worth of the new spaces or upgrades in terms of revenue, productivity, goodwill, etc.
- Deciding whether the worth justifies the cost (rough numbers are good here)
- Identifying the skills needed from team members who would complete phase 2
- Identifying specific individuals and firms who would make up the project initiation team and the cost for their work
- Preparing a plan for phase 2 work, including objectives, personnel, budget, and schedule
- Securing plan approval and necessary funding

If the owner already owns the land but is open to how it will be used, then this work may begin by exploring different purposes and include one or more viable options for further investigation.

Information sources for project data depend on the type of project. For an owner-occupied building, the market information is mostly internal. Market information for tenant-occupied buildings is externally focused and includes speculative buildings the owner intends to sell on completion.

Typically, the total project expenditure is divided into two types of costs. **Soft costs** include design consultancy fees, specialty testing and expert fees, and other costs arising from documenting the site and the proposed design. **Hard costs** include construction cost (including labor), plus the applicable municipal, state or provincial, and federal regulatory fees. Bank financing and carrying costs may also be included in the assessment of hard costs. Designers must justify the soft costs and estimate hard costs as accurately as possible to assist with the development of the project's financial outline.

At this stage, an awareness of how to bring funds to the project is important. For example, there are federal and state tax incentives, Internal Revenue Service (IRS) benefits from cost segregation studies, solar or renewable energy usage incentives, and low-interest loans available for energy-efficient projects. Utilities often have incentives or product rebates for energy efficiency measures, which are driven by regulatory or demand management requirements. There can also be incentives for going through the IPD process. When combined, these incentives and benefits can dramatically reduce hard costs. Any team member may bring knowledge of incentives for building construction to the team; it is not solely the responsibility of the owner.

Sequence of Events

The sequence of events, particularly as regards meeting the requirements defined in the IPD checklist, is

1. Owner decides to adopt IPD to take advantage of the method's benefits and to differentiate the building from the regular market.
2. Owner assembles the project justification team.
3. Project justification team assesses the potentials of the project in several possible variations.

Should viable versions of a project be presented, the project justification team

- Prepares documentation outlining the nature of the project and demonstrating the project viability and benefits. This documentation includes descriptions of performance conditions that will inform the initial basis of design documents.
- Prepares a plan for phase 2.

Team Roles

Design Team Member. The typical MEP engineering group may not be a member of this intentionally small and low-cost team, but could be asked to consult with the team to create rough projections of cost, performance, and service life of building elements.

At this stage, there is an idea (but no design yet) about the project, and the site is typically known. Projections for building performance that support the estimate for the return on financial investment must be developed. Building cost estimates and performance expectations are usually based on the owner's past projects of a similar type, or minimum code-compliant design. However, the benefits of state-of-the-art (SOA) systems, which can provide better comfort, efficiency, noise levels, return on investment, etc., should be recognized before budgets are fixed. The benefits can outweigh budgetary constraints when evaluating SOA systems, and at this junction budgets are more flexible.

A member of the design team may be called upon to explain such things as differences from systems used in the owner's last similar project, a minimum code-compliant building, or the improvements possible with contemporary HVAC technology and design practices. This explanation must define the differences between types of systems, what they offer in terms of higher productivity due to better conditions for occupants, lower operating costs due to energy-efficient design or more robust equipment, and costs of construction. (*Note*: the team should have experts in building performance and cost estimating to help with this work).

In this phase, any design team member asked to participate needs good verbal communications skills, flexibility in developing alternative performance scenarios, and good technical writing skills to communicate the relevant information to the team. He or she will also benefit from a developed ability to work with others and the capacity to draw on the experience of other design disciplines to quickly produce a thorough analysis.

Systems likely to be evaluated are

- Building envelope characteristics such as percentage openings, U-values, and water management strategies
- Ventilation systems, including energy reduction and energy recovery
- Cooling systems
- Heating systems
- Energy transfer (between heating and cooling) systems such as variable-refrigerant-flow (VRF) systems
- Air distribution systems

Integration Leader. The integration leader leads the effort to determine and document what performance requirements will help meet the needs of the intended occupants. This is the first rough pass at this information and captures things such as energy consumption targets that might require higher-cost construction, more comfortable conditions to increase worker productivity, etc. This information is the foundation of the basis of design documents used by commissioning specialists.

The integration leader may be the project manager for this phase of work. That person is also be instrumental in planning the integrated project delivery process and identifying the required team members.

Performance Requirements

Performance requirements can be affected by decisions made during this phase and require analysis and advice from the HVAC engineer regarding

- Indoor air quality
- Indoor environmental conditions that affect comfort, productivity, and safety of occupants
- Operating costs, including energy and maintenance
- Acoustic performance
- Air quality and safety of neighboring properties
- Greenhouse gas (GHG) emission requirements (refrigerant selection)

HVAC systems performance requirements are relative to the overall quality of the facility being proposed. For commercial buildings, facility quality is related to the target rent, which is assumed to be in the range of the target market. For institutional projects, high-quality facilities are often specified, but potentially outside of the cost range of the project. Regardless of facility quality, building codes require compliance with, and sometimes incremental improvement from, ASHRAE *Standards* 90.1, 62.1, 62.2, 55, etc. As these standards are improved in the pursuit of reduced resource consumption and more reliable design and operational performance, facility quality levels are increased. If the owner sets a budget for the project based solely on experience, opportunities for better, more marketable spaces with lower operating costs may be lost.

Tools

Tools useful to this phase validate assumptions regarding building performance and capital or operations costs. Historical data on the energy performance of similar building types in the same climate zone is a key starting point. Similarly, historical data on local construction costs inform understandings of predicted costs. Real estate surveys of market conditions and rental costs per unit area provide data for the revenue side of the equation.

Energy use intensity figures in energy units over areas, such as kilowatt hours per square metre (kWh/m^2), are easily multiplied by gross building area to create operational estimates. National databases of energy performance are available where the owner does not have access to a portfolio of buildings in the region. Examples include

- U.S. Energy Information Administration: CBECS
- Natural Resources Canada: National Energy Use Database
- ENERGY STAR: Portfolio Manager

Standard estimating handbooks are also used to identify construction costs. In the absence of a design, indicative estimates on a unit floor area or building volume basis are common. Common estimating references include RSMeans *Building Construction Cost Data* and Hanscomb's *Yardsticks for Costing*.

For the revenue side of the ledger, reports on costs from real estate associations and brokers support predictions of revenue for a potential project. Unit-area-based costs are the finest level of detail required. Attention to the terms of rents is crucial, because the opportunities for return to the owner vary greatly between all-inclusive and triple net leases. Data from the local chapter of the Building Owners and Managers Association (BOMA) or recent reports from brokers are used. Potential incentives for specialty applications can be recorded, but may need to be reduced by a factor representing the risk of the final project not qualifying for the incentive, or the incentive amount being reduced.

Documentation

- Financial justification documents required by the owner to secure financing for the project
- First version of owner's project requirements (OPR), including first version of building performance requirements
- Plan to complete phase 2, including key team members, objectives, funding required, and schedule

2.3 PHASE 2: PROJECT INITIATION

The existing team from phase 1 is expanded to prepare a more detailed project description, providing the scope of work for design professionals in preparation for design and development work. Ideas from phase 1 are developed in greater detail and scrutinized for their continued relevance.

Purpose

- Assess the owner's resources and identify the internal and external participants needed for fully integrated project development
- Continue development of a more complete OPR, replacing assumptions made in phase 1 with information developed by the phase 2 team
- Decide if the project will be delivered by an IPD method or other integrated approach
- Prepare the communications materials that explain the IPD process for incoming new participants, including designers, constructors, and potentially investors
- Secure funds to hire the project team
- Recruit the team experts who will continue the project

Prerequisites

- There is a viable project to be developed.
- A preliminary project description exists that
  - Includes building size and quality.
  - Identifies the intended occupants of the building, the approximate performance they will need, and what they will expect from the spaces.
  - Documents early ideas about building performance. The form of the information may be related to assumed operating costs and replacement cycles rather than explicit system performance requirements.
- An approved, funded plan for completion of this phase exists.

Team

During this phase, the team grows from the initial members of phase 1 to the extended group that will complete much of the work in phases 2, 3, and 4. At the beginning of the phase, the team includes

- Team leader (may be the integration specialist or owner)
- Owner (and/or an employee authorized to make decisions and able to obtain information)
- Integration specialist
- Financial analyst
- Expert in documenting occupant requirements (facility planning/commissioning basis of design fundamentals); could be the commissioning agent or integration specialist
- Facility operations and maintenance specialist

Team makeup at the end of phase 2 and start of phase 3 depends on whether the project will proceed as an IPD or an IBD project. For IPD, recommended team members include

- Owner-appointed project manager (owner employee preferred, *not* an external project manager);
- Integration specialist
- Facility operations and maintenance specialist
- Commissioning agent
- Architect
- Structural engineer
- Civil engineer
- General contractor or construction manager
- Mechanical engineer (HVAC, plumbing, fire protection, building management/controls system)
- Building sciences engineer
- Mechanical contractor
- Electrical engineer (power, lighting, fire alarm, communications, etc.)
- Electrical contractor
- Cost estimator
- Energy analyst or modeling specialist

If the project is to be limited to an IBD, the contractors would be excluded from the team. The rest of this chapter assumes that an IPD project delivery method has been adopted.

Most of the disciplines required for the whole project are represented here. Some specialty design or construction teams may be added in phase 3 if necessary. This might include tenants/occupants (if fit-out is part of the project), an acoustic specialist, lighting specialist, landscape architect, LEED specialist, scenographer, etc.

Work

The team must research and document the building performance necessary to satisfy the needs of all project customers (owner and occupants). The team self-organizes to ensure that information is approached in an orderly fashion and that all relevant opinions are incorporated. Investigate the owner's capacity for managing innovation with respect to state of the art systems. The first formal draft of the OPR is prepared in this phase. The objective of all design team work is to produce a building and systems that meet the performance targets set forth in the OPR.

- Consider the rough OPR from phase 1 and improve it by eliminating unvalidated assumptions and replacing them with factual information provided by the phase 2 team.
- Owner assesses the capabilities of personnel available from the owner's O&M organization.
- Owner identifies and recruits personnel.
- Decide the project delivery method: IBD with a conventional tendering based on a complete building design package, or IPD with a construction management and guaranteed maximum price (GMP) approach.
- Document the expectations and participant responsibilities for IPD.
- Prepare a charter of values or project charter that establishes priorities for interdisciplinary responses to the OPR. (See Terminology section for definitions.)
- Identify and recruit design team members from architectural and engineering firms.
- Identify and recruit construction leaders.
- Negotiate fee agreements with all team members to support the IPD process, educating the potential team members about what is expected.
- Register with programs that provide incentives for IPD.
- If the project team is going to colocate, establish the location and space requirements of the workplace, then lease space or arrange internal resources to house the design team activities.
- Review IT resources of the assembled team and decide on the IT platform and programs to be used.
- The newly recruited team reviews and validates the project justification, now estimating project cost and value based on more in depth understanding of what the owner and occupants need.
- Owner decides whether spending to complete phase 3 is justified.
- Prepare a plan to complete phase 3, including resources, schedule, and budget.
- Secure owner approval to proceed with concept development.

Sequence of Events

1. Document owner's O&M capabilities to help identify necessary new participants.
2. Identify required design resources.
3. Decide on project delivery method (IBD or IPD) based on nature of OPR.
4. Recruit expanded and final phase 2 resources.
5. Prepare initial charter of values for the project in consultation with the expanded team.
6. Decide if the team will colocate, or otherwise define working approaches to facilitate integration if physical colocation is not planned.
7. Identify and secure colocation space if required, or establish equipment setup and system to support virtual colocation if the team members are geographically distant.
8. Prepare the next edition of the OPR based on updated assumptions.
9. Confirm that there is a viable project and that funding should be made available for concept development.
10. Prepare a plan for phase 3 and obtain owner approval to prorole of design team member. As the project is just being started, no time has yet been spent on concept design. This time is best used to lay out as many potential options as reasonable and explore how they respond to the requirements of the space or occupants. This is the time for conventional goal setting meetings, where the owner and designer discuss preferred systems and the challenges of specific applications in the project as described.

In phase 2, the owner's requirements are first assembled in an OPR document. The team helps develop the OPR by noting the usual contributions made by their disciplines, and the implications for operations and maintenance or cost. Where the preliminary OPR creates special conditions needing extra attention from the designers, those items need to be flagged for further discussion.

A design team member will likely be asked to consult with the team to create the rough assumptions of cost, performance, and service life, made for building services elements.

A team member should review the performance requirements in greater depth, revising (if necessary) the phase-1 recommendations based on new information. Preferably, this should be done by a member who also participated in phase 1, but can also be done by a new team member.

In this phase, a prospective design team member needs good verbal communications skills, flexibility in developing alternative performance scenarios, and good report or letter-writing skills to present relevant information to the team.

Because concept design has not yet begun, there are no systems to evaluate, but there are strategies for building services that form part of the OPR. The designer needs to address the pros and cons of a variety of strategies when developing the OPR. Specifically, the HVAC engineer will use the completed OPR as the basis of concept development, and will likely present desired performance outcomes such as

- Building envelope characteristics typical to the standard building types used in financial planning, including percentage openings, U-values, and water management strategies
- Ventilation strategies, including energy reduction and energy recovery
- Cooling strategies (air distribution, radiant, desiccant, district, central, local)
- Heating strategies (air distribution, hydronic distribution, steam, district, central, local)
- Energy transfer (between heating and cooling systems) strategies

Team Roles

The **integration leader** facilitates the cross-functional teamwork and may be the project manager for this phase of work. This person is also instrumental in planning the integrated project delivery process and identifying the required team members.

The **commissioning agent** works closely with the owner and owner's O&M staff to document ideas from discussions of building services strategies in a form appropriate for the OPR and as directions for future designers.

Performance Requirements

Performance requirements are formally set during this phase and require analysis and advice from the HVAC engineer on

- Indoor air quality
- Indoor conditions that affect comfort, productivity, and occupant safety
- Operating costs, including energy and maintenance
- Acoustic performance
- Air quality and safety of neighboring properties
- Refrigerant quality (in case of industrial refrigeration)
- New conditions or service requirements that have arisen during development of the OPR

Tools

- Marketing research tools to determine needs of owner and intended occupants
- Cost estimating tools (both construction and life-cycle costs)
- Various simulation tools

Documentation

- Updated financial justification documents required by the owner to support new or expanded financing for the project
- OPR, completed as necessary to begin concept development of all building systems
- Fee agreements that reflect work required by an IPD project, executed by firms committing employees to the project team
- Plan to complete phase 3, including key team members, objectives, funding required, and schedule

2.4 PHASE 3: CONCEPT DEVELOPMENT

Concept development begins the design process, wherein the assembled team identifies planning configurations and building services systems that respond to the OPR. The selected final concept is later developed into the project to be delivered.

For the first time, diverse specialists come together and work to cover all aspects of building design. The team considers reasonable ways (concepts) to meet the OPR, compares them, and selects the concepts to be developed in technical detail in phase 4. For an IPD project, the discussion of concepts includes the construction expertise of a general contractor or construction manager (and possibly major subcontractors), which brings greater security to ideas regarding constructability, cost, and scheduling. If necessary, the team brings in specialists in select concepts.

Purpose

The purpose of this phase is to select the set of spatial configurations and building systems concepts to be designed and built (the BOD). Key objectives to meet that end are

- Developing different aspects of the OPR in greater depth
- Considering various concepts for accomplishing the OPR
- Selecting the systems concepts that will comprise the BOD

Prerequisites

- Phase 2 work is complete and accepted by owner.
- Funding for phase 3 is approved (first draft of the OPR is complete and owner interest in the IPD has not changed).
- People assigned to the project team are empowered and authorized by their employers to make timely decisions. They are not required to secure approval from superiors before contributing to team decisions.
- The designers are engaged and supportive of a multidisciplinary approach to design.
- The assembled IPD team has agreed on a development approach to the work, responsive to the OPR. For example, a project with net-zero energy goals would adopt a passive design approach that minimizes loads before designing systems to serve anticipated loads. Varying iterations of concepts are to be expected as they mature.

Team

The same team assembled during phase 2 continues work throughout phase 3.

Work

During concept development, the design team works together in earnest. The deliverables are an updated OPR and a BOD. To produce these documents in an IPD context, much work must be accomplished by the team:

- Hire new team members (firms and individuals) needed to complete phase 3.
- Complete the OPR by researching the performance requirements in greater detail and more broadly. This may include thorough marketing research to define required building performance for the

intended occupants, carefully assessing the exact uses and occupancies, and producing detailed definitions of the conditions required to satisfy the market place expectations and statutory (code) requirements.

- Agree on the method and measures the team will use to select the concepts for the BOD.
- Prepare a reasonable set of alternative concepts for each system to create the space environments.
- Perform analysis as needed to quantify differences between competing concepts in terms of the measures agreed upon. Examples include
  - Expected durability of building systems, including enclosure
  - Tightness of environment control
  - Energy conservation
  - Initial cost
  - Operating cost
  - Fit of owner's O&M capability with system O&M requirements
  - Flexibility for future changes
- Select types of systems to be designed and built.
- Prepare the comprehensive whole-project BOD to document the selected concepts.
- Identify and resolve any conflicts between the OPR and expected performance of selected systems. Update the OPR accordingly.

Sequence of Events

In phase 3, the team participates in regular multi-stakeholder (cross-functional) meetings with clear objectives and agendas. Participants develop concepts to accomplish the OPR. Content of the meetings should be tailored to the project; however, some elements are true for all projects.

Meetings are working time for developing concepts, rather than simply presentation venues. They are focused thematically and develop responses to specific questions live in the meeting. Where questions cannot be immediately answered, the issues are identified for work to be undertaken outside the meeting and returned to in the next agenda. The team may wish to cascade issues, wherein a topic is introduced in one meeting, a response is presented in a second meeting, and a decision is made in a third meeting, allowing time for fine tuning of the scenario or issue between meetings.

A kickoff meeting introduces all participants, presents the OPR, and gathers first thoughts about preferred systems, materials, and methods. The team must first organize itself for the work at hand; establish ground rules; agree on site for colocation if appropriate and get work spaces set up; select the phase team leader; and agree on how the team will make decisions throughout the project. A charter of values containing the hierarchies of values to be used and descriptors of the project to be used by all must be established and documented, formally setting out the objectives of the project. This agreement can be consulted later to resolve issues stalemated at finer levels of detail.

The early meetings ensure that everyone understands project issues and concerns. During these meetings, everyone hears the same information at the same time and gains an understanding of all project aspects, including those outside of their own expertise. The team must first assess the completeness of the OPR delivered in phase 2. If necessary, learn more about user environment requirements for specific spaces, including safety, productivity and comfort. Ensure that the OPR includes the environment or system performance attribute by name, the measurable acceptance limit(s) that define success, and the method to be used to measure performance for owner acceptance of the project.

After establishing an acceptable level of understanding of the OPR, the team must agree on the criteria that will govern the selection of systems from the list of options. At minimum, these include

- Performance relative to OPR
- Initial cost
- Operating cost
- Constructability
- Life expectancy and degree of difficulty to maintain performance
- Availability of the required materials, equipment, and constructors

Strategy Development. An integrated project is concerned with all aspects of building performance, but still needs a way to work through the different building systems to avoid unnecessary rework. Each system influences the performance of the others. When looking at controlling energy consumption, and therefore operating costs, some preliminary calculations (e.g., boiler sizing, heating distribution sizing) can only be done after understanding what the building enclosure efficiency is. Accordingly, following a passive load reduction design path is a generic starting point for effective design of heating and cooling services. Ventilation and plumbing design come from the design building population, and are somewhat independent of the hierarchy. In all circumstances, objectives such as energy efficiency are secondary to providing the facility requirements set out in the OPR and refined in the charter of values. For passive energy design in cold climates, the order of events is as follows:

1. Minimize building envelope load by optimizing thermal properties of the opaque envelope with the area and thermal properties of fenestration.
2. Minimize electricity consumption for lighting by coordinating lighting requirements with fenestration and matching the size of control zones to anticipated daylight conditions. Use occupancy-based controls where lighting is not influenced by daylight conditions
3. Minimize connected internal electrical loads using small control zones and occupancy-based controls.
4. Separate ventilation services from space heating and cooling. Optimize ventilation energy requirements, considering heat recovery on exhaust and relief air, fan motor performance and controls, and static pressure in distribution; consider space planning strategies that facilitate cross ventilation.
5. Optimize potable water supply layouts for low pressure losses. Consider use of the lowest-flow plumbing fixtures available at reasonable costs. Use efficient pumps.
6. Serve remaining heating loads with optimized boiler and pumping efficiency, plus optimized distribution layouts with low pressure losses for hydronic systems. Look for low-pressure air systems and optimized fan design in air-side systems.
7. Optimize delivery of cooling, considering use of outdoor air or radiant cooling. Consider heat rejection chillers providing preheating for domestic hot water or boiler water. Coordinate cooling strategies with ventilation strategies for use of outdoor air.

In subsequent meetings, the potential detailed concepts for inclusion in the project are identified and assessed. The team lists the types of systems that would be reasonable for the type and location of the building. Teams usually begin by deciding on the concepts for passive elements of the building, which are those that contribute to or detract from performance only by their existence (e.g., amount of insulation in the building envelope). Examples include

- Building location and orientation
- Presence of site issues such as soil contamination, infrastructure quality issues, or wetland areas requiring offsetting measures on other sites
- Availability of municipal infrastructure, potable water, sanitary sewers, stormwater management, natural gas, electricity, and capacity of those systems
- Potential for renewable energy installations

- Transportation issues around the site, including access for equipment and materials, and impacts on adjacent neighbors and surrounding neighborhoods
- Special requirements for control of light trespass and noise generation
- Foundations: pilings, raft slab on grade, foundation walls with footings, etc.
- Structure: steel frame, concrete, wood frame, etc.
- Roof: sloped, flat; insulation types; water barrier types
- Ground insulation, moisture and air barrier systems
- Exterior walls: type and amount of fenestration, type of entryways and performance as infiltration barriers, opaque wall systems and their moisture, air and thermal barrier performance
- Ventilation systems: operable windows, mechanical; various types
- Heating: hot water, steam, electric resistance, direct-fired gas, heat pump/radiators, air handlers
- Cooling: chilled water, direct expansion, heat pump, swamp coolers; if chilled water, then water or air cooled;
- Energy recovery and reuse: VRF heat pumps, energy recovery wheels, heat pipes, air-to-air heat exchangers, circulating condenser water system
- Service hot water: district steam, gas fired, electric, solar
- Electrical power: utility, solar, wind (or combination); single-phase, three-phase (and at what service voltage)
- Lighting: type(s) and controls
- Control system: building management system, stand-alone equipment controls; including all systems such as HVAC, lighting, plumbing, electrical power or limit to HVAC systems
- Elements serving special conditions unique to the OPR, etc.

In each meeting, individual concepts are developed and ranked according to their perceived value. Once a concept is completed it should be evaluated and compared, based on the charter of values established in the first meeting. Preferred options are identified for further development. If required, specialists may be engaged. When analyzing and discussing each topic, the team must

- Determine how the concept responds to the performance and operating attributes of each building system.
- Ensure that each attribute has a measurable target value and acceptance range.
- Define the method to be used to measure each attribute.
- Decide whether any selected systems require specialists to be part of the team. If so, identify these specialties and recruit the needed team members.
- Based on the definitions, rank the various options, using selection criteria, and agree on the systems to be included in the building. The set of concepts selected is now the BOD for the project. With the BOD defined, the team prepares a cost estimate for the project using the selected systems, validates that the project is financially viable, and amends the OPR if the selected systems will either enhance or diminish the expected performance. These changes must be made with the full knowledge and agreement of the owner and entire project team.
- Finally, prepare a plan to complete phase 4, including key team members, objectives, funding required, and schedule. Secure owner approval of the plan.

Team Roles

Design Team Member. As for all phase-3 participants, the design team member's role is to participate in discussions about all disciplines and lead discussions in their specialty. Throughout the meetings, the team member will be called to

- Contribute to discussions developing the OPR, providing reasonable performance targets based on the type of building and systems to be included.
- Contribute to the BOD content.
- For the **HVAC engineer** specifically: be a key member of concept identification and selection, providing guidance on which HVAC systems (with relevant building envelope requirements) are reasonable to consider based on climate, type of building, etc. Identify any promising new HVAC systems and approaches.
- Assess the ability of each system to meet the OPR.
- Be a present and active contributor to the entire design process, providing opinions of how systems will be affected by all project decisions.
- Provide guidance and opinions about team decisions in which members have experience, even if it is outside their specialty.

Integration Leader. In this phase, the integration leader needs to have a strong overview of how all building systems work together. Senior architects, senior project managers, senior commissioning specialists, general contractors, or construction managers may have the necessary skills, depending on the OPR and team members available. The integration leader facilitates concept planning meetings by

- Setting meeting agendas in coordination with the owner and designers
- Identifying the various participants required for the meeting, including the duration of their participation
- Ensuring that all participants contribute to and are heard in the meeting
- Challenging participants to properly investigate all options on the table, especially when they appear to be stuck, asking sometimes difficult questions
- Documenting interim results, issues raised, and challenges presented
- Updating the OPR and charter of values with the input of all stakeholders in response to changes agreed during design
- Preparing meeting minutes that identify next steps

Additional integration tasks are required in support of the meetings. These include

- Identifying where new expertise or additional participants are required
- Managing OPR revision documentation
- Managing the assembly of concept documentation, the BOD.

Performance Requirements

During IPD meetings, using the OPR as a basis, the team must determine the performance requirements to be met, as well as how they will be measured. Performance requirements to be developed include

- Building envelope: thermal and moisture control, plus airtightness performance of whole building
- Indoor environment requirements: acoustical quality, ventilation rates, materials used, location of makeup air intakes, etc.
- All HVAC systems and their ability to meet the OPR and be adaptable for long-term changes to technologies and building use
- Lighting systems and their effect on heating and cooling loads
- Domestic (service) water heating and other plumbing systems (particularly for lab and industrial buildings)

Tools

- Planning tools for multi-stakeholder, multicriteria decision making (checklists, flip charts, sticky notes, roles of sketch paper, markers, etc.)
- Investigative tools such as mind-mapping software (or freehand drawing)
- Marketing research tools to determine needs of owner and intended occupants
- Computer visualization, model building, and presentation tools such as SketchUp (www.sketchup.com)

- Construction costing documentation (unit area basis)
- Simple energy modeling (shoebox models) or spreadsheets for design day assessments
- A meeting room environment that will facilitate brainstorming sessions, breakout sessions, presentations
- Refreshments and snacks

Documentation

- Updated OPR document that captures improvements made and changes agreed to as various concepts were selected and potential conflicts with the OPR were identified and resolved
- BOD document that captures the agreed set of concepts for
  - Site plan
  - Building envelope, including fenestration and door to wall ratios
  - Rough floor plans, sections, elevations
  - Single line schematics for ventilation, heating distribution, cooling distribution, lighting, and main power distribution
  - Selected systems for:
    - Ventilation
    - Space heating
    - Space cooling
    - System controls and communications
    - Electric and natural lighting
    - Electrical power and communication
    - Domestic (service) hot water
- Updated financial justification documents required by the owner to support new or expanded financing for the project
- Fee agreements that reflect work required by an IPD project, executed by firms committing employees to the project team
- Plan to complete phase 4, including key team members, objectives, funding required, and schedule

2.5 PHASE 4: DESIGN

Phase 4 produces the design of the building to be constructed, adequately completed for accurate cost estimating. The team expands the concepts into full designs, including design of specialty systems, updating the OPR as they identify gaps and opportunities.

Keep in mind that both the OPR and BOD are living documents that will likely be amended as design progresses.

Purpose

- Complete the design documents ready for competitive pricing for IBD projects.
- Complete the design documents and cost estimate for use in construction contracts.

Prerequisites

- OPR is complete
- BOD is complete
- Funding is approved for phase 4
- All team members needed for phase 4 have been assigned and/or hired
- All team members are committed to the integrated work process

Team

- Integration specialist
- Empowered owner employees authorized and qualified to make decisions immediately as required by designers
- Occupants or user group representatives
- Design professionals: facility programming specialist, architect, landscape architect, civil engineer, mechanical engineer, electrical engineer, energy analyst/modeler
- Commissioning agent
- General contractor/construction manager, mechanical contractor, electrical contractor
- Specialty contractors: prefabricators, facade specialists, renewable energy designers and installers, testing labs, building performance test contractors, controls specialists, building automation specialists
- Incentive program representatives from energy or water utilities where programs are available

If the project is limited to IBD, then the constructors would be excluded from the team.

Work

- Prepare a target design cost and construction budget, and update it regularly as work progresses. It will become a more accurate predictor of the final project cost as design work progresses and exact design elements are defined. If the cost is deemed to be unacceptably high, consider ways to reduce the cost of the subject system without diminishing building performance. If a compromise between cost and performance must be made, then document the agreed change to acceptable performance, acceptable cost, or both. Iterate the design and cost estimating until the project is financially viable.
- If there are misunderstandings of the scope of work in the design documents during costing, improve clarity of the documentation so the same misunderstanding does not arise during construction.
- Confirm the order of development for the building systems, following the BOD and with understanding of the impact of one system on others in the whole building.
- Expand concepts presented in the BOD to represent the correct areas and volumes, allowing accurate sizing of building services.
- Complete the schematic design:
  - Flow diagrams of everything relevant to the developed design
  - Initial building services concepts are sized for optimum capacity and distribution systems are planned
  - Flow of people in/out of building and spaces; their activities while occupying spaces; relationships to OPR/BOD environment conditions (may amend OPR/BOD for needed clarifications); internal transportation systems like escalators and elevators
  - Flow of work processes and materials that rely on building systems such as process heating and cooling systems
  - Flow of energy via heating and cooling systems (heating and cooling loads) and via energy reuse systems such as heat pumps and energy recovery units; electrical power for space loads and lights
  - Flow of ventilation and exhaust air
  - Flow of water for use and consumption
  - Flow of waste (sewage, trash, process scrap)
  - Flow of people, air, power, fire control/extinguishing fluids in response to emergency situations (fire and evacuation)
- Complete design development:
  - Develop systems concepts agreed to in phase 3 and documented in the BOD into complete systems designs to produce and facilitate the flows defined in schematic design and satisfy requirements for space environments defined by the OPR.
  - Complete plans and specifications for all building systems and equipment, including how to confirm they meet performance requirements before owner acceptance.
  - Have designers coordinate the work in multidisciplinary review sessions as the system descriptions mature.
  - Have construction specialists lead the design team in constructability reviews of the documents, as the descriptions of the building systems are approaching completion. Designers revise the documents where constructability can be improved.

- Have owner's O&M staff lead the team in operational review (see the Terminology section) of the systems as the design matures.
- Prepare the commissioning protocols to be followed to prove that the building and its engineered systems meet the OPR's performance requirements.
- Produce the construction documents (plans, specifications, and commissioning protocols) that will govern construction. Only minor revisions will be required from this phase forward, such as those needed to address contractor questions and satisfy code officials.

• Finalize cost estimates based upon the developed design.

Sequence of Events

1. Organize the team and work practices.
2. Prepare a target design cost and construction budget. Update the cost estimates while making design decisions.
3. As design progresses, ensure that conflicts between systems or with the OPR or BOD are discussed and resolved by the entire team. If compromises are necessary, document them and revise the OPR or BOD, securing approval from the owner. These changes must be made with the full knowledge and agreement of the owner and entire project team.
4. Prepare and document the schematic design and ensure that the entire team agrees that it is complete and correct.
5. Coordinate locations and operations of building systems.
6. Prepare developed design documents.
7. Undertake constructability reviews as building systems definitions progress.
8. Reiterate these steps as necessary to create the complete integrated design.
9. Prepare a plan to complete phase 5, including key team members, objectives, funding required, and schedule. Secure owner approval of the plan.

Team Roles

Design Team Member.

• Work closely with building scientist to thoroughly understand expected envelope performance and resulting loads on HVAC systems.
• Ensure that all information needed to design the systems (HVAC, water, structure, etc.) is captured and reflected in the schematic system diagrams.
• Ensure that systems are designed well and reflected in the final design documents.
• Ensure that complex systems that work across disciplines are well integrated and that the design documents explain the integrated system(s) for both construction and O&M by the owner after occupancy. Examples include
  - Smoke control systems: it is critical that smoke control systems be integrated between HVAC, building management system (BMS), fire alarm, electrical power, and architectural egress pathways. A subteam to work on these systems and create cross-functional documents ensures (1) emergency power (internal or from electrical systems) keeps critical BMS functions operating, (2) the smoke control panel for the local fire department meets their requirements and functions well, (3) power to fans and other devices have the required supervision through the fire alarm and/or BMS, etc.
  - Mechanical rooms HVAC: a common oversight in large buildings is HVAC of mechanical rooms that house many pumps, boilers, chillers, steam and hot-water piping, steam vents, domestic water heaters, and motor controllers that shed heat. It is important that the HVAC engineer compile all these heat loads and provide for cooling the room, so it is a safe and reasonably comfortable space for O&M personnel to work there.
  - Access to HVAC equipment: equipment may require catwalk systems in enclosed spaces that require integration between HVAC, architectural, owner O&M, and structural design team members so that equipment can be safely and easily accessed for routine maintenance and repair.
  - Plenums: it is critical to know exactly how much open area is available for air movement through plenums. This means integrating their design with every other discipline working in the same space (e.g., plumbing pipes, structural steel, electrical conduit, communications cables, ceiling grids). An air plenum though a 1 m tall space between a ceiling and the deck above can go away when a 760 mm beam reduces it to 240 mm, and every other trade is trying to get through the restricted, leaving inadequate (or no) open area for air movement.
  - Controls: to ensure that the building will be operated in accordance with design intent, the owner, design team, and project integrator must understand and plan for good off-site monitoring capability of building control systems by the design team, contractors, and project integrator (as applicable) before and after the building has been turned over to the occupants.

• Be a present and active contributor to the entire design process, providing opinions of how systems will be affected by all project decisions, influencing other design professionals to make their systems decisions and designs integrate well for the good of the whole-building performance.
• Ensure that changes to the OPR or BOD are well understood by the entire team, documented, and made with conscious awareness by all involved.
• Work with the commissioning agent to ensure that the test procedures and performance acceptance limits defined in the commissioning protocols and OPR represent what can be expected from the systems designed. If not, work with the team to align these documents.
• Provide guidance and opinions about team decisions in which members have experience, even if it is outside their specialty.

Integration Leader.

• Setting meeting agendas
• Facilitating cross-functional teamwork of the project, beginning with initial team organization
• Facilitating conflict resolution discussions and documenting outcomes
• Ensuring that all decision making is focused on building performance to meet the OPR and BOD
• Ensuring that decisions to alter the OPR or BOD are well documented, made by the team with full knowledge, and agreed to by the owner
• Keeping records of decisions made and follow-up work required

Performance Requirements

This phase produces the design for the entire building, so the work affects all aspects of building performance. The goal is to meet the performance requirements set in phase 3.

Where there is an opportunity to upgrade performance requirements, document the opportunity along with the newly proposed and accepted requirement

If a performance condition must be downgraded, identify the cause and the mitigating measures to be deployed in different systems or locations that will maintain the whole-building performance level.

Tools

- Typical architecture and engineering design and calculation systems
- Building performance modeling systems
- Life-cycle analysis tools
- Construction cost estimating
- Three-dimensional CAD systems
- BIM systems

Documentation

- Complete set of schematic design drawings
- Complete set of developed design drawings suitable for pricing, including
  - Plans, sections, elevations, details, system schematics, riser diagrams, etc.
  - Diagrams, tables, and schedules
  - Performance requirements for all spaces and systems, including measurements techniques for proving acceptable performance (final OPR)
  - Commissioning tests to be performed and contractors' responsibility to perform the tests and achieve acceptable performance
  - Updated BOD
- Updated financial justification documents required by the owner to support new or expanded financing for the project
- Plan to complete phase 5, including key team members, objectives, funding required, and schedule

2.6 PHASE 5: CONSTRUCTION PREPARATION

Phase 5 produces the needed agreements between contractor(s) and owner, authorizing contractors to begin construction. It also produces the construction permit documents.

For an IBD project, this process is usually the same as with a conventional design-bid-build approach. The prime consultant assembles the pricing documents and releases them to contractors. Over the pricing period, the designers provide clarifications of intent based on questions from the contractors and decide the acceptability of alternatives proposed by the contractors. Once the proposals are received from contractors, the design team assists the owner with evaluating proposals and negotiations, leading to the signing of a construction contract.

For IPD projects, rather than a hand-off from designer to constructor, there is simply a shift of team activity from design to construction. The design team reduces its input to a supporting role for the construction team. Conversely, the principal contractors mobilize their forces to implement the work as described in the "issued for construction" documents.

The OPR becomes part of the commissioning protocols and is issued as part of the contract documents, along with the BOD, to define acceptable performance and design intent. Construction scope of work includes achievement of acceptable building performance. Therefore, the OPR and BOD may be distributed to subcontractors by the general contractor (GC) or construction maintenance (CM) contractor as needed.

Purpose

- Agreement between the owner and prime contractor on the scope and price of construction and execution of construction contracts between them and those between the prime contractor and the mechanical and electrical contractors
- Obtaining building permit(s) necessary to start work
- Integration of new members into the project team and establishing the means, methods, lines of communication, and authority they will work within to decide changes during construction

Prerequisites

- Design documents have been issued and are suitable to secure bids and negotiate pricing.
- Funding is approved for phases 5 and 6, so that construction contracts may be executed.

Team

- General contractor or construction manager
- Major subcontractors (structural, mechanical, electrical)
- Integration specialist
- Empowered owner employees authorized and qualified to make decisions immediately as required by designers
- Design professionals: facility programming specialist, architect, civil engineer, mechanical engineer, electrical engineer, energy analyst/modeler
- Commissioning agent
- Specialty contractors: prefabricators, facade specialists, renewable energy designers and installers, testing labs, building performance test contractors, controls specialists, building automation specialists

If the project is to be limited to IBD, then the constructors would be excluded from the team.

Work

If the project has been proceeding as an IBD project,

- Identify prospective contractors and ask them to bid.
- Prepare bid instructions and send bid requests.
- Answer questions raised by bidders.
- Confirm constructability and methods with GC/CM and lead trades.
- Decide whether bid qualifications are acceptable, particularly where they may affect performance relative to the OPR or systems concepts relative to the BOD.
- Examine bids and select contractors.
- If necessary based on bid prices, revise the design, OPR, and BOD to reduce cost of construction by reiterating the steps in phase 4.
- Negotiate, prepare, and execute construction contract(s).
- Produce construction contract documents plans, specifications, and commissioning protocols:
  - Reflect answers to bid questions.
  - Reflect agreed changes from bid qualifications.
  - Issue construction documents for permitting and contract reference.

If the project has been proceeding as an IPD project, the main contractors have already been selected and have been part of the design team. Cost estimates were complete in phase 4. The business agreement(s) for construction was drafted in phase 2, awaiting the agreed upon price for completion and execution. The plans and specifications issued at the end of phase 4 are the contract documents. Phase 5 requires that

- The owner and contractor(s) finish and execute the construction contract.
- The design team makes any changes needed so that the phase 4 plans and specifications are acceptable to the building officials during permit review.

Prepare a plan to complete phase 6, including key team members, objectives, funding required, and schedule:

- Update the team charter prepared in phase 3 documenting the project priorities in support of the OPR, revising the protocols for decision making so they are appropriate to the construction phase.

- Update the means and methods for project communication and decision making that will continue the cross-functional team decision making focused on meeting the OPR.
- Prepare the construction schedule.
- Update the budget, including agreed cost of construction or its limits.

Sequence of Events

If it is an IBD project, manage the bid process and finalize the construction/contract documents; If it is an IPD project, make any changes to the phase-4 plans and specifications needed to meet the project's purpose, issue the construction/contract documents, and finalize the construction contract(s).

Team Roles

Design Team Member.

- Answer questions that may arise from the bid process and amend plans and specifications as warranted.
- Be a present and active contributor to discussions about bid questions, bid qualifications, and design changes that may be required, and provide opinions of how systems will be affected by these decisions.
- Ensure that changes to the OPR or BOD are well understood by the entire team and made with conscious awareness by all involved.
- Provide guidance and opinions about experience members may have with bidding contractors, even if it is outside their specialty.
- Complete the design elements for which they are responsible, in coordination with other design disciplines and with the assistance of trades.

Integration Leader.

- Facilitating cross-functional teamwork of the project, which now ensures changes proposed during construction are decided with the same rigor and transparency as those made during design
- Revising the team charter to reflect that the principal activity is now construction and that priorities in communications may change
- Facilitating sound decision making focused on building performance, although overall project management now moves to the general contractor
- Ensuring that all decision making is focused on building performance to meet the OPR, that decisions to alter the OPR or BOD are made by the team with full knowledge and agreement by the owner, and that such decisions are well documented
- Keeping records of decisions made and follow-up work required

Performance Requirements

This phase may change the design for the key building systems. Therefore, the work affects all aspects of building performance. The goal is to meet the performance requirements set in phase 3.

Where there is an opportunity to upgrade performance requirements, document the opportunity along with the newly proposed and accepted requirement.

If a performance condition must be downgraded, identify the cause, and identify the mitigating measures to be deployed in different systems or locations that will maintain the whole building performance level.

Tools

- Typical architecture and engineering design and calculation systems
- Building performance modeling systems
- Life-cycle analysis tools
- Construction cost estimating
- Three-dimensional CAD systems
- BIM systems
- Project management and scheduling systems
- Data recording and tracking tools

Documentation

- Complete "issued for construction" plans, specifications, and commissioning protocols
- Updated team charter
- Executed construction contracts (minimum would include general, mechanical and electrical contractors)
- Meeting records and logs of all agreements reached that are a basis for the final contract
- Plan for phase 6, including the key team members, objectives, funding required, and schedule

2.7 PHASE 6: CONSTRUCTION

Phase 6 is the construction of the building, followed by startup, testing, and debugging of all systems, verifying that they perform as required by the contract documents and local authorities.

The main work of this phase is to build the building and its systems as defined by the contract documents. This work is done by the contractors. The rest of the team provides support and oversight to ensure that the building is built according to the design and that decisions made during construction will lead to systems performing as required by the OPR.

Near the end of phase 6, systems will be shown to operate well enough for the owner to safely use the building, which occurs in phase 7.

Purpose

- Construct the building.
- Get systems operating well enough to make the building safe and reasonably comfortable for occupancy.
- Secure permission from the authorities having jurisdiction (AHJs) to occupy the building.

Prerequisites

- Drawings, specifications and commissioning plans are approved, and permits have been issued to begin construction.
- The project price is agreed between the owner and contractor(s).
- Contracts between the owner and main contractors have been executed.
- Means and methods for project team communication and decision making are clearly defined.
- The construction documents include answers to all bid questions and scope of work change agreements.
- The construction documents include all cost reduction design changes and related OPR changes.
- The team agrees that commissioning work completed in accordance with construction documents will prove that building performance meets the OPR.
- The contractors are prepared to perform the commissioning tests and inspections required by construction documents.
- The plan to complete phase 6, including key team members, objectives, funding required, and schedule, is complete and approved by the owner.

Team

- General contractor or construction manager
- Major subcontractors (structural, mechanical, electrical)
- Integration specialist
- Owner's facility management/maintenance staff

- Design professionals: facility programming specialist, architect, civil engineer, mechanical engineer, electrical engineer, energy analyst/modeler
- Commissioning agent
- Specialty contractors: prefabricators, facade specialists, renewable energy designers and installers, testing labs, building performance test contractors, controls specialists, building automation specialists

Work

The work is described as it would occur in an IPD project where the contractors were part of the integrated cross-functional team before or, at latest, during design. During construction, the difference between an IBD and an IPD project is that, in an IPD, the general and specialty contractors have participated in the design and thus have eliminated potential conflicts between systems and other constructability challenges. Although unanticipated site conditions may still cause difficulty for IPD projects, it is expected that activities documented in the design drawings will be relatively conflict and delay free.

The work of this phase is to build the building and its systems as defined by the contract documents. This work is done by the contractors. The rest of the team provides support and oversight to ensure that the building is built according to the design and that decisions made during construction will lead to systems performing as required by the OPR.

The owner, designers, and commissioning agent perform the following work throughout construction:

- As shop drawings are prepared, new subcontractors are hired and materials and equipment are purchased; the team must consider the effect that any proposed changes will have on building performance. The team ensures that changes proposed are approved or rejected with the same rigor and transparency as during design. Should proposed changes enhance or diminish building performance, the OPR and the projected project cost must be revised and accepted by the owner.
- During construction, there are inevitable imperfections in the design and unanticipated construction obstacles that must be overcome. The integrated team now works together to facilitate construction and to solve problems in ways that do not diminish the building's performance relative to the OPR.
- They make routine visits to the job and observe the work, reporting what is and is not being done in accordance with plans and specifications.
- As systems are installed, the process of start-up, testing, and debugging occurs. This work is done by the contractors and the commissioning agent. The goal of this work is usually to get systems working well under the weather conditions of the time and without normal owner use and occupancy. This part of commissioning may show that acceptable performance cannot be achieved because construction did not adhere to designs or designs do not perform as intended. In these cases, the team works together to solve the problems and either achieve required performance or agree that the performance is insignificantly deficient and acceptable as is.
- Near the end of this phase, the AHJs inspect work and supervise tests of systems, particularly life safety systems. As with commissioning tests, if performance is not acceptable to the AHJs, then the team works together to solve the problems and achieve required performance.

Sequence of Events

1. Main contractors begin procurement of subcontractors, materials, and equipment, resulting in submittals review by the rest of the project team.
2. Contractors begin construction and proceed through the stages of
   a. Site work, civil, and utility services construction
   b. Foundations
   c. Superstructure and infill for floors, roofs, and walls
   d. Exterior assemblies, including fenestration
   e. Building services: plumbing and fire protection, ventilation, heating and cooling, electrical power systems, lighting systems, and controls and communications
   f. Finishes and fit-up
3. Whole team resolves problems that arise during construction and ensures that resolutions do not diminish building performance

Team Roles

Design Team Member.

- Review shop drawings and submittals for materials and equipment. Ensure that what the contractors plan to do is in agreement with the intent of the design documents. Inform the rest of the team if information shows that the work of other disciplines may be affected by departures from the design, and ensure that the entire team reviews the situation and agrees on what the contractor will be required to do. Ensure that any substitution of equipment or material will not diminish building performance without prior acceptance by the owner.
- Routinely visit the project, observe the work, and report observations. If the work does not adhere to the contract documents, then bring the situation to the attention of the entire team, and agree on its resolution to ensure the performance of all systems will be acceptable.
- Be a present and active contributor to discussions of construction work and situations that may require design changes, whether to HVAC systems or others. Provide opinions of how systems will be affected by changes to other systems. For example, a seemingly simple wall move may require a significant change to an HVAC system.
- Support the start-up, test, and debug work to help contractors and the commissioning agent efficiently bring systems to successful operation. Lead the effort to make design changes if needed so that the whole team can make integrated supporting changes.
- Answer questions (requests for information [RFIs]) promptly to keep construction progressing on schedule. Bring questions that may affect other systems to the attention of the whole team for answers.
- Ensure that changes to the OPR or BOD are well understood by the entire team and made with conscious awareness by all involved.

Integration Leader.

- Facilitating the cross-functional teamwork of the project, which now requires ensuring that changes proposed as construction progresses are decided with the same rigor and transparency as those proposed during design
- Supporting contractors by facilitating the cross-functional resolution of field problems efficiently and quickly; bringing everyone affected by a situation (contractors, designers, commissioning, and owner employees) together as needed to make integrated decisions
- Ensuring that all decision making is focused on the building performance to meet the OPR and that decisions to alter the OPR are made by the team with full knowledge and agreement by the owner and are well documented
- Keeping records of decisions made and follow-up work required

Performance Requirements

This phase may require changes to the design for the key systems of the building. Therefore, the work affects all aspects of building performance. The goal is to meet the performance requirements set in phase 3.

Where there is an opportunity to upgrade performance requirements, document the opportunity along with the newly proposed and accepted requirement.

If a performance condition must be downgraded, identify the cause, and identify the mitigating measures to be deployed in different systems or locations that will maintain the whole building performance level.

Tools

- Typical architecture and engineering design and calculation systems
- Building performance modeling systems
- Life-cycle analysis tools
- Construction cost estimating
- Three-dimensional CAD systems
- BIM systems
- Project management and scheduling systems
- Data recording and tracking tools

Documentation

- Review of comments on shop drawings and submittals
- Design for revision drawings and specifications
- Site instructions, contemplated change notices, and change orders
- Formal questions and answers (RFIs) between contractors and designers
- Records of all decisions made by the team
- Updates to the OPR, if needed

2.8 PHASE 7: OWNER ACCEPTANCE

Final commissioning (monitoring and tuning of systems) begins after the owner occupies the building and it begins to perform under its intended conditions.

Phase 7 accomplishes the hand-off from the contractors to the owner. Formal acceptance of the building by the owner happens in accordance with the construction contracts. During this phase, the owner or occupants begin using the building. The owner's facility management/maintenance staff is provided with the documentation and training they will need to successfully operate and maintain the building so that it performs in accordance with the OPR throughout its life. The owner accepts responsibility to occupy, operate, and maintain the building. The project team remains responsible for proving that the building performs as required by the OPR.

Purpose

- Prepare the owner's facility management/maintenance staff to operate and maintain the building properly.
- Have the owner occupy the building and begin its intended use, thus beginning the period during which the building is proven to operate as intended during normal operating conditions.

Prerequisites

- Construction is complete in accordance with the construction documents and certified as such in accordance with the commissioning requirements.
- Owner's facility management/maintenance staff members were present during construction and agree that systems are maintainable.
- All systems are operating as intended and certified as such in accordance with the commissioning requirements.
- The AHJs have performed all their necessary inspections and tests and have approved the building for occupancy.
- Owner's facility management/maintenance staff members agree that they have been trained to properly operate and maintain all building systems.
- Plan for phase 7 is complete, including key team members, objectives, funding required, and schedule.

Team

- General contractor or construction manager
- Major subcontractors (structural, mechanical, electrical)
- Integration specialist
- Owner's facility management/maintenance staff
- Design professionals: facility programming specialist, architect, civil engineer, mechanical engineer, electrical engineer, energy analyst/modeler
- Commissioning agent
- Specialty contractors: prefabricators, facade specialists, renewable energy designers and installers, testing labs, building performance test contractors, controls specialists, building automation specialists

Work

- Support the owner during move-in, when they integrate their own equipment into the building systems.
- Organize and carry out owner training programs. The training team includes
  - System designers
  - Commissioning agent
  - Installing contractors
  - Equipment manufacturers
- Produce operation and maintenance documents, including
  - "As built" plans and specifications
  - Up-to-date OPR
  - Training manuals
  - Equipment owner's manuals
  - Maintenance procedures
- Set up performance monitoring systems in the BMS, including alarm limits that reflect the acceptable performance ranges set in the OPR.
- Ensure off-site monitoring capability of building control systems is functioning and adequate.

Sequence of Events

1. Owner move-in
2. Owner training coincident with delivery of documentation
3. Establishment of maintenance procedures and incorporation into the owner's maintenance management system
4. Setup of performance monitoring systems for long-term use by the owner and final-phase commissioning work

Team Roles

Design Team Member.

- Be a present and active contributor to training the owner about the systems and how they interact and are integrated with other systems in the building. When training is done, ensure that the owner understands the performance requirements documented in the OPR and the monitoring systems that detect departures from acceptable performance so repairs can be made to return to desired performance.
- Work with the rest of the team to produce the documentation that the owner needs to operate and maintain the building. This includes the final OPR, as-built plans and specifications, equipment manuals, controls system programming, resource contact information, etc.

Integration Leader.

- Facilitating the cross-functional teamwork of the project, particularly the training sessions, to ensure that they are effective and that the owner's staff actively engages in the process
- Completing the final update of the OPR and delivering to owner
- Keeping records of decisions made and follow up work required

Performance Requirements

This is the knowledge transfer phase, during which the owner prepares to operate and maintain the building. Therefore, the work affects all aspects of building performance. The goal is to educate the owner and set up their maintenance systems to meet the performance requirements, set in phase 3, throughout the life of the systems.

Tools

- Typical architecture and engineering design and calculation systems
- Building performance monitoring systems (energy and indoor environment quality data)
- Three-dimensional CAD systems
- Visual presentation tools
- Technical writing skills
- BIM systems
- Computerized maintenance management systems (CMMS)
- Data recording and tracking tools
- Capital asset tagging and tracking system

Documentation

- Complete as-built plans and specifications
- Equipment owner's manuals
- Manufacturers' training materials
- Preventive maintenance procedures installed in the owner's maintenance management system

2.9 PHASE 8: USE, OPERATION, AND MAINTENANCE

Phase 8 spans the warranty period of the building, usually one year. During this time, the commissioning agent and owner's facility management/maintenance staff monitor performance of all building systems to ensure that they operate as intended during normal operating conditions and through all seasons. The commissioning agent leads the work to tune systems for proper performance, if needed, and relies on other team members (contractors and designers) as needed to achieve satisfactory systems performance, particularly as systems respond to changing conditions.

Purpose

- Ensure that operating performance under normal use and occupancy meets the OPR.
- Confirm that O&M personnel are in place and prepared for ongoing operation to maintain building performance in accordance with the OPR.
- Complete the project, as agreed by all team members.

Prerequisites

- All systems are operating and performing in accordance with the OPR but have not yet performed under intended conditions.
- The owner has the complete documentation needed for operation, maintenance, and repair of the building from contractors and designers.
- All required documents and maintenance procedures are incorporated into the owner's maintenance management system.
- The owner's O&M people are trained in the proper operation and maintenance of the integrated whole-building systems.
- The owner is prepared to operate and maintain building performance in accordance with the OPR.
- The team's plan to monitor performance during the warranty period, tuning and repairing systems as necessary to achieve performance in accordance with the OPR, is complete.

Team

- General contractor or construction manager
- Major subcontractors (structural, mechanical, electrical)
- Integration specialist
- Owner's facility management/maintenance staff
- Design professionals: facility programming specialist, architect, civil engineer, mechanical engineer, electrical engineer, energy analyst/modeler
- Commissioning agent
- Specialty contractors: prefabricators, facade specialists, renewable energy designers and installers, testing labs, building performance test contractors, controls specialists, building automation specialists

Work

At this stage, all systems are operating and performing in accordance with the OPR, but have not yet performed under intended conditions. The commissioning team monitors performance of all systems relative to the performance requirements set in OPR. Systems that do not meet the performance requirements will be tuned, reworked, and, in the worst case, redesigned and replaced as necessary to achieve acceptable performance.

If redesign is necessary, the work will be as described in previous design and construction phases.

Contractors continue work to complete minor deficiencies observed during construction and since owner move-in.

The owner's facility management/maintenance staff participate in identifying unacceptable performance, tuning systems, and troubleshooting alongside the commissioning agent and installing contractors. This effort is part of the owner's training for long-term building operation and maintenance.

The project team works together at the end to ensure that everyone is satisfied that the building as built is performing in accordance with the OPR.

Sequence of Events

- Monitor performance of all systems.
- Take required action to make all systems perform in accordance with the OPR.
- Work with the owner's facility management/maintenance staff to ensure that they are prepared to keep all systems operating as intended.
- Reach consensus across the entire team that the project is complete with all systems performing as intended.

Team Roles

Design Team Member.

Visit the project, observe the work, and close out open deficiencies noted in field reports as contractors' complete corrective work.

Support tuning and troubleshooting work to help the owner, contractors, and commissioning agent efficiently bring the systems to successful operation. Lead the effort to make design changes if needed, so that the whole team is able to make integrated supporting changes.

Integration Leader.

- Facilitate cross-functional teamwork of the project, particularly if redesigns are needed to achieve acceptable performance.

- Ensure that all decision making is focused on building performance to meet the OPR and that decisions to alter the OPR are made by the team with full knowledge and agreement by the owner and are well documented.
- Facilitate the final team meetings to reach consensus about work remaining to complete the project, and ultimately to agree that the project is finished.
- Keep records of decisions made and follow-up work required.

Performance Requirements

This phase may require changes to the design for the key systems of the building. Therefore, the work affects all aspects of building performance. The goal is to meet the performance requirements set in phase 3.

If a performance condition must be downgraded, identify the cause, and identify the mitigating measures to be deployed in different systems or locations to maintain the whole building performance level.

Tools

- Performance monitoring and data collection systems and devices
- Data analysis tools, such as statistical problem solving
- Troubleshooting tools and skills
- Building performance modeling systems
- Life-cycle analysis tools

Documentation

- Commissioning report
- Documents from team members (in accordance with contracts and AHJ requirements) attesting that the project is complete and performing as intended

3. TERMINOLOGY

Italicized terms in definitions are defined elsewhere in this section.

BOD. Basis of design

Budget control. Traditionally, there are two types of budgets the design team must manage during the design phase: design cost and construction cost. Note that this is not an absolute, because owners could incorporate some or all of the operating-related budgets into the equation.

Design cost control begins with design team resource allocation, budgeting, and scheduling while preparing the fee proposal. Once a complete scope of work has been defined, a project budget analysis is prepared and submitted to the client with the fee proposal. In the SDP model, regular monitoring of actual design cost, as compared to the original project budget analysis, and scope of work should help avoid scope creep and ensure that projects are delivered within the design fee budget. The *IBD* model requires that design fee budget control include an additional oversight element. Although infinite evaluations may lead to the absolute best built solution, design fee structures have a practical limit on how many evaluations are affordable. It is therefore financially critical for the design professional to develop a clear strategy at the time of fee negotiation so that all parties agree on the extent and quantity of strategy evaluations, how the fee is structured to reflect the applied effort at the time of service, and how additional services are accommodated if additional evaluations are required.

Responsible control of **construction cost** budgets can vary depending on the project delivery model. Design-bid-build models place the design team in an oversight role. Design-build allows the contracting entity to control cost of the delivered solution. Design-CM brings in a third-party construction manager (CM), who is responsible for project delivery within the defined construction budget. IBD is achievable under any of these delivery models. However, each requires accurate cost projections to support realistic system evaluation. Likewise, the construction budget needs to represent a level of funding that supports construction of the final system solutions. Cost projection and cost control work hand in hand throughout the iterative evaluation process.

Building information modeling (BIM). Building information modeling extends the initial position of *three-dimensional CAD* to an object-based approach, documenting information about building elements in a master database of construction information. Information recorded about each building object can go beyond physical dimensions to include performance properties such as structural strength or thermal conductivity, its installation scheduling, service life, capital cost, maintenance requirements, or any other description of a delivered service. Development of a BIM model is essentially constructing the building in a virtual environment. All BIM objects are located in three dimensions referenced to a common origin, which makes services like clash detection automatic. The origin can be geolocated, allowing the BIM model to communicate with and incorporate survey data or other geolocated object descriptions.

Initially, a hope for BIM was that all disciplines could work from a common reference database, enabling everyone to work with the most updated information. However, having everyone work from a common platform requires all disciplines to work with the same software and version, requiring coordination of software updates. This is not feasible in many cases, resulting in the more common experience of each discipline developing its information independently and requiring a coordinated reintegration to achieve a complete model. Regardless of the complexities of this approach, BIM platforms deliver faster and more accurate documentation than simple CAD methods.

Charter of values. A charter is a document that establishes the rules of engagement, obligations and benefits, or relationships between members of an organization. For a building design effort, a project charter, building design charter, or similarly named document of agreements, augments the *OPR* by establishing hierarchies of importance for the many possible solutions to design requirements. A hierarchy of importance is necessary for the charter to be useful in guiding choices between competing potentials in project development. For example, with regard to the energy efficiency of a project, the OPR may specify a required energy use intensity for the finished building, but the charter may, based on attitudes presented in the OPR, establish a hierarchy that prioritizes investment in the building enclosure over investments in heating or cooling equipment efficiencies.

Commissioning. Commissioning is a systematic process of applying QA/QC procedures to the design and construction of a building, to verify that key elements of the design are, in fact, constructed as designed, and started, tested, operated, and maintained so that the building realizes designer intent and owner expectations.

ASHRAE *Guideline* 0 defines commissioning of HVAC systems as "[a] quality-focused process for enhancing the delivery of a project. The process focuses on verifying and documenting that the facility and all of its systems and assemblies are planned, designed, installed, tested, operated, and maintained to meet the owner's project requirements."

Several types of HVAC commissioning processes are available: overall, construction, and existing building commissioning (or retrocommissioning). The commissioning process described here applies to new construction and major renovations.

In new construction projects, the overall HVAC project commissioning approach is recommended. It starts at the inception of a building project, during predesign, and continues through the design, construction, acceptance, training, operation, maintenance, and post-acceptance phases, integrated as part of the entire project.

The owner selects and contracts with an HVAC commissioning authority (CA) at very beginning of the predesign phase. The commissioning authority

- Develops the scope of commissioning and reviews design intent during predesign
- Reviews the design to ensure the HVAC project accommodates the commissioning process
- Coordinates with the owner, design engineer, and HVAC contractor
- Issues commissioning specifications to address owner requirements, define contractors' responsibilities, and review contractors' submittals

This leads to HVAC construction commissioning and completion of the rest of the commissioning process.

Commissioning is a rigorous and intensive process that should be used when integrated-system-based design solutions are provided. See Chapter 44 for more information.

Compensation models. How firms get paid for their work differs between SPD, *IPD*, and *IBD* projects. The standard for sequential and IBD projects is design-bid-build. IPD usually uses some form of cost + fee with guaranteed maximum price (GMP). There are variations on both of these compensation models.

Those leading the field of IPD have developed models that ensure all contributors to the project (including the design team) are compensated for only their cost as the project progresses, then share the profits, which increase if they work effectively together, when the project is done. For businesses or government agencies that have no choice but to use design-bid-build, they must be creative with defining these three areas of work if they want to use IPD.

Delivery of solutions in the built world is accomplished in many ways and through various delivery techniques. Whether it is design-bid-build, design-build, design-construction manager (design-CM), etc., each delivery method requires interaction between design professionals that represent inclusive elements of the project.

Constructability. This term describes the efficacy with which a facility can be built. A project that is deemed "easily constructable" has fewer risks of schedule delays and change orders arising from poor coordination or confusion over construction sequencing.

At project outset, constructability is measured by how well construction documents provide the construction team with the information necessary to complete and deliver a project that meets the owner's expectations and documented project requirements. A constructability review is an organized process of reviewing construction documents during the design phases to make recommendations to the owner and design team about how the design may better define expected construction work results. In *IBD* projects, a constructability review is an additional activity, wherein knowledgeable construction representatives provide objective feedback on the constructability of developing system solutions. In *IPD* projects, the construction representatives are part of the design team and contribute their knowledge of constructability as the documents are being prepared.

Critical operations. Some design objectives are critical to the future operation of particular facilities (e.g., data centers, emergency response, law enforcement, government, health care, shelters, manufacturing, pharmaceutical facilities). For example,

- Designers of facilities that require high **reliability** must focus on ensuring that systems and components meet the specified probability that they will operate for the duration of use. As the required reliability increases, infrastructure design must respond in kind with system redundancy and diversity.
- Designers of facilities that require high **availability** must focus on ensuring that systems and components meet the specified probability they will operate and be accessible when required for use.
- **Scalability** may dictate that infrastructure have provisions for expansion and growth relative to dynamic business factors and technology development.

Drawings. Drawings are graphic representations of the work on a project and include plans, elevations, sections, details, legends, notes, abbreviations, and schedules. They are often diagrammatic and rarely show every detail required to construct a facility. Drawings show quantities, extents, and spatial relationships to one another of the elements of construction and existing conditions and surroundings. They may identify a particular product, material, finish, or process many times. However, the particular product, material, or process should be specified only one time in the specifications. Descriptions and identifiers on the drawings should be simple, concise, and generic. *IBD* does not change this basic definition.

IBD does have an effect when it comes time to communicate the system solutions onto drawings that will be used for construction. Coordination now becomes an appropriate and critical IBD tool. The project team must take time to ensure that the integrated work results are correctly identified throughout the drawing set.

The project team should avoid issuing drawings in decoupled groups or individual sheets during the procurement phase. Bidding in isolation is just as detrimental as design in isolation when it comes to achieving integrated solutions.

Energy modeling. Energy modeling uses scientific methods and analytical tools to estimate energy consumption patterns of a given facility, constructed of given materials, located in a given climate zone, and operated according to given schedules. These tools and methods range from simple hand calculations and spreadsheets to the most sophisticated software tools, designed to consider numerous building configurations, various zoning options, and multiple systems. Some of the more common software tools include programs free for download such as the U.S. Department of Energy's (DOE) EnergyPlus or DOE-2/eQUEST. Commercial products are also available to support building load calculation and detailed energy performance modeling.

Energy modeling should be used to help integrate and optimize a building's energy performance over the facility's expected life cycle. Successful application of this tool comes from evaluating system solutions as early as possible to develop best-fit solutions for the developing design, thus minimizing radical design changes late in the design phases.

Energy modeling may also be used if it becomes necessary to *value engineer* a project after the design phase is complete. Simple substitutions of less costly materials, products, equipment, or systems during the value engineering stage of a highly integrated building design may have serious and profound negative effects on the building's future energy and environmental performance if not properly analyzed before acceptance.

Energy models should only be developed by team members who have extensive experience in creating such models and who truly understand the dynamics of building operations. Energy modeling is used to estimate the energy performance of a building and its systems for comparison to other alternatives performing under similar conditions and constraints at a given time, and is used for informed and intelligent decision making on building orientation, window/wall ratio, envelope insulation levels, daylighting features, and HVAC system selection. Weather patterns change; plug loads and technology use change; users' preference for thermostat set points often differ from those modeled; material properties change and degrade over time; system and equipment maintenance may be kept current or deferred after owner occupancy; and hours of usage and operation change. These are just a few reasons why modeled energy use rarely tracks favorably with actual energy use. Keep the following points in mind when using energy models for system evaluation:

- Model results are not a guarantee of actual or future performance.
- Model results are not a guarantee of actual or future energy costs.

See Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals* for an in-depth discussion of modeling methods for systems design and design optimization.

Energy use. Energy performance objectives can be as simple as providing minimum prescriptive energy code compliance, or as detailed as providing a net zero energy performance facility. The extent and complexity must be tailored to each project. Objectives that may be encountered include the following:

- Provide minimum prescriptive compliance per applicable energy code requirements.
- Improve energy performance by an owner-defined percentage beyond applicable energy code benchmark(s).
- Provide a facility site energy density of less than owner-defined consumption per unit area (energy use intensity [EUI] site).
- Provide a facility source energy density of less than owner-defined consumption per unit area (EUI source).
- Provide owner-defined percentage of facility's source energy from renewable resources.
- Limit owner-defined percentage of facility's source energy to nonrenewable or consumable resources.

Typically, energy-related objectives address consumption, efficiency, and generation (site and source) issues, and many variations, combinations, and. themes are possible. The project's underlying objectives should be fulfilled before accumulating performance-rating points becomes the primary focus. See also Chapter 37.

Environmental stewardship. Waste reduction is a pressing need in the built world. The capacity of landfills to absorb construction debris is not limitless, and reuse and recycling can help mitigate landfill overuse. When materials cannot be harvested or obtained from the project site, using new construction materials that include recycled content is a proactive consideration.

As concerns with global climate change and greenhouse gases increase, minimizing the carbon footprint of the facility may become a critical objective. This will require a unique collaborative effort to minimize the sum of the embodied energy and carbon emissions of all processes and components required to construct, own, operate, and maintain a facility.

General operations. Accessibility priorities may dictate that some elements have unique requirements to ensure proper performance and serviceable attention during the operational life. Accessibility has an infrastructure cost effect that must be factored into the total ownership cost.

Replaceability objectives may define where facility infrastructure can be located so that replacements can be made when the useful life has expired. Total ownership solutions should plan for the costs to replace equipment and not leave this as a hidden burden for the facility owner to bear later.

Many owners face **repurposing** (reconfiguring a space or changing its use). Objectives that plan for churn can help mitigate complete replacement of facility services if changes need to be made.

Indoor environmental quality (IEQ). IEQ objectives vary with the programmed use for the building. Each aspect of IEQ must be considered.

Acoustical comfort may require attention for certain facilities or sites. Theaters, for example, have specific noise criteria necessary for proper operation. Meeting these criteria for specific buildings requires knowledgeable collaboration by all parties that control the source noise, transmission paths, and measured point of sound pressure. See Chapter 49 of this volume, and Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*.

Depending on the facility, **thermal comfort** may be critical. The project team must clearly understand the individual facility's thermal conditions and range of acceptable variation. This criterion significantly affects the size, type, and complexity of potential infrastructure solutions. See Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*.

Depending on the climate and operational needs, **humidity** or **moisture control** may be appropriate. This objective can be further expanded to address building protection, occupant comfort, or process needs. See Chapter 64 of this volume, and Chapter 36 of the 2017 *ASHRAE Handbook—Fundamentals*.

Ventilation effectiveness deals with the practical and reliable means of providing ventilation air into the breathing zone of the facility occupants. ASHRAE *Standard* 62.1 identifies zone air distribution effectiveness E_z ranging from 0.5 to 1.2 for various air distribution configurations. An possible objective is to limit HVAC solution configuration to systems that provide an E_z value of 1.0 or greater.

Light quality can be a concern for some operations. The quality of ambient light in a space can have direct effect on occupants' productivity. Properly applied and controlled, daylighting can improve the visual quality of the occupied space and reduce energy consumption by decreasing the need for artificial indoor lighting systems.

Integrated building design (IBD) and integrated project delivery (IPD). IBD integrates only the activities of design professionals. IPD extends integration to include constructors in the design process and follow-through. Thus, the team addresses issues of constructability, scheduling, and cost control during design so that construction can be more efficient. These skills may reduce project capital cost and/or improve delivery schedules. Accessing the skills of the constructor does involve a trade-off: a shift from using a price based on completed design documents, prepared in the absence of input from builders, to the cost of a project being established by a sequence of price definitions, developed as the project design matures.

IPD offers increased flexibility in directing scope to match a desired cost. This mitigates the risk of making a contractual connection to construction expertise before a project is "finished" in a design sense. It also enhances the initial benefits offered by the integration of design professionals through access to additional knowledge.

Both approaches emphasize optimizing system solutions based on the project's objectives, in the context of whole-building performance. Optimizing system solutions requires the participation of all team members. For IPD to succeed and be beneficial, the entire project delivery team must be committed to, understand, and remain engaged in the process, from setting the owner's program requirements to the completion of construction, commissioning, handover and startup, and operations and facility management.

Life-cycle cost analysis tools. All system evaluations share a common need to demonstrate the financial effects relative to total ownership cost. This requires a comprehensive comparison of capital, utility, energy, maintenance, replacement, disposal, and occupant costs for the facility's projected life. Life-cycle cost analysis (LCCA) provides a means of examining how each of these factors impact the owner's cost obligations.

A comprehensive methodology for facilitating life-cycle comparisons can be found in the National Institute of Standards and Technology's *Handbook* 135 (NIST 1996). NIST provides a number of supplemental publications and tools that should be used in conjunction with this source, including the following:

- Annual supplements to *Handbook* 135, providing annually updated energy price indices and discount factor multipliers

- The DOE's Building Life-Cycle Cost (BLCC) computer program, which provides an electronic means of applying the methodology of *Handbook* 135

All of NIST's life-cycle publications, tools, and annual updates may be downloaded from the U.S. Department of Energy's Federal Energy Management Program web site (energy.gov/eere/femp/). Chapter 38 contains more information on LCCA.

Operational review. Operational reviews should be conducted during design development and construction document phases. Depending on the owner, this type of review may be increased to correspond with evaluation scenarios. Operational review can also be one of the decision-making criteria used on a project.

Reviewers should be knowledgeable about systems, equipment, controls, operation, and maintenance. Ideally, the review should include representation from the group that will be ultimately responsible for operating the facility. During the review, sequences of operation should be thoroughly reviewed to ensure that integrated solutions are truly integrated. Equipment location should be reviewed to verify that required maintenance clearance and accessibility are provided. Drawings and specifications should be checked to ensure that

- The appropriate level of system and component commissioning has been prescribed.
- Adequate and usable closeout documentation has been itemized.
- Sufficient training has been scheduled for operational staff.

Operational constraints must be considered when system solutions are developed. Nonconventional systems and equipment can be somewhat intimidating for building operators, so issues of perceived complexity and risk must be mitigated. Solutions must be kept in perspective with the client's ability to operate and maintain the facility. Operational review is an excellent process to address these concerns.

OPR. Owner's project requirements.

Programming. When new facility space is required, the owner must first evaluate available options. These include build new, modify existing, or relocate. Scenarios should be debated to determine which option provides the best fit alternative.

Risk management. Risk management includes the following:

- Systematic, consistent application of written standard office procedures
- Judicious implementation of QA/QC procedures
- Comprehensive record keeping
- Timely and accurate communications
- Written contracts that include certain basic terms and conditions for all services rendered

Because *IBD* involves significant collaboration, team members need to practice a policy of keeping good, complete, and current records of the facts discussed and decisions made (and by whom) in meetings, during site visits, in emails, and during telephone conversations. Most errors and omissions (E&O) and liability insurance carriers and their legal counsels offer guidance, and customarily provide publications on risk management as part of their service to their insured. Team members should be well versed in how to practice proactive risk management so that fear of liability does not reduce collaborative participation.

Specifications. The project manual is the textual description of the work and other requirements for a project; it includes procurement and contracting requirements, general requirements, and technical specifications for the work of the project.

Specifications describe the administration, quality, products, materials, workmanship, warranty, testing, and start-up requirements of the work of a project. For uniformity in structure, location of information, consistency, and quality control, it is best if the specifications are organized into divisions and subdivisions (sections) that correspond to the major divisions of work required to complete the project as defined in *MasterFormat* (Construction Specifications Institute).

MasterFormat includes some very important sections to address in *IBD* delivery, including the following in division 01, General Requirements:

- Submittal procedures
- Sustainable design reporting
- Closeout submittals
- Sustainable design closeout documentation
- Facility performance requirements
- Sustainable design requirements
- Facility environmental requirements
- Indoor air quality requirements
- Facility services performance requirements
- HVAC performance requirements
- Integrated automation requirements
- Commissioning
- General commissioning requirements

Tools are in place in the industry to support communication of integrated system design into work results that can be consistently located. Further study of the *MasterFormat* structure demonstrates that individual facility services, such as HVAC, have defined specification structures to support effective communication of system solutions.

Three-dimensional CAD. Three-dimensional CAD (computer-aided drafting) uses graphical computer interfaces to create representations of buildings or building elements that can be viewed in three dimensions. This technique supports coordination efforts between design disciplines to identify spatial conflicts between building systems. Three-dimensional CAD systems do not necessarily automate tasks such as clash detection, and may require human intervention to deliver those services.

Value engineering. Value engineering is commonly an exercise undertaken when the project appears to be over budget and costs must be reduced. In the worst cases, costs are reduced from the most expensive items in a line item budget without reference to the *OPR* or performance requirements. Value engineering in *IBD* and *IPD* projects is most successfully used in the evaluation of concept options in phase 3 and the ongoing evaluation of detailed design solutions in phase 4. No final method, assembly, or system should be accepted as part of the BOD without performance and financial analysis. In this way, value is maintained and the misuse of "value engineering" avoided.

Vulnerability (hazard containment and protection). Global events and operational needs may dictate addressing building vulnerability. The facility infrastructure may require protection from seismic incidents, explosive blasts, or chemical and biological contamination. Indoor operations that create explosion, chemical, biological, or radiological hazards may also require attention. Additionally, protecting occupants in the facility may be an inclusive or stand-alone priority. In any case, vulnerability objectives create some challenging opportunities for collaboration, and demand that the project team have an effective prioritization system in force on the project. See Chapter 61 for more information.

Water usage. *IPD* objectives for water usage typically focus on conservation and reclamation efforts. Water has a cost associated with its use, and should be included when modeling the total ownership cost of a facility.

Water conservation and reclamation do not apply only to plumbing; HVAC systems can consume significant amounts of water and are prime candidates for environmentally responsible project objectives. Sample objectives with a HVAC influence include the following:

- Reclaim all cooling condensate discharge for use in graywater systems. Note that reclaimed graywater can be used in a host of facility service applications, such as cooling tower makeup, landscape irrigation, urinal flushing, etc.
- Capture all facility storm water drainage for use as graywater makeup for HVAC, plumbing, and landscaping needs.

Increase concentration limits and/or decrease cycles on cooling tower blowdown to limit water consumption. This, of course, must be balanced against the suitability of an integrated maintenance program and limited to local water quality characteristics that do not contribute to scale, corrosion, fouling, or microbial growth.

CHAPTER 61

HVAC SECURITY

OWNER'S PROJECT REQUIREMENTS 61.1
RISK EVALUATION 61.2
HVAC SYSTEM SECURITY AND ENVIRONMENTAL HEALTH AND SAFETY DESIGN 61.3
CHEMICAL INCIDENTS 61.6
BIOLOGICAL INCIDENTS 61.9
RADIOLOGICAL INCIDENTS 61.10
EXPLOSIVE INCIDENTS 61.11

THIS chapter is intended to be an overview of HVAC security considerations relative to natural events, accidents, terrorism, and national threats, as well as addressing chemical, biological, radiological, and explosive (CBRE) incidents that do not cause major structural damage to a building or its infrastructure. This added focus on CBRE incidents, either accidental (e.g., an industrial spill) or premeditated, is intended to be a general overview and not used as design guidelines.

Because of the nature of security, there is not much documentation available pertaining to designing, constructing, renovating, operating, commissioning, or recommissioning and maintaining HVAC equipment and systems from a security and environmental health and safety (EHS) standpoint. Organizations such as the U.S. Department of Defense have guidelines that are considered highly confidential and are only shared with others on an as-needed basis. In other situations, special security organizations follow behind the design and/or construction teams with security measures that are not shared with these design/construction organizations. As a result, the owner's project requirement (OPR) document should include a security and EHS statement, and the HVAC design engineer must include information in the basis of design (BOD) document to raise awareness of the approach and level of security and EHS for the specific project.

In general, HVAC security and EHS apply to all building applications based on a broad range of reasons, needs, and requests. They play a particularly important role for businesses such as pharmaceutical companies, property managers of high-profile commercial buildings where workers and visitors come and go on a regular basis throughout the day and night, and convention centers and sport stadiums entertainment venues where thousands of people are present for a few hours. Recently, security considerations have expanded to include all building programs, whether a K-12 school, movie theater, or simply a tenant fit-out of a small business space.

This chapter is not intended to be used for design or development of life safety systems or procedures, or for protection of personnel during an incident; rather, it offers an approach to HVAC security and EHS that includes a segment in the design team BOD document that can address HVAC security, EHS, commissioning, and recommissioning of systems; details the need to provide proactive maintenance of these components and systems; and provides descriptions of some CBRE incidents and their associated effects on buildings, building equipment, and occupants, along with general guidelines for how to deal with their effects on building infrastructure.

Since September 11, 2001, more published information has been available about procedures for preventing, mitigating, and remediating terrorist or other CBRE incidents. ASHRAE's (2003a) *Report of Presidential Ad Hoc Committee for Building Health and Safety under Extraordinary Incidents* discusses many aspects of buildings, building infrastructure, and measures that can both reduce the threat and/or damage from such incidents. Several departments of the U.S. federal government, including the Federal Emergency Management Agency (FEMA), Department of Homeland Security (DHS), National Institute for Occupational Safety and Health (NIOSH), Centers for Disease Control (CDC), and Department of Defense (DOD), have produced reports and guidelines for dealing with terrorist threats to buildings (see the Bibliography). Emphasis is generally on actions to reduce the potential harm to building occupants and minimizing the potential for an accident, both reducing the threat of harm, by instituting procedures that reduce the hazard during an incident.

HVAC security and EHS begin in the building program phase of a renovation or new construction project. The design team should address the level of security via a risk evaluation and document the level of security and EHS to be invested in the building program. For most buildings, the risk evaluation will fall into the category of low to medium, but do not overlook the potential for high risk based on the building's application.

In almost any case of a terrorist event affecting a building, its infrastructure, or its occupants, the affected building and its immediate surroundings are likely to be in police or military control for several days (or longer) after the event. During this period, the role of the building(s) owner or facilities management and physical plant staff is to assist in controlling or remediating the affected areas through their knowledge of the building and its infrastructure systems. Assessment of damage or remaining danger to the building or personnel is difficult, particularly with chemical, biological, and radiological events, in which the contaminating agent often is invisible and is only revealed through adverse health effects. As such, there are no specific guidelines for how or when a building can be brought back online and readied for occupancy; each event is unique. Any preparation or response protocol for CBRE incidents internal or external to the facility should be designed to consider the specifics of the building and its occupants. It is impossible to provide general guidelines for incidents that are so unpredictable and potentially so devastating. This chapter attempts to shed light on design intent, construction administration, commissioning, and recommissioning, and on some of the possible effects on buildings, their systems, and their occupants, which may aid in the development of a more specific protocol in line with a particular facility's needs.

1. OWNER'S PROJECT REQUIREMENTS

The initial process of any building program is establishing the owner's project requirement (OPR) document, which is an abbreviated overview of the owner's project goals. Both the OPR and the BOD must be drafted in the conceptual phase of a renovation or new construction project. The OPR covers a wide range of categories to document the owner's intent in investing in this new construction, renovation, or infrastructure project. The OPR identifies the drivers that will shape the design, how it will be constructed, the energy budget, and how it will be operated and maintained over the building's life. It also sets a construction budget and project timeline. Security and EHS requirements may remain confidential, with

---

The preparation of this chapter is assigned to TG2, Heating Ventilation and Air-Conditioning Security (HVAC).

limited documentation between the owner's security professionals and the designer. A separate design team and construction team also could be brought into the project after design is completed and before the owner begins occupancy, to fulfill the BOD.

When drafting an OPR, the building owner, owner representative, and the design team should consider the following:

- Who are the main occupants?
- What is the intended use of the building?
- What is the total planned population of the building, including visitors and service staff?
- What types of operations will the facility and/or occupants conduct?
- What is the planned response to an incident? Will occupants evacuate, shelter in place, or carry on normal activities uninterrupted?
- How will the building staff become aware of a threat, and what is the likely notification time?
- What level of protection is required against threats?
- Will some occupants have planned responses that differ significantly from the general building plan?
- What level of access will the general public be allowed in the building?
- Does the owner have a dedicated security team and/or consultant?
- What life safety measures are planned for the building?
- Will occupants be required to remain in the building after an incident (e.g., in a high-security prison)?
- Are there any unique environmental health concerns (e.g., explosive atmosphere, laboratory)?

In addition to the preceding, the design engineer should also consider lessons learned from past HVAC security process failures associated with the type of building (e.g., for a hospital project: emergency generators and primary HVAC equipment located below flood water levels that took out the emergency power and special HVAC central air systems serving in-patient space). An Internet search of related issues and concerns is advised.

The OPR should be complete and exhaustive, and should adequately cover the owner's overall goals for the building's HVAC security. Many HVAC security measures are relatively low in cost and effort during new construction or renovation planning, but may require significant cost and effort if implemented after construction is completed. Therefore, it is critical to capture these requirements early in any design process.

All projects should include some minimal level of HVAC security design and planning. These measures are typically included in the life safety requirements, specific designs, or best practices typically applied to building construction. These **baseline measures** include equipment or design features that can be applied to all buildings at a minimal cost and effort to provide basic protection against internal and external threats. Baseline measures support the safe sheltering in place and/or evacuation of occupants during an incident. Many baseline measures can be implemented in an existing facility with little or no additional engineering design or cost, and with minor alteration to the facility operations. **Enhanced measures** include equipment or design features beyond the baseline level, and are intended for facilities with identified risks or critical operations. Costs for design, construction, and sustainment can be significant, depending on the measures selected; however, the protection afforded by these systems typically allows longer-term sheltering in place or continuous uninterrupted operations for the duration of the incident. Specific design features and equipment to provide these measures of protection are discussed later in this chapter. A building's particular HVAC security design uses its own unique collection of HVAC security measures, depending on risk and requirements.

2. RISK EVALUATION

In parallel with development of the OPR, a risk evaluation should be conducted for the building and its planned design. FEMA and other industry organizations have developed various guidance documents and software to assess the risk and appropriate response from both external and internal events. Significant detail regarding risk management for catastrophic events is included in ASHRAE *Guideline* 29-2009.

Risk is a function of the **probability** of an event occurring and the **consequence** of this event. For HVAC security and EHS planning, the probability of a catastrophic event occurring is typically nearly zero. This probability is shaped by multiple factors, including the facility's occupants, its location, and nearby objects that may pose a threat. The consequence of an event, however, is usually considered extremely high. Factors to be considered include potential loss of life, failure of critical infrastructure, and remediation time and effort.

Figure 1 presents a generalized framework for managing building security risks. The key considerations for a risk analysis include the following:

- Vulnerabilities: what elements of the building design, construction, location, or operations present opportunities for catastrophic events?
- Acceptable vulnerabilities: what identified vulnerabilities cannot or should not be addressed, and thus must be accepted as operational risks?
- Impact: what are the consequences of an adverse event, including remediation, reconstruction, and lost business, and how does this compare to the cost of implementing HVAC security measures?
- Constraints: what limitations exist that would shape the HVAC security design of a building?

Successful risk evaluation should include a review of all facets of the planned building design and operations to determine the risk. This evaluation may include the following areas of assessment:

Building and occupants

- Identification of potential high-value targets
- Identification of specific vulnerabilities
- Classification of occupants and operations
- Assessment of benefits of containment versus evacuation

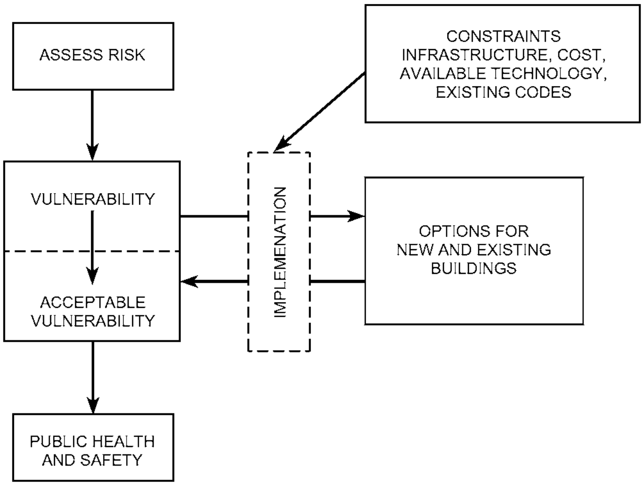

Fig. 1 Risk Management Framework
(Adapted from ASHRAE *Guideline* 29-2009)

Potential threats and vulnerabilities

- Identification of potential aggressors
- Identification of potential delivery systems

Likely support mechanisms

- Identification of likely first-responder units
- Identification of infrastructural support

Post-event remediation

- Consideration for potential consequences if building is unoccupied or unusable for extended periods
- Estimation of relative magnitude of remediation measures

Examples of considerations that may increase the overall risk assessment of the facility include the following:

- Potential effect of building remaining unoccupied for extended periods
- Military and government command centers
- Significant landmarks
- Critical infrastructure elements
- Single-failure point operations or equipment
- Corporate headquarters or critical operations centers
- Transportation hubs
- Communications nodes
- Popular tourist destinations
- Approach and takeoff areas for major airports
- Sites open to the public
- Sites frequently targeted by protests and demonstrations
- Locations near significant potential hazards such as nuclear power plants or chemical manufacturing facilities
- Locations adjacent to major shipping and transportation routes where external events may affect building occupants (e.g., truck fire, ruptured tanker car on train)
- Sites frequently subjected to severe natural or weather events, such as tornados, hurricanes, or earthquakes

Obviously, this list is not exhaustive, and many buildings may have unique circumstances or characteristics that warrant specialized HVAC security measures. Generally, it is difficult or impossible to completely mitigate against all risks; thus, the overall goal of a risk evaluation and implementation of security measures is to move subsequent evaluated risks to lower levels. That is, if a building's overall risk is assessed as high, measures should be implemented such that subsequent risk assessments for the same building would be medium or low.

3. HVAC SYSTEM SECURITY AND ENVIRONMENTAL HEALTH AND SAFETY DESIGN

Building design and operations during a CBRE event should leverage strongly from the OPR and risk evaluation documents. This section presents generalized recommendations and practices for HVAC system security design, and detailed information on specific threats is provided in subsequent sections. The basis of design (BOD) document should include an HVAC security and EHS segment that highlights the mechanical system design intent as it pertains to the OPR and risk evaluation.

Figure 2 presents a generalized basis of design HVAC security and EHS section, which can be enhanced on a project-by-project basis.

3.1 MODES OF OPERATION

Three main building situations should be considered in HVAC security design: evacuation, sheltering in place, and uninterrupted.

Consultant(s)
- None
- In-house security management
- Outside security consultant
- Government security (at time of design; confidential)
- Government security (at time of construction; highly confidential)

Risk Evaluation Status (see risk evaluation document for more detail)
- Baseline: No specialized operations, tenants may be relocated, long-term nonoccupancy presents minimal challenge
- Enhanced: Specialized or unique operations, larger facilities with high populations, long-term nonoccupancy undesirable
- Critical: Highly specialized or unique operations, high importance or visibility, long-term nonoccupancy unacceptable

Design Features: HVAC Security
- List Features

Design Features: Environmental Health and Safety
- List systems with enhanced air filtration and MERV rating
- List systems with enhanced safeties and alarms and types of devices used
- List zoning application
- List air intake minimum height above grade requirements
- List equipment to be located above exterior historical flood level data
- List systems to be on emergency power

Commissioning, Operation, Maintenance, and Recommissioning
- Commission beginning in design phase through construction phase
- Continuous commissioning in warranty phase
- Operation training and documentation beginning in design phase
- Preventive maintenance work order ready to implement in construction/commissioning phase
- Predictive maintenance features
- Mode of operation: evacuation, shelter-in-place, uninterrupted operation (list systems by one of these three categories)

Fig. 2 HVAC Security and Environmental Health and Safety Basis of Design Segment

Each mode presents unique challenges, costs, and benefits, and each should be reviewed and compared to the risk assessment and OPR to determine which best meets the building owner's needs.

Evacuation

Evacuation is the immediate, rapid, and controlled egress of occupants from a facility in the event of an emergency. This mode is commonly used in fire protection engineering. Planning and design for evacuation includes measures to prevent catastrophic failure of the facility for a short duration, and egress direction support, including emergency lighting, signage, and doors.

This mode is effective in many cases and generally is the easiest to implement. However, this mode may not be effective against external threats where personnel may evacuate directly into the path of a threat, and can present difficulty for triage and containment. Typically, minimal cost and design efforts are required to implement an evacuation during an event, because most buildings are required to include similar measures and equipment for fire protection and smoke removal. Also, typically limited or no additional training is required for building occupants, most of whom are familiar with normal evacuation procedures.

Shelter-in-Place

This is short-duration occupancy of a facility or section thereof to avoid immediate threats. This mode requires occupants to remain in the building during the event and seal the building against intake or further dissemination of threats until the immediate danger has passed. Although some facilities provide full-building shelter-in-place coverage, many designate discrete rooms or areas for occupants to remain in. The normal expected duration is on the order of several hours or less.

Sheltering in place is an effective protective measure when implemented properly and quickly after identification of a threat. Many government and military facilities implement some level of sheltering in place. Effective application requires immediate identification of a threat and subsequent shutdown of HVAC systems to prevent the spread of contamination in the building. Additionally, designated shelter-in-place locations may include some food and water supply for occupant consumption during an event, as well as means of communication with emergency responder personnel. Generally during a shelter-in-place event, occupants do not continue normal work because of the anxiety of the event and the potential requirement for occupants to move into a common area (e.g., conference room, break room) without normal work equipment. Because durations are typically expected to be several hours or less, no bedding is required, and the relative population density can be high. Implementation of a shelter-in-place strategy requires early coordination and training of building occupants to avoid confusion during an event.

Uninterrupted Operation

Uninterrupted operation is the continuous occupancy and use of a building, or some portions therein, during an event without contamination of personnel and equipment. This mode allows for occupants to continue doing work without evacuating or sheltering in place. Although some buildings may complete this mode by providing personal protective equipment to occupants, many have installed collective protection systems in the building HVAC systems, including advanced filtration, airflow balancing, controls, and architectural modifications. Collective protection is achieved by filtering all incoming air to a building and providing this air at an overpressure to spaces, thus creating a protective zone where personnel can continue to operate during an event.

This mode can be extremely effective against both internal and external threats, depending upon configuration and design. Typically, buildings can operate in these modes for hours or days, depending upon the threat; however, with this extended duration, bedding, food, and water, along with lower population densities, should be considered. The relative cost (both capital and sustainment) for this mode can be extremely high, so it is generally used only for critical facilities such as command centers and vital infrastructure elements.

3.2 SECURITY AND EHS DESIGN MEASURES

Multiple measures can be implemented to provide HVAC security and protections, some of which are discussed in this section. It is important to consider that these measures are typically combined with other design elements to enhance building protection, and that not all measures may be applicable to all buildings or locations. The BOD is the documentation of design criteria, set points, parameters, and narrative that outlines the HVAC system security. Again, because of the nature of the security OPR, BOD documentation may not be published. BOD considerations may include some or all of the following measures.

Emergency Power

HVAC systems that are designed to respond to a CBRE incident by continuing to operate should be powered from an emergency electrical power distribution system. Some considerations may include redundant external feed from two sources, generator sets, and/or uninterruptible power supplies (UPS). Any of these options may require significant first cost as well as maintenance and sustainment costs. In designing emergency power for the HVAC system, carefully consider the location of emergency generator(s) and associated switchgear and motor control center so that they are well above flood water levels. Other considerations are to ensure electrical power is provided to the building automation system (BAS) so that the HVAC security system functions with the building automation computer under emergency power.

Redundant Design

Similar to power loss, failure of a critical component can place overall building HVAC security in jeopardy. Building designers should consider including redundant equipment in systems, such as air-handling units, blowers, or motors. Robust systems should include automatic control of these components, thus allowing for switchover from a failed component to the back-up immediately and automatically. If redundant systems cannot be installed, the owner should consider stocking critical or hard-to-find components in the facility so failed components can be replaced quickly in case of a failure.

System Shutdown and/or Isolation

Rapid shutdown and/or isolation of air-handling units, including outdoor air intakes, can prevent or limit intake of contaminants into the air distribution system and thus decrease the potential spread of these agents. Many facilities use digital controls networks that readily allow the addition of a shutoff actuator button. For manual initiation, these buttons should be located in one or more areas regularly accessible by building occupants or normally staffed locations (e.g., security guard stations, central lobbies, reception desks) and treated in a manner similar to fire alarm activation stations. Automatic initiation methods using external detectors may be used, but the rate of false positives and negatives, capabilities of existing detection technology, and overall reaction time should be considered. On activation, the system should initiate rapid closure of air distribution dampers and rampdown of equipment to prevent movement of air through areas of the building. In these cases, consider using a spring-shut damper, although precautions such as bypass or relief duct systems should be taken in case of potential system damage by these closures.

Protective Equipment

Many facilities have begun to distribute **personal protective equipment (PPE)** to facility occupants. This equipment, including escape hoods and respirators, may be issued to building staff as well as being placed in centrally available locations for occupant and visitor use. Equipment is generally intended for single-time use to allow occupants to safely evacuate the building during an event. Several manufacturers can provide this equipment, with varying levels of protection, shelf life, and recertification requirements. The designer should consider the overall burden to the building when providing PPE to occupants, including capital costs, training, shelf life, and life-cycle costs for the equipment.

100% Outdoor Air Operation

Normal air-handling systems using returns present an issue for internal release scenarios, because these returns can carry contaminants from the release point in its zone and redistribute throughout the HVAC systems, possibly contaminating the entire building. Designing air-handling systems that use 100% outdoor air is a good alternative to prevent this type of distribution, and limits the spread of contaminants in a space. Although 100% outdoor air systems can present a significant cost and energy burden, this may be offset by the added capability for occupant protection. Typically, this approach is suitable for small buildings or sections of a building. Alternatively, the designer may consider using local terminal units with integrated fans to provide local recirculation and meet space heating or cooling demands, thus reducing the outdoor air required to each unit.

HVAC Zoning

Using multiple HVAC zones in a building allows localized control of the air movement equipment, and can limit the transport mechanisms for contaminant spread. Each zone, especially when enclosed with walls or partitions, can contain airborne contaminants without widespread movement to adjacent spaces. HVAC zoning can provide occupants with enhanced control over the systems in their spaces and can also help limit the spread of airborne diseases such as influenza.

Increased Standoff Distances

Close proximity to publicly accessible areas increases the risk of an external event having catastrophic consequences for a facility. The presence of a buffer with controlled or limited access can significantly lessen the effect of an airborne contaminant release or blast. This standoff area must have limited access to the general public and should limit vehicular traffic to emergency access, deliveries, and facility maintenance. Increased standoff distances also provide additional area for emergency first responders during or after an event. Although these buffer areas present an additional cost associated with capital investment, they also provide occupants with aesthetic benefits, including additional green space.

Occupant Notification Systems

The moments immediately before, during, and after an event can be confusing for building staff and occupants, especially if some occupants panic and do not fully understand what actions should be taken. Most buildings include some type of notification system that can be used to communicate to occupants in critical situations. Systems include loudspeakers, alarm horns and strobes, automated telephone alerts, or computer notification systems; at minimum, many buildings can implement mass e-mail notification or designation of certain personnel to serve as runners with little or no cost. Building managers may consider providing emergency action information cards for all occupants to keep in their work spaces, to refer to during an emergency.

Air Intake Protection

For new buildings and HVAC systems, fresh-air intakes should be elevated to help prevent malicious acts (e.g., inserting a hazardous material directly into the intake) and minimize the concentration of hazardous materials during a ground-level release. Intakes should be placed at the highest practical level on the building, at least 3 m above grade. Most ground-level releases near the building will remain close to ground level, and the concentration of hazardous material in the air decreases with increasing height. Existing fresh-air intakes close to ground level can be modified to prevent physical tampering by placing fencing or barriers or building a plenum around the intake to limit potential intake of contaminants. Physical access to system intakes should be limited, and security cameras focused on intake areas may be considered. To prevent direct tampering of intakes, a sloped screen should be installed at the top of the intake to prevent direct insertion of any hazardous substance or container.

Increased Prefiltration Efficiency

A relatively simple and cost-effective protective measure that can be undertaken in most every facility is upgrading existing prefilters to a higher-efficiency model. An increase in prefiltration efficiency can prevent the intake of a significant fraction of external airborne material, including biological and radiological particles; a related benefit includes the reduction of airborne allergens entering a building, thus resulting in a potential decrease in worker health issues and absenteeism. Typically, increased efficiency prefilters present a relatively minimal cost increase as compared to standard prefilters, and require no system modifications or additional maintenance.

Additional Filtration

As with increased prefiltration, adding additional filtration can reduce or eliminate airborne threats entering a building. Multiple options and levels of efficiency are available, ranging from cost-efficient low-efficiency models to military-grade filtration. Full-time filtration provides occupants with protection without the requirement for advance notification; however, part-time or standby systems can be effective if advance warning or detection is available. The current standard used in government, military, and private-sector buildings includes high-efficiency air filtration (HEPA) filters for biological and radiological threats, and activated and impregnated carbon filters for chemical threats. These filtration measures present significant capital and sustainment costs, which may make these systems unaffordable for lower-cost, noncritical buildings.

Location of Mechanical Equipment

When designers develop plans for building mechanical systems, one of the main considerations is system accessibility for regular maintenance and replacement. However, in some cases, the placement of mechanical systems may present security risks. Mechanical and electrical rooms should be placed in secure areas of the building that are not accessible to the general building population, and should be located away from any potential hazards such as flood areas, hazardous materials storage, loading docks, central lobbies, and areas that may be vulnerable to vehicle impact. Where possible, mechanical spaces should be accessible by maintenance personnel from within the facility to allow repair during an event.

Physical Security Measures

Many physical security measures can be applied to HVAC systems and overall building protection that may prevent the release of a hazardous material or contaminants. Security screening at entry points can help detect containers that may contain hazardous materials. This screening may include x-ray scanning, metal detectors, or manual searching of personal belongings such as briefcases and handbags. Rooftop access should be restricted to authorized personnel, because mechanical equipment, exhaust stacks, and ducting may allow introduction of contaminants. Rooftop entries and exits should be monitored and controlled by the building security system.

Air Supply Quantities and Pressure Gradients

Many contaminant releases depend on air movement to move contaminants throughout the building. Small differential pressures between spaces, often less than 25 Pa, can influence this transport. These gradients may be effectively used to limit the spread of airborne contaminants between offices, corridors, and common areas. HVAC designers may consider providing a small excess of air to selected areas to effectively overpressurize these spaces with respect to adjacent spaces. This is of particular importance in systems where the HVAC system includes filtration equipment, allowing the protected space to be maintained at an overpressure with clean filtered air.

Sensors

Detection and early warning of a threat are extremely important to building protection. With rapid notification, building staff can implement measures to protect against the threat, including initiating sheltering in place or evacuation. However, implementing a robust detection system can pose many challenges. Technology is being developed in both the government/military and commercial sectors, but these new devices still have limitations. Currently, although many products exist for point and standoff detection, some of these methods still place a significant burden on the building staff, such as laboratory-scale analysis for confirmation and specially trained personnel. In all cases, designers should consider the sustainment cost and relative frequency of false positives/negatives when specifying detection equipment.

Mailroom and Lobby Measures

The mailroom and central lobbies of buildings are highly vulnerable areas: they act as building interfaces with the general public. In most buildings, these are areas where uncleared personnel or packages come in proximate contact with the facility and where threats can cause the greatest harm. These areas should be given special consideration and additional protective measures to ensure all threats are minimized.

In entry areas, many buildings have mandatory security access procedures for regular building occupants as well as visitors. Security measures such as magnetometers, x-ray scanners, and personnel screening may be used to limit potential hazards from entering the building. Designers should consider using segregated HVAC systems in lobby areas with dedicated air-handling units (AHUs) for the lobby area, and maintaining the lobby spaces at a negative differential pressure with respect to interior spaces. Lobby windows and doors should include blast-resistant glazing and construction, and walls between the lobby and general building interior may include enhanced blast resistance ratings. Security or reception personnel should have controls in their work areas to allow rapid lockdown of all building entries and exits.

The anthrax mailings of 2001 highlighted the vulnerability of buildings to attack by mailborne threats. The U.S. Postal Service and package delivery companies have since implemented enhanced security, but building owners may consider additional measures. Mailrooms and package-receiving areas should include the measures described for lobbies, especially segregated HVAC systems that maintain these areas at a negative pressure compared to the rest of the building. Some facilities have enhanced mail- and package-screening procedures, including separate mail-handling facilities, x-ray or metal detection scans, individual parcel opening and screening, and laboratory analysis of packages. At minimum, mailroom staff should review incoming mail and immediately notify law enforcement of any suspicious letters and packages, such as those with exposed wires, irregular shapes or weights, misaddressed labels, or unexpected senders or locations.

3.3 COMMISSIONING AND RECOMMISSIONING

To ensure equipment and system performance per the BOD, HVAC security and EHS should be commissioned following ASHRAE *Guideline* 29's recommendations. Recommissioning after a set number of years, or designing the BAS to provide continuous commissioning, is also recommended.

3.4 MAINTENANCE MANAGEMENT AND BUILDING AUTOMATION

Because of the nature of HVAC security, operation is a critical requirement as it pertains to reliability and repeatability. Similar to how emergency generators are operated once a week, once a month, and fully loaded annually, HVAC security systems need to be operated on a scheduled basis to ensure the equipment will respond in an emergency situation. Operation of the building automation system is an integral part of this routine exercising of the HVAC systems.

Proactive maintenance management also contributes to system performance and reliability. Modern facilities most likely have computerized maintenance management software (CMMS) system to manage the maintenance process and documentation of this process. It is important to emphasize the value of documentation management; the design engineer should account for this in the design phase, specifying in the operation and maintenance requirements that the CMMS system will be populated and the work orders formatted and ready to be used before project closeout. These requirements should complement the CMMS database criteria so that project closeout documents are electronic and compatible with the CMMS system. Predictive maintenance should also be incorporated into the engineered systems in sync with the continuous commissioning design, operation, and reporting.

Building automation plays an important role in maintenance management, as well as day-to-day HVAC operation. Take care to limit access to these building systems so the sequences of operation are not compromised in an emergency or incident. Building systems may be disrupted by action from within the building or from an outside actor (e.g., via the Internet).

4. CHEMICAL INCIDENTS

A chemical incident is defined as the accidental or intentional release of a gaseous or vaporous compound into breathable air. Releases of toxic liquids, solids, or powders are not addressed in this chapter. A release may occur inside or outside a building, and may be of short duration (e.g., from a broken container, an accidental valve opening, or a terrorist incident) or sustained (e.g., from a leaking storage tank or broken supply line). Descriptions of classes of and individual air contaminants, including chemicals, are found in Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals*, and removal techniques are covered in Chapter 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and Chapter 47 of this volume. Discussions in this chapter are limited to chemicals that are considered acutely toxic or corrosive, and present immediate danger to building occupants or systems.

Industrial buildings, where harmful chemicals may be used routinely, are likely at higher risk for internal chemical incidents than a typical commercial building, but, because of training, established procedures, and experienced personnel, they are also likely to be more prepared to handle an incident. Most commercial buildings, except for some government and high-profile buildings, do not have procedures in place for handling a chemical incident. A terrorist chemical event in a typical commercial building adds new difficulties, because details of the release are not known until long after the incident, and affected buildings and occupants are generally caught off guard, with little or no procedure in place for handling the event.

Chemical substances that can cause physical distress when introduced into breathable air are numerous; this chapter addresses only gaseous or vaporous compounds, and of those, addresses only two groups (1) those specifically known as chemical agents (in terms of warfare/terrorist activities) that might be intentionally introduced into a building's environment, and (2) a few common industrial gaseous substances that might accidentally be introduced into a building HVAC system through external or internal release, thus requiring HVAC or facility remediation of some kind. The purpose of this section is to address buildings that have no expectation of an accidental chemical release, based on the activities performed within the facility, as opposed to those of surrounding, related facilities (e.g., industrial facilities that have their own response plans). For control of airborne gases and vapors that are used as part of the building's normal operation, such as in laboratories or industrial processes, see Chapter 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and any of the application-specific chapters in this volume.

4.1 TYPES OF CHEMICAL AGENTS

Intentional contamination of facilities and their HVAC systems (and thus very ready dispersion to occupants) with gaseous or vaporous chemical substances has become a real concern. Chemical agents are classified by the U.S. Army (2005) as either toxic or incapacitating. Toxic chemical agents include nerve, blister, lung-damaging, and blood agents. Any of these agents may be introduced in sufficient quantity so as to injure building occupants and, in the process, compromise the building's HVAC system. Irritating agents (e.g., tear gas), which cause temporary trauma through reflexive action but are not generally lethal, are not considered by the U.S. military to be chemical agents.

Incapacitating Agents

Incapacitating agents are defined by the U.S. DOD as chemical agents that produce temporary physiological or mental effects, or both, that make individuals unable to make a concerted effort to perform their assigned duties. In occupational medicine, *incapacitation* generally means *disability*, and denotes the inability to perform a task because of a quantifiable physical or mental impairment. Thus, by definition, any of the chemical warfare agents may incapacitate a victim; however, by the military definition, incapacitation refers to impairments that are temporary and nonlethal, and does not include low-dose "lethal" agents. Incapacitating agents may cause symptoms that persist for hours to days, but are temporary and recoverable even without treatment. Incapacitating agents can be classified as either central nervous system (CNS) depressants or stimulants.

CNS depressants are compounds that depress or block activity of the CNS by inhibiting the transfer of information across synapses. Common CNS depressants include

- 3-quinuclidinyl benzilate (BZ)
- Cannabinols
- Phenothiazines
- Fentanyls
- Hypnotics

CNS stimulants cause excessive nervous activity by facilitating transmission of impulses across certain synapses that may otherwise be insufficient pathways. The brain becomes flooded with information, making concentration and decision making difficult. The most common CNS stimulant is d-lysergic acid diethyl amide (LSD).

Symptoms of poisoning by these agents include confusion, disorientation, restlessness, dizziness, staggering, or vomiting. Some may cause dryness of mouth, elevated temperature, pupil dilation, slurred/nonsensical speech, inappropriate behavior, and hallucinations. If several personnel exhibit any such behavior, it is prudent to move outside the building, because these agents are usually delivered by smoke-producing munitions or aerosols and are introduced through the respiratory system.

Irritants

Irritants can be classified as either tear-producing or vomiting-producing agents. The sole purpose of irritants, which include tear gas, riot control agents, and lachrimators, is to produce immediate discomfort and eye closure, thus rendering the victim incapable of fighting or resisting. Irritants cause eye discomfort, and some may cause vomiting; all are usually introduced to an environment as a gas. Police forces use irritants for crowd control. Irritants were used before World War I, and, during the war, they were the first chemical agents used, well before better-known agents such as chlorine, phosgene, and mustard gas.

Tear gas (CS) and chloroacetophenone (CN; sold in diluted form as a protective spray) are by far the most important pulmonary irritants. Capsaicin (methyl vanillyl nonenamide) is the active ingredient in pepper spray, also called OC (oleoresin capsicum). Pepper spray has, to some extent, replaced CN as a personal protective agent, with less dangerous effects. As its common name implies, the active ingredient is the burning agent in pepper plant fruits.

Although CS and CN are the most important agents in this class, several others require mention. Chloropicrin (PS) and bromobenzenecyanide (CA) were developed before World War I. Both largely have been replaced, because they were too lethal for their intended effects but not lethal enough to compete with the more effective blistering and nerve agents. PS still is used occasionally as a soil sterilant or grain disinfectant.

Toxic Chemical Agents

Nerve Agents. Nerve agents are organophosphate ester derivatives of phosphoric acid, and are among the deadliest of rapid-onset chemical agents. Nerve agents can be divided into G and V agents. **G agents** are fluorine- or cyanide-containing organophosphates. These agents are colorless and have an odor that ranges from weakly "fruity" to odorless. In an unmodified state, G agents are highly volatile, resulting in low persistency. However, they can be combined with various thickening substances, increasing persistency and penetration of intact skin. The primary hazard of G agents is vapor contact because of their high volatilities.

V agents are sulfur-containing organophosphates. These agents are low-volatile oily liquids, resulting in increased persistency. The increased persistency makes V agents primarily a contact hazard.

Common nerve agents include

- VX
- Tabun (GA)
- Sarin (GB)
- Soman (GD)
- Cyclosarin (GF)

Both G and V agents are potent inhibitors of the enzyme acetylcholinesterase (AChE) and present the same symptoms after exposure. Inhibiting AChE allows acetylcholine to accumulate, which mimics a massive release of acetylcholine in the nervous system. Nerve agents may be absorbed through any body surface (skin, eyes, respiratory) or ingested. Symptoms of nerve agent poisoning include

- Sweating and/or muscular twitching
- Pupil contraction, eye pain, or blurred vision
- Headache, pain
- Weakness
- Nausea, vomiting (particularly in ingestion)
- Mucous secretions in respiratory pathways, nose, or throat
- Wheezing, coughing
- Severe exposure: convulsions; vomiting; red, pinpoint eyes; unconsciousness; or respiratory failure

Mild exposure to nerve agents may cause anxiety, restlessness, and giddiness. Further exposure results in the listed symptoms and/or memory impairment, slowed reactions, or difficulty in concentration. Moderate exposure, if diagnosed and monitored, shows abnormalities in electroencephalograms (EEGs) as well as the symptoms listed. Reactions to nerve agents are immediate (i.e., within minutes of exposure). Recovery from nerve agent exposure is slow, usually days, and susceptibility to the agent is increased for months afterward.

Nerve agents are liquid at room temperature, but their volatilities can vary. Highly volatile agents (G agents) can be easily introduced as vapors into HVAC systems, whereas low-volatility agents (V and thickened G agents) can be introduced as droplets or vapors by mechanical means. Highly volatile agents are less persistent and require less intense cleanup than naturally persistent, highly volatile agents, which require intense cleanup if introduced into a building. For the most part, these agents are moderately soluble in water and highly soluble in lipids. They are rapidly inactivated by strong alkalis and chlorinating compounds, which are used in the decontamination/neutralization of these agents.

If nerve agents are suspected, evacuate the facility immediately. Because many nerve agents are (or can be made) persistent and dose is accumulative, evacuation is necessary. A facility must be decontaminated if exposed to nerve agents.

Blister Agents. Blister agents (vesicants) can be classified as mustards, arsenicals, and urticants. These agents are generally used as warfare agents meant to degrade fighting efficiency rather than to kill. They are usually thickened to make them persistent and contaminate surfaces, but may be introduced as a gas or vapor. Vesicants result in burns and blisters to the skin, eyes, and/or respiratory tract.

Mustard agents contain either sulfur or nitrogen and are persistent in cold and temperate conditions. They can be combined with other substances to thicken the agent, increasing their persistency. Warmer temperatures decrease persistency, but concentrations in air can be high because of the greater evaporation rate. Common mustard agents include

- Sulfur mustard (H and HD)
- Nitrogen mustards (HN)

Arsenical agents contain a central arsenic atom. These agents hydrolyze rapidly with water and lose most of their vesicant properties. Arsenicals are more volatile than mustards and are less toxic than other blister agents. Common arsenical agents include

- Lewisite (L)
- Mustard-lewisite (HL)
- Phenyldichloroarsine (PD)

Urticants are halogenated oximes and have a disagreeable, penetrating odor. The most recognized urticant is phosgene oxime (CX), which is one of the most irritating substances known.

The most likely routes of exposure are inhalation, dermal contact, and ocular contact. Depending on the particular vesicant, clinical effects may occur immediately (as with phosgene oxime or lewisite) or may be delayed for 2 to 24 h (as with mustards). Blister agents must be cleaned from the skin and membranes immediately to lessen their effects. Persons exposed to blister agents must be handled so as not contaminate those helping them. Evacuation is necessary, and contaminated people should be kept outdoors to prevent accumulation of the vesicant in a confined space. Effects of exposure include

- Mild to severe conjunctivitis, possibly progressing to ulceration
- Lesions on skin; burns
- Itching
- Pain (immediate with exposure to lewisite)
- Respiratory damage (in small doses may take time to appear as bronchitis, etc.)

Vesicants are, for the most part, soluble in nonaqueous solvents, not in water. They are more dangerous as liquids, because the degree to which they cause health problems is related to their concentration on body surfaces. In general, they have high vapor pressures and thus are easily vaporized in a confined space. Decontamination of exposed surfaces is needed.

Lung-Damaging Agents. Lung-damaging (choking) agents are those that primarily attack lung tissue, causing pulmonary edema. Examples include

- Phosgene (CG)
- Diphosgene (DP)
- Chlorine
- Chloropicrin (PS)

As choking agents, most of these agents (except for diphosgene) exist as gases at room temperature and pressure, and are thus easily spread through ventilation systems. Exposure symptoms include

- Choking sensations, coughing
- Tightness in chest
- Nausea, vomiting
- Headache

Because these agents are gaseous, they will disperse. They all have specific odors; for example, CG smells like fresh-mown hay. Thorough ventilation of contaminated areas is necessary. Choking agent gases typically are heavier than air, and thus tend to accumulate in low-lying areas.

Blood Agents. Blood agents, also known as cyanogens, interfere with the absorption and use of oxygen at the cellular level, and thus are usually introduced through the respiratory system. Examples include hydrogen cyanide (AC) and cyanogen chloride (CK). These agents are highly volatile and gaseous at temperatures over 21°C and are nonpersistent even at low temperatures. They therefore dissipate quickly in air, especially hydrogen cyanide, which is light; cyanogen chloride is heavier than air and tends to collect in low places. These two blood agents have different symptoms. Symptoms of exposure to AC include

- Faint odor of almonds
- Internal hemorrhaging
- Pink skin color
- Highly toxic, high concentrations can cause immediate death

CK symptoms include

- Intense irritation to the lungs and eyes
- Coughing
- Tightness in chest
- Dizziness
- Unconsciousness
- Respiratory failure

Because these agents are not persistent, thorough ventilation should dissipate the gases.

Other HVAC-Compromising Gases and Vapors

Accidental contamination of facility HVAC systems by gaseous or vaporous chemical substances has been a real concern for years, mainly because of the extensive production, use, and transport of large quantities of hazardous materials for manufacturing purposes. Intentional contamination of a facility could be accomplished with chemicals other than the specific chemical agents discussed previously. Contamination inside a building should result in immediate evacuation. However, external contamination might entail evacuation to a more distant location or shelter in place (i.e., not evacuating). Contamination from an incident in the immediate vicinity of (but external to) a facility might require shutdown of the facility's HVAC system for a short period of time. For instance, a large corrosive spill nearby might necessitate staying in a building for protection while transportation is arranged (if not available immediately). This might occur at a school where children would be more susceptible to injury upon exiting the building, having no way to evacuate a safe distance. Because the situations and possibilities are so varied, this discussion is limited to more typical scenarios.

Toxic Gases. The most common toxic gas that might threaten a facility and its personnel is carbon monoxide (CO), which is colorless, odorless, and tasteless. Carbon monoxide is produced by incomplete combustion of fossil fuels (gas, oil, coal, wood) used in boilers, engines, oil burners, gas fires, water heaters, solid-fuel appliances, and open fires. Dangerous amounts of CO can accumulate when, as a result of poor installation, poor maintenance, or failure, an appliance's fuel is not burned properly, or when rooms are poorly ventilated and the carbon monoxide is unable to escape. Because CO has no smell, taste, or color, it is important to have good ventilation, maintain all appliances regularly, and have reliable

Table 1 Corrosive Gases and Vapors

Corrosive Gases	Corrosive Acidic Vapors	Corrosive Basic Vapors
Hydrogen cyanide	Hydrochloric acid	Sodium hydroxide
Ammonia	Sulfuric acid	Ammonium hydroxide
Sulfur dioxide	Nitric acid	Caustic soda
Chlorine	Hydrofluoric acid	Potassium hydroxide
Hydrogen bromide	Acetic acid	Other hydroxides
Boron trichloride	Other acids	
Monomethylamine		
Phosphorus pentafluoride		

detector alarms installed to give both a visual and audible warning in case of a dangerous build-up of CO. Scenarios involving toxic gases usually entail evacuation to a safe distance. HVAC systems normally require cleaning using clean purge air the through the ventilation distribution system.

Corrosive Substances. Corrosive gases and vapors encompass a large class of materials. A few are purely gaseous in nature at room conditions, but some vapors result from the vapor pressure created by a liquid (or solid) presence. Some examples of corrosive gases and vapors are given in Table 1.

Corrosive gases and vapors are hazardous to all parts of the body, although some organs (e.g., eyes, respiratory tract) are particularly sensitive. The magnitude of the effect is related to the solubility of the material in body fluids. Highly soluble gases (e.g., ammonia, hydrogen chloride) cause severe nose and throat irritation, whereas lower-solubility substances (e.g., nitrogen dioxide, phosgene, sulfur dioxide) can penetrate deep into the lungs. Exposed skin may also be at risk for irritation or burns at higher concentrations or longer-term exposures. For some substances, warnings such as odor or eye, nose, or respiratory tract irritation may be inadequate. Accidents involving corrosive substances inside or outside a building require cleanup and decontamination of the facility's HVAC system and other equipment, because of the substances' persistence. In some cases, physical damage to a building's infrastructure may result from exposure to corrosives (e.g., etching of metal surfaces, which can lead to holes in ducting and compromised wiring). Building codes outline methods of design and installation for mechanical and electrical systems in corrosive environments (NFPA *Standard* 70), but in buildings that are not classified as such, and thus are not constructed accordingly, systems may be damaged when exposed to corrosive chemicals. In such a case, the building and its systems should be thoroughly inspected and tested before reoccupation.

5. BIOLOGICAL INCIDENTS

Biological incidents involve the intentional or accidental release of unwanted bioaerosols and/or biocontaminants in or around a building, such that the building's integrity or usefulness is compromised. Bioaerosols are airborne particulates derived from living organisms and include living microorganisms, viruses, spores, and toxins derived from remnants or fragments of living tissue. Bioaerosols are in the air, both indoors and outdoors, and their presence mostly goes unnoticed except for seasonal allergies or an occasional cold. There is an evolved balance between the types and levels of bioaerosols in the ambient air and the animals breathing that air. That balance can be disturbed locally by the purposeful or accidental release of a bioaerosol in or around a building. Unfortunately, bioaerosols are difficult to detect and identify in real time, because identification generally involves DNA analysis or other skilled analytical techniques. As a consequence, bioaerosols may be fully distributed in a building hours or days before anything is detected, much less identified, and the first sign of an incident may be symptoms of personnel.

Table 2 Limited List of Human Pathogenic Microorganisms

Bioaerosol	Incubation Period, Days	ID_{50}, Organisms	LD_{50}, Organisms
Bacillus anthracis (anthrax)	2 to 3	10 000	28 000
Ebolavirus spp. (Ebola)	14 to 21	10	Low
Francisella tularensis (tularemia)	1 to 14	10	Low
Hantavirus (Hanta)	14 to 30	N/A	N/A
Variola spp. (smallpox)	12	N/A	N/A
Yersinia pestis (bubonic plague)	2 to 6	N/A	N/A

There are hundreds of known bioaerosols that are pathogenic to humans to varying degrees. These include the spore-forming bacteria *Bacillus anthracis* (commonly known as anthrax), *Variola* spp. (the virus that causes smallpox), the bacteria *Yersinia pestis* (cause of bubonic plague), and many others. Human susceptibility varies by microorganism, and is gaged by several dose measures:

- **ID_{50}, mean infectious dose**, is the number of microorganisms or bioaerosol particles that causes 50% of an exposed population to be infected.
- **LD_{50}, mean lethal dose**, is the number of microorganisms or bioaerosol particles that causes death in 50% of an exposed population.

One of the greatest threats in a biological incident or attack is toxins, which are poisonous chemicals produced by living organisms and that may have effects resembling those of chemical agents. Toxicity and lethality of toxins vary, but highly toxic, stable toxins pose a risk for weaponization. Two classifications of potentially threatening toxins are neuro- and cytotoxins. **Neurotoxins** interfere with nerve impulse transmission and have significant effects on the nervous system. However, they can work in different manners, inhibiting or stimulating various enzymes and blocking various receptors. Effects are similar to those of chemical nerve agents, and include convulsions or paralysis, blurred vision, seizures, and muscle fatigue. **Cytotoxins** disrupt or destroy cells and cellular processes such as protein synthesis and other biochemical process. Symptoms may be similar to those of chemical blister, choking, and vomiting agents, as well as nausea, diarrhea, rashes, inflammation, and necrosis. Toxins can be produced by a variety of organisms such as bacteria, fungi, mold, algae, plants, and animals.

A summary of potential bioaerosol weapon agents is given in Table 2 along with ID_{50} and LD_{50} values. A more comprehensive list can be found in Kowalski (2003). More detailed descriptions of bioaerosols, their health effects, and methods of measurement can be found in most epidemiology texts. *Bioaerosols: Assessment and Control*, from the American Conference of Governmental Industrial Hygienists (ACGIH 1999), is a recommended starting point for quantitative determination of bioaerosol levels. General information on bioaerosols, their health effects, and their removal from building airstreams is found in Chapters 10 and 11 of the 2017 *ASHRAE Handbook—Fundamentals*, as well as Chapter 29 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

The primary threat to buildings from airborne biological incidents is adverse health effects to building occupants. Once an event happens, there is an immediate danger to building occupants from the initial dose, but there is also the risk of prolonged exposure from contaminated surfaces and reaerosolization of the agent. Depending on the agent, the prolonged exposure risk may dissipate quickly if the pathogenic organism has a short life outside a host, or it may remain indefinitely until the contaminating agent is fully removed. Anthrax, which is a spore-forming bacterium, falls into this latter category because it can lie dormant in many environments for long periods of time, only to come out of dormancy when exposed to a proper host. Excluding incidents of extreme mold growth (which is not covered in this chapter; see, e.g., ASHRAE [2003b] for information), biological incidents present no real threat to the integrity of building equipment; however, building equipment may play an important role in both distribution and possible removal of air contaminants. Remediation after an incident is likely to involve comprehensive cleaning of building equipment (particularly air-handling equipment), and may require removal and replacement of contaminated systems. Techniques for remediating contaminated equipment include surface cleaning with bleach or alcohol solutions, treatment with ultraviolet (UV) light, and volume gaseous treatments with ozone, hydrogen peroxide, or gas plasma. New technologies and procedures are under development, particularly since the anthrax events of 2001 in the United States. See the Bibliography and Online Resources for sources of information on the latest developments in remediation technology.

It is important to determine as much as possible about a release, whether purposeful or accidental, as rapidly as possible. It may be more difficult to completely assess the nature of a purposeful release, because it may contain more than one pathogenic agent, with different incubation periods, and the release may have taken place in several locations. Accidental releases are more likely to be a single pathogen at a single location, and the release is more likely to have been known to occur.

Biological pathogens have been weaponized to enable delivery in a variety of forms. Effective delivery of bioagents to a large population is difficult because of the need to get relatively large doses to large numbers of people. Dilution of contaminants in ambient air is rapid, and very large numbers of organisms are required to produce lethal concentrations. The confines of a building and controlled air exchanges rates can help maintain concentrations of agents for longer periods of time than would occur in outdoor air. However, filtration and real-time killing mechanisms in building air-handling systems can remove or render ineffective airborne bioaerosols. Engineering requirements for design of filtration or other techniques for treating indoor air are addressed more fully in other publications (e.g., NIOSH [2003]). Information is rapidly evolving; for the latest, consult the most recent versions of publications on building protection.

6. RADIOLOGICAL INCIDENTS

The occurrence of a significant accidental or intentional radiological release to the environment is of low probability because there are limited locations where considerable amounts of radiological material reside. These sources include spent fuel or low-level radioactive waste (radwaste) storage facilities, nuclear generating stations, and weapons fabrication and storage facilities. These facilities are usually analyzed beforehand, as part of the construction licensing process, for postulated accidental releases of radiological material and the consequences to both on- and off-site personnel.

An intentional release of radiological material is most likely to be in the form of the deployment of a nuclear weapon or a **radiological dispersal device (RDD)**, sometimes called a **dirty bomb**. It is normally assumed that a terrorist group is highly unlikely to possess and use conventional, sophisticated nuclear weapons because of the difficulties of obtaining or independently developing the necessary materials and technology. Development and deployment of an RDD, however, is considered viable because of its simplicity of design. RDDs combine conventional explosives and radioactive material, and are designed to scatter dangerous amounts of radioactive material over a general area. Terrorist use of RDDs also seems more likely because radiological materials used in medicine, agriculture, industry, and research are comparatively more obtainable than weapons-grade uranium or plutonium. A significant amount of the damage from an RDD would be from the initial blast. See the section on Explosive Incidents for design of HVAC system protection against blast effects.

6.1 RADIOACTIVE MATERIALS' EFFECTS AND SOURCES

Decay of radioactive materials produces energetic emissions (ionizing radiation) that can effect changes in human tissue cells. These energetic emissions are divided into **alpha** particles, **beta** particles, and **gamma/x-rays**. Alpha and beta radiation can only travel very short distances (about a metre, maximum) and do not have enough energy to penetrate the outer layers of human skin; they are, however, a hazard if directly inhaled or ingested. Gamma and x-rays can travel long distances in air and can pass through the body, potentially exposing internal organs to significant damage, depending on the amount absorbed. The radiation effect on humans is usually measured in sievert (Sv), the product of the absorbed dose and the biological efficiency of the radiation.

In developing an RDD, a significant quantity of radioactive material must first be collected. Some common radioactive materials currently used in industry include

- Colbalt-60 (Co-60), cesium-137 (Cs-137), and iridium-192 (Ir-192) are used in cancer therapy, industrial radiography and gages, food irradiation, oil well production, and medical implants. These are all considered gamma emitters.
- Strontium-90 (Sr-90) is used in the production of radioisotope thermoelectric generators (RTGs), which produce electricity for remote devices such as spacecraft. This is considered a beta emitter.
- Plutonium-238 (Pu-238) and americium-241 (Am-241) are used in oil well production, RTGs, and industrial gages. These are considered alpha emitters.

6.2 RADIOLOGICAL DISPERSION

Dispersion may be by conventional explosives, using aircraft to disperse the material in the form of an aerosol or particulate, or simply placing a container of radioactive material within a confined area or facility. In most cases, a dirty bomb or other RDD would have localized effects (based on the strength of material used) ranging from less than a city block to several square kilometres. The area affected by the dispersion of the material is a function of various factors, including

- Meteorological conditions, including atmospheric stability and wind speed
- Local topography, location of buildings, and other landscape characteristics
- Amount and type of radioactive material dispersed
- Dispersal mechanism (e.g., particulate, aerosol)
- Physical and chemical form of the radioactive material (e.g., dispersal as fine particles versus heavier droplets or particulate)

Radioactive material released as either an aerosol or fine particulate in a plume spreads roughly at the speed and direction of the prevailing wind velocity. The conditions of atmospheric stability (sometimes referred to in terms of the Pasquill stability classification) also determine the fallout's overall spread and concentration. Atmospheric dispersion computer models are sometimes used to predict the spread, location, and concentration of a postulated radioactive plume. These analytical tools can be useful in providing early warning to residences and facilities projected to be in the affected fallout path.

6.3 RADIATION MONITORING

Radioactivity cannot be seen, smelled, or tasted by humans. However, in the United States, there are many radiation-monitoring programs available at the federal, state, and local level that can measure radiation levels and/or track the released radiation plume. There may be a local facility (e.g., a nuclear power plant) that can track radiological fallout in the affected area. State-level officials have access to various monitoring programs for their areas. These programs use current weather patterns and wind velocities to track radiological plumes and provide public warning. Depending on the severity of the release, the radioactive plume may travel hundreds of kilometres or, more typically, be localized.

6.4 FACILITY RESPONSE

Physical safety of personnel should be of primary concern in responding to a radiological event. Time, distance, and shielding are the three most important aspects to minimizing the effects of human exposure to ionizing radiation. Shielding with stone, concrete, or other dense materials is usually not considered in the initial design of most commercial buildings. However, most facilities use these materials for structural strength (foundations and basements) or for fire protection in protective corridors and stairways. Consider developing procedures to instruct building occupants to immediately move to identified safe locations in the facility in the event of a known or suspected release. Limiting the time of exposure to a radiation field also helps reduce the total amount of exposure and subsequent health effects. Distance from the radiation source is the greatest factor in reducing the amount of direct (deep-dose) exposure, especially if the hazard is present for a considerable time period. The distance required to minimize this dose is usually small (little more than a metre).

Perhaps the greatest potential hazard from the release of low-level radiological debris from an RDD is inhalation or ingestion. Health effects from ingested contamination particles that enter the body from breathing, cuts/abrasions, eating, or drinking can be more severe than external exposure, depending on the amount of material consumed. Individuals should be instructed to move to more isolated rooms, or areas in the facility that may be isolated or filtered from significant inleakage of contaminated air. Distribution of personal protection equipment (PPE) should also be considered, depending on the risk assessment of a potential threat. If the release is determined to be internal, an organized evacuation should occur (consider developing evacuation procedures). Because evacuees may have become externally contaminated, an egress plan should be considered that includes a radiation detection monitoring procedure implemented either by internal personnel or by local emergency authorities. This procedure may include instruction to dispose of outer clothing and the use of showers to remove radioactive particles from body surfaces.

7. EXPLOSIVE INCIDENTS

Detonation of high explosives near a building generates pressures that act on all exposed surfaces. The magnitude of pressure depends on the size and shape of the charge, distance from the charge, and any intervening barriers. In addition to increased pressures, blasts may generate projectiles from either loose materials or fragments from damaged components. This section considers only loads that do not generate significant structural damage; it is assumed that, if the structure is severely damaged, continued operation of the HVAC systems is not crucial. Also, it is important to remember that life safety is the primary goal of all protective systems. This section deals strictly with HVAC equipment and systems, but any solutions must not compromise the safety of building occupants.

7.1 LOADING DESCRIPTION

Detonation of high explosives generates a pressure wave (blast wave) that propagates out from the explosion with decreasing velocity. The free-field blast wave, far from any surfaces, is characterized by a rapid, almost instantaneous increase in pressure, followed by a gradual decay in pressure and a negative-pressure phase. A typical free-field blast overpressure P_{so}, reaching the target at time t_A, is shown in Figure 3. When the blast wave impinges on a rigid surface, the pressure is reflected (P_r) and magnified over the free-field values. Peak pressure varies inversely with the cube of the distance from the explosion. Intervening barriers may reduce the blast load, but quantifying the effect is difficult, and great care must be taken when determining the resulting loads.

Internal explosions can generate extremely large loads on HVAC equipment. In addition to short-duration reflected pressures generated by the explosion, a quasi-static pressure may develop, greatly increasing the impulse to which the equipment is exposed. The magnitude and duration of quasi-static loading is a function of room volume and vented area.

In addition to direct air blast, HVAC equipment in buildings subjected to explosions can experience large accelerations and relative displacements caused by the resulting structure motion. The structure responds to loads imposed both through the foundation (ground shock) and from the air blast (air shock). In general, accurately predicting the time history of motion in the building is extremely difficult. However, because structural design of equipment is based on peak loads, there is usually no need to determine the full time history. Methods are available for predicting the peak motion caused by a given event, including the frequency dependence of the response.

Blast loads can also enter the interior space of buildings through utility openings, even if the building shell is undamaged. The blast can damage the passageway itself, and can also build up pressure in the building and subsequently damage other equipment. Pressure build-up depends upon the opening area and volume of interior space, as well as the pressure differential.

Explosions can produce primary and secondary fragments that may damage equipment and piping. Primary fragments are generated from the explosive casing, whereas secondary fragments result from damage to the structure and nonstructural components (e.g., concrete spalling, glass breakage). Predictions of fragment size and velocity can be used to estimate damage to equipment, ducts, and piping.

7.2 DESIGN CONSIDERATIONS

The best protection from any explosive effects is to locate equipment in a nonvulnerable area. Assuming the exterior building shell is

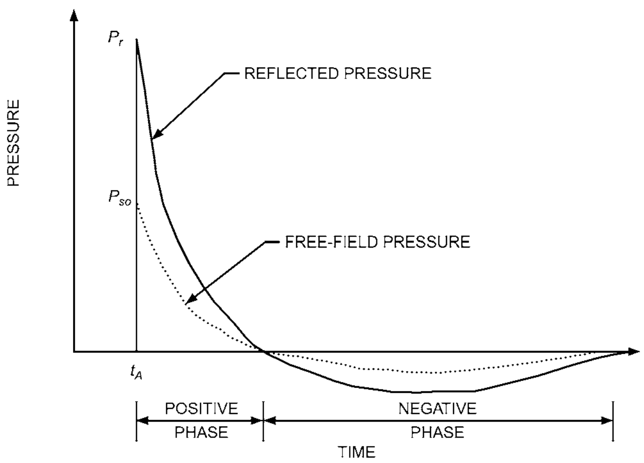

Fig. 3 Free-Field and Reflected Pressure Wave Pulses

adequately designed, any interior room may be considered protected. Barrier walls can protect equipment that must be externally located, or equipment can be positioned far enough away from any possible blast location that pressures are reduced below damaging levels. In general, correctly locating equipment is the least expensive option for handling blast loads. Hardening equipment, anchorage, and connection should be considered only after relocation has been eliminated as a possibility.

In addition to the direct air blast, equipment in a building subject to a blast experiences a support shock loading. Guidelines for the maximum shock that can be withstood by various equipment types are given in Chapter 56. Although general information can be obtained from these tables, it is important to realize that the data are several decades old and may not apply to modern HVAC equipment. If the shock is greater than the equipment's capacity, it may be possible to provide a shock isolation system to lower the demand. The isolation system works by decoupling horizontal motion of the support structure from that of the equipment. Note that this is different from typical equipment isolation applications, which are generally concerned with vertical vibrations of the equipment itself.

Although it has been stated that proper seismic design also protects against blast loads, this is not generally true. The effect of blast loading on equipment has some similarities to that of seismic loads, but there are some key differences. Both loads generate horizontal and vertical forces that act on equipment. However, in both magnitude and distribution, seismic forces are proportional to equipment mass, whereas blast loads are proportional to the equipment surface area. The effect is essentially the same for some types of equipment, such as pumps, where the mass and surface area distributions are approximately identical. However, equipment covered by a sheet metal shell is loaded very differently. Seismic loads are applied directly to the heavy components in the shell, whereas blast loads are applied to the shell itself, with little or no load acting directly on the interior components. Thus, even equipment that has been seismically rated or certified needs additional investigation for blast resistance.

In contrast, anchorage design is identical for blast and seismic loads. Properly designed seismic anchorage for most equipment in moderate to high seismic zones is adequate for reasonable levels of blast loading. In either case, loads applied to equipment are used to determine shear and uplift loads on the anchorage that are checked against the allowable load for the specific attachment hardware. Although in reality the dynamic reactions from the resulting equipment motion are the actual anchorage force, for nonisolated equipment it is usually conservative to assume a static distribution of the maximum applied loads. This is not always the case for isolated equipment, because resonance of the load, equipment, and isolation system may produce dynamic forces well above those predicted from a static analysis.

When designing HVAC systems for blast load, it is important to remember that there are two types of failure. The first is a temporary loss of service, such as might be caused by tripping a breaker. The second, more serious case involves actual damage to the equipment or system. It is important to determine which scenario is important for the system, and design accordingly. Preventing temporary outages is, in general, much more expensive than preventing a catastrophic failure.

Exposed piping and ductwork are also subject to both pressure and fragment loading. Pressure loading can be carried through proper selection and spacing of supports. The flexure and shear capacities of the pipe or duct, and the capacity of the support, determine the spacing. Fragment effects are more difficult to analyze, because the exact size and velocity of any fragments are impossible to predict. The only way to fully protect against fragments is to locate the pipe or duct where fragment impact is not possible.

Openings in the building for HVAC or other purposes must also be designed for blast effects. HVAC systems can be damaged by pressure propagated through the opening or blockage of the opening. Grilles or louvers can be analytically designed to resist the blast load, preventing blockage and allowing continued operation. Additionally, the pressure increase in ducts, and subsequently in interior rooms, can be calculated. Properly designed silencers may reduce pressure in ducts. Design of openings for blast resistance must also be closely coordinated with protection from chemical and biological agents.

ULTRAVIOLET germicidal irradiation (UVGI) uses short-wave ultraviolet (UVC) energy to inactivate viral, bacterial, and fungal organisms so they are unable to replicate and potentially cause disease. UVC energy disrupts the deoxyribonucleic acid (DNA) of a wide range of microorganisms, rendering them harmless (Brickner et al. 2003; CIE 2003). Early work established that the most effective UV wavelength range for inactivation of microorganisms is between 220 and 280 nm, with peak effectiveness near 265 nm. The standard source of UVC in commercial systems is low-pressure mercury vapor lamps, which emit mainly near-optimal 253.7 nm UVC. Use of germicidal ultraviolet (UV) lamps and lamp systems to disinfect room air and air streams dates to about 1900 (Reed 2010). Riley (1988) and Shechmeister (1991) wrote extensive reviews of UVC disinfection. Application of UVC is becoming increasingly frequent as concerns about indoor air quality increase. UVC is now used as an engineering control to interrupt the transmission of pathogenic organisms, such as *Mycobacterium tuberculosis* (TB), influenza viruses, mold, and potential bioterrorism agents (Brickner et al. 2003; CDC 2002, 2005; GSA 2010; McDeVitt et al. 2008; Rudnick et al. 2009).

UVC lamp devices and systems are placed in air-handling systems and in room settings for the purpose of air and surface disinfection (Figure 1). Control of bioaerosols using UVC can improve indoor air quality (IAQ) and thus enhance occupant health, comfort, and productivity (ASHRAE 2009; Menzies et al. 2003). Detailed descriptions of UVGI components and systems are given in Chapter 17 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Upper-air (also commonly called upper-room) devices are installed in occupied spaces to control bioaerosols (e.g., suspended viruses, bacteria, fungi contained in droplet nuclei) in the space. In-duct systems are installed in air-handling units to control bioaerosols in recirculated air that may be collected from many spaces, and to control microbial growth on cooling coils and other surfaces. Keeping the coils free of biofilm buildup can help reduce pressure drop across the coils and improve heat exchanger efficiency (therefore lowering the energy required to move and condition the air), and eliminates one potential air contamination source that could degrade indoor air quality. UVC is typically combined with conventional air quality control methods, including dilution ventilation and particulate filtration, to optimize cost and energy use (Ko et al. 2001).

This chapter discusses these common approaches to the application of UVC products. It also surveys the most recent UVC design guidelines, standards, and practices and discusses energy use and economic considerations for the application of UVC systems. Photocatalytic oxidations (PCOs), another UV-based HVAC application, are not discussed in this chapter, but are addressed in Chapter 47 of this volume.

The preparation of this chapter is assigned to TC 2.9, Ultraviolet Air and Surface Treatment.

1. FUNDAMENTALS

Ultraviolet energy is electromagnetic radiation with a wavelength shorter than that of visible light and longer than x-rays (Figure 2). The International Commission on Illumination (CIE 2003) defines the UV portion of the electromagnetic spectrum as radiation having wavelengths between 100 and 400 nm. The UV spectrum is further divided into UVA (wavelengths of 400 to 315 nm), UVB (315 to 280 nm), UVC (280 to 200 nm), and vacuum UV (VUV; 200 to 100 nm) (IESNA 2000). The optimal wavelength for inactivating microorganisms is 265 nm (Figure 3), and the germicidal effect decreases rapidly if the wavelength is not optimal.

UV Dose and Microbial Response

This section is based on Martin et al. (2008).

UVGI inactivates microorganisms by damaging the structure of nucleic acids and proteins at the molecular level, making them incapable of reproducing. The most important of these is DNA, which is responsible for cell replication (Harm 1980). The nucleotide bases (pyrimidine derivatives thymine and cytosine, and purine derivatives guanine and adenine) absorb most of the UV energy responsible for cell inactivation (Diffey 1991; Setlow 1966). Absorbed UV photons can damage DNA in a variety of ways, but the most significant damage event is the creation of pyrimidine dimers, where two adjacent thymine or cytosine bases bond with each other, instead of across the double helix as usual (Diffey 1991). In general, the DNA molecule with pyrimidine dimers is unable to function properly, resulting in the organism's inability to replicate or even its death (Diffey 1991; Miller et al. 1999; Setlow 1997; Setlow and Setlow 1962). An organism that cannot reproduce is no longer capable of causing disease.

UVGI effectiveness depends primarily on the UV dose (D_{UV}, μJ/cm^2) delivered to the microorganisms:

$$D_{UV} = It \quad (1)$$

where I is the average irradiance in μW/cm^2, and t is the exposure time in seconds (note that 1 J = 1 W/s). Although Equation (1) appears quite simple, its application can be complex (e.g., when calculating the dose received by a microorganism following a tortuous path through a device with spatial variability in irradiance). The dose is generally interpreted as that occurring on a single pass through the device or system. Although the effect of repeated UV exposure on microorganisms entrained in recirculated air may be cumulative, this effect has not been quantified, and it is conservative to neglect it.

The survival fraction S of a microbial population exposed to UVC energy is an exponential function of dose:

$$S = e^{-kD_{UV}} \quad (2)$$

where k is a species-dependent inactivation rate constant, in cm^2/μJ. The resulting single-pass inactivation rate η is the complement of S:

$$\eta = 1 - S \quad (3)$$

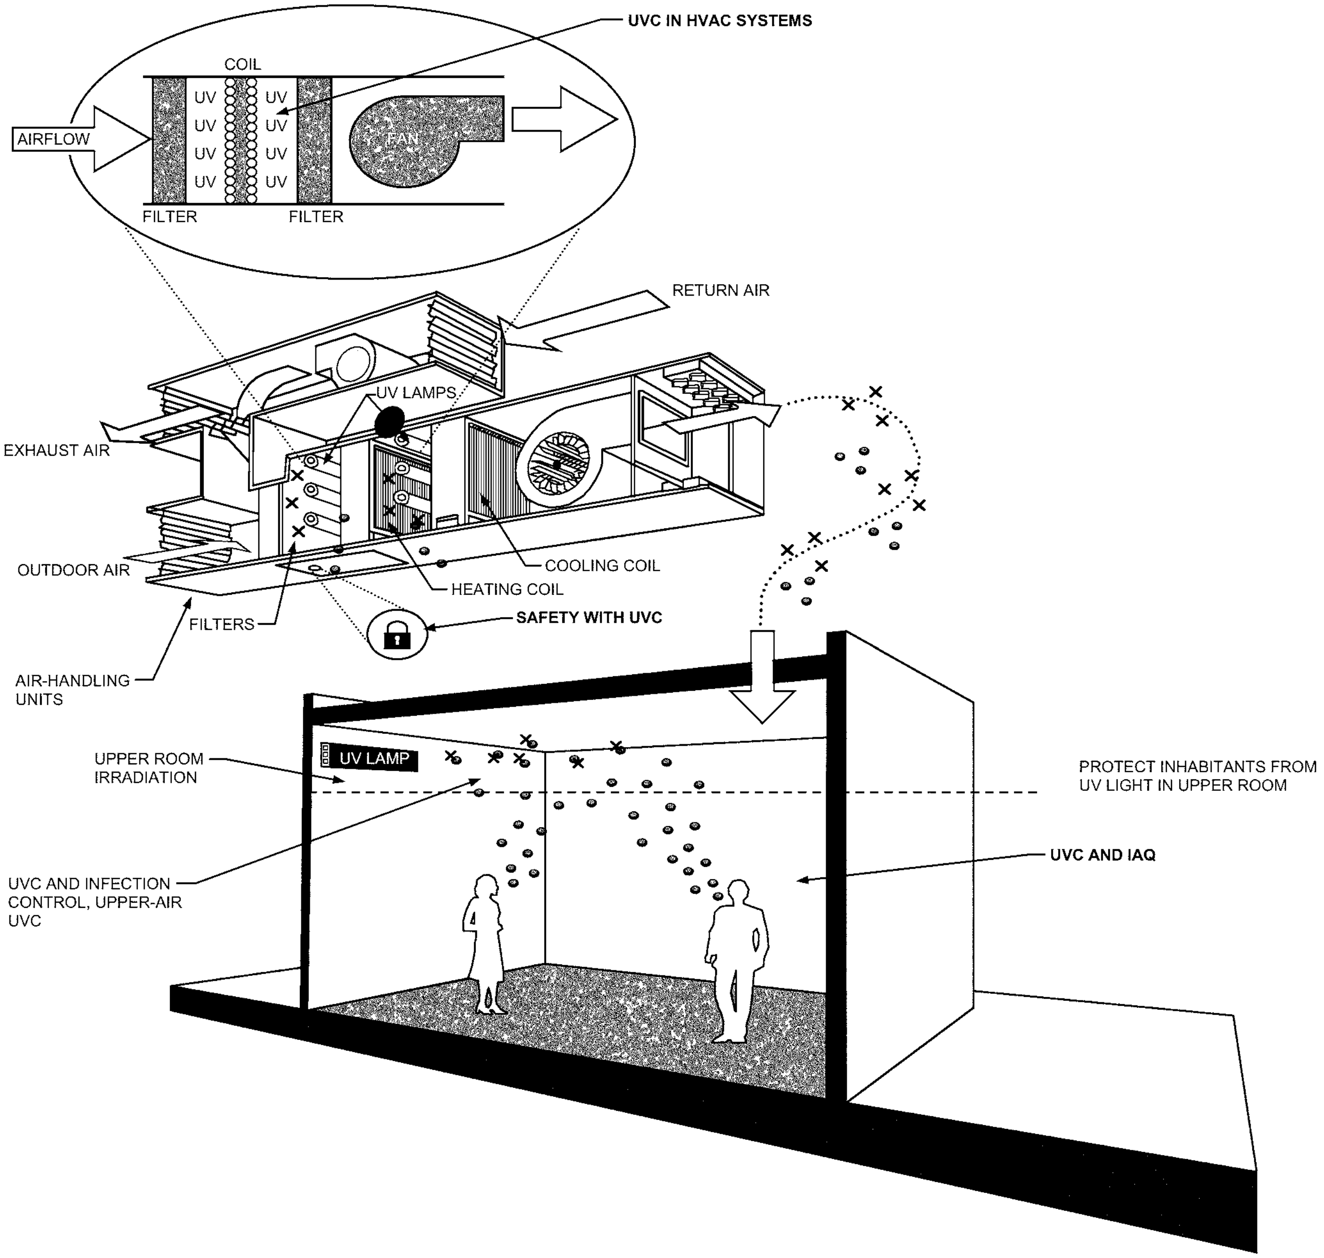

Fig. 1 Potential Applications of UVC to Control Microorganisms in Air and on Surfaces
(ASHRAE 2009)

and is a commonly used indicator of overall UVC effectiveness, representing the percentage of the microbial population inactivated after one pass through the irradiance field(s).

Inactivation rate constants (*k*-values) are species-dependent and relate the susceptibility of a given microorganism population to UV radiation (Hollaender 1943; Jensen 1964; Sharp 1939, 1940). Measured *k*-values for many species of viruses, bacteria, and fungi have been published in the scientific literature and previously summarized (Brickner et al. 2003; Kowalski 2009; Philips 2006). As shown in Figure 4, bacteria are generally more susceptible to UVC energy than fungi, but this is not always the case (see Chapter 17 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*). It is more difficult to generalize when it comes to viruses. Reported *k*-values for different species of microorganisms vary over several orders of magnitude. Consequently, choosing which *k*-value to use for UVC system design is often difficult and confusing. The variation in reported *k*-values makes generalizing the use of Equation (2) particularly complicated for heterogeneous microbial populations. Even accurately determining *S* for one specific microorganism can be difficult, because the reported *k*-values for the same species sometimes differ significantly.

Variations in published *k*-values may relate to differences in conditions under which the UV irradiance of the microbial population was conducted (in air, in water, or on surfaces), the methods used to measure the irradiance level, and errors related to the microbiological culture-based measurements of microbial survival (Martin et al. 2008). Because no standard methods are currently available for the determination of inactivation rate constants, care is necessary when applying values reported in the literature to applications under different environmental conditions.

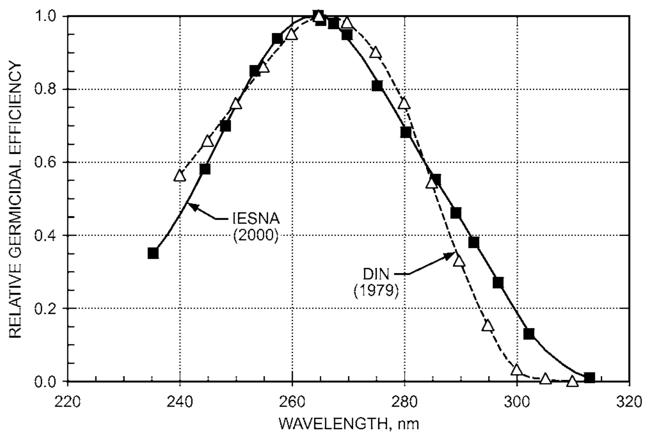

Fig. 3 Standardized Germicidal Response Functions

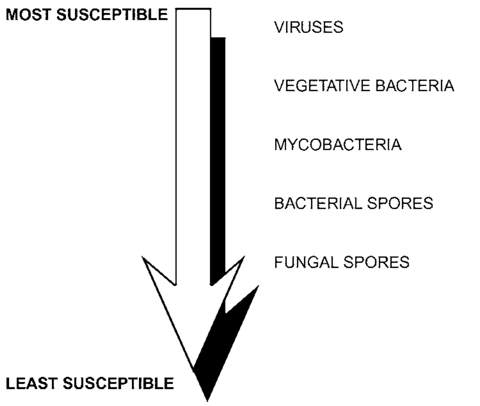

Fig. 4 General Ranking of Susceptibility to UVC Inactivation of Microorganisms by Group

UV Inactivation of Biological Contaminants

The focus of this chapter is application of UVC energy to inactivate microorganisms, specifically bacteria, fungi, and viruses on surfaces and in air streams. The application of UVC for upper-air treatment generally applies to pathogenic bacteria and viruses. Under some circumstances, these pathogens have the potential to be transmitted throughout the HVAC system.

As shown in Table 1, infectious diseases can be transmitted by a variety of means. UVC is effective against microorganisms in the air that flows through the UVC irradiation field and on irradiated surfaces.

As shown in Table 2 and Figure 4, viruses and vegetative bacteria are the generally most susceptible to UV inactivation, followed by Mycobacteria, bacterial spores, and finally fungal spores. Within each group, an individual species may be significantly more resistant or susceptible, so this ranking should be used only as a general guideline. Note that the spore-forming bacteria and fungi also have vegetative forms, which are markedly more susceptible to inactivation than are the spore forms. Viruses are a separate case. As a group, their susceptibility to inactivation is even broader than for the bacteria or fungi.

2. TERMINOLOGY

Just as it is customary to express the size of aerosols in micrometers and electrical equipment's power consumption in watts, regardless of the prevailing unit system, it is also customary to express total UVC output, UVC irradiance and fluence, and UVC dose using SI units.

Multiply I-P	By	To Obtain SI
Btu/ft^2 (International Table)	1135.65	$\mu J/cm^2$
$Btu/h \cdot ft^2$	315.46	$\mu W/cm^2$
To Obtain I-P	**By**	**Divide SI**

Burn-in time. Period of time that UV lamps are powered on before being put into service, typically 100 h.

Table 1 Modes of Disease Transmission

Exposure	Examples
Direct contact with an infected individual	Touching, kissing, sexual contact, contact with oral secretions, or contact with open body lesions Usually occurs between members of the same household/close friends/family
Indirect contact with a contaminated surface (fomite)	Doorknobs, handrails, furniture, washroom surfaces, dishes, keyboards, pens, phones, office supplies, children's toys
Droplet contact	Infected droplets contact surfaces of eye, nose, or mouth Droplets containing microorganisms generated when an infected person coughs, sneezes, or talks Droplets are too large to be airborne for long periods of time, and quickly settle out of air
Airborne droplet nuclei (residue from evaporated droplets) or other particles containing microorganisms ~ ≤ 5 µm	Size allows them to remain airborne for long periods of time Organisms generally hardy (capable of surviving for long periods of time outside the body, resistant to drying) Organisms enter the upper and lower respiratory tracts
Fecal-oral	Usually associated with organisms that infect the digestive system Microorganisms enter via ingestion of contaminated food/water and shed in feces Lack of proper hygienic and sanitation practices
Vectorborne	Transmission through animals Bite, feces of a vector, contact with outside surface of a vector (e.g., a fly)

Table 2 Representative Members of Organism Groups

Organism Group	Member of Group
Vegetative Bacteria	*Staphylococcus aureus* *Streptococcus pyogenes* *Escherichia coli* *Pseudomonas aeruginosa* *Serratia marcescens*
Mycobacteria	*Mycobacterium tuberculosis* *Mycobacterium bovis* *Mycobacterium leprae*
Bacterial Spore	*Bacillus anthracis* *Bacillus cereus* *Bacillus subtilis*
Fungal Spores	*Aspergillus versicolor* *Penicillium chrysogenum* *Stachybotrys chartarum*
Viruses	Influenza viruses Measles SARS Smallpox

Cutaneous damage. Any damage to the skin, particularly that caused by exposure to UVC energy.

Disinfection. Compared to sterilization, a less lethal process of inactivating microorganisms.

Droplet nuclei. Residual viable microorganisms in air, following evaporation of surrounding moisture. These microscopic particles are produced when an infected person coughs, sneezes, shouts, or sings. The particles can remain suspended for prolonged periods and can be carried on normal air currents in a room and beyond to adjacent spaces or areas receiving exhaust air.

Erythema (actinic). Reddening of the skin, with or without inflammation, caused by the actinic effect of solar radiation or artificial optical radiation. See CIE (2011) for details. (Nonactinic erythema can be caused by various chemical or physical agents.)

Exposure. Being subjected to infectious agents, irradiation, particulates, or chemicals that could have harmful effects.

Fluence. Radiant flux passing from all directions through a unit area, often expressed as J/m^2, J/cm^2, or (µW·s)/cm^2.

Irradiance. Power of electromagnetic radiation incident on a surface per unit surface area, typically reported in microwatts per square centimeter (µW/cm^2). See CIE (2011) for details.

Mycobacterium tuberculosis. The namesake member of the *M. tuberculosis* complex of microorganisms, and the most common cause of tuberculosis (TB) in humans. In some instances, the species name refers to the entire *M. tuberculosis* complex, which includes *M. bovis*, *M. africanum*, *M. microti*, *M. canettii*, *M. caprae*, *M. pinnipedii*, and others.

Ocular damage. Any damage to the eye, particularly that caused by exposure to UV energy.

Permissible exposure time (PET). Calculated time period that humans, with unprotected eyes and skin, can be exposed to a given level of UV irradiance without exceeding the NIOSH recommended exposure limit (REL) or ACGIH Threshold Limit Value® (TLV®) for UV radiation.

Personal protective equipment (PPE). Protective clothing, helmets, goggles, respirators, or other gear designed to protect the wearer from injury from a given hazard, typically used for occupational safety and health purposes.

Photokeratitis. Defined by CIE (1993) as corneal inflammation after overexposure to ultraviolet radiation.

Photokeratoconjunctivitis. Inflammation of cornea and conjunctiva after exposure to UV radiation. Exposure to wavelengths shorter than 320 nm is most effective in causing this condition. The peak of the action spectrum is approximately 270 nm. See CIE (1993) for details. Note that different action spectra have been published for photokeratitis and photoconjuctivitis (CIE 1993); however, the latest studies support the use of a single action spectrum for both ocular effects.

Radiometer. An instrument used to measure radiometric quantities, particularly UV irradiance or fluence.

Threshold Limit Value® (TLV®). An exposure level under which most people can work consistently for 8 h a day, day after day, without adverse effects. Used by the ACGIH to designate degree of exposure to contaminants. TLVs can be expressed as approximate milligrams of particulate per cubic meter of air (mg/m^3). TLVs are listed either for 8 h as a time-weighted average (TWA) or for 15 min as a short-term exposure limit (STEL).

Ultraviolet radiation. Optical radiation with a wavelength shorter than that of visible radiation. (See CIE [1987] for details.) The range between 100 and 400 nm is commonly subdivided into

UVA: 315 to 400 nm
UVB: 280 to 315 nm
UVC: 200 to 280 nm
Vacuum UV 100 to 200 nm

Ultraviolet germicidal irradiation (UVGI). Ultraviolet radiation that inactivates microorganisms. UVC energy is generated by germicidal lamps that kill or inactivate microorganisms by emitting radiation predominantly at a wavelength of 253.7 nm.

UV dose. Product of UV irradiance and specific exposure time on a given microorganism or surface, typically reported in millijoules per square centimeter (mJ/cm^2).

Wavelength. Distance between repeating units of a wave pattern, commonly designated by the Greek letter lambda (λ).

3. UVGI AIR TREATMENT SYSTEMS

Design Guidance

Early guidelines published by General Electric (Buttolph and Haynes 1950), Philips (1985), and Westinghouse (1982) are still used by many system designers today. First et al. (1999), Kowalski (2003, 2006, 2009), NIOSH (2009), and Riley et al. (1976) made meaningful advances in the analysis and modeling of UVGI systems that improved guidance for system design, yet no consensus guidelines exist that comprehensively address all aspects of UVGI system design required to ensure desired performance.

UVC system design today relies on performance data from lamp, ballast, and fixture manufacturers and the experience of system designers. Many equipment manufacturers have methods for estimating the UV dose delivered, which may include using tabulated data charts, mathematical modeling, and complex formulas. Like most HVAC components, UVC systems are often oversized to ensure performance. This oversizing, though conservative, can potentially increase equipment and utility costs, and may result in less energy-efficient systems.

Although application support for UVC technologies is growing and many successful systems have been installed, “the most important needs in the area of UVGI are industry standards to rate devices and installations, as well as guidance for installation and maintenance” (EPA 2017). ASHRAE Technical Committee 2.9, Ultraviolet Air and Surface Treatment, was created in 2003 (initially as a Task Group, converted to a standing Technical Committee in 2007) in part to address these deficiencies by initiating research programs, preparing Handbook chapters, and serving as the cognizant committee for developing the needed standards. So far, two new ASHRAE standards have been developed that provide end users with ratings of equipment performance and aid UVC system designers in selecting appropriate components:

- ASHRAE *Standard* 185.1, Method of Testing UV-C Lights for Use in Air-Handling Units or Air Ducts to Inactivate Airborne Microorganisms, establishes a test method for evaluating the efficacy of UVC lights for their ability to inactivate airborne microorganisms installed inside general ventilation systems.
- ASHRAE *Standard* 185.2, Method of Testing Ultraviolet Lamps for Use in HVAC&R Units or Air Ducts to Inactivate Microorganisms on Irradiated Surfaces, establishes a similar test method to measure the intensity of ultraviolet lamps on irradiated surfaces under typical HVAC&R operating conditions.

Work is ongoing to initiate round-robin testing between laboratories that can potentially conduct testing on UVC devices according to these new standards. Such testing will generate critical data on the repeatability of the testing methods and identify issues that must be addressed in updates to the standards.

For any application, the ability of UVC to inactivate microorganisms is a function of dose. **Dose** is the length of time of exposure multiplied by the irradiance measured in $\mu W/cm^2$ (see Chapter 17 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more details). A key difference between surface decontamination and airborne inactivation of organisms is exposure time. In a duct system, exposure time is on the order of seconds or fractions of seconds because of the rapid movement of air through the duct. Therefore, the irradiance must be sufficiently high to provide the dose necessary to inactivate the pathogen in seconds or a fraction of a second, depending upon the configuration and characteristics of the UVC system.

As mentioned previously, organisms differ in their susceptibility to UVC inactivation. Depending on the application, a public health or medical professional, microbiologist, or other individual with knowledge of the threat or organisms of concern should be consulted during the design process.

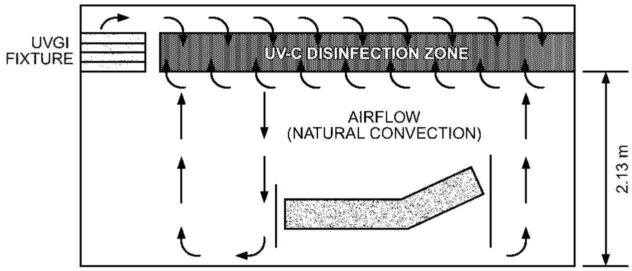

Fig. 5 Typical Elevation View of Upper-Room UV Applied in Hospital Patient Room

Upper-Air UVC Devices (Fixtures)

The primary objective of upper-air UVC placement and use is to interrupt the transmission of airborne infectious pathogens within the indoor environment. The source of these infectious organisms may be infected humans, animals, or bioaerosols introduced for terrorism purposes. Humans are the predominant sources of airborne agents that infect people (ACGIH 1999). The measles and influenza viruses and the tuberculosis bacterium are three important infectious organisms known to be transmitted indoors by means of air shared, by any means, between infected and susceptible persons. Studies of person-to-person outbreaks indicate at least two transmission patterns: within-room exposure such as in a congregate space, and transmission beyond a room through corridors and by entrainment in ventilation ductwork, through which air is then recirculated throughout the building. ASHRAE also provides guidance on protecting buildings from extraordinary incidents in which a bioterror agent is aerosolized into a building (ASHRAE 2003).

UVC is used, in combination with other environmental controls, to protect building occupants in all areas of concern (Brickner et al. 2003; Kowalski and Bahnfleth 2003). Since the 1930s (Riley and O’Grady 1961; Wells 1955) and continuing to the present day (First et al. 2007a, 2007b; Miller et al. 2002; Xu et al. 2003), numerous experimental studies have demonstrated the efficacy of upper-air UVC. Additionally, evidence of effectiveness has been established for inactivating tuberculosis (Escombe et al. 2009; Mphaphlele et al. 2015), reducing measles transmission in a school, and the interruption of influenza transmission within a hospital (McLean 1961).

Various upper-air UVC devices are designed to generate a controlled UVC field above the heads of occupants and to minimize UVC in the lower, occupied area of the room. Settings appropriate to upper-air UVC placement include congregate spaces, where unknown and potentially infected persons may share the same space with uninfected persons (e.g., a medical waiting room or homeless shelter). Common corridors potentially used by unknown infected persons in a medical facility would also benefit from upper-air UVGI fixtures. Upper-air UVC also covers situations where untreated recirculated air might enter an occupied space (see Figures 5 and 6 for illustrations of upper-air pathogen control using UVC). Upper-air UVC is very effective in areas with no, or minimal, ventilation; 2 air changes per hour (ach) equivalency, up to normal recommended levels of 6 ach can be achieved. Ventilation patterns (natural and mechanical) should promote good air mixing in the space equipped with UVC so that infectious microorganisms encounter the UVC zone and are inactivated, thus reducing the risk of exposure of occupants to airborne infectious agents. Recent studies that have used natural ventilation and UVC have shown that upper-air UVC is an effective, low-cost intervention for use in TB infection control (Escombe et al. 2009; Mphaphlele et al. 2015).

Upper-air UVC devices are designed and installed to irradiate only air in the upper part of the room (Figures 7 and 8). Parameters for UVC effectiveness include room configuration, UV fixture

(Centers for Disease Control and Prevention)

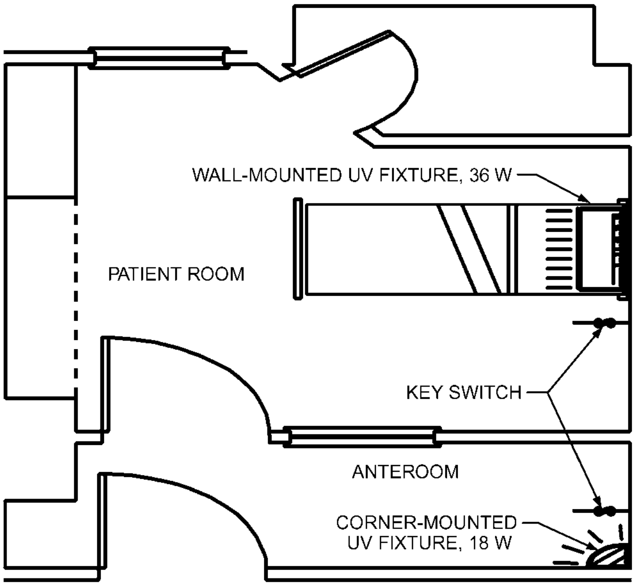

Fig. 9 Suggested Layout of UVC Fixtures for Patient Isolation Room
(First et al. 1999)

placement, and the adequacy of air currents in bringing contaminated air into the upper UV zone. UVC devices should be placed appropriately spaced to accommodate the area, shape, and height of the space in which air is to be disinfected. Figures 9 to 11 show examples of upper-air fixture placement. An upper-air computer-based tool can calculate the average fluence in the upper room (Rudnick et al. 2012; Vincent et al. 2013; Zhang et al. 2012). Additionally, computational fluid dynamics (CFD) is being used to understand the interaction between airflow and upper-air UVC (Gilkeson and Noakes 2013; Xu et al. 2013; Zhu et al. 2013).

Upper-air UVC devices typically use low-pressure UVC lamps in tubular and compact shapes and accommodate a variety of electrical wattages and voltages. Beyond lamp size, shape, and ballasts, fixtures are available in open or restricted energy distribution, depending on the physical space to be treated. UVC fixtures are selected based on the floor-to-ceiling height. Ceiling heights above 3 m may allow for more open fixtures, which may be more efficient because they may allow for a larger irradiation zone. For occupied spaces with lower ceilings (less than 3 m), various louvered upper-air UVC devices (wall-mount, pendant, and corner-mount) are available for use in combinations and are mounted with at least 2.1 m from the floor to the bottom of the fixture. The fixture should be mounted so that its UV energy is distributed parallel to the plane of the ceiling. Device construction and placement prevent excessive ultraviolet energy from striking occupants below. For example, in high-risk areas such as corridors of infectious disease wards, a maximum UV irradiation of 0.4 μW/cm² at eye level is an acceptable engineering guide (Coker et al. 2001). No long-term health effects of UVC exposure at these levels in the lower occupied part of rooms are known. Figure 5 shows a typical elevation and corresponding UV levels, and Figure 6 illustrates typical UVC energy distribution in a room.

Application guidance with placement criteria for UV equipment is provided by Boyce (2003), CDC (2005), CIE (2003), Coker et al. (2001), First et al. (1999), IESNA (2000), and NIOSH (2009). An example of the guidance provided by Coker et al. is shown in Table 3. Additionally, manufacturer-specific advice on product operation and placement should be followed. A new computer-aided lighting software program is being modified to help automate the placement of fixtures, and to calculate the uniformity and average UV provided (Brickner et al. 2009). Upper-air UVC fixtures that are typically used in developed countries are often cost-prohibitive for use in less developed parts of the world. International guidance is needed to understand best practice for UVC application in the developing

Table 3 Suggested UVC Fixture Mounting Heights

Design Concept: Congregate setting, high occupancy, shared air with adjacent auditorium (multipurpose room). Dropped ceiling for an open office plan. Look for long path lengths, evenly space fixtures along one wall.

L = length, *W* = width, *H* = floor-to-ceiling height, *A* = area covered, *V* = room volume, *MH* = mounting height above finished floor, *N* = number of UVGI fixtures, *W* = nominal wattage, WM = wall mounted, CM = ceiling mounted

Fig. 11 Example Upper-Air UVGI Layout for A Meeting Room

world where extensive drug-resistant TB is an increasing global threat (Nardell et al. 2013).

Some upper-air installations rely on air convection and mixing to move air from the lower to the upper portion of the room, where it can be irradiated and airborne microorganisms inactivated (Kethley and Branc 1972). The overall effectiveness of upper-air UVC systems improves significantly when the air in the space can be well mixed. Although convection air currents created by occupants and equipment can provide adequate air circulation in some settings, mechanical ventilation systems that maximize air mixing are preferable. If mechanical ventilation is not possible, fans can be placed in the room to enhance mixing. Many fixtures incorporate a safety switch that breaks the circuit when fixtures are opened for servicing and should contain baffles or louvers appropriately positioned to direct UV irradiation to the upper air space. Baffles and louvers must never be bent or deformed.

A UVC installation that produces a maintained, uniform distribution of UV irradiance averaging between 30 and 50 μW/cm² is effective in inactivating most airborne droplet nuclei containing mycobacteria, and is presumably effective against viruses as well (First et al. 2007a, 2007b; Miller et al. 2002; Xu et al. 2003). Beyond UVC irradiance, effectiveness of upper-air UVC is related to air mixing, relative humidity, and the inherent characteristics of the pathogenic organisms being addressed (Ka et al. 2004; Ko et al. 2000; Rudnick 2007). Effectiveness can improve greatly with well-mixed air (First et al. 2007a, 2007b; Miller et al. 2002; Riley and Permutt 1971; Riley et al. 1971), so ventilation systems that maximize air mixing receive the greatest benefit from upper-air UVC. Relative humidity should be less than 60%; levels over 80% rh may reduce effectiveness (Kujundzic et al. 2007; Xu et al. 2003).

Depending on the disinfection goals, upper-air devices should be operated similarly to in-duct UVC systems. Systems designed to reduce or eliminate the spread of airborne infectious diseases in buildings with continuous occupancy and/or with immunocompromised populations should be operated 24 h per day, 7 days per week. Upper-air systems designed for improved indoor air quality installed in more traditional commercial buildings may be operated intermittently, or powered on during hours of normal building occupancy and powered off when the facility is empty. This may provide acceptable indoor air quality during periods of building occupancy, simultaneously saving energy and requiring less frequent lamp replacements. However, intermittent operation must be factored into the initial system design because cycling UV lamps on and off may negatively affect lamp and ballast performance and life.

In-Duct UVC Systems: Airstream Disinfection

The principal design objective for an in-duct UVC air disinfection system is to distribute UV energy uniformly in all directions throughout the length of the duct or air-handling unit (AHU) to deliver the appropriate UV dose to air moving through the irradiated zone with minimum system power. Enhancing the overall reflectivity of the inside of the air handler can improve UVC system performance by reflecting UVC energy back into the irradiated zone, thus increasing the effective UV dose. Using materials such as aluminum or other highly reflective materials can increase reflectivity. Properly designed in-duct UV air disinfection systems are also able to maintain the cleanliness of cooling coil surfaces and condensate pans, when the UV lamps are installed in close proximity to this equipment. On the other hand, systems designed specifically for coil and condensate pan applications may not be adequate for proper air disinfection.

Design dose is a function of the design-basis microbe (i.e., the targeted microorganism with the smallest *k*-value) and the desired level of disinfection. Generally, single-pass inactivation efficiencies are specified, analogous to the specification of a particulate filter MERV rating. In some cases, the design disinfection level may be a true performance specification based on the exposure in an occupied space. Determining this value requires analysis of the entire system that is used to determine the single-pass performance. Which approach is selected depends on the type of application. Laboratory/hospital installations are more likely to have specific, identified targets than, for example, school or office installations. The required average irradiance for a typical in-duct system is on the order of 1000 to 10,000 μW/cm^2, but it could be higher or lower depending on the application requirements.

In-duct air disinfection systems should be designed to have the desired single-pass inactivation level under worst-case conditions of air temperature and velocity in the irradiated zone. The worst-case performance reflects the combined effect of the number/power of UVC fixtures; air residence time, which is inversely proportional to air velocity; and lamp/ballast characteristics, including wind chill effect and depreciation (as discussed in Chapter 17 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*). Lee et al. (2009) showed that it may be advantageous to use simulation to determine the design condition, given the complex interactions between air temperature, velocity, and lamp performance. Lamps may be located anywhere in an air conveyance system; however, some locations provide more efficiency and potentially greater benefit. In most cases, the lowest maximum velocity in a system occurs inside an air-handling unit. For this reason, and because it provides the ability to treat air from many spaces and simultaneously irradiate cooling coils and condensate pans, this is a very common choice, although systems may also be located in air distribution ducts.

Because they are typically installed in air handling units, most in-duct systems are designed for an air velocity of around 2.5 m/s. At this velocity, an irradiance zone 2.4 m in length achieves a 1 s exposure. As a rule of thumb, in-duct systems should be installed in a location that can provide a minimum of 0.25 s of UV exposure; otherwise, system cost and power consumption will be excessive. UVC devices are most often located downstream of the heating/cooling coils. However, in some cases, mounting fixtures upstream of the coil may result in lower in-duct temperatures, resulting in a more optimum lamp performance temperature and more cost-effective disinfection. The trade-off is reducing the effectiveness of disinfection of the cooling coil and forgoing irradiation of the drain pan that lamps mounted downstream of the coil provide.

In-duct air disinfection systems designed to reduce the spread of airborne infectious diseases (e.g., tuberculosis, influenza) in buildings with continuous occupancy and/or with immunocompromised populations (e.g., hospitals, prisons, homeless shelters) should be operated on a continuous basis. However, properly designed systems installed in more traditional commercial buildings (e.g., offices, retail) can be operated intermittently, or powered on during hours of normal building occupancy and powered off when the facility is empty. This may save energy costs and require less frequent lamp replacement while providing acceptable indoor air quality during periods of occupancy. However, the effect of intermittent operation on lamp and ballast life must be factored into the design analysis: cycling reduces the operating hours to failure of hot cathode lamps. In-duct UVC should always be used in combination with proper filtration. Filters may help to protect UV lamps from dust and debris accumulation which may reduce UV output over time, and filters enhance the overall air cleaning capabilities of the system.

Studies of Airstream Disinfection Effectiveness

Laboratory studies (e.g., RTI 2005; VanOsdell and Foarde 2002) conclusively demonstrate the ability of commercially available equipment to achieve a high level of disinfection of moving airstreams. These studies have generally involved tests with surrogates rather than actual infectious disease agents, but it can be assumed that an infectious agent with a *k*-value similar to an experimental surrogate will be similarly inactivated. Previous field studies showed clinical effectiveness (i.e., reduced incidence of infection) (Nagy et al. 1954; Rentschler and Nagy 1940), but similar recent studies are lacking. Although pilot studies have begun (Bierman and Brons 2007; Rudnick et al. 2009), further recorded field studies are needed to benchmark installed system performance. Many UV airstream disinfection systems have been installed in hospital environments to help reduce pathogens by complementing conventional dilution/filtration systems.

4. HVAC SYSTEM SURFACE TREATMENT

Coil and Drain Pan Irradiation

Conditions in HVAC systems can promote the growth of bacteria and mold-containing biofilms on damp or wet surfaces such as cooling coils, drain pans (Levetin et al. 2001), plenum walls, humidifiers, fans, energy recovery wheels, and filters. Locations in and downstream of the cooling coil section are particularly susceptible because of condensation and carryover of moisture from coil fins. Cooling coil fouling by biofilms may increase coil pressure drop and reduce airflow and heat exchange efficiency (Montgomery and Baker 2006). Filters capture bacteria, mold, and dust, which may lead to microbial growth in damp filter media. As the growth proliferates, a filter’s resistance to airflow can increase. This can result in more frequent filter changeouts and increased exposure to microbes for maintenance workers and building occupants. As airflow and coil performance degrades, so does the air quality in occupied spaces (Kowalski 2006).

Conventional methods for maintaining air-handling system components include chemical and mechanical cleaning, which can be costly, difficult to perform, and dangerous to maintenance staff and building occupants. Vapors from cleaning agents can contribute to poor air quality, chemical runoff contributes to groundwater contamination, and mechanical cleaning can reduce component life. Furthermore, system performance can begin to degrade again shortly after cleaning, as microbial growth reappears or reactivates.

UVC can be applied to HVAC systems, typically in air-handling units, to complement conventional system maintenance procedures (Bahnfleth 2011) and has been shown to be effective in reducing air-side pressure drop and increasing air-side heat transfer coefficient of wetted cooling coils (Bahnfleth 2017). A large dose can be delivered to a stationary surface with a low UVC irradiance because of the essentially infinite exposure time, making it relatively easy to cost-effectively prevent the growth of bacteria and mold on system components. In contrast to air disinfection irradiance levels, which may exceed 1000 μW/cm^2, coil surface irradiance levels on the order of 1 μW/cm^2 can be effective (Kowalski 2009), although 50 to 100 μW/cm^2 is more typical. Using reflectors to focus lamp output on surfaces may reduce the power required for surface treatment, but at the expense of reducing air treatment effectiveness. Potential advantages of UVC surface treatment include keeping surfaces clean continuously rather than periodically restoring fouled surfaces, no use of chemicals, lower maintenance cost, and potentially better HVAC system performance.

Lamps can be installed to target problematic components such as cooling coils, condensate pans, or filters (Figure 12), or applied to give broad distribution of UVC energy over an entire enclosure (e.g., mixing box/plenum) that might have microbial activity. Like in-duct air-treatment equipment, systems for surface treatment in air-handling units should be designed to withstand moisture and condensate and selected to operate over a full range of system operating conditions.

Alternative and Complementary Systems

ASHRAE (2014) identifies the following demonstrated ways of reducing airborne infectious disease transmission:

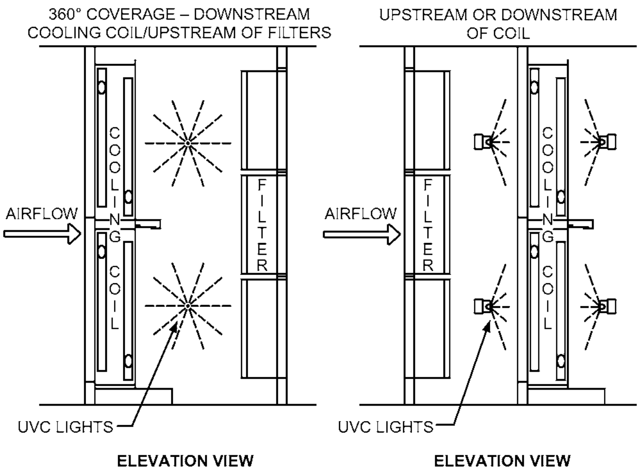

Fig. 12 Section View of Typical HVAC Surface Treatment Installations

- UVC
- Dilution, personalized, and source capture ventilation
- In-room airflow control
- Room pressure differentials
- Filtration

From one perspective, these may be viewed as distinct, mutually exclusive alternatives for bioaerosol control. In principle, ventilation alone, filtration alone, or UVC alone can yield the same level of control of a given contaminant source. However, in most cases, multiple modes of air quality control are used in the same system, often as a result of code requirements. For example, air quality codes for commercial buildings based on ASHRAE *Standard* 62.1 minimally require both dilution ventilation and particulate filtration at prescribed levels.

When used in combination with other mandatory air treatment modes, UVC provides an incremental benefit. For example, if a particulate filter removes 85% of a given agent in an incoming airstream and a UVC system with a single-pass efficiency of 85% for the same contaminant is installed in series with it, the combined filter/UVC system would have a combined single-pass capture and inactivation efficiency of approximately 98% (i.e., the incremental benefit of adding an 85% efficient device is only 13%). Situations involving ventilation, filtration, and UVC can be evaluated quantitatively by analyzing the entire system.

An example of this type of analysis was given by Nazaroff and Wechsler (2009) for several common arrangements of air cleaners in combination with ventilation. The performance of an air cleaner added to a system with ventilation is defined in terms of an effectiveness ε, which is the difference in contaminant concentration in a space of interest caused by adding an air cleaner and the concentration that would exist without the air cleaner:

$$\varepsilon = \frac{C_{baseline} - C_{control}}{C_{baseline}} \tag{4}$$

where $C_{baseline}$ is the concentration without the air cleaner and $C_{control}$ is the concentration after addition of the air cleaner. This performance measure would show, for example, that adding UVC to a system with a low ventilation rate would have a higher effectiveness (i.e., greater impact) than adding the same device to the same system with a higher ventilation rate. The extension of this concept to multiple-space systems and multiple air cleaners and air cleaner types is straightforward. System designers can use such methods to obtain more accurate cost/benefit estimates and to optimize the characteristics and placement of air cleaners.

Even in the absence of the constraints imposed by building codes, the system designer should consider the potential benefits of combining air treatment methods. For example, the cost of particulate filters and their negative impact on fan energy use increase in inverse relation to the sizes of particles to be controlled (i.e., filters for smaller particles tend to be more expensive and have higher pressure drop than filters for larger particles). On the other hand, many larger microorganisms that may be resistant to UVC, such as some fungal spores, can be captured effectively by filters of moderately high efficiency and cost (Kowalski 2009). In addition, using UVC to suppress microbial growth on filters that capture but do not kill is a potential complementary use of these two technologies. Ultimately, the decision to use or not use one of the available, effective microbial control methods should be based on a complete analysis that considers overall performance goals for air quality, impact on energy use, and economic factors. Such an analysis is illustrated for a typical air disinfection system by Lee et al. (2009), as discussed in the following section.

5. ENERGY AND ECONOMIC CONSIDERATIONS

The major costs of owning and operating a UVC system include initial equipment and installation costs, maintenance costs (primarily lamp replacement), and energy cost (direct cost of lamp operation plus impact on heating and cooling energy consumption). For a given system, these costs are relatively straightforward to estimate. The benefits of a UVC system are not so easily quantified. Energy use is of concern, and it is also the major operating cost component of most systems. Considerations of energy conservation measures inevitably lead to the issue of cost effectiveness. Therefore, it is appropriate to discuss energy use in conjunction with its economic impact.

Air treatment systems and room surface disinfection systems have the objective of improving the safety, health, and productivity of building occupants through reduced incidence of infectious disease and sick building complaints. Although many studies exist to support claims of UVC's effectiveness in these applications, it is difficult to express the resulting benefits in economic terms. A conservative approach to economic evaluation is to compare the costs of alternative approaches such as dilution ventilation and particulate filtration that have the same effectiveness.

When alternative systems are compared with UVC, all associated costs must be carefully estimated. Increased ventilation adds to heating- and cooling-coil loads and may also affect fan energy use. Particle filtration systems have their own associated installation and maintenance costs and may significantly increase air-side pressure drop and, therefore, fan energy consumption.

Cooling-coil treatment systems have the two-fold objectives of maintaining coil performance and minimizing energy use by reducing air-side flow resistance and increasing the overall heat transfer coefficient relative to a conventionally maintained, mechanically and chemically cleaned coil.

Field studies in the United States (Bahnfleth and Firrantello 2017; Firrantello and Bahnfleth 2017a) and Singapore (Wang et al. 2016a, 2016b) in hot, humid climates report significant improvements in air-side pressure drop and heat transfer coefficient. A system in Tampa, FL, experienced a 22% reduction in pressure drop and 15% increase in air-side heat transfer coefficient after less than two months of surface treatment system operation. Similar results were obtained from a system in Singapore. Improvement in heat transfer coefficient of the Singapore system cooling coil (Wang et al. 2016b) resulted in a chilled-water flow rate reduction of 8.0 to 11.9% and an increase in chilled-water temperature difference of 0.4 to 0.6 K. Changes in performance in drier climates were less dramatic, as indicated by a laboratory study in Colorado (Luongo et al. 2017; Luongo and Miller 2016) and field data from a system in State

College, PA (Bahnfleth and Firrantello 2017). As in the case of air disinfection systems, costs to install and operate coil treatment systems are easily estimated, but though there are many reports of significant improvement in performance, there are relatively few peer-reviewed studies documenting its real-world performance (summarized by Bahnfleth 2017).

Economic analysis of UVC coil treatment based on field measurements (Firrantello and Bahnfleth 2017b; Wang 2017) indicates that energy consumption of germicidal lamps is less than corresponding savings in fan, chiller, and pump energy. However, annual energy savings vary greatly between hot, humid climates where coils are continuously wet and temperate ones in which coils may be dry or inactive for several months per year. Thus, cost effectiveness of coil treatment based on energy savings alone is not certain. Economic performance appears much more favorable when reductions in maintenance cost and improvements in air quality are included in the analysis. Firrantello and Bahnfleth (2017c) modeled effects of air disinfection by a coil treatment system on sick leave for six typical buildings in 16 climate zones. They found that, although typical sizing practices for coil UVC systems only reduced illness-related costs by 3.5%, the monetized value of this improvement was 20 times the energy cost to operate the system.

Upper-Air UVC Devices

The effectiveness of upper-air UVC performance has often been described in terms of equivalent air changes per hour (ach): that is, by the rate of outside airflow measured in room volumes per hour that would achieve the same reduction of microbial air contamination in a well-mixed space. Riley et al.'s (1976) study of UVGI efficacy found that one 17 W UVC lamp covering 18.6 m^2 produced 10 equivalent ach versus a natural die-off of 2 ach when a surrogate for tuberculosis was released in the room. The UVC lamp took less than 20 min to inactivate the bioaerosol, versus over 30 minutes for a natural die-off. In a bioaerosol room study, McDevitt et al. (2008) showed seasonal variations of between 20 to 1000 equivalent ach for a surrogate for smallpox. Ko et al. (2001) modeled the cost of using three air-cleansing strategies to control transmission of tuberculosis in a medical waiting room. They calculated a present value per avoided tuberculin skin test conversion (evidence of infection) of $1708 for increased ventilation, $420 for HEPA filtration, and $133 for upper-air UVC: that is, UVC was less expensive by a factor of 3 to 13. Another metric is cost to provide a typical level of treatment per unit of floor area. The estimated health care benefit, typical of such analyses, was much larger than the cost: roughly $430/$m^2$ per year.

In-Duct Air Disinfection

Bahnfleth et al. (2009) and Lee et al. (2009) used simulation to investigate the energy use and operating cost of in-duct UVC air treatment applied upstream or downstream of the cooling coil in a cooling-only variable-air-volume system located in New York and compared it with equivalent added particulate filter. A representative MERV 12 filter was estimated to provide the same performance as UVC designed for 85% single-pass inactivation under design conditions. They computed not only the costs associated with the alternatives considered, but also estimated the health benefit using a method based on the Wells-Riley equation as applied by Fisk et al. (2005). They found that locating the UVC system upstream of the cooling coil in the normally warmer mixed-air section of the air-handling unit reduced its required size by roughly 50% relative to a downstream location using typical in-duct lamp characteristics. Annual energy cost at an average electric rate of $0.10/(kW·h) ($0.03/MJ) was approximately $0.22/$m^2$ for the downstream location and $0.11/$m^2$ for the upstream location, whereas the additional MERV 12 filter cost $1.08/$m^2$. Annualized life-cycle cost, including installation and maintenance, was $7.97/$m^2$ for the downstream location, $4.09/$m^2$ for the upstream location, and $19.27/$m^2$ for MERV 12 filtration. The drawback to the more economically advantageous upstream UVC location is that it is considered a less favorable location for cooling coil irradiation, which many air treatment systems are designed to do as a benefit of increased airflow and heat exchange efficiency and reduced coil cleaning.

Upper-Air Versus In-Duct

Economic factors clearly favor an upper-air fixturing when the building being treated with UVC has no air distribution system. When a recirculating central air distribution system is present, a choice becomes possible between upper-air devices, which must be distributed throughout occupied spaces, and in-duct systems, which can be centralized. As noted in the preceding discussion of in-duct systems, an annual operating cost of $0.11 to $0.22/$m^2$ is possible at an electric rate of $0.10/kW·h ($0.03/MJ). The same study (Lee et al. 2009) estimated an installed cost for equipment of $1.40 to 2.69/$m^2$. By comparison, a typical upper-air system might cost more than $21.53/$m^2$ to install and more than $0.11/$m^2$ to operate, based on typical sizing procedures and current equipment costs. This comparison seems to strongly favor in-duct systems where they are applicable, but is based on an assumption of equal performance that may not be valid. In a health care setting, controlling transmission of airborne pathogens at their source would suggest an upper-room approach. However, where feasible, a whole-building approach to UV should be considered.

Cooling Coil Surface Treatment

Cooling coil surface treatment is done as an alternative to periodic mechanical and chemical cleaning of coils. By suppressing the formation of biofilms and mold growth on coils, coil irradiation should reduce air-side pressure drop, increase heat transfer coefficient, and reduce both fan and refrigeration system energy consumption. Several studies have documented the ability of coil irradiation to reduce microbial growth (Levetin et al. 2001; Shaughnessy et al. 1998). No peer-reviewed studies have yet been published to document the effect of coil irradiation on energy consumption, but there are many strong anecdotal reports of its effectiveness. As noted previously, the U.S. General Services Administration has sufficient confidence in this application to include it in its mechanical requirements (GSA 2018).

6. ROOM SURFACE TREATMENT

Environmental contamination in health care settings and transmission of health-care-associated pathogens to patients occurs most frequently via contaminated hands of health care workers and transmission of pathogens to patients (Boyce 2010). A primary concern in health care settings has been reducing nosocomial infections and finding new approaches for these environments to help eliminate infections from hospital settings. Hospital-acquired infections generate a high financial burden for the health care industry and the consumer. In the United States, an estimated 1.7 million hospital-acquired infections occur annually, leading to about 100,000 deaths (U.S. HHS 2009). UVC for surface disinfection, particularly in health care settings, has been applied to reduce the number of microorganisms on surfaces, and consequently UVC should contribute to a reduction in these healthcare-acquired infections (HAIs). Scientific studies have shown reductions in viable infectious agents on surfaces after UV exposure. However, further evidence of reductions in HAIs is needed, as well as a method to test various portable UVC devices being used for "whole-room" decontamination.

Various portable UVC devices are available for hospitals, which can be easily moved into patient rooms, surgical suites, ICUs, and other critical areas that need surface and air disinfection during a terminal cleaning process or when a patient is diagnosed with a disease transferred by pathogens. Some of the pathogens of interest and their reduction in health care settings are multidrug resistant, such as methicillin-resistant *Staphylococcus aureus* (MRSA), *Clostridium difficile*, *Acinetobacter baumannii*, and vancomycin-resistant *Enterococci* (VRE). These pathogens can be inactivated by proper application of UVC energy. A study by Rastogi et al. (2007) investigated the efficacy of UVC disinfection of *Acinetobacter baumannii* on contaminated surfaces relevant to medical treatment facilities. The UVC exposure to surfaces resulted in ≥4-log (CFU) reduction in viable cells of *A. baumannii*.

UVC fixtures can also be installed in surgical suites to disinfect surfaces and air between or during procedures. A 19-year study on UVC during orthopedic surgery showed that 47 infections occurred following 5980 joint replacements. The infection rates for total hip replacements decreased from 1.03% to 0.72% ($p = 0.5407$), and for total knee replacements from 2.20% to 0.5% ($p < 0.0001$). The study concluded that UVC appears to be an effective way to lower the risk of infection in the operating room during total joint replacement (Ritter et al. 2007). Safety precautions must be followed when applying UVC during surgery to protect workers from accidental exposure (see the following discussion of intensity of source) or upper air fixtures may be used as discussed previously. Tools used in healthcare applications can be irradiated with UVC for simple surface disinfection. However, UV irradiation should never replace sterilization of surgical instruments.

UVC surface disinfection could also be applied in schools, morgues, nursing homes, and homeless shelters: surfaces can be irradiated with fixed or portable in-room UVC fixtures that serve as part of the room's disinfection methodology.

Application of UVC to any surface is based on the UV dose delivered to the surface. The dose (μJ/cm^2) of UVC needed to disinfect a surface depends on the selected target and desired disinfection level. Different microorganisms require various levels of UVC energy for inactivation (see Figure 4). Vegetative forms of bacteria tend to be more susceptible to UVC energy than spore-forming microorganisms. UVC irradiates all line-of-sight objects and into shadowed areas (e.g., tables, chairs, surgical equipment, objects) through reflection, so the desired level of disinfection can be achieved, even on surfaces which are not directly irradiated. Different materials absorb and reflect UVC energy at different rates, depending on the overall reflectivity of the materials, irradiation time, and intensity. UVC surface disinfection should only be applied as an adjunct to normal surface cleaning procedures of the facility. No living organisms, including animals and plants, should be in the room when UVC is used. It should be noted that most organic compound-based materials degrade when exposed to UVC energy.

The same principles as for in-duct applications apply here. There are two primary methods of UVC delivery: direct (line of sight) and indirect (reflection). Most surface applications use a direct source, where the source (typically a mercury vapor lamp) is contained in an assembly designed to direct the UVC energy at a particular surface or in a particular direction with no impedance to the energy beam. In an indirect application, the energy is reflected onto a surface using a reflective material. The reflected UVC energy can be measured to determine accurately when a given amount of the UVC dose has been delivered to the desired target.

The basics of determining the radiant energy levels to a surface are as follows:

Length of exposure. When disinfecting surfaces, it must be first determined if the target is moving or stationary. This helps to determine if there are any limiting factors associated with the length of exposure time. In most surface disinfection applications, time is relative to intensity, meaning that increasing the intensity of the source can decrease the exposure time necessary. It is important to remember that microorganisms vary, requiring a higher or lower intensity for inactivation, depending on their structure (Brickner et al. 2003).

Intensity of source. UVC lamp and equipment manufacturers normally provide the intensity of a given source (lamp or fixture) at a given distance. A distance correction factor may be needed when calculating a desired dose or intensity for a surface. UVC energy follows the same inverse square law for intensity as visible energy and other electromagnetic sources: the amount of energy at the surface is measured in proportion to the square of the distance from the energy's source (UVC lamp), assuming no loss through scattering or absorption. Temperature and airflow corrections may also be necessary, depending on the location of the application. The intensity of a source is given in power per unit area (i.e., μW/cm^2).

Distance from source to surface. In a point irradiation application, the distance is relatively easy to calculate. Calculating time requirements and intensity levels for a three-dimensional object or space is more complex. The varying distances from the source are the first challenge, because the object itself creates a shadowing effect, and any shadows from the local environment must be taken into consideration. However, portable devices are available that effectively measure the reflected dose from shadow areas and offer quantifiable results.

Studies on in-room UVC disinfection devices have shown that UVC can be successfully applied to reduce microbiological loads of surfaces located in shadow areas in addition to line of sight (Rutala 2009). The reductions were up to 4-log for organisms such as MRSA, VRE, *Acinetobacter*, and *C. difficile*. Furthermore, it was concluded that UV room decontamination with the test device reduced colony counts of pathogens by greater than 99.9% within 20 min. Note that, depending on the portable or stationary UVC device, performance could greatly differ with respect to irradiation time, because overall dose delivered to surfaces is the critical measure of portable device performance.

7. SAFETY

Hazards of Ultraviolet Radiation to Humans

UVC is a low-penetrating form of UV compared to UVA or UVB. Measurements of human tissue show that 4 to 7% of UVC (along with a wide range of wavelengths, 250 to 400 nm) is reflected (Diffey 1983) and absorbed in the first 2 μm of the stratum corneum (outer dead layer of human skin), thus minimizing the amount of UVC transmitted through the epidermis (Bruls 1984).

Although UV is far more energetic than the visible portion of the electromagnetic spectrum, it is invisible to humans. Therefore, exposure to ultraviolet energy may result in transient corneal inflammation, which can go unnoticed.

Ocular damage generally begins with **photokeratitis** (inflammation of the cornea) but can also result in **photokeratoconjunctivitis** (inflammation of the conjunctiva [ocular lining]). Symptoms, which may not be evident until several hours after exposure, may include an abrupt sensation of sand in the eyes, tearing, and eye pain, possibly severe. These symptoms usually appear within 6 to 12 h after UV exposure, and resolve fully within 24 to 48 h. Acute overexposure to UVC radiation may cause some incapacity due to eye discomfort, but this generally abates after several days, leaving no permanent damage.

Cutaneous damage consists of erythema, a reddening of the skin akin to sunburn (but without tanning). The maximum effect of erythema occurs at a wavelength of 296.7 nm in the UVB band. UVC radiation at a wavelength of 253.7 nm is less effective in causing erythema. Because ultraviolet radiation is carcinogenic, questions have been raised concerning open-air UVC systems. The International Commission on Illumination (CIE) completed a review of UVC photocarcinogenesis risks from germicidal lamps using basic biophysical principles: because of the attenuation provided by the stratum corneum and epithelial tissues of the skin, upper-air disinfection can be safely used without significant risk for long-term delayed effects such as skin cancer (CIE 2010).

Sources of UV Exposure

UVC energy does not normally penetrate through solid substances and is attenuated by most materials. Quartz glass, soda barium glass, and TFPE plastic have high transmissions for UVC radiation.

UVC energy can reflect from most metals and several types of painted and nonpainted surfaces; however, a surface's ability to reflect visible light cannot be used to indicate its UV reflectance. The fact that a blue glow can be observed on a metal surface from an operating low-pressure UV fixture lamp could indicate the presence of UV, and a measurement should be performed to ensure there is no exposure risk. The lack of reflected blue light clearly indicates the absence of UV energy. Note that ultraviolet energy is invisible to the normal human eye; however, it follows the same optical path as the visible blue light spectrum generated by the UVC lamp.

Well-designed and commissioned UVC installations, education of maintenance personnel, signage, and use of safety switches can help to avoid overexposure. During commissioning and before operation of the UVC installation, hand-held radiometers with sensors tuned to read the specific 254 nm wavelength should be used to measure stray UVC energy and should be used in upper-air systems.

Exposure Limits

In 1972, the Centers for Disease Control and Prevention (CDC) and National Institute for Occupational Safety and Health (NIOSH) published a **recommended exposure limit (REL)** for occupational exposure to UV radiation. The REL is intended to protect workers from the acute effects of UV exposure, although photosensitive persons and those exposed concomitantly to photoactive chemicals might not be protected by the recommended standard.

Exposures exceeding CDC/NIOSH REL levels require that workers use personal protective equipment (PPE), which consists of eyewear and clothing known to be nontransparent to UVC penetration and which covers exposed eyes and skin.

UV inspection, maintenance, and repair workers typically do not remain in one location during their workday, and therefore are not exposed to UV irradiance levels for 8 h. Threshold Limit Value® (TLV®) consideration should be based on real-time occupancy of spaces treated by UVC (ACGIH 2007; Sliney 2013). This recommendation is supported by UV monitoring data from First et al. (2005), which showed that peak meter readings poorly predict actual exposure of room occupants.

Evidence of Safety

During the height of the tuberculosis resurgence in the United States in the 1990s, the Tuberculosis Ultraviolet Shelter Study (TUSS), a double-blind, placebo-controlled field trial of upper-air UVC, was conducted at 14 homeless shelters in six U.S. cities from 1997 to 2004 (Brickner et al. 2000). Following available recommended placement, installation, and maintenance guidelines, each building in the study was evaluated for treatment with upper-air UVC fixtures. At the conclusion of the study, the safety of room occupants was evaluated using data from a total of 3,611 staff and homeless study subjects regarding eye and skin irritation. Analysis showed no statistically significant difference in the number of reports of symptoms between the active and placebo periods. There was one definite instance of UV-related photokeratoconjunctivitis (from eye overexposure). This occurred from a placement of an elevated bunk bed in a dormitory where a single bed had been used when the UV fixtures were first installed. By moving the UV fixture, this incident was resolved (Brickner and Vincent 2013). This study demonstrated that, with careful application, side effects of UV overexposure can be avoided. Because of the enclosed nature of in-duct UVC systems, with careful adherence to safety guidelines, these systems should not result in UV exposure.

Because in-duct UVC systems are installed inside air-handling units or ventilation ductwork, typical building occupants are not expected to be exposed to UV energy. On the other hand, building facilities workers and maintenance personnel are at risk of high UV exposures with in-duct systems. To minimize the risk to these workers, UVC systems should be designed with specific safety features and all workers that could potentially work around the UV fixtures should receive UV-specific training.

Safety Design Guidance

Upper-air systems should have on/off switches and an electrical disconnect device on the louvers. If UV radiation measurements at the time of initial installation exceed the recommended exposure limit, all highly UV-reflecting materials should be removed, replaced, or covered. UV-absorbing paints containing titanium oxide can be used on ceilings and walls to minimize reflectance in the occupied space.

Warning labels must be posted on all upper-air UV fixtures to alert personnel to potential eye and skin hazards. Damaged or illegible labels must be replaced as a high priority. Warning labels must contain the following information:

- Wall sign for upper-air UVC
  Caution: Ultraviolet energy. Switch off lamps before entering upper room.
- General warning posted near UVC lamps.
  Caution: Ultraviolet energy. Protect eyes and skin.

Upper-air UVC fixtures can vary widely in their luminaire efficiency factors, which rates the performance of emitted UVC from a fixture. Zhang et al. (2012) developed a protocol and performed gonioradiometric measurements (i.e., measuring both radiance and irradiance at concurrent angles) for upper-air UVGI fixtures, which is now being used to test total UVC fixture output (Leuschner and Salie 2013). These gonioradiometric measurements are reported in standard IES format compatible with computer-aided design (CAD) lighting software adapted for use with upper room UVC devices (Rudnick et al. 2012; Vincent et al. 2013).

In-duct systems should be fully enclosed and sealed to prevent leakage of UV radiation to unprotected persons or materials outside of the HVAC equipment. The fifth edition of UL *Standard* 1995, which carries a November 2019 compliance date, requires that no opening permit leakage of UVC greater than 0.1 μW/cm^2, and that points of intentional access to UV sources must be equipped with an interlocking mechanism that deenergize the UV source. All access panels or doors to the lamp chamber and panels or doors to adjacent chambers where UV radiation may penetrate or be reflected should be interlocked and have warning labels posted in appropriate languages. Labels should be placed on the outside of each panel or door, in a prominent location visible to people accessing the system. At a minimum, the labels should state

- General warning posted near UVGI/UVC lamps
  Caution: Ultraviolet energy. Protect eyes and skin.
- Multilingual warning posted on the door of air handlers where UVC is present in ductwork.
  Caution: Ultraviolet energy in duct. Do not switch off safety button or activate lamps with door open.

Lamp chambers should have door safety interlock switches and electrical disconnect devices. Disconnection devices must be able to be locked or tagged out, and should be located outside the lamp chamber, next to the chamber's primary access panel or door. Switches should be wired in series so that opening any switched access deenergizes the system. It is recommended that on/off switches for UV lamps not be located in the same location as general room lighting; instead, they should be in a location that only authorized persons can access and should be locked or password protected to ensure that they are not accidentally turned on or off.

The lamp chamber should have one or more viewports of UVC-absorbing materials. Viewports should be sized and located to allow an operating UV system to be viewed from outside of the HVAC equipment.

8. INSTALLATION, START-UP, AND COMMISSIONING

The operating instructions and advice of UVC system designers and lamp manufacturers should always be followed to ensure the proper operation of any UVGI/UVC system. It is important to operate any such system within the temperature and relative humidity ranges considered during the system design process. The following section presents some general guidelines for initially verifying and maintaining adequate system performance.

Upper-Air UVC Devices

Those responsible for the commissioning process should inspect fixture placement and eye level irradiance measurements using a 254 nm selective radiometer. UVC levels can be measured with a UV radiometer directly facing the device at eye height at various locations in a room and must be taken in the same location each time. UVC measurements should be taken at eye level (between 1.68 and 1.83 m) at compass points from each figure. Check reflective surfaces (e.g., TVs, monitors). CAD software can be used to preview safety of UVGI/UVC upper room installations (Vincent et al. 2013). Incorporate readings into final commissioned drawings. If the readings indicate an eye-level exposure that exceeds the 8 h TLV for UVC of 6 $\mu J/cm^2$, the UV systems must be deactivated until adjustments can be made or the manufacturer can be contacted. Measurements should be made at initial installation, whenever new UV lamps are installed (newer lamp designs may provide increased irradiance), and whenever modifications are made to the UVC device or room (e.g., adjusting fixture height, relocating or repositioning louvers, adding UV-absorbing or -reflecting materials, changing room dimension or modular partition height).

In-Duct UVC Systems

Installation, start-up, and commissioning of in-duct UVGI systems are straightforward. Those responsible for installation should ensure that the system is installed as designed and that all lamps, ballasts, and/or fixtures are the same as included in the final design. Take care to ensure that all safety interlocks and view ports are installed in appropriate positions and functional. Once the UV lamps are powered on, ensure that all lamps are burning. Unfortunately, there are no good methods for in situ testing of in-duct system performance, so relying on final design parameters is essential to ultimate system performance.

9. MAINTENANCE

All UVC systems require periodic inspection, maintenance, and lamp replacement to ensure proper system performance. Whenever maintenance is performed on UVC systems, the appropriate safety guidelines outlined elsewhere in this chapter should be carefully followed.

Material Degradation

UVC energy can be detrimental to most organic materials. If the UVC is not applied properly and sensitive materials are not shielded or substituted, degradation can occur. However, the degradation may not be enough to cause failure of the material if UVC only penetrates micrometers into the material before the degradation plateaus off, leaving a still fully functional material, as found by ASHRAE research project RP-1509, sponsored by TC 2.9 (Kauffman 2010). Air filters are known to be sensitive to degradation by UVC, especially those made from synthetic materials. Glass fibers by themselves are unaffected by UV exposure, but binding materials in glass fiber filters may be degraded. As a general rule, synthetic air filters should not be exposed to UVC.

Lower doses, or those typically sized for cooling coil surface treatment, of UVC exposure to organic materials resulted in much slower rates of degradation (Kauffman 2017). Although UVC photodegradation is of concern, proper material selection or metallic shielding of components significantly reduces the problem, and components can be expected to meet product design life. As a simple, practical approach, it is wise to shield all organic material components within about 1.5 m of the UV lamp. Some indoor plants do not tolerate prolonged UVC exposure and should not be hung higher in the room where upper air UVC devices are installed.

Visual Inspection

Maintenance personnel should routinely perform periodic visual inspection of the UVC lamp assembly. Typically, a viewing port or an access door window is sufficient for in-duct applications. Closer visual inspection may be required for upper-air systems because a single burned-out lamp in a multilamp fixture may not be apparent from the lower room. Personal protective measures are required for this close-up inspection.

Any burned-out or failing lamps should be replaced immediately. If lamps become dirty in dusty environments, they should be cleaned with a lint-free cloth and isopropyl alcohol. Care should be taken to ensure no film remains on the surface of the lamps after cleaning. This film could reduce UV output from the lamp. Complete lamp fixtures should be replaced whenever they are visibly damaged or in accordance with manufacture warranty guidelines.

Radiometer

Another means of monitoring UVC lamps is with a stationary or portable radiometer. These are generally used to monitor the “relative” output of the UVC system by measuring the UV intensity produced by the lamps. Caution is needed when using a radiometer in critical applications, because these devices are intended only to give a relative indication of the lamp output unless measured identically each time with a calibrated instrument. Radiometer sensors can degrade over time with constant exposure to UV. If accurate measurements of UV intensity are required, a calibrated laboratory radiometer should be used, and readings must always be taken in the exact position each time as the readings are extremely sensitive to inverse square law losses and gains.

Lamp Replacement

UVC lamps should be replaced at the end of their useful life, based on equipment manufacturer recommendations or radiometer measurements. Where applicable, it may be prudent simply to change lamps annually (8760 h when lamps are run continuously) to ensure that adequate UV energy is supplied by a given system. Lamps can operate after their useful life, but at reduced performance, and require regular measurement to ensure that a maintained level of UVC is being generated. A blue visible light emitted from the lamp does *not* indicate that UVC is present. The typical rated life of UVC lamps is 9000 h of operation. Switching lamps on and off too often may lead to early lamp failure, depending on the ballast type used. Consult the lamp manufacturer for specific information on expected lamp life and effects of switching.

Lamp and Ballast Disposal

UVC lamps should be treated in the same manner as other mercury-containing devices, such as fluorescent lamps. Some lamps may need to be treated as hazardous waste and not discarded with regular waste, although low mercury lamps may be an exception; however, check state and local codes for proper determination. The U.S. EPA's universal waste regulations allow users to treat mercury lamps as regular waste for transport to a recycling facility (EPA 2018). This simplified process was developed to promote recycling. The National Electrical Manufacturers Association maintains an online list of companies claiming to recycle or handle used mercury lamps (NEMA 2009). The most stringent of local, state, or federal regulations for disposal should be followed.

UVC systems currently depend on the use of an electronic ballast to provide the UV lamp with power; however, many older systems used magnetic ballasts instead. Magnetic ballasts manufactured before 1979 contain polychlorinated biphenols (PCB) in the dielectric of their capacitors (EPA 2017). Recycling is the best way to dispose of all magnetic ballasts. The process allows the reuse of copper and aluminum wire, steel laminations, and steel cases, and disposes of capacitors and potting compound as hazardous waste in high-temperature incinerators.

Failed electronic ballasts should be treated as electronic waste. Many lamp and ballast recyclers are expanding their businesses and becoming certified to accept electronic waste. Some recyclers now accept both lamps and electronic ballasts.

Personnel Safety Training

Workers should be provided with as much training as necessary, including health and safety training, and some degree of training in handling lamps and materials. Workers should be made aware of hazards in the work area and trained in precautions to protect themselves. Training topics include the following:

- UVC exposure hazards
- Electrical safety
- Lock-out/tag-out (for in-duct units)
- Health hazards of mercury
- Rotating machinery (for in-duct units)
- Slippery condensate pans (for in-duct units)
- Sharp unfinished edges (for in-duct units)
- Confined-space entry (if applicable) (for in-duct units)
- Emergency procedures

Workers expected to clean up broken lamps should be trained in proper protection, cleanup, and disposal.

No personnel should be subject to direct UV exposure, but if exposure is unavoidable, personnel should wear protective clothing (no exposed skin), protective eyewear, and gloves. Most types of eyewear, including prescription glasses, may be sufficient to protect eyes from UV, but not all offer complete coverage. Standard-issue safety goggles or clear full-face masks may be the best alternative.

If individual lamp operating conditions must be observed, this should preferably be done using the view port or window(s).

During maintenance, renovation, or repair work in rooms with upper-air UV systems, all UVC devices must be deactivated before personnel enter the upper part of the room.

For in-duct systems, access to lamps should be allowed only when lamps are deenergized. The lamps should be turned off before air-handling unit (AHU) or fan shutdown to allow components to cool and/or to purge any ozone in the lamp chamber (if ozone-producing lamps are used). If AHUs or fans are deenergized first, the lamp chamber should be opened and allowed to ventilate for several minutes. Workers should always wear protective eyewear and puncture-resistant gloves for protection in case a lamp breaks.

Access to the lamp chamber should follow a site-specific lock-out/tag-out procedure. Do not rely on panel and door safety switches as the sole method to ensure lamp deenergizing. Doors may be inadvertently closed, or switches may be inadvertently contacted, resulting in unexpected lamp activation.

If workers enter the condensate area of equipment, the condensate pan should be drained and any residual water removed.

In general, avoid performing readings with the fan running and workers inside an AHU (e.g., only to test for output reduction caused by air cooling). Tests of this nature should be instrumented and monitored from outside the equipment.

Lamp Breakage

If workers break a lamp, they should warn all other workers to exit the HVAC equipment area. Panels or doors should be left open and any additional lamp chamber access points should also be opened. Do not turn air-handling unit fans back on. After 15 min, workers may reenter the HVAC equipment to begin lamp clean-up.

If a lamp breaks in a worker's hand, the worker should not exit the HVAC equipment with the broken lamp. The worker should carefully set the broken lamp down, and then exit the space. When possible, try not to set the broken lamp in any standing condensate water. Follow standard ventilation and reentry procedures.

Cleanup requires special care because of mercury drop proliferation and should be performed by trained workers. As a minimum, workers should wear cut-resistant gloves, as well as safety glasses to protect eyes from glass fragments. Large bulb pieces should be carefully picked up and placed in an impervious bag. HEPA-vacuum the remaining particles, or use other means to avoid dust generation.

CHAPTER 63

SMART BUILDING SYSTEMS

Automated Fault Detection and Diagnostics 63.1
Sensing and Actuating Systems 63.7
Smart Grid Basics 63.9

SMART building systems are building components that exhibit characteristics analogous to human intelligence. These characteristics include drawing conclusions from data or analyses of data (rather than simply generating more data or plots of data), interpreting information or data to reach new conclusions, and making decisions and/or taking action autonomously without being explicitly instructed or programmed to take the specific action. These capabilities are usually associated with software, but they can also be possessed by hardware with embedded software code, or firmware. The line between systems that are "smart" and "not smart" is blurry, and, for purposes of this chapter, does not need to be absolutely defined. The purpose of this chapter is to introduce readers to emerging technologies that possess some of these smart characteristics.

Smart technologies offer opportunities to reduce energy use and cost while improving the performance of HVAC systems to provide better indoor environmental quality (IEQ). This chapter covers smart systems and technologies in the fields of automated fault detection and diagnostics, sensors and actuators, and the emerging modernized electric power grid and its relationship to buildings and facilities.

1. AUTOMATED FAULT DETECTION AND DIAGNOSTICS

Many buildings today use sophisticated building automation systems (BASs) to manage a wide and varied range of building systems. Although the capabilities of BASs have increased over time, many buildings still are not properly commissioned, operated, or maintained, which leads to inefficient operation, excess expenditures on energy, poor indoor conditions at times, and reduced lifetimes for equipment. These operation problems cause an estimated 15 to 30% of unnecessary energy use in commercial buildings (Katipamula and Brambley 2005a, 2005b). Much of this excess consumption could be prevented with widespread adoption of **automated fault detection and diagnostics (AFDD)**. In the long run, automation even offers the potential for automatically correcting problems by reconfiguring controls or changing control algorithms dynamically (Brambley and Katipamula 2005; Fernandez et al. 2009a; Katipamula and Brambley 2007; Katipamula et al. 2003a).

AFDD is an automatic process by which faulty operation, degraded performance, and failed components are detected and understood. The primary objective is early detection of faults and diagnosis of their causes, enabling correction of the faults before additional damage to the system, loss of service, or excessive energy use and cost result. This is accomplished by continuously monitoring the operations of a system, using AFDD processes to detect and diagnose abnormal conditions and the faults associated with them, then evaluating the significance of the detected faults and deciding how to respond. For example, the temperature of the supply air provided by an air-handling unit (AHU) might be observed to be chronically higher than its set point during hot weather. This conclusion might be drawn by a trained analyst visually inspecting a time series plot of the supply air temperature. Alternatively, a computer algorithm could process these data continuously, reach this same conclusion, and report the condition to operators or interact directly with a computer-based maintenance management system (CMMS) to automatically schedule maintenance or repair services.

Automated diagnostics generally goes a step further than simply detecting for out-of-bounds conditions. In this air-handler example, an AFDD system that constantly monitors the temperature and humidity of the outdoor, return, mixed, and supply air, as well as the status of the supply fan, hot-water valve, and chilled-water valve of the air handler, might conclude that the outdoor-air damper is stuck fully open. As a result, during hot weather, too much hot and humid outdoor air is brought into the unit, increasing the mechanical cooling required and often exceeding the capacity of the mechanical cooling system. As a result, the supply air temperature is chronically high. This is an example of how an AFDD system can detect and diagnose this fault.

Over the past two decades, fault detection and diagnostics (FDD) has been an active area of research among the buildings and HVAC&R research communities. Isermann (1984), Katipamula and Brambley (2005a, 2005b), and Rossi and Braun (1997) described an operations and maintenance (O&M) process using AFDD that can be viewed as having four distinct functional processes, as shown in Figure 1. With only a few exceptions, most AFDD systems for building applications existing today lack the evaluation process (Katipamula and Brambley 2005a, 2005b). Automated correction after detection and diagnostics has been another active area of research in the past decade (Brambley and Katipamula 2005; Fernandez et al. 2009a; Katipamula and Brambley 2007; Katipamula et al. 2003a, 2003b).

As shown in Figure 1, the first functional step of an AFDD process is to monitor the building systems and detect abnormal (faulty) conditions. This step is generally referred to as the **fault detection**

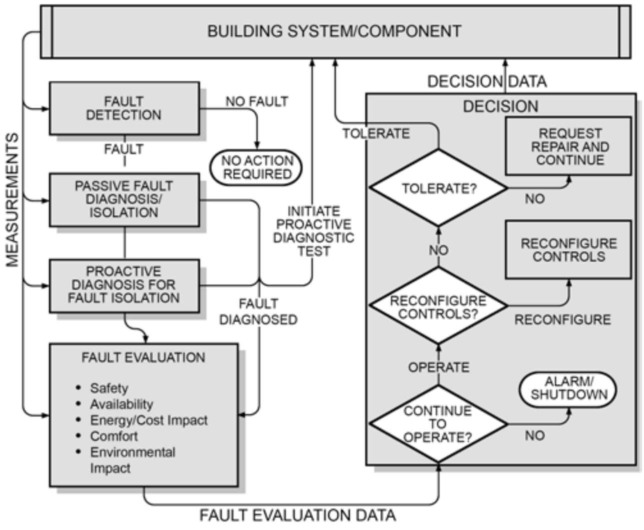

Fig. 1 Generic Process for Using AFDD in Ongoing Operation and Maintenance of Building Systems
Adapted from Katipamula and Brambley (2005a)

The preparation of this chapter is assigned to TC 7.5, Smart Building Systems.

phase. If an abnormal condition is detected, then the **fault diagnosis** process identifies the cause. If the fault cannot be diagnosed using passive diagnostic techniques, proactive diagnostics techniques may be required to isolate the fault (Katipamula et al. 2003a). Following diagnosis, **fault evaluation** assesses the impact (energy, cost, and availability) on system performance. Finally, a decision is made on how to react to the fault. In most cases, detection of faults is easier than diagnosing the cause or evaluating the effects of the fault. Detailed descriptions of the four processes are provided in Katipamula and Brambley (2005a, 2005b) and Katipamula et al. (2003a).

Applications of AFDD in Buildings

AFDD has been successfully applied to critical systems such as aerospace applications, nuclear power plants, automobiles, and process controls, in which early identification of malfunctions could prevent loss of life, environmental damage, system failure, and/or damage to equipment. In these applications, AFDD **sensitivity**, the lowest fault severity level required to trigger the correct detection and diagnosis of a fault, is a vital feature; **false-alarm rate** is the rate at which faults are incorrectly indicated when no fault has actually occurred. A high false-alarm rate could result in significant economic loss associated with investigation of nonexistent faults or unnecessary stoppage of equipment operation.

The ability to detect faults in HVAC&R systems has existed for some time, and has been used primarily to protect expensive equipment from catastrophic failure, ensure safety, and provide alarms when a measured variable goes outside its acceptable operating range. In recent years, the motivation for development and use of AFDD has expanded to include expectations of improved energy efficiency and indoor air quality (IAQ), as well as reduced unscheduled equipment downtime (Braun 1999). Developers expect that AFDD will someday be applied ubiquitously, leading to prolonged equipment life for everything from large equipment (e.g., chillers) to small components (e.g., individual actuators).

The need for AFDD capabilities has been established by surveys, site measurements, and commissioning assessments that have documented a wide variety of operational faults in common HVAC&R equipment and systems.

AFDD shows promise in three areas of building engineering: (1) commissioning, (2) operation, and (3) maintenance.

Commissioning of existing buildings involves, in part, ensuring that systems are installed correctly and that they operate properly. Faults found during commissioning include installation errors (e.g., fans installed backward), incorrectly sized equipment, and improperly implemented controls (e.g., schedules, set points, algorithms). Most commissioning actions that discover these faults, which include visual inspections and functional testing, are performed manually. Data are collected during some tests using automated data loggers, and analysis might be done with computers, but the process of interpreting the data and evaluating results is performed manually. AFDD methods could automate much of the functional testing and interpretation of test results, ensuring completeness of testing, consistency in methods, records of all data and processing, increased cost effectiveness, and the ability to continuously or periodically repeat the tests throughout the life of the facility (Katipamula et al. 2003a; PECI and Battelle 2003). AFDD methods applied during initial building start-up differ from those applied later in a building lifetime. At start-up, no historical data are available, whereas later in the life cycle, data from earlier operation can be used. Selection of methods must consider these differences; however, automated functional testing is likely to involve short-term data collection, whether performed during initial building commissioning or during routine operation later in the building's lifetime, and therefore, the same methods can be used regardless of when the functional tests are performed. Such a short time period is generally required for functional testing to eliminate the possibility that the system being tested changes (e.g., performance degrades) during the test itself. Besides use in functional testing, AFDD methods could be used to verify the proper installation of equipment without requiring visual inspection. Labor intensity could be minimized by only performing visual inspections to confirm installation problems after they have been detected automatically.

During **building operation**, AFDD tools can detect and diagnose performance degradation and faults, many of which go undetected for weeks or months in most commercial buildings. Many building performance problems are automatically compensated by controllers so occupants experience no discomfort, but energy consumption and operating costs often increase. For example, when the capacity of a packaged rooftop air conditioner decreases because of refrigerant loss, the unit runs longer to meet the load, increasing energy use and costs, and occupants experience no discomfort (until design conditions are approached). AFDD tools can detect these, as well as more obvious, faults.

AFDD tools not only detect faults and alert building operation staff to them, but also identify causes of faults so that **maintenance** efforts can be targeted, ultimately lowering maintenance costs and improving operation. By detecting performance degradation rather than just complete failure of physical components, AFDD tools can also help prevent catastrophic failures by alerting building operation and maintenance staff to impending failures before failure occurs. This condition-based maintenance allows convenient scheduling of maintenance, reduced downtime from unexpected faults and failures, and more efficient use of maintenance staff time.

AFDD Methods

AFDD tools use many different methods for detecting faults and subsequently isolating or diagnosing their causes. Table 1 lists acronyms that may be encountered in AFDD technical publications. Note that they are not unique to AFDD.

Figure 2 shows a categorization of these methods (Katipamula and Brambley 2005a), in which fault detection and diagnostic methods are organized into three primary categories based on (1) quantitative models, (2) qualitative models, and (3) process history. Over 190 AFDD studies associated with building systems have been published (Kim and Katipamula 2018), with 62% classified as process history based, 26% qualitative model based, and 12% quantitative model based.

Quantitative model methods use quantitative models of the underlying equipment, relationships between types of equipment, and processes occurring in the equipment and its components. Sets of quantitative mathematical relationships capture the underlying physics of the processes. The quantitative results from applying the models to actual driving conditions represent baseline performance without faults. Differences between measured performance and the baseline performance from the models under identical driving conditions, known as **residuals**, are used to detect the occurrence of faults. Quantitative models can be based on detailed fundamental physical principles and engineering relationships or on simplified models representing the physical processes. Analyses of residuals can also be used to distinguish among possible causes of a fault to provide a fault diagnosis. Quantitative model-based methods are applicable to information-rich systems, where satisfactory models can be built in an affordable way and sufficient sensors are available to provide the data that are required. Methods described by Castro (2002), Dexter and Ngo (2001), Haves and Norford (1997), Li and Braun (2007a, 2007b, 2007c, 2007d, 2009a), Norford et al. (2002), Reddy (2007a), Seem and House (2009), Shaw et al. (2002), and Siegel and Wray (2002) fall into this category.

Qualitative model methods include qualitative physics-based methods and rule-based methods. Qualitative-physics-based methods express the underlying physical relationships (equations) as qualita-

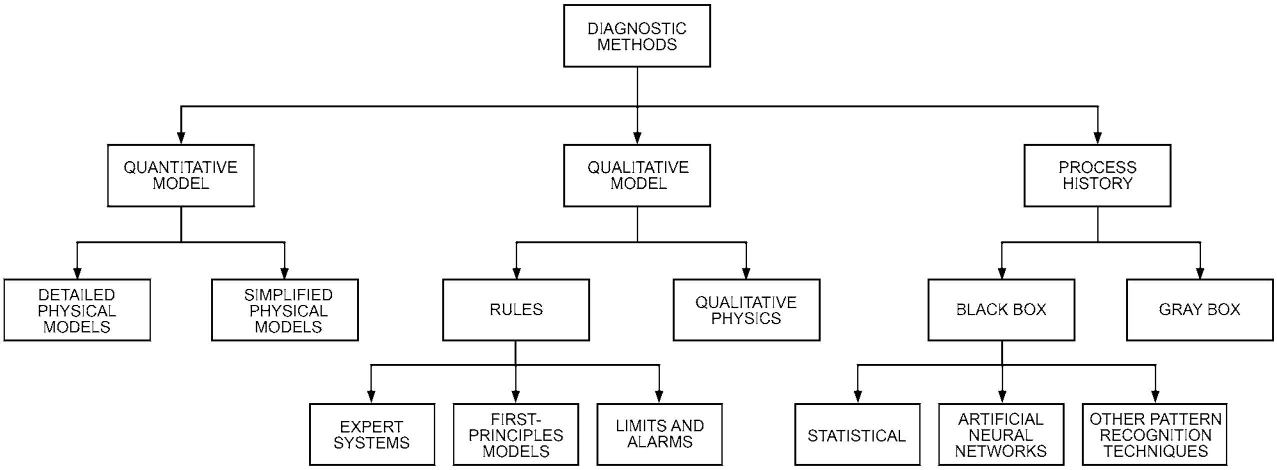

Fig. 2 Classification Scheme for AFDD

Table 1 AFDD Acronyms

AFFD	Automated fault detection and diagnostics
ANN	Artificial neural network
AR	Autoregressive
ARMA	Autoregressive moving average
BPNN	Back-propagation neural network
CUSUM	Cumulative sum
GRNN	General regression neural network
JAA	Joint angle analysis
PCA	Principal component analysis
PID	Proportional integral and derivative
RNN	Recurrent neural network
SPC	Statistical process control
SAX	Symbolic aggregate approximation
SVM	Support vector machine

tive expressions (De Kleer and Brown 1984) but have seen limited use in AFDD for HVAC&R. Rule-based methods have been applied widely as the basis for AFDD for HVAC&R, using rules based on the rules of thumb used by expert practitioners in a field (**expert systems**); rules derived from knowledge of the fundamental physical processes occurring in HVAC&R components, equipment, and systems (i.e., the equations governing the physical processes); and alarms based simply on conditions exceeding prescribed upper and/or lower bounds for acceptable values of variables during operation (e.g., an alarm triggered by duct static pressure exceeding its upper limit). The techniques presented by Dexter and Ngo (2001), Gerasenko (2002), House et al. (2001, 2003), and Lo et al. (2007) are some examples.

Process-history-based methods depend on the availability of a large amount of historical data. These methods include **black-box** (input-output) models derived from the data and **gray-box** models that use first principles or engineering knowledge to specify the mathematical form of terms in the model but for which parameters (e.g., coefficients in the model) are determined from process data. Of the 123 process-history-based studies, 72% are black-box models and the remainder are gray-box (Kim and Katipamula 2018). Black-box methods include statistically derived models (e.g., regression), artificial neural networks (ANNs), and pattern-recognition techniques. Of the 110 black-box studies, 63% are statistical models using polynomial regression, logical regression, principal component analysis (PCA), autoregression (AR), and partial least squares methods (Kim and Katipamula 2018). Approaches based on process history primarily apply to large systems such as whole buildings, where it is difficult to construct an analytical model that captures all important physical behaviors adequately in a cost-effective way, but existing instrumentation yields sufficient data for analysis. Methods used by Bailey (1998), Choi et al. (2004), Li and Braun (2003), Reddy et al. (2003), Riemer et al. (2002), Rossi (2004), and Rossi and Braun (1997) can be classified in this category.

Kim and Katipamula (2018) provide an updated review of AFDD studies published since 2004. Table 2 lists new studies by category, as mentioned in the article.

For further details of each of the basic modeling techniques and AFDD methods, any constraints that would limit the application of each technique, and to assess strengths and weaknesses of each technique for application to fault detection and diagnostics, see Katipamula and Brambley (2005a, 2005b) and Kim and Katipamula (2018). The latter source also includes an analysis of AFDD methods by building system in addition to the review by AFDD method discussed above. Table 3 classifies the studies after 2004 by building component type.

Benefits of Detecting and Diagnosing Equipment Faults

The benefits of AFDD have been validated in part by studies that documented common HVAC equipment operating faults and their effects (Breuker and Braun 1998a; Breuker et al. 2000; Comstock et al. 2002; House et al. 2001, 2003; Jacobs 2003; Katipamula et al. 1999; Kim 2013; Lee and Lu 2010; O'Neill et al. 2014; Prakash 2006; Proctor 2004; Rossi 2004; Seem et al. 1999; Sutharssan et al. 2012; Wichman and Braun 2009). Faults examined included economizers not operating properly, incorrect refrigerant charges, condenser and filter fouling, faulty sensors, electrical problems, chillers with a variety of faults, air-handling units with too little or too much outdoor-air ventilation, stuck outdoor-air dampers, and other problems.

Studies of the benefits of HVAC fault detection and correction have found positive savings. Rossi's (2004) fault survey of unitary equipment used measurements by service technicians to compute four performance indices from which unit efficiency was estimated and savings potential calculated. Half of the equipment was estimated to have a savings potential of at least $170/year, and 33% had a potential of at least $225/year. (Note that costs were current as of 2004.) Li and Braun (2007e) investigated the following factors that affect the economics of air conditioning: (1) energy efficiency ratio (EER) or coefficient of performance (COP), which quantifies the energy performance of the refrigeration cycle (lower scores equal greater operating costs); (2) cooling capacity Q_{cap}, the degradation of which can affect comfort in the conditioned space, increase com-

pressor run times, and reduce equipment lifetimes; and (3) sensible heat ratio (SHR), which can decrease with many faults, leading to higher total equipment load and greater energy consumption for the same sensible building load. All three factors can be combined in an overall **economic performance degradation index (EPDI)**, which is defined as the net increase in the total operating costs (Li and Braun 2007e) and is given by

$$\text{EPDI} = \frac{1}{1-r_{\Delta \text{SHR}}}\left(\frac{1}{1-r_{\Delta \text{COP}}} \times \frac{\bar{C}_{utility}}{\bar{C}_{utility}+\bar{C}_{equip}} + \frac{1}{1-r_{\Delta cap}} \times \frac{r_{equip}\bar{C}_{equip}}{\bar{C}_{utility}+\bar{C}_{equip}}\right) - 1 \quad (1)$$

where

$r_{\Delta \text{SHR}} = \frac{(\text{SHR}_{normal} - \text{SHR})}{\text{SHR}_{normal}} = 1 - r_{\text{SHR}}$ = degradation ratio of SHR

$r_{\Delta \text{COP}} = \frac{(\text{COP}_{normal} - \text{COP})}{\text{COP}_{normal}} = 1 - r_{\text{COP}}$ = degradation ratio of COP

$r_{\Delta cap} = \frac{(Q_{cap,\,normal} - Q_{cap})}{Q_{cap,\,normal}} = 1 - r_{cap}$ = degradation ratio of capacity

r_{SHR} = SHR/SHR$_{normal}$ = SHR ratio

r_{COP} = COP/COP$_{normal}$ = COP ratio

r_{cap} = $Q_{cap}/Q_{cap,\,normal}$ = capacity ratio

SHR = actual sensible heat ratio

COP = average actual coefficient of performance

Q_{cap} = average actual equipment cooling capacity

$\bar{C}_{equip}$ = average equipment price, \$/kWh

$\bar{C}_{utility}$ = $\bar{C}_{elec}\bar{W}_{normal}$ = average normal cost of operation, \$/h

$\bar{C}_{elec}$ = average electricity price, \$/kWh

$\bar{W}_{normal}$ = power consumption of unit (including both compressors and fans)

The subscript "normal" on a variable indicates that the variable corresponds to the fault-free operating condition.

The total cost penalty ΔOC of not correcting faults, which equals the cost savings from servicing the faults, can be determined from the EPDI from the relation

$$\Delta \text{OC} = \text{EPDI} \times \text{OC}_{normal} = \text{EPDI}/(1 + \text{EPDI}) \times \text{OC} \quad (2)$$

where OC is the total cost of operation before servicing to correct faults, and OC$_{normal}$ is the total cost of operation expected after correction of the faults (i.e., the cost of fault-free operation).

Using this overall economic performance degradation index, Li and Braun (2007c) estimated the operating cost savings associated with the application of AFDD for rooftop air conditioners in California. Monitoring of 20 field sites, which included small retail, play areas for fast-food restaurants, and modular classrooms in coastal and inland California, for three years found operating cost savings from \$5 to \$51/kW·yr, the precise savings depending on the specific location and application.

AFDD has the potential to reduce service costs as well as operating costs. Li and Braun (2007b) also developed an economic evaluation procedure to estimate service cost savings, which includes savings from reduced preventive maintenance inspections, fault prevention, lower-cost FDD, better scheduling of multiple service activities, and shifting service to the low season. Based on the 20 monitored field sites, \$30/kW·yr (around 70% of the original service costs) can be saved if the AFDD technology in Li and Braun (2007a) could be fully applied. To fully apply the AFDD technology, hardware and software costs were estimated at \$250 to \$600 for individual units, and \$700 to \$1500 for a site with four units. Payback periods were less than one year, with savings in operating costs of \$5 to \$50/kW·yr and an estimated 70% reduction in service costs. (Note that costs were current as of 2007.)

Criteria for Evaluating AFDD Methods

AFDD sensitivity and false-alarm rate are important criteria for evaluating AFDD methods not only for critical systems but also for HVAC&R systems. However, the trade-offs between the savings that could be achieved with early detection of a fault and the cost associated with a false alarm are not easily quantified. The sensitivity of AFDD for HVAC&R applications has been evaluated in terms of loss of efficiency and loss of capacity of the monitored system (Breuker and Braun 1998a, 1998b; Comstock et al. 2001; Reddy 2007b). Many early building automation systems provided an unmanageably large number of alarms, often leading to the alarms either being ignored or turned off. This experience suggests that overly sensitive AFDD methods that provide many false alarms could lead to frustration by users and be disabled by O&M staff. AFFD tools should, therefore, minimize the occurrence of false alarms.

Sensitivity and false-alarm rate are useful for quantifying performance of an AFDD tool; however, AFDD tools and the methods underlying them have numerous other characteristics that affect their performance and the cost of implementation. Dexter and Pakanen (2001) identified the following characteristics that should be considered when selecting an AFDD method or tool: (1) sensors and control signals used, (2) design data used, (3) training data required, and (4) user-selected parameters. Generally, it is desirable to limit each of these.

Types of AFDD Tools

The prevalence of faults in HVAC&R systems, as evidenced by the findings of studies cited previously, and the expectation of performance gains achievable by detecting and diagnosing faults (e.g., improved energy efficiency, occupant comfort, indoor air quality, reduced unscheduled equipment downtime), have spurred the development of a wide range of AFDD algorithms. AFDD tools are created by implementing these algorithms in software. The level of complexity of an AFDD tool rises with the number of components and systems analyzed; however, addressing a broader range of components and systems also generally improves the richness of the types of faults that can be discovered. Some of the types of AFDD tools that have been developed for HVAC&R applications are described here.

Portable Service Tools. Portable service tools are generally applied while a technician is servicing equipment and, therefore, collect data over only short periods of time (e.g., minutes or hours rather than days, weeks, or months), which usually correspond to a steady-state system operating conditions. These products are used by service technicians, commissioning agents, and others to evaluate system performance to guide selection and implementation of corrective measures to address faults. The sensors themselves may be temporarily or permanently installed. If permanently installed, a portable service tool is connected to them during equipment or system servicing. Common measurements include dry-bulb air temperature, air relative humidity, refrigerant temperatures measured on the surfaces of tubes, and refrigerant pressures. These portable tools can perform data acquisition and analysis, providing results on site during servicing. With this class of diagnostic tool, data are collected usually at steady-state operating conditions for a relatively small period of time (e.g., minutes).

An example portable AFDD service tool is one for rooftop packaged air-conditioners. For systems that use direct-expansion vapor compression, diagnostic tools use several performance indicators (e.g., superheat, subcooling, airflow rate) that have corresponding performance expectations based on system characteristics and operating conditions. Patterns of changes in these parameters compared to expected values during proper operation are used to identify occurrence of specific faults. Data and diagnostic messages are then provided to the user to guide the servicing or repair of the system. The diagnostic tool can then be used to validate that the repair has been performed properly and corrected the fault.

Controller-Embedded AFDD. Control-embedded AFDD software code resides in local device- (or application-) specific controllers, where it can be integrated tightly with control logic and have access to data at the sampling interval of the controller. Access to these higher-frequency data may enable the detection of faults, such as unstable control loops, that might be difficult to detect using data collected at longer data-trending intervals. Embedded AFDD tools can reduce network traffic by executing the AFDD code in local controllers and propagating only key parameters or results to higher levels of a BAS architecture for additional analysis, data visualization, and reporting. Embedding AFDD software in controllers can also facilitate integration of the outputs with the alarming capabilities of the building automation system. Computational and memory limits may place practical constraints on the complexity and size of the code embedded in local controllers.

AFDD Software Deployed on Networked Workstations

AFDD software deployed on a BAS-connected workstation uses data collected by the BAS and, in some cases, data from other sensors (e.g., a separate, non-BAS wireless sensor system). The software usually resides on a computer that is part of a BAS or has access to stored data from a BAS. The BAS may serve one or several buildings (e.g., a campus). Generally, workstation-based software uses data collected or recorded at sampling intervals between one and five minutes. Data acquisition and analysis may be near real time or periodic over longer time intervals (e.g., daily) and depend on the specific application. Because the AFDD is implemented on a computer having significant computational resources, analytical methods and historical data can be processed with more complex algorithms than possible with handheld devices and local controllers. A key strength of workstation AFDD software is its ability to detect system-level faults arising from interactions among components. For example, a rogue variable-air-volume (VAV) box controller may cause air-handling unit (AHU) fan power to exceed an expected level during an unoccupied period. In turn, if the VAV box controller has embedded AFDD, the workstation application will be able to report not only the fault at the AHU level, but also the underlying fault at the VAV box. Workstation AFDD software can require extensive effort for configuration before use. In particular, mapping points from the BAS to the AFDD tool can be cumbersome and depends on the number of measurement and control points used by the AFDD tool.

Web-Based AFDD Software. Web-based AFDD software is an extension of controller-embedded and workstation-based capabilities. It may obtain data from the BAS, independent data acquisition systems, and controller-embedded AFDD software, but uses the Internet to remotely acquire and display results. This feature allows gathering data for many buildings and supports enterprise-wide reporting. AFDD processing and analysis may be done locally at the building, with only results reported, or remotely. Updating software remotely is another advantage of web-based AFDD. A significant challenge for web-based AFDD is Internet security, which may require additional hardware and software administration, even if the access is periodic and not continuous.

Current State of AFDD in Buildings

During the 1990s, research and development on AFDD methods for HVAC&R systems grew significantly, yet few commercial AFDD products exist today. AFDD products available commercially are generally very specialized or are not fully automated. Reasons for the lack of widespread availability and use of AFDD systems may include lack of demand by the building O&M community, possibly as a result of insufficient information on the improvements and cost savings possible from AFDD; lack of adequate sensors installed on building systems; the higher cost of reliable sensors; high perceived cost-to-benefit ratio for AFDD; lack of acceptable benchmarks to quantify the potential benefits; the difficulty of accessing real-time data for third-party AFDD software; and few FDD capabilities built directly into building automation systems.

Furthermore, AFDD methods have generally been tested only in laboratories or special test environments (Breuker 1997; Breuker et al. 2000; Castro et al. 2003; Gomez et al. 1996; Li and Braun 2003). Some notable exceptions are reported by Braun et al. (2003), Castro et al. (2003), Dexter and Pakanen (2001), Downey and Proctor (2002), and Katipamula et al. (2003b). Many tools have not been adequately characterized with respect to detection sensitivity and the rate of occurrence of false alarms in real buildings.

Most AFDD methods developed to date work well when a single dominant fault is present in a system, but when multiple faults occur simultaneously or are already present when AFDD is initially applied, many of the methods fail to properly detect or diagnose the causes of the faults. Research in the last decade or so has begun to address detection and diagnosis of multiple simultaneous faults. For example, Braun et al. (2003) extended the previous work by Breuker and Braun (1998b) and Rossi and Braun (1997) to diagnose multiple simultaneous faults. This work has been extended by Li and Braun (2004a, 2004b, 2007a, 2007b, 2007c, 2007d, 2009a, 2009b, 2009c).

As with other software, AFDD tools require installation and, in some cases, input of configuration data before they are ready for use with building systems. Setup can include the installation of sensors dedicated to the AFDD tool or not present in existing monitoring and control systems. Configuration may require specifying the type and possibly even the model of equipment on which the AFDD will operate. It can also include specifying the type of or basis for control (e.g., air-side economizers may be based on dry-bulb temperature or enthalpy; see the section on Air Handler Sequencing and Economizer Cooling in Chapter 43). Furthermore, fault detection and diagnosis must be followed by evaluation of the fault and decision making regarding whether, when, and how to correct the faults identified.

Future for Automated Fault Detection and Diagnostics

The commercial availability of AFDD tools is increasing, though somewhat slowly, demonstrating some recognition of their value. As market penetration and experience in use increase, the need for improvements will grow accordingly. Key technical issues still to be completely addressed include the following (Katipamula and Brambley 2005b):

- Eliminating the need to handcraft and configure AFDD systems
- Automatic generation of AFDD systems
- Identifying the best AFDD method for each HVAC&R application
- Developing decision-support tools for using AFDD in operation and maintenance
- Developing prognostic tools to transform HVAC&R maintenance from corrective and preventive to predictive, condition-based maintenance
- Lowering the cost of obtaining data for AFDD and O&M support

Some AFDD tools require users to implement data collection from building automation systems, which is often difficult, costly, and beyond the capabilities of many end users. Other tools require the input of values or selections for many configuration parameters (e.g., the specific method used to control an economizer). Solutions for these problems include (1) developing AFDD tools that include databases sufficient to cover many equipment models, (2) delivering AFDD as part of equipment control packages, and (3) developing methods for automatically generating AFDD tools. The first approach was introduced in a hand tool for air-conditioning service providers more than a decade ago. The second approach of embedding AFDD onboard equipment controls has started to be used by some manufacturers of equipment and equipment controls (e.g., chillers). The third approach, involving rapid automatic generation of AFDD, requires research before it emerges in products.

Progress in developing low-cost sensors is being made, although market penetration is still relatively low in the building industry. Joshi et al. (2015a, 2015b, 2015c) and Noh et al. (2015) describe integrated wireless sensors for temperature, humidity, and light level that are formed using inkjet-printed flexible substrates. Development of autonomous driving vehicles should aid in the development, availability, and cost reduction of sensors that have crossover potential to the building industry.

Use of open communication standards for BAS (e.g., BACnet®) is increasing, and use of Internet and intranet technologies is pervasive. These developments make integration of third-party software with AFDD features that use BAS data easier, lowering the cost-to-benefit ratio of deploying AFDD systems. To benefit from these changes, facility managers, owners, operators, and energy service providers need the capabilities and resources to better manage this information and, as a result, their buildings and facilities.

2. SENSING AND ACTUATING SYSTEMS

Sensors

The typical sensors used in smart building systems are not far different from those used in all buildings. Smart building systems rely on sensors to measure quantities such as temperature, humidity, pressure, occupancy, electric power and energy use, fossil fuel energy use, light levels, air speeds, carbon dioxide, and electric harmonics. See Chapter 37 of the 2017 *ASHRAE Handbook—Fundamentals* for in-depth discussion of measurement techniques for such quantities.

Traditional sensors are connected to control systems via twisted pairs of wires, which conduct voltage or current signals. Sensor calibration (i.e., mapping from electronic signals back to measured physical quantities) can be complicated by nonlinear and/or time-varying functions, which are often implemented in software code by field engineers. The calibration process is time consuming and error prone. In practice, sensors are subject to various defects; therefore, sensor data should not be used without validation. Under certain conditions, multiple physical sensors of different kinds should be used for reliable measure of a physical quantity. Truly smart buildings require pervasive use of smart sensors that possess intelligence and memory to identify, recalibrate, and repair defective sensors.

The intelligence of smart sensors can be described in four categories, discussed in the following paragraphs.

Local Intelligence. In local intelligence, the signal and data-processing capability reside at the local sensor node. For example, some fire detectors are equipped with multiple physical sensors to reduce false alarms and increase reliability, using complicated algorithms. Other sensors may be equipped with flash memory to store historical data. Another type of local intelligence is the ability to compute information based on raw sensor measurements. For instance, a photoresistor can be used to measure luminance, but the mapping from voltage across the resistor in the meter to luminance is not linear. A smart sensor is equipped with circuitry that calculates the desired quantity onboard, either through analog or digital approaches.

Networking Intelligence. Sensors with networking intelligence allow bidirectional communications via scalable, secure, and robust computer networks. Traditional sensors are connected to ports on panels via twisted pairs of wires. While implementing control sequences, engineers must embed the port number and detailed sensor characteristics to calculate the physical quantity of measurement from electronic signals. In practice, there is usually only one quantity that is measured by each sensor, and the direction of information flow is always in one direction from the sensor to control panels. As shown in Figure 3, smart sensors support bidirectional communications, are individually addressable, and form scalable, reliable, and robust networks. Networked sensors can be integrated by either wired or wireless approaches:

- *Wired sensors.* Some sensors are equipped with network ports and can be plugged directly into building control networks. They may support protocols including BACnet (ASHRAE *Standard* 135), LonWorks® (ISO 2012), Modbus® (Modbus 2012), etc.
- *Wireless sensors.* Wireless protocols, such as ZigBee® (ZigBee Alliance 2008), Z-Wave® (Z-Wave® Alliance 2014), and WirelessHART® (IEC *Standard* 62591) are designed for low-energy, low-data-rate sensors. Wi-Fi (IEEE *Standard* 802.11), WiMax (IEEE *Standard* 802.16), Bluetooth® (Bluetooth SIG 2013), and GSM cellular protocols (Eberspächer et al. 2009) are also found in different types of sensors.

Data Object Intelligence. In this approach, structured data and commands are encapsulated within sensor data objects. Traditional sensors do not have computation capabilities to process high-level commands from control systems. For sensors with data object intelligence, sensor vendors ship sensors with detailed data sheets and sophisticated instructions on diagnostics. It is nontrivial work for field engineers to understand the detailed differences between hundreds of sensors and to implement proper sensor-handling logic in control systems; this type of intelligence automates those tasks. BACnet (ASHRAE *Standard* 135) and IEEE *Standard* 1451 are representative standards that support object models:

- *BACnet*. This protocol supports data objects in traditional system architectures. In addition to reading from sensors, a controller can send commands/messages to sensors. Note that commands are not sent to physical sensors, where information flow is always from sensor to panel. For example, the panel can receive a "who-is" query from other BACnet devices and respond accordingly to describe its attached sensors.
- *IEEE* Standard *1451.* This smart sensor standard has been adopted by the automobile industry for test data acquisition. It features **transducer electronic data sheets (TEDS)**, which make

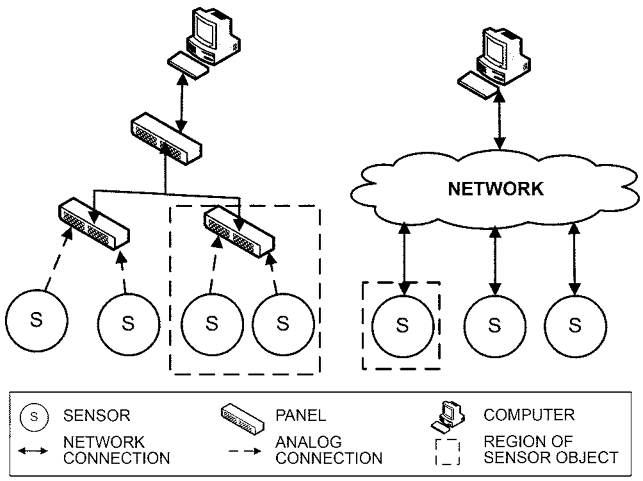

Fig. 3 Traditional Twisted-Pair Wired Sensing Architecture Transmitting Analog Signals (Left) versus Computer Network Architecture Capable of Exchanging Digital Information (Right)

plug-and-play operation feasible. Because sensor data, including calibration parameters, are embedded in TEDS, calibration can be conducted automatically. Numerous IEEE *Standard* 1451 vendors provide smart sensors for HVAC systems. However, the technology has not yet been widely adopted by the building industry, partially because of its high device cost.

Web Automation Intelligence. With this approach, sensor data objects are exposed as web services and integrated with web applications. Today, many sensors are connected to the Internet and expose web services via standard or proprietary application programming interfaces (APIs). These devices are often referred as the "Internet of things," or IoT. For example, a personal weather station can measure and submit air quality data to the cloud, where the data are shared with the world through the Internet. Various vendors collect building performance data from customer sites via the Internet, process the raw data in the cloud, and expose results of business analysis to the web for applications of weather monitoring, lighting control, remote FDD, and IEQ monitoring. Some web data object standards including XML standards, such as Sensor Model Language (SensorML) (OGC® *Standard* 12-000), Transducer Markup Language—TransducerML (retired) (OGC® *Standard* 06-010r6), and numerous OASIS standards for smart grid and security.

The four levels of intelligence for smart sensors are interdependent. Local intelligence is the foundation for the entire architecture. Networking intelligence enables bidirectional data exchange and shields users from the detailed data transportation mechanism. Data object intelligence offers an abstracted and concise sensor data interface for effective software integration and serves as the enabling technology for plug-and-play sensors. As the result, engineers are liberated from tedious work such as manual sensor calibration. The web automation intelligence is the most advanced form of "smart" for sensors. Propelled by increasing applications in cloud computing, smart grid, and mobile devices, smart sensors with web automation intelligence could be widely used to enable smart building systems.

Actuators

The typical actuators used in smart buildings are similar to those used in all buildings. Smart buildings rely on actuators to, among other tasks, modify air flows through damper control and other means, modify chilled-water flow, adjust steam flows, shut off electrical devices, and adjust shading devices. See Chapter 7 of the 2017 *ASHRAE Handbook—Fundamentals* for in-depth discussion of control actuation approaches for building systems.

A smart actuator is one that can correct itself and is possibly self powered. It can also have some sort of display showing the status of the actuator, either on the actuator itself, or on monitoring software having data sent to it directly from the actuator.

Smart actuators are relatively new and are still in the research phase. Not many commercially available smart actuator technologies are currently on the market. Research is ongoing to develop self-correcting HVAC actuators that detect soft faults (e.g., problems in computer software, incorrect set points) and automatically correct to the proper operating condition, as well as to develop ways to automatically correct hard faults (e.g., bent damper linkages) by adjusting actuator response to compensate for the faults (Fernandez et al. 2009a; Siemens VAI 2008). Other efforts have pursued developing self-powered actuators that communicate using wireless mechanisms. These devices can control valves and dampers and are powered through harvested thermal or vibrational energy. Because actuators require more energy than sensors, power management is critical in such devices to ensure that they function as desired.

As smart actuators mature, the HVAC field could benefit from this new technology through potential energy savings (e.g., preventing energy waste from faulty actuators and by using self-powered actuators) and through potential maintenance cost savings (e.g., from automated calibration).

Sensor and Actuator Integration

To achieve truly smart buildings, smart sensors and actuators must take advantage of all data obtained throughout the building. Communication between devices is therefore critical. With the large number of sensing and actuating points, conventional sensor wiring may become impractical, especially when attempting to implement these systems on existing buildings. For these reasons, communication (via wireless means and power lines) is a vital technique to integrate smart devices to make a complete building network.

Chapter 41 provides an in-depth discussion of wireless technologies, suitable applications for wireless devices, and selection of wireless systems. For smart sensing and actuating, low-data-rate technologies are most appropriate, though radios based on IEEE *Standard* 802.11 could be used because of their large market. Although reliable communications are of paramount importance when considering wireless communications, low maintenance becomes critical when many devices are present in a building. One of the key maintenance concerns is the need to replace batteries, because many of these devices may not have convenient access to line power (or may use batteries in case of line power failure or interruptions). Protocols for low-data-rate applications attempt to minimize energy consumption of these devices by taking steps such as putting the devices to sleep when they are not actively taking measurements, performing actions, or transmitting or receiving commands. IEEE *Standard* 802.15.4 is one such protocol that specifies the physical layers and media access control of radios appropriate for low-data-rate applications. This standard forms the basis of specifications such as ZigBee (ZigBee Alliance 2008), ISA *Standard* 100.11a, WirelessHART (IEC *Standard* 62591), and proprietary protocols, such as MiWi™, which add upper layers to IEEE *Standard* 802.15.4 to increase usability.

Reliability of Wireless Communications in Buildings. Attenuation of signals by building materials and interference from other devices make long-distance signal travel difficult. To overcome these problems, different network topologies can be implemented to make the network more robust. For example, a mesh network can allow each device to transmit and receive, communicating with other devices to relay messages through the network to their intended destinations or to enable direct communication between devices without the need for central control equipment. The intelligence can, therefore, be moved down to specific portions of the building.

Wired Power Line Communications (PLC). Power line communication can also be used to reduce the cost and effort in deploying smart sensors and actuators throughout a building. In this type of communication, signals are sent over the same wires that carry alternating current (AC) electric power in a building. This approach reduces the need to run dedicated control system wiring and is especially useful in existing buildings. Some installation of wiring may still be needed to connect the sensor or actuator to the nearest electrical outlet. Modulated signals are typically sent at frequencies away from the common 50 to 60 Hz frequency of AC electricity. Bandwidth that is appropriate for streaming Internet traffic can be achieved, but noise on the lines and components of the electrical system (e.g., transformers) can make the signal unavailable in certain installations. IEEE *Standard* 1901 provides specifications for providing high-speed broadband networking over power lines using frequencies below 100 MHz. A variety of commercial protocols are available to provide a suite of products that can communicate with each other.

Physical integration of the sensors and actuators is not the final step in developing the components of a smart building; integrating the data streams seamlessly is a challenge, considering the potentially large number of devices. IEEE *Standard* 1451 provides guidance that aims to create plug-and-play devices that automatically report key operating parameters to other devices connected to them. Standards such as these will help to ease the burden in configuring sensing and actuating systems in buildings.

3. SMART GRID BASICS

This section provides the basis for understanding changes occurring in the electric grid infrastructure and the interaction of current and future buildings with the grid. Because this is a rapidly evolving topic area, readers are encouraged to seek additional information on the latest changes and future directions. For additional resources and information, refer to the U.S. Department of Energy's SmartGrid.gov (smartgrid.gov) and Energy.gov (www.energy.gov/oe/technology-development/smart-grid/smart-grid-primer-smart-grid-books) web pages.

Brief History of Electric Power Grid

In the early days of commercial electric power, direct current (DC) electricity was transmitted at the same voltage as end users (consumers) required, thus limiting the distance over which electricity could be transmitted. Direct current, however, could not easily be increased in voltage for long-distance transmission without incurring significant line losses. Different classes of loads (e.g., lighting, fixed motors, traction/railway systems) required different voltages, and so used different generators and transmission lines. This specialization of generation and transmission was inefficient for low-voltage, high-current circuits, because generators needed to be near their loads. Thus, the electric grid seemed to be developing into a distributed generation system, with large numbers of small generators located near their loads. However, as electricity use increased, it soon became apparent that using common generating plants and transmission networks for all loads yielded economies of scale that could lower costs and the overall capital investment required. This standardization of the grid also enabled more efficient use of all grid assets.

By allowing multiple generating plants to be interconnected over a wide area on a common network, the cost of electricity was reduced. The most cost-effective and efficient plants could supply electric power reliably to geographically distributed and temporally varying loads. Remote and low-cost sources of energy, such as hydroelectric power or mine-mouth coal, could be exploited to lower energy production cost.

Rapid industrialization in the early 20th century made electric power systems a critical part of the infrastructure in most industrialized nations. Interconnection of local generation plants and small distribution networks was driven by the needs of World War I, with large electric power plants built by governments to provide electricity to munitions factories. Later, these generating plants were used to supply civil loads through long-distance transmission lines. In the United States, an important part of developing the grid occurred with the passage of the Rural Electrification Act of 1936, which provided federal loans for installation of electrical distribution systems to serve rural areas of the United States. The funding was channeled through cooperative electric power companies, most of which still exist today. These member-owned cooperatives purchased power on a wholesale basis and distributed it using their own network of transmission and distribution lines. Because electricity must be produced at the exact rate at which it is consumed, the electric power grid is the largest and one of the most tightly controlled machines in the world today.

Electric Power Grid Operational Characteristics

The modern electric grid is modeled as three interconnected domains (Figure 4). The **generation system** produces electric energy. This domain contains a set of power stations and distributed energy generators (e.g., residential solar photovoltaic systems). The electricity generated is conditioned to reduce losses and is then transmitted over long distances across the **transmission system**. The transmission system typically consists of high-voltage wires that distribute electricity hundreds of miles. When needed to power loads within a region, the electricity is reconditioned (i.e., converted and/or stepped down in voltage) and distributed to customers over the **distribution system**. The distribution system is ordinarily a network of medium-voltage wires that distribute energy across a metropolitan area. The distribution system also includes electrical substations that transform the energy to the low voltages needed by customer loads and transmit it over the wires connected to the customer.

A **transmission grid** is a network of power stations, transmission lines, and substations. Electricity is usually transmitted within a grid as three-phase alternating current (AC). Single-phase AC is used only for distribution to end users, because it is not suitable for large, polyphase induction motors. In the 19th century, two-phase transmission was used but required either four wires or three wires with unequal currents. Higher-order-phase systems require more than three wires, but deliver marginal benefits.

In the United States, the transmission grid is divided into several regional operating units that manage overall electric transmission within their own territories and between regions (see Figure 5).

The capital cost of electric power stations is so high, and electric demand so variable, that it is often less expensive to import some

portion of the needed power than to generate it locally. Because nearby loads are often correlated (e.g., hot weather in the Southwestern United States might cause many people to use air conditioners simultaneously), electricity often comes from distant sources. Because of the economics of load balancing, wide-area transmission grids now span across countries and even large portions of continents. The web of interconnections between power producers and consumers ensures that power can flow, even when a few links are inoperative.

The unvarying (or slowly varying over many hours) portion of the total electric system demand is known as the **base load** and is generally served by large generation facilities (which are efficient for this purpose because of economies of scale) with low variable costs for fuel and operations. Such facilities might be nuclear, natural-gas, or coal-fired power stations or, in some locations, hydroelectric plants. Variable renewable energy sources, such as solar photovoltaics, wind, and wave power, because of their intermittency, are not considered base-load capable (unless firmed by storage) but can still add power to the grid. The remaining power demand is supplied by intermediate load-following plants and peaking-power plants, which are typically smaller, faster-responding, and higher-cost sources, such as combined-cycle or combustion turbine plants fueled by natural gas.

Subtransmission is part of an electric power transmission system that runs at relatively lower voltages. It is uneconomical to connect all distribution substations to the high main transmission voltage, because the equipment is larger and more expensive. Typically, only larger substations connect with this high voltage. The electric power is stepped down and sent to smaller substations in towns and neighborhoods. Subtransmission circuits are usually arranged in loops so that a single line failure does not cut off service to a large number of customers for more than a short time. Although subtransmission circuits are usually carried on overhead lines, buried cable is also used in urban areas.

The amount of power that can be sent over a transmission line is limited. These limits vary depending on the length of the line and can depend on the ambient temperature. For a short line, heating of conductors because of line losses sets a thermal limit. If too much current is drawn, conductors may sag too close to the ground or other obstructions (e.g., trees), or conductors and equipment may be damaged by overheating. For intermediate-length lines on the order of 100 km, the limit is set by the voltage drop in the line. For longer AC lines, system stability limits the power that can be transferred. Approximately, the power flowing over an AC line is proportional to the cosine of the phase angle of the voltage and current at the receiving and transmitting ends. This angle depends on system loading and generation, and it is undesirable for the angle to approach 90°. Very approximately, the allowable product of line length and maximum load is proportional to the square of the system voltage. Series capacitors or phase-shifting transformers are used on long lines to improve stability. High-voltage DC lines are restricted only by thermal and voltage drop limits, because the phase angle is not material to their operation.

To ensure safe and predictable operation, the components of the transmission system are controlled with generators, switches, circuit breakers, and even loads. The voltage, power, frequency, load factor, and reliability capabilities of the transmission system are designed to provide reliable, cost-effective performance for customers.

The transmission system provides for base- and peak-load capability, with safety and fault tolerance margins. The peak-load times vary by region largely because of differences in the industry mix. In very hot and very cold climates, home air-conditioning and heating loads can have a significant effect on the overall load at times. These loads are typically highest in the late afternoon in the hottest part of the year, and in mid-mornings and mid-evenings in the coldest part of the year. This variability causes the power requirements to differ by season and the time of day. Distribution system designs take the base and peak loads into consideration.

Electricity produced by the generation system has to match the energy consumed by the loads, or the system becomes unstable. The transmission system usually does not have a large storage capability to match the varying energy consumed by loads. Thus, fast-acting balancing generation units (known as spinning reserves) are connected to the transmission system and kept matched to the load to prevent overloading failures of the generation equipment.

Typical Building Load Profile

Figure 6 depicts a typical commercial building load profile in relation to the utility system load profile. The profile reflects the building's individual characteristics, including building use, occupancy and equipment schedules, equipment characteristics, and building control strategies used. In contrast, the utility system load is the aggregate of all the individual loads, including commercial facilities, but also includes residential, industrial, and public facilities. Although individual commercial facility electric loads may have the same general shape as the utility system load, they may not have an identical shape and may peak at different times given the aggregation of the many loads that make up the system load. Understanding the relationship between the load profile of an individual facility and the overall system profile provides the basis for optimizing electricity use and costs to the mutual benefit of the grid and the customer.

Utility Demand Response Strategies

Demand response is the change in electric usage by end-use customers from their normal consumption patterns in response to changes in the price of electricity over time, or to incentive payments designed to induce lower electricity use at times of high wholesale market prices or when system reliability is jeopardized (DOE 2006).

Flexible load shape attempts to achieve a load shape composed of end-use services with varying degrees of reliability, allowing the utility the flexibility to control/adjust end-use demand in accordance with supply capability. In exchange for accepting a lower level of reliability, a customer receives some financial incentive. A flexible load shape may be achieved using interruptible loads, energy management systems, or individual customer load control devices imposing service constraints.

Peak shaving reduces the amount of energy purchased from a utility company during the peak. Many businesses pay for their electricity consumption on a time-of-use basis. Peak demand charges typically apply to electricity consumed within the peak hours, whereas lesser charges apply to the remainder of the day.

Direct load control involves the utility disabling and enabling consumer end uses. A communication system between the utility and the customer transmits control instructions to a receiver and control actuator on the customer's premises that enables activation/deactivation of customer loads. Many utilities use direct load control to reduce peaking requirements, and consider control only during the most probable days of the system peak. Other utilities use direct load control to reduce operating cost and dependence on critical fuels.

Valley filling involves increasing energy consumption in a time period when the electric system is under used. Valley filling may be particularly desirable where the long-run marginal cost of electricity is less than the average price of electricity. Properly priced off-peak load can decrease the average price for the customer and provide cost or capacity benefits to the utility. Valley filling can be accomplished in several ways, including using thermal energy storage (water or space heating or cooling).

Load shifting moves energy consumption to another time period, typically when prices are lower. Common options include storage water heating, storage space heating, cool storage, and

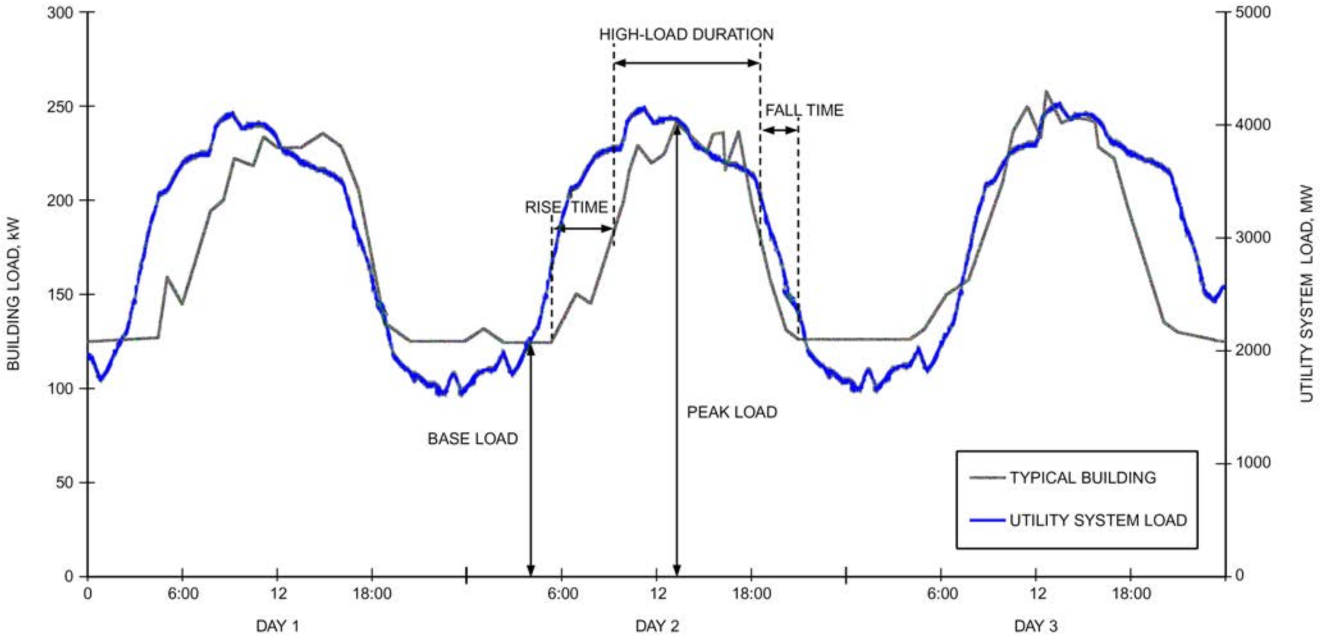

Fig. 6 Example Commercial Building Load Profile in Relation to Utility System Load
Adapted from Price (2010)

time-of-use or other special rates. The shifting usually occurs within a 24 h period. The total energy used by a customer need not be significantly affected by load shifting.

Strategic conservation is directed at reducing end-use consumption, often through increased efficiency. The change reflects a reduction in sales and a change in the use pattern. Examples include weatherization and appliance efficiency improvement.

Strategic load growth increases end-use consumption by increasing energy sales beyond the valley-filling strategy. The emphasis is often on increasing total sales without regard to the seasonal or daily timing of the load. Strategic load growth may involve area development, electrification, and increased market share of loads that are or can be served by competing fuels.

Utility Rate Options and Strategies

Public regulatory bodies provide incentives to drive customer behaviors using electric tariff design. To increase the reliability and use of existing generation assets or reduce the need for additional generation/transmission assets, there are two methods to reduce customer demand during peak consumption times. Utility customers can be induced to provide demand response either through **dynamic pricing tariffs**, retail electric rates that reflect short-term changes in wholesale electricity costs (e.g., hourly pricing or critical-peak pricing), or through **demand response programs** that offer customers payments in return for reducing consumption when called upon to mitigate high market prices or reserve shortfalls. Table 4 shows common types of demand response programs.

Modern Smart-Grid Strategy

The smart grid represents a modern grid concept that would replace dated infrastructure with currently available and future technologies that enable safe and secure two-way flows of electricity and information between customers and their electricity providers. In the typical grid configuration, energy predominately flows one way, from utilities to consumers, and information flows almost exclusively one-way, from consumers' power meters to grid operators. However, with the smart grid, energy and information would flow easily from the grid to customers, and vice versa, in real time.

Table 4 Common Types of Demand Response (DR) Programs: Price Options and Incentive- or Event-Based Options

Price-Based DR Programs: Higher Prices Used to Induce Demand Reduction	
Time of use (TOU) rates	Rates with fixed price blocks that differ by time of day.
Critical peak pricing (CPP)	Rates include a prespecified, extra-high rate that is triggered by the utility and is in effect for a limited number of hours.
Real-time pricing (RTP)	Rates vary continually (typically hourly) in response to wholesale market prices.
Incentive- or Event-Based Programs: Incentives Provided to Induce Demand Reduction	
Direct load control	Customers receive incentive payments for allowing utility a degree of control over certain equipment.
Demand bidding/ buyback programs	Customers offer bids to curtail load when wholesale market prices are high or identify how much they would be willing to curtail at posted prices.
Emergency demand response programs	Customers receive incentive payments for load reductions when needed to ensure reliability, but curtailments are voluntary.
Capacity market programs	Customers receive incentive payments or rate discounts/bill credits for providing load reductions as substitutes for system capacity.
Interruptible/ curtailable programs	Customers receive a discounted rate or bill credit for agreeing to reduce load upon request. If participants do not curtain when requested, they can be penalized.
Ancillary services market programs	Customers receive payments from a grid for ancillary services provided. Require that customers are able to adjust load quickly.

Sources: FERC (2006), Goldman et al. (2010).

The vision for the modern electric grid is one that

- Motivates and includes the consumer
- Accommodates all generation and storage options
- Enables markets
- Provides power quality for 21st-century needs

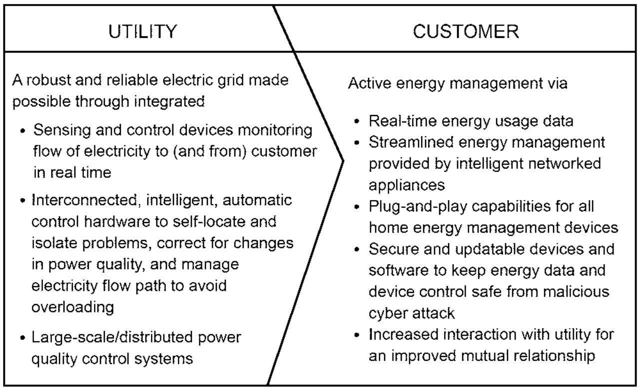

Fig. 7 Benefits of Smart Grid as Viewed by Utilities and Customers
Lott et al. (2011)

- Resists attacks
- Self heals
- Optimizes assets and operates efficiently
- Provides less expensive electric power more cleanly

Two-way flows of energy and information would provide customers with valuable information about their electricity prices and consumption patterns. This would enable customers to better manage their electricity use. On the utility side, the grid could be more accurately balanced, brownouts or blackouts could be avoided, and outages could be quickly mitigated. Advantages of the smart grid to the utility and to consumers are compared in Figure 7.

Investments in the smart grid are expected to yield the following four long-lasting effects (Lott et al. 2011):

- Next-generation electric power grid infrastructure that replaces the existing grid
- Substantial improvements in energy efficiency that bring financial and environmental benefits
- Greater use of renewable generation
- Widespread use of distributed generation

Other future changes include development and application of various energy storage (distributed and centralized) strategies that will benefit from increased research (e.g., batteries, thermal, phase change, etc.), and development and commercialization efforts by educational, government, and industry entities.

This smart-grid strategy is intended to enable a new kind of load response, in which loads and generation are on an equal footing with equal visibility of the value of electricity in real time. It includes use of automation and other tools to enable even small customers to manage load in response to the real-time value of energy. It focuses on integrating renewables and higher reliability and resiliency, as well as distributed energy (customer-owned generation and storage) and advancing the regulatory framework to enable customers (and small generators) to manage the distributed energy resources and load in a variable-price environment.

Relevance to Building System Designers

As the modern grid develops, buildings will need grid communications to know the condition of the grid and to determine how to respond to it. Facilities can be operated in ways that support grid reliability while potentially lowering their costs of operation by managing loads and storage to contribute to balancing grid-wide demand and changes to the generation mix. An example is Open Automated Demand Response (OpenADR™), a research and standards development collaboration for power demand management. Typically, OpenADR is used to communicate data and signals that turn off powered devices when electrical demand is high. See OpenADR Alliance (undated) for more information.

Buildings and facilities should be designed for operation in an environment where electricity is valued in real time, varying throughout the day. Building owners, managers, and designers should consider incorporating automation to allow shifting and shedding loads, as well as planning to allow for thermal energy storage and renewable energy generation systems integration. Further, there should be some consideration of microgrid operations, with additional fossil-fuel-based distributed generation (fuel cells, diesel generators, etc.) and electrical storage capability on site.

In the future, not only will electricity costs become more dynamic, energy prices will continue to rise. Controlling energy costs begins with energy efficiency as the cornerstone of an overall energy management plan. Strategies for developing a site-specific plan can be found in EPA (undated).

The success of the smart grid depends on interoperability and communication between energy service providers and facility energy management systems to effectively manage supply and demand. ASHRAE *Standard* 201-2016, Facility Smart Grid Information Model, defines an abstract, object-oriented information model to enable appliances and control systems in homes, industrial facilities, and other buildings to manage electrical loads and generation sources in response to communication with a smart electrical grid and to communicate information about those electrical loads to the utility and other electrical service providers. This model defines a comprehensive set of data objects and actions that support a wide range of energy management applications and electrical service provider interactions, including on-site generation, demand response, electrical storage, peak-demand management, direct load control, and other related energy management functions. This standard will become part of the Smart Grid Interoperability Panel (SGIP; www.sgip.org) catalog of standards recommended for adoption by utilities and energy service providers.

MEASURING BUILDING DAMPNESS 64.12
Water Activity 64.12
Moisture Content 64.12

INDOORS, buildings should always be dry. When building interiors get damp and stay damp, problems often emerge for their occupants and for the building's structure, materials, and furnishings.

Persistent indoor dampness has been associated with human health problems, increased risk to buildings' structural fasteners and exterior enclosure, shortened useful life of furnishings, and reduced acceptability to occupants because of odors and stains. These and related problems can be costly and disruptive, as well as annoying to all concerned (ASHRAE 2013).

Human Health

The U.S. National Academy of Medicine and the World Health Organization determined that there is a clear association between damp buildings and negative health effects (NIM 2004). The U.S. Department of Energy's Lawrence Berkeley National Laboratory estimated the cost of documented dampness-specific health effects to be more than $3.5 billion each year (Mudari and Fisk 2007), and health hazard evaluations of buildings around the world have repeatedly shown that indoor dampness is neither normal nor desirable from a health perspective (e.g., NIOSH [2013]). Although not all of the mechanisms are well understood at this time, cognizant public health authorities agree that damp buildings can lead to health problems.

Energy Conservation

Insulation can be compromised when rain and snow melt water leaks into roofs or exterior walls, and when indoor humidity condenses inside walls. When insulation gets wet, it allows more heat to pass through the building enclosure. The increased heat flow wastes energy, increases the difficulty of meeting energy reduction goals, and adds needless costs to building operation.

Sustainability

Damp buildings generate corrosion, rot, and mold, which damage structural fasteners (Zelinka 2013), materials, and finishes. Therefore, a building and its furnishings are not sustainable (because their useful lives are shortened) unless they are designed and constructed to prevent moisture accumulation.

Costs

Fixing a moisture problem after construction is roughly 10 times as expensive as correcting a drawing at the design stage, and remediating a mold problem is roughly 100 times as expensive as correcting that drawing. Thus, it is far more cost effective (and more sustainable) to avoid problems at the design stage than to repair problems caused by moisture-risky design.

The preparation of this chapter is assigned to TC 1.12, Moisture Management in Buildings.

Avoiding Litigation Risk

Humidity and moisture-related problems in buildings have been the single largest category of claims against the errors and omissions insurance of architects and engineers (84%). Also, moisture-related damage is the single most-litigated construction defect against contractors (NAIC 2008).

1. COMPLEX CAUSES

Based on investigations of problem buildings, dampness sufficient to cause problems seldom has a single cause. More often, a series of events, including decisions in many areas of professional and personal responsibility, combine in complex ways to cause a problem. Therefore, it is not appropriate to assign responsibility for building dryness to any single group, because it is not likely that any one group acting alone, can prevent a problematic level of dampness, mold, or microbial growth.

The interactions that lead to the amount and duration of moisture accumulation that creates problems are similarly complex. Figure 1 shows an example: the classic and problematic practice of installing vinyl wallpaper on the indoor surfaces of exterior walls in a mechanically cooled building in hot, humid climates.

High-dew-point outdoor air infiltrates through exterior walls. Its moisture is then absorbed into hidden cool surfaces of interior gypsum wallboard. Because the vinyl wallpaper is relatively impervious to water vapor transport, moisture accumulates in the gypsum board, resulting in mold growth and eventually decay, rot, or corrosion of structural members or their fasteners.

Note that the problems illustrated by Figure 1 resulted from more than one element: high outdoor dew point for many days or weeks, extensive humid air infiltration into the enclosure, chilled indoor surfaces, vinyl wallpaper, and untreated paper-faced gypsum board. If any one of those elements were absent, little or no mold growth might have occurred. In this example,

- The owner or interior designer decided to install vinyl wall covering rather than a more permeable wall covering.
- The architectural designer designed and/or the contractor built a building that allows extensive humid air infiltration, and also selected untreated gypsum wall board for a location likely to experience high humidity in a climate where high humidity continues for many months.
- The HVAC system was apparently designed and/or installed such that it overcools wall surfaces. The toilet exhaust duct system was also either designed, installed, or operated such that it extracts air from building cavities as well as from the bathroom, thereby increasing humid air infiltration and leading to high relative humidity inside the cavities. High relative humidity inside cooled walls leads to moisture absorption and high water activity in vulnerable paper-based backing of the wall board.

This example illustrates that risks from multiple decisions made by many different professionals usually act in combination to

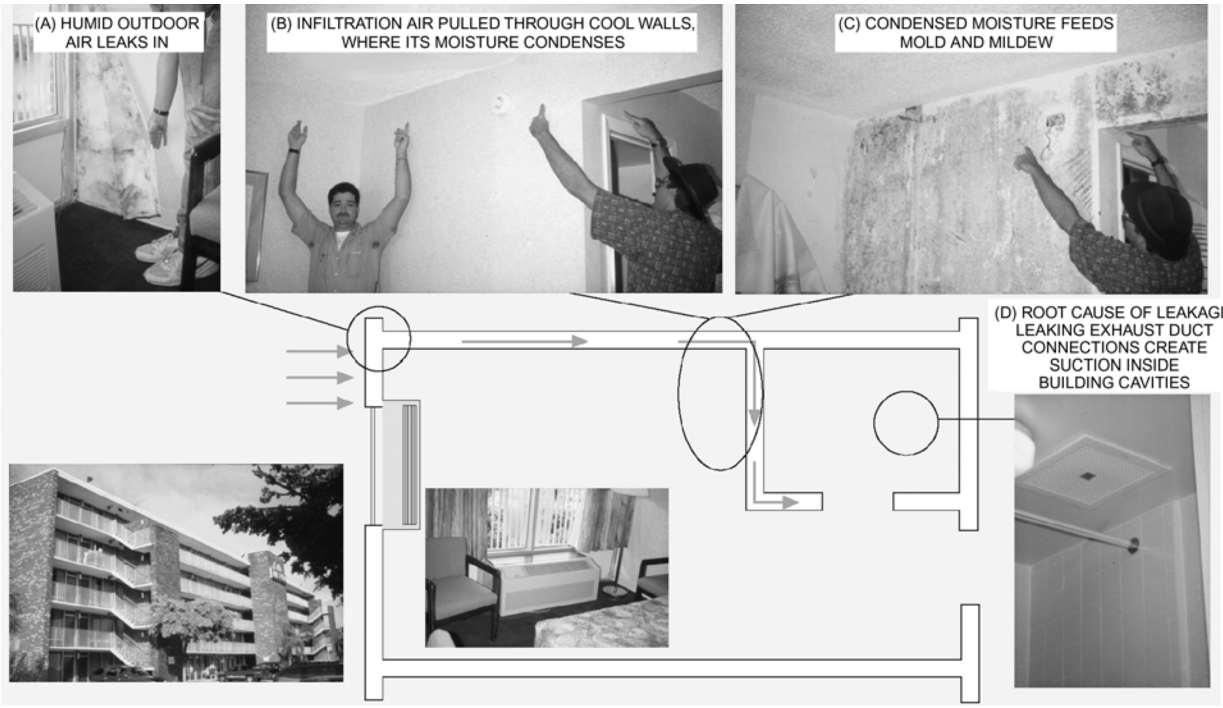

Fig. 1 Mold Caused by Complex Combination of Factors

produce enough moisture accumulation in the wall cavities, for a long-enough period, to create a microbial growth problem.

Further, the risk of excess moisture accumulation can be either increased or reduced by occupants as they use the building. For example, if the occupants of an apartment generate a significant amount of moisture from cooking and cleaning activities without opening windows or using exhaust fans, excess moisture accumulation and mold growth may occur, most commonly on the inside surfaces of exterior walls during cold weather. A building is a complex and dynamic system, and the actions of its occupants are an integral and constantly changing component of that system.

Finally, with respect to health issues, people in the same building are often quite different in their individual sensitivities to airborne microbial contaminants. A low level of contamination that causes adverse health effects for one sensitive individual often causes no health effects for others.

Consequently, the prudent course of action is to keep all of the materials that make up a building and its HVAC systems as dry as possible, consistent with their normal functions. Building professionals and building occupants can reduce risks by

- Remembering that the risk factors for microbial contamination and corrosion are excessive long-term moisture accumulation in materials, repeated wetting, or catastrophic water damage.
- Making decisions and taking actions to keep the building and its systems, furnishings, and finishes as dry as possible, given the function of the component in question and the available resources. To help establish threshold levels of concern for material dampness, microbiologists and building investigators observe that mold growth is rarely a problem when the water activity of interior building materials and furnishings is held consistently below 0.8 (below an equilibrium relative humidity of 80% rh in the surface layers of a material, as opposed to 80% in the nearby air) (ASHRAE *Standard* 160).
- Being aware that, if adequate resources are not made available to keep the building, systems, and contents dry, the risk of microbial growth (including mold) will increase.
- Addressing persistent dampness inside a building; stagnant water in condensate drain pans; or constantly damp insulation, filters, or sound lining of HVAC systems.

2. MOISTURE TOLERANCE AND LOADS

Concrete, masonry, stone, and heavy wood timbers are much less moisture sensitive than untreated paper-faced gypsum board, light gage steel studs, and carpet adhesives. That is why the traditional heavy construction assemblies typical of buildings built before the twentieth century sometimes tolerated rainwater loads and moisture accumulation in exterior walls with fewer problems than the lighter construction of most modern buildings.

Consequently, it is useful to recognize that not all buildings have the same risks, and each type responds differently to equal amounts of humidity and moisture accumulation. When building materials and finishes tolerate moisture exposure, as in the case of a ceramic tile-lined shower room, there is less risk of mold and microbial growth than if that same shower room were lined with painted gypsum wall board.

Similarly, not all exterior surfaces of the same building are subject to the same level of environmental moisture stress. Risks from rain exposure and moisture accumulation are quite different on each face of the building. Beginning with the matter of moisture loading, Figure 2 shows an example of the fact that the volume of rain often depends on the predominant direction of wind-driven rain. In Toronto, Canada, the majority of the rain comes from the east (Straube and Schumacher 2010). In other locations, most of the wind-driven rain can come from quite different directions, varying by season of the year.

Also, the drying potential of the building varies according to building orientation. For example, in the northern hemisphere, the northern side of a building is shaded from direct solar radiation, reducing the annual drying potential on the north wall to far less on the south and west sides of the same building. In the northern

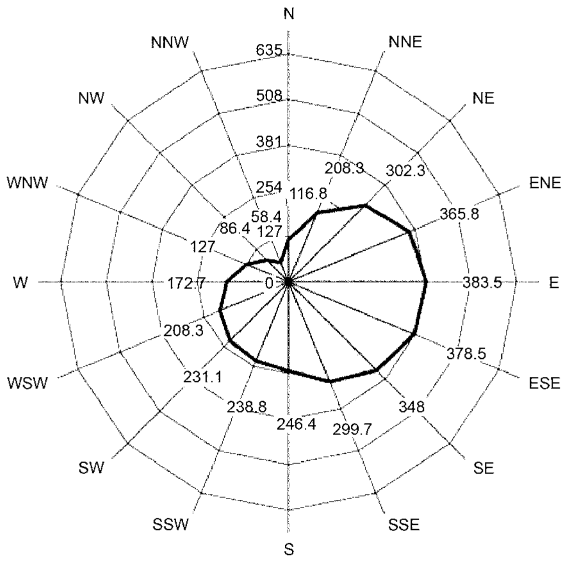

Fig. 2 Rain Loads Versus Wind Speed and Direction (mm per year)
(Straub and Schumacher 2010)

hemisphere, the risks of equal amounts of rain are much higher on the north side than on the southern and western elevations.

Therefore, when designing any building enclosure, it is useful to recognize differences in moisture tolerance of materials and to remain aware of differences in moisture loading and drying potential both outside and inside the building. Chapter 45 outlines useful suggestions for architectural designers to limit the potential for problems in building enclosures.

The concern continues after construction is complete. An owner of an existing building should recognize that some types of construction and some systems and assemblies in a building are more subject to problems from moisture accumulation than others. Building operations become more economical and the building itself becomes more sustainable when designers avoid moisture-sensitive materials and assemblies in parts of the building where annual water exposure is high and drying potential low, rather than treating all parts of all buildings equally. In both design and operation, an appropriate hierarchy of concern will be based on how much water a given problem can potentially add to moisture-sensitive indoor materials and furnishings.

Construction planners and building owners should be aware that at every stage of design, construction, and operation, the owner's program requirements (OPR) need to clearly define the key moisture management decisions, who will make them, and who will ensure each decision is carried out in practice (EPA 2014). For example, if there is no requirement to design and operate the HVAC system to keep the building dry during unoccupied, as well as occupied, hours, the HVAC designer and building operator might well assume that mold protection in a school during summer vacation is not a measure that the owner is willing to pay for.

Architects should keep in mind that the side of the building that has the greatest annual wind and rain exposure needs the most water-resistant materials and the most effective building enclosure design details.

Engineers should remember that buildings in hot and humid climates experience thousands of hours at high outdoor dew points, so the ventilation and makeup air systems must be sure to dry incoming air with more certainty than buildings in dry climates.

Building owners and operators should remember that, no matter what the construction age or type, rainwater leaks are a bigger concern than high humidity, and plumbing leaks are a bigger concern than air leakage from ducts.

All of these problems can cause mold growth, but a simple rule applies to all circumstances: more moisture exposure means a higher potential for problems in a shorter amount of time. Therefore, designers and owners benefit from understanding some of the specific factors that have historically been most influential in dampness problems.

3. RISK FACTORS AND MITIGATION

Each area of professional and occupant activity involves decisions and actions that either increase or reduce the risk of problems related to moisture, mold, and other microbial growth. In most cases, the individuals involved are not aware they are making fateful decisions. When reviewing these factors, it is important to remember that moisture and mold problems can develop for different reasons in cold and hot climates, and can also occur through mechanisms caused by regionally specific building designs, material selections, and construction practices in different parts of the world. Therefore, recommendations based on local conditions are often needed to avoid dampness-related problems.

3.1 HVAC SYSTEMS

Risk Factors

- Failing to dry the ventilation air, and failing to measure and limit the ventilation and exhaust air to the amounts needed for the use of the building and for the number of people actually occupying the building at any given time. Needless amounts of exhaust and ventilation, and ventilation without dehumidification during humid outdoor conditions, have been responsible for major and widespread mold growth problems in hot and humid climates. Whenever any building (in any climate) is mechanically cooled and ventilated, the indoor dew point must remain low enough to keep the indoor surface relative humidity below 80%, even on hidden cool surfaces. Keeping the indoor air dew point below 15°C is a reliable means of avoiding high surface relative humidity (Harriman and Lstiburek 2009).
- Failing to ensure that system operation during unoccupied periods keeps the indoor dew point low enough to maintain a water activity below 0.8 in building materials and furnishings (30-day average surface relative humidity below 80% in surfaces cooled by air-conditioning systems). Mold and microbial growth accelerate when the indoor dew point stays high while surfaces are intermittently chilled by cooling systems. Moisture accumulation and mold have often been observed in unoccupied schools, vacation homes, hotel rooms, institutional dormitories, and military barracks; this happens when there is no independent dehumidification that keeps indoor dew points low when cooling systems are reset to higher temperatures (Harriman and Lstiburek 2009).
- Failing to make air distribution components and joints in return plenums and supply and exhaust ducts sufficiently airtight. Joints and connections must be tight enough to prevent suction that otherwise pulls humid outdoor air into the building, and/or leakage that allows cold supply air to chill surfaces inside humid building cavities (Harriman and Lstiburek 2009; Harriman et al. 2001).
- Failing to keep the long-term average indoor air pressure positive with respect to the outdoors when the outdoor dew point is higher than indoor surface temperatures (Harriman et al. 2001).
- Failing to prevent dirt and dust accumulation on cooling coils and on duct surfaces and sound lining downstream of cooling coils. Accumulating a damp layer of dust can lead to microbial growth. Install access panels that allow inspection and cleaning of the condensate pans and areas upstream and downstream of cooling coils to ensure the condensate pan is not accumulating water, that

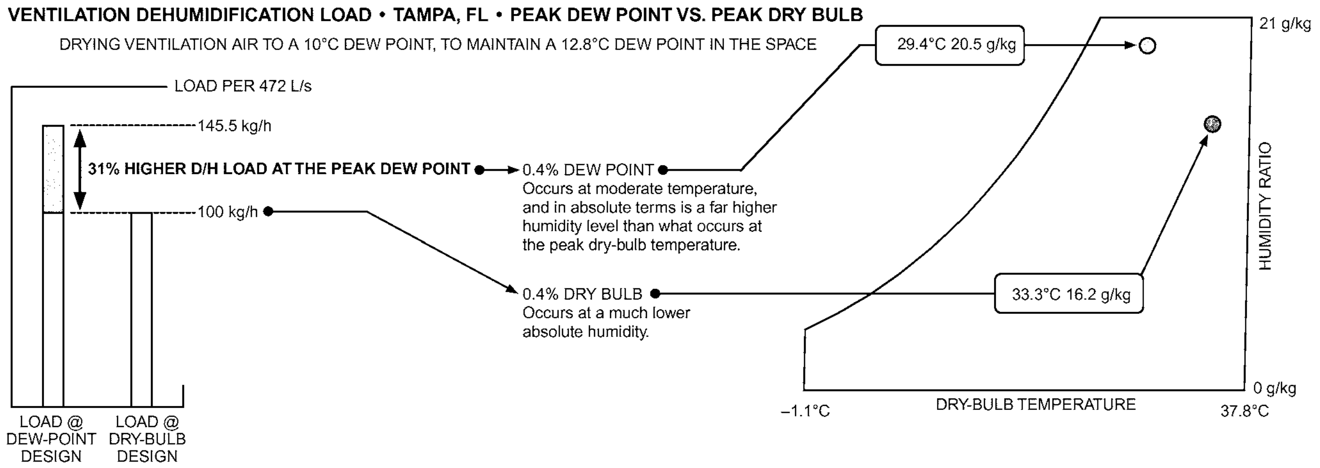

Fig. 3 Dehumidification Load Versus Peak Outdoor Dew Point Design and Peak Dry Bulb

coils are clean, and that upstream and downstream surfaces are clean and dry. Regular cleaning and ultraviolet lamps can reduce the impact of occasional lapses in filtration. Over time, however, effective filtration is the most important factor in preventing microbial growth in parts of the system likely to accumulate moisture during normal operation.

- Failing to keep air velocity through cooling coils low enough to prevent droplet carryover into downstream duct work and filters, leading to microbial growth in those locations (Harriman and Lstiburek 2000).
- Failing to install condensate drain traps deep enough to allow free-flowing drainage of normal cooling coil condensate, and failing to install traps and condensate drain lines with a diameter large enough to allow maintenance personnel to both observe clogs and clean out anything that obstructs free-flowing drainage (Harriman et al. 2001).
- Failing to install accessible cleanouts in condensate drain lines to allow periodic removal of algae and the particulate, feathers, sticks, and leaves that typically wash off the coil. Note also that copper piping has been effective in limiting biological accumulation in condensate drain lines (Harriman et al. 2001).
- Failing to ensure that the temperature of chilled-water systems stays low enough, and water flow rates through the coils stay high enough, to effectively dry the air. Note that this problem is most common when a building or a system is not equipped with a separate dehumidifier (Harriman and Lstiburek 2009).
- Redistributing microbial air contaminants, including mold, from a contaminated space into occupied areas. Examples of contaminated spaces can include parts of the building under construction or renovation, hidden building assemblies (e.g., damp crawlspaces or attics), or spaces above dropped ceilings or below raised floors (Harriman and Lstiburek 2009).

Risk Mitigation

- Ensure that all ventilation air is dried to a dew point below the dew point maintained inside the building when the building is being mechanically cooled (Harriman and Lstiburek 2009; Harriman et al. 2001).
- Design ventilation dehumidification components based on the humidity loads at peak outdoor dew point, rather than the loads at the peak outdoor dry-bulb temperature. Figure 3 shows the large difference between these conditions in Tampa, FL; Figure 5 provides more detailed examples in other climates (Harriman and Lstiburek 2009; Harriman et al. 2001).
- Ensure that there are HVAC systems and controls that keep the indoor air dew point below 10°C when the building is unoccupied, such as during summer vacations of schools and universities, long-term remote deployments of personnel who occupy military barracks and dormitories, and off-season vacancy of vacation homes, apartments, and condominiums.
- Ensure that all condensation inside HVAC components and air distribution ductwork is drained away to an appropriate sanitary drain or condensate collection system (Harriman et al. 2001).
- Ensure that indoor surfaces of both occupied and unoccupied spaces are not cooled to temperatures so low as to create an average surface relative humidity of over 80% lasting for more than 30 days, or surfaces cold enough to allow condensation (ASHRAE *Standard* 160).
- Note that the relative humidity of air measured in the occupied space or return air does not indicate the relative humidity in the thin boundary layer of air in contact with cool surfaces. Monitoring and controlling indoor dew point compared to indoor surface temperatures is the more useful metric for preventing persistent dampness. For example, in buildings that are mechanically cooled during hot or humid weather, drying the ventilation air to an air dew point below 12.8°C nearly always ensures that surface relative humidity stays below 80%, even on cool surfaces. In contrast, if the indoor air relative humidity were 55% at 25.6°C, any surface cooled below 18.9°C would have a relative humidity above 80% (Harriman and Lstiburek 2009).
- Keep the indoor dew point low enough to ensure that there is no condensation on the exposed surfaces of cool HVAC components or on moisture-sensitive building materials or furnishings. Note that the caution against condensation and long-term average surface relative humidity above 80% applies not only to visible surfaces in occupied spaces but also to any moisture-sensitive materials inside hidden building cavities and unconditioned spaces (Harriman et al. 2001).
- Ensure that large-capacity humidifiers are installed as multiple modular stages rather than a single large units, and controlled so they do not overload the air with humidity, reducing the risk of condensation inside air distribution systems or inside exterior walls and roofing assemblies (Harriman et al. 2001).
- Ensure that cold HVAC and plumbing components and systems such as chilled-water pipes and valves, supply air ducts, cold domestic water lines, and cold condensate drain piping are sufficiently insulated to keep the temperature of all of their surfaces at least 4 K above the dew point of the surrounding air. Note that pipes often pass through unconditioned spaces such as basements,

crawlspaces, and attics. Any insulation on chilled piping must be continuous and complete, and also be equipped with an effective vapor retarder, or be itself a vapor retarder to limit high surface relative humidity on cold pipes as they pass through high-dew-point spaces and building cavities (Harriman and Lstiburek 2009).

3.2 ARCHITECTURAL FACTORS

Risk Factors

- Vinyl wall covering on exterior and demising walls of buildings in hot and humid climates. Problems have frequently occurred behind vinyl wall covering when the building lacks a continuous, sealed air barrier that effectively keeps humid outdoor air out of the cavities inside the exterior and interior walls (Harriman and Lstiburek 2009).
- Damp basements and crawl spaces (DOE 2005). In residences in cold climates, humid air from damp basements and crawlspaces is often carried upward into a cold attic by stack effect. The moisture condenses into the roof sheathing and supports mold growth. In hot climates, the water vapor may condense or be absorbed into the flooring of the first floor, because that surface has been cooled by air conditioning in the occupied space.
- Water accumulating next to or under the building's foundation, often because of exterior grading that has compacted, sloping inward toward the foundation after freeze/thaw cycles in cold climates, or because of decorative edging around shrubbery that creates a pond near the foundation (ASTM 2010; Rose 2005).
- Rain leaks through joints around windows, doors, or other wall penetrations such as through-wall air-conditioning units, electrical fixtures, exhaust ducts, or structural fasteners, or leakage through joints where different types of exterior cladding come together (Harriman and Lstiburek 2009).
- Absence of effective flashing around windows, doors, skylights, and other penetrations of the building's walls or roof (ASTM 2007).
- Absence of an effective, continuously sealed air barrier covering all six sides of the building envelope, allowing leakage of humid air from either indoors or outdoors into cool exterior walls, crawlspaces, roof assemblies, or attics (see Chapter 45) (ASHRAE *Standard* 90.1).
- Absorptive exterior cladding such as brick veneer, stucco, or masonry, which retains rainwater but is not backed by a free-draining and vented air gap in front of a water-resistant vapor barrier equipped with effective flashing (Derome and Saneinejad 2009).

Risk Mitigation

- Roof overhangs of at least 600 mm or more (CMHC 1998). In both tall and low-rise buildings, a roof overhang greatly reduces the volume of rainwater that ends up on the wall.
- Sill pan flashing under windows and doors to force any water leakage outward onto an effective water barrier and then out of the building wall (ASTM *Standards* D7338, E2112; Harriman and Lstiburek 2009; JLC 2007).
- Crawlspaces lined with water and vapor barriers that are sufficiently sealed to prevent infiltration into the building from surface water and moisture from the soil and humid air (DOE 2005).

3.3 BUILDING OPERATIONAL DECISIONS

Risk Factors

- Failing to turn off exhaust fans and close ventilation air dampers when the building is unoccupied (to reduce humid air infiltration when systems are not providing dehumidification).
- Failing to effectively exhaust humid air from showers, spas, decorative water fountains, indoor landscaping irrigation, and swimming pools.
- Failing to dry outdoor air brought into the building for ventilation or to replace exhaust air, when the outdoor air dew point is above 15°C.
- In cold weather, humidifying indoor air to dew points high enough to create condensation or surface relative humidity above 80% or water activity above 0.8 at the surface of moisture-sensitive surfaces inside walls, above insulated ceilings, or in attics for extended periods (e.g., days, weeks).
- Failing to ensure that the temperature of chilled-water systems stays low enough, and that flow rates through the coils stay high enough, to effectively dry the air when the chilled-water systems are the only means of removing excess humidity from the building. This problem often occurs when chilled-water temperatures are reset to save energy when the building is unoccupied during hot and humid weather; under these circumstances, a separate dehumidification system may be necessary to prevent problems associated with persistent dampness (Harriman et al. 2001).

Risk Mitigation

- Mop and dry up spilled liquids or wash water promptly, limiting the amount of water that soaks into walls, carpeting, or flooring materials.
- Repair plumbing leaks quickly, and dry up any water leakage that resulted from such leaks within 24 to 48 h.
- Keep irrigation spray heads aimed carefully away from the building, preventing the frequent soaking of exterior walls and foundation.
- Maintain the slope of exterior landscaping so that rainwater and irrigation spray flows away from the foundation rather than accumulating there.
- Keep rainwater runoff from the roof at least 1 m away from the foundation.
- Prevent microbial growth in HVAC components and air distribution systems, and remove mold and other microbial contaminants from air flowing through HVAC systems, to prevent contaminants from being distributed throughout the building (ACGIH 1999; AIHA 2008; EPA 2001).
- In hot and humid weather, operate systems so they limit the dew point of the indoor air to less than 10°C, when the building is not occupied.

3.4 OCCUPANT DECISIONS

Risk Factors

- Failing to operate exhaust fans or open windows to effectively remove humid air from cooking or from baths and showers, especially in small homes or apartments with many people or long cooking operations that lead to a large percentage of hours per week or month at a high indoor dew point.
- Failing to exhaust humid air from clothes driers or drying clothes on racks indoors without effective exhaust of the resulting humidity. The problems associated with this error are especially severe during cold weather, when exterior walls and attics are cold, creating large condensing surfaces.
- Growing an unusually large number of live plants indoors, without exhausting or using dehumidifiers to remove the humidity they respire. Problems created by this oversight have been seen to be especially severe in cold climates and indoor spaces used to grow medicinal or recreational cannabis.
- In cold weather, humidifying the indoor air to dew points high enough to create condensation or surface relative humidity above 80% or surface water activity or materials inside cooled walls and attics for days or weeks at a time.

- Storing large amounts of documents, furniture, or cardboard boxes in damp basements or crawlspaces, or in contact with cool walls or foundations.

Risk Mitigation

- Keep shower or tub splash within the tub enclosure, limiting the amount of water that can soak the floor or walls.
- Install and operate quiet, humidity-activated exhaust fans in bathrooms and in spaces used for growing large numbers of plants. Set the fan to start operating when humidity in the space rises above 70% rh.
- Mop and dry spilled liquids or wash water promptly, limiting the amount of water that soaks into walls, carpets, or flooring materials during cleaning operations, and dry any water that remains within 24 to 48 h.
- Repair plumbing leaks quickly, and dry any water accumulation within 24 to 48 h.
- Keep irrigation spray heads aimed carefully, preventing repeated soaking of exterior walls and foundation.
- Maintain the slope of the landscaping so that rainwater and irrigation runoff flows away from the foundation rather than accumulating there.
- Keep rainwater runoff from the roof at least 1 m away from the foundation.
- Remove mold and other microbial contaminants from the residence promptly, using appropriate engineering controls such as high-efficiency particulate air (HEPA) filtration and temporary negative pressure containments to keep contaminants from becoming airborne and distributed throughout the building (ACGIH 1999; AIHA 2008; EPA 2001; IICRC *Standard* S520).

4. SOLUTIONS

4.1 ARCHITECTURE AND DESIGN

Suggestions in this section are traditionally within the control of the owner, architect, and general contractor. These can help accomplish three tasks that reduce the risk of indoor dampness: (1) keep rain off and away from the building envelope, (2) help materials drain water and resist its effects when leaks eventually occur, and (3) keep humid air from infiltrating into the building envelope (especially through the historically problematic large gaps in the long joints where the roof meets the walls).

Roof Overhang

Ideally, the roof should project at least 600 mm beyond the walls all around the building. This greatly reduces the risks of water leakage, because much less rainwater ends up on the walls over the life of the building.

The baseline risk of mold and moisture problems depends on how much water contacts the exterior walls. More hours of contact and a higher volume of water generates more risk when gaps and cracks occur (by design, during construction, or over the building's lifetime). The further the roof extends beyond the walls, the less rainwater will flow down those walls to challenge every joint and seam.

A roof projection of about 600 mm is likely to cut the annual rain volume flowing down the walls and windows by roughly 50% in both tall and low-rise buildings. The exact reduction depends on many factors, but 50% is a reasonable approximation of the load reduction value of an overhang. Longer projections are even better because they reduce the rain volume still further, but studies of moisture problems in buildings indicate that even in very rainy climates, very few major moisture problems occur where the roof projection is at least 600 mm beyond the exterior walls (CMHC 1998). As a side benefit, the wider the overhang, the greater the reduction in solar-driven cooling load, which reduces energy consumption in air-conditioned buildings.

A useful option for taller buildings is to increase the length of the overhang. Interestingly, in high-rise buildings, most of the annual rain load reaches the building as it blows in from the sides during periods of wind-driven rain; the building's 600 mm overhang catches the approaching wind and forces it to roll into a protective cylindrical air mass near the roof line. That rolling cylinder of air acts as a sort of dry protective bumper, forcing most of the oncoming rain-laden wind up, over, and around. Consequently, most of the rainwater never reaches the surface of the building.

Waterproof Drainage Plane

To further reduce risks, exterior walls can be designed with a three-part drainage plane behind the exterior cladding. An effective drainage plane consists of three components:

- Waterproof drainage layer with flashing at its base that forces any water leakage back out of the wall assembly.
- Air gap to allow smooth flow of any leakage water down the surface of that waterproof layer.
- Flashing that prevents water from entering the wall above and around penetrations (e.g., windows, doors, air-conditioning unit sleeves). The flashing is integrated with the waterproof layer such that any leakage water is eventually redirected back out of the wall to the weather side of the cladding.

In theory, exterior cladding can be designed as a barrier system, so that no water ever gets into the exterior wall. However, in practice, whether due to extreme weather, oversight during construction, or aging of materials, some water usually gets in.

In some cases, the wraparound air barrier described in the following section can also act as the waterproof layer, if (1) both design and installation of the joinery are done carefully, and (2) the air barrier is adequately supported to minimize flexing. There is no inherent conflict between the functions of air barrier and water barrier; both are vapor permeable. However, keep in mind that an air barrier must be structurally strong enough to resist the full design wind load, and a waterproof membrane needs to remain waterproof. If an air barrier flexes and stretches over time under wind loading, its seams may not remain waterproof. With sheets, it is also important to remember that the waterproof layers must overlap shingle style, so that each seam sheds water rather than traps it.

Combining the functions of water barrier and air barrier is less complex when using spray-applied, vapor-permeable but waterproof membranes. In contrast, when the sheets are assembled into a combined air barrier/waterproof layer, all joinery must resist wind loads over time, and it must be detailed to ensure that all its joints and seams shed water.

In addition to the air barrier and waterproof layer, buildings clad with brick, stone, or stucco need vapor barriers on the exterior side of the wall insulation because these materials act as moisture reservoirs: unless equipped with specialized coatings, they soak up rainwater. This is not always a problem for the material itself, but it often creates problems for more moisture-sensitive sheathing behind that cladding. Solar heat drives large amounts of hot water vapor out of the cladding and inward into the sheathing. In hot, humid, and mixed climates, it is important to line the drainage gap for brick or stucco with a vapor barrier, and that layer may act as the waterproof layer and air barrier as well.

Keep in mind that although exterior waterproof layers and air barriers are needed in all buildings, vapor barriers are needed in a much smaller percentage of buildings and must be thoughtfully located to avoid problems. Walls must be able to dry, ideally both inwards and outwards. Exterior vapor barriers have often prevented this necessary drying. Except behind the claddings described previously, it is usually best to avoid exterior vapor barriers in hot and mixed climates. In cold climates, if any vapor barrier is needed, it should be located toward the inboard of the insulation. In cold weather, the vapor flows become more complex. For example, a vapor barrier outside of the insulation could lead to accumulation of moisture that would freeze during the winter.

The basic goal is to keep humid air out of any cold wall. In cold climates, the humid air is on the indoor side, so a combination vapor barrier/air barrier is useful in that location. In hot climates, an air barrier (not a vapor barrier) located near the outside of the wall is usually the best way to keep humid air out of exterior walls that are chilled by the indoor air conditioning. However, the optimal location for a vapor barrier is complex and depends on many other factors that are beyond the scope of this chapter. For more about the different functions and locations for vapor barriers, air barriers, and waterproof layers, see Chapters 25, 26, and 27 of the 2017 *ASHRAE Handbook—Fundamentals* and Chapter 45 of this volume. Also, consider using an hourly hygrothermal modeling program to analyze the behavior of the proposed enclosure over a full year, rather than a single-point analysis that looks only at extreme conditions.

Sill Pans and Flashing

To be effective, flashing must extend around the entire perimeter of windows and doors. It must be designed and installed so that any water leak above, beside, or through the window framing or door is caught by a watertight pan under the window or door, and redirected back out of the wall and onto the waterproof drainage plane (ASTM 2016).

In commercial and institutional buildings, sill pans are often made of metal for maximum durability. It is important to ensure that a metal sill pan does not form a thermal bridge that allows heat leakage. This is important from an energy perspective in all seasons, and also from a moisture management perspective during cold weather. If the indoor edge of the sill pan is cold in the winter, it could lead to condensation and moisture accumulation inside the wall.

The architectural designer (as opposed to the craftsperson installing the flashing) is in the best position to select the sill pan material and to define how all the layers in the wall must be integrated with this flashing. For best results, the architectural plans should show the layer integration in isometric projection, with each layer and its installation sequence defined and illustrated. Most importantly, the architectural drawings need to clearly show how these layers all come together in the corners.

The architectural designer (as opposed to the craftsperson installing the flashing) is in the best position to define how all the layers in the wall must be integrated with this flashing. For best results, the architectural plans should show the layer integration in isometric projection, with each layer and its installation sequence defined and illustrated. Most importantly, the architectural drawings need to clearly show how these layers all come together in the corners.

Many designers assume that flashing integration is a question of means and methods, and therefore a contractor responsibility. Depending on the contracts, this may sometimes be the case. But in most situations, designing and detailing the exterior walls with all their complex layers and corners is better left to the architectural designer. This is especially true of the complex inside and outside corner details. It is rarely sufficient to design the layers in section drawings and then hope that the contractor will be able to guess how they are supposed to meet in the corners and still be watertight. The three-dimensional integration of the flashing layers, especially the sill pan flashing, is usually the responsibility of an architectural designer.

When there are no drawings to three-dimensionally show the sill pans, the window flashing at the head and jambs, and how all the layers go together in the corners, the architectural design of the flashing is effectively assigned to the installer. That may not always be the person who is best equipped to make complex decisions that involve both form and function as well as material compatibility, construction sequencing, economics, and long-term durability. Additionally, even very capable craftspeople are rarely compensated financially for absorbing responsibility for such design decisions.

Wrap-Around Air Barrier

Continuous exterior air barriers reduce the risk of indoor moisture problems. Air leakage into or out of wall assemblies has been one of the most common sources of moisture accumulation and mold problems in all climates. In a heating-dominated climate, humidified air that leaks outward through the building envelope may encounter temperatures low enough to cause condensation inside the assembly. A similar problem can occur in a cooling-dominated climate: when warm, humid air enters through cracks and gaps, the moisture it carries can condense or be absorbed when the air contacts the cooler surfaces inside the building.

Consequently, air barriers must be continuous, without gaps, cracks, or open seams. In short, the ideal air barrier is continuously sealed around all penetrations and fasteners, and it must wrap around all six sides of the entire building. From a moisture control perspective, pay special attention to air barrier continuity at the roof/wall joint; most air leakage occurs where the walls meet the roof. In traditional designs, this roof/wall joint was sometimes designed to leak (e.g., vented soffits). However, air leakage has proven highly problematic for humidity control, moisture control, and energy consumption. The state of the art is to design and construct buildings that do not leak air, as reflected in the guidance of ASHRAE *Standard* 90.1 and the requirements of building codes in Canada and standards for U.S. government buildings.

Mold-Resistant Gypsum Board

When gypsum board is used on or inside exterior walls, or installed over interior concrete or masonry walls, it is prudent to specify products certified by the manufacturer to be resistant to mold growth and moisture damage. Although cement board is generally the preferred material for the lining of showers and bathtubs, any additional gypsum wall board installed in the walls or ceilings of bathrooms, shower rooms, or laundry rooms should also be resistant to moisture and mold growth.

In parts of the building which can often be moist, it is wise to use moisture-tolerant and mold-resistant wall board. These products provide a useful degree of tolerance for common shortcomings of conventional construction, which begin with construction moisture. Excess construction moisture and plumbing leaks have been responsible for mold and moisture problems in buildings in all climates. In hot and humid regions, rain is a constant challenge on construction sites; in cold climates, the construction season is so short that the building must often be closed in before the concrete and block have had enough time to dry out with ambient air circulation alone.

Mold and moisture problems do not happen in the concrete or masonry block itself, because those materials are moisture tolerant. Problems arise when flooring adhesives are applied over damp concrete, or when untreated, paper-faced gypsum wall board covers damp masonry block. Therefore, it is useful to specify that any masonry or concrete covered by gypsum board must be dried before gypsum board is installed. Further, manufacturers typically recommend against mounting gypsum board in direct contact with masonry block, even when masonry appears to be dry. Instead, install gypsum board over furring strips that allow an air gap between the masonry and the gypsum board, or install the board over a layer of low-permeability foam insulation board that is in direct contact with the masonry.

Exterior walls also benefit from moisture-tolerant wall board. Water leakage and humid air infiltration are probable at some point during the life of the building, no matter how well built it is at the beginning.

Permeable Interior Wall Finish for Exterior Walls

To reduce risks of trapping moisture inside walls in hot climates, specify that any paint or other wall finish for the indoor surface of an exterior wall must have a net value above 860 ng/(Pa·s·m^2), including the effect of any adhesive.

Impermeable vinyl wall covering on the indoor surface of exterior walls has proven to be frequently problematic, especially in hot and humid climates. In tens of thousands of buildings, vinyl wall covering has been largely responsible for massive mold growth inside exterior walls. Figure 4 shows an example of the problems frequently seen on vinyl-covered exterior walls. The same problems can occur with certain types of paint, notably the epoxies and high-durability latex paints. The vinyl or impermeable paint acts as a vapor barrier, preventing effective drying of moisture that often collects inside exterior walls. Moisture can accumulate through many mechanisms, including leaks in the drainage plane, aging of joints, or humid outdoor air infiltrating and condensing moisture in the material behind the vinyl. There is no practical way to prevent 100% of occasional episodes of moisture accumulation, so it is imperative that moisture not remain trapped inside the wall, as happens when vinyl wall covering is adhered to exterior walls.

In recent years, manufacturers have developed permeable or semipermeable vinyl wall covering. Quantified permeability of these products is often uncertain. Risks of moisture accumulation can be reduced by specifying that the system as a whole (wall covering plus its adhesive) must have a value (ASTM *Standard* E96-16) above 860 ng/(Pa·s·m^2).

4.2 HVAC SYSTEMS

Suggestions provided here are traditionally under the control of the HVAC designer, installer, and the building operations staff. These steps can reduce risks by ensuring that the indoor dew point stays below the typical surface temperatures of an air-conditioned building and its HVAC components. They also save energy and reduce the risk of moisture accumulation by preventing cold air from escaping from ducts to chill indoor surfaces, and by avoiding the problems created when humid outdoor air is pulled through walls and through attics instead of through the HVAC system.

Dedicated Outdoor Air Systems (DOAS)

There are many reasons to separate a building's ventilation air system from its heating and cooling systems by using a DOAS, but from the perspective of reducing risk of moisture accumulation, the most important reason is to ensure that incoming outdoor air is always dried below the indoor dew point, typically to a dew point of 12.8°C or lower. Additionally, if the DOAS units are equipped with return air connections, as shown in Figure 5, they can act as effective whole-building dehumidifiers when the building is unoccupied or when the ventilation air flow requirement is reduced.

If incoming ventilation and makeup air is not dried out before it enters the building, it is very difficult to keep excess humidity from being absorbed into the building's interior finishes and building materials. Incoming ventilation and makeup air typically carries more than 80% of the building's annual dehumidification load; if this load is not intercepted and removed by a dedicated dehumidification component such as that typically included in a DOAS system, the cooling equipment will struggle to remove the humidity load and often overcools the building as a result. Overcooling leads to discomfort, energy waste, and cooler surfaces. Figure 6 illustrates the consequences in a building that was overcooled instead of dehumidified, resulting in moisture absorption by those cold surfaces and subsequent mold growth. (Note that this level of mold growth occurred in spite of hospital-grade, nonabsorptive epoxy wall paint.)

Maximum 12.8°C Indoor Dew Point for Mechanically Cooled Buildings in Hot or Humid Climates

Another way to reduce the risk of building moisture problem is to design the HVAC systems so they remove enough humidity to keep

Fig. 4 Impermeable Vinyl Wall Covering on Exterior Wall

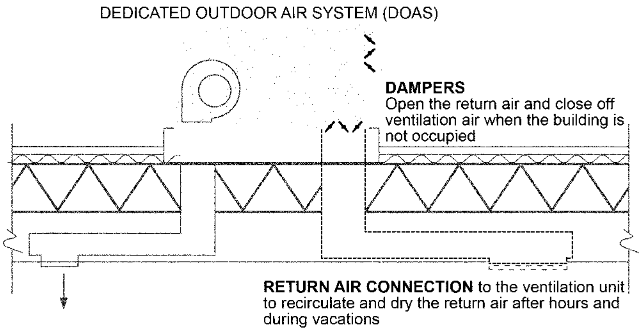

Fig. 5 Dedicated Outdoor Air System (DOAS) with Return Air Connection for Drying After Hours

Fig. 6 Mold Resulting from Humid Air Infiltration in Overcooled Health Clinic

the indoor dew point below 12.8°C during occupied periods and below 15°C during unoccupied periods.

Support for this maximum is documented in ASHRAE publications based on the collective experience and judgment of the authors and reviewers of those publications (Fischer and Bayer 2003; Harriman and Lstiburek 2009; Harriman et al. 2001; Spears and Judge 1997). Note, however, that the 12.8°C control level is not yet incorporated in an ASHRAE standard and has therefore not been subjected to public review. Consequently, each owner and designer must decide what indoor dew point maximum is prudent given the climate, the needs of the building, and the risks for that building and its occupants from any moisture or microbial growth problem. Following is the logic behind this control level, which should help readers use their own judgment about the prudent maximum dew point for different types of buildings, occupancies, and climates.

Keeping the dew point below 12.8°C protects the building from indoor condensation and excessive moisture absorption into cool surfaces. The 12.8°C dew point also allows comfort at higher dry-bulb temperatures, which reduces cooling energy consumption and provides comfort for a wider variety of activity levels and body types. At or below a 12.8°C dew point, occupants rarely need to overcool the space in order to achieve comfort (Fischer and Bayer 2003; Spears and Judge 1997).

Another reason for specifying a dew point maximum in place of a relative humidity maximum is that, in the past, guidance based on relative humidity has been ineffective in preventing moisture accumulation and the associated problems. A maximum 65% rh has been a traditional criterion, and some standards and codes still suggest that as a limit, but building failures have shown that this criterion is not always effective in preventing mold. Consequently, recent publications from ASHRAE, the U.S. Environmental Protection Agency (EPA), and U.S. General Services Administration (GSA) recommend a maximum dew point as a reasonable compromise between the competing goals of energy consumption, comfort, and mold avoidance during both occupied and unoccupied hours (EPA 2013; GSA 2014; Harriman and Lstiburek 2009; Harriman et al. 2001).

The basic problem with the 65% rh maximum is that it does not address what happens at the surface of cool materials, which is where problems occur. For example, consider 65% rh in an unoccupied office or day care center closed at night, or on weekends. The building's thermostat is often reset to 29°C to save energy. At that temperature, 65% means air has a dew point of 23°C. When the air-conditioning system begins to chill the building back down for occupied operation, any surface now cooled to 23°C has a surface relative humidity of 100%, not the 65% value shown by the HVAC control sensors (which measure the air). Air-conditioning systems' humidity sensors cannot measure the surface relative humidity on all of the cold surfaces on and behind the walls and above the ceilings.

Keeping the indoor air at or below a 12.8°C dew point avoids such confusion and provides an effective margin of safety for keeping building materials dry. At that dew point, the relative humidity at cool surfaces is very unlikely to rise to levels that promote the amount of mold growth shown in Figure 6.

Holding a building below a 12.8°C dew point is a conservative suggestion for standard operation, representing the collective experience of many who have investigated moisture problems in buildings. This limit will almost certainly reduce the risks of moisture problems caused by HVAC issues to a negligible level, and also reduce the risks of minor water leakage associated with architectural design and construction. Although the lower dew-point limit may also save energy, cost increases in terms of equipment and operating expense are possible. Many buildings all over the world have exceeded this criterion for a significant portion of their operating hours without any documented moisture or mold problems. Whether problems arise depends on many factors, including the sensitivity of the building material and of the furnishings and finishes, and (perhaps most importantly) the number of hours that interior surfaces are able to absorb moisture from the indoor air. The number of high-dew-point hours varies with climate, and often varies according to the design and operation of the HVAC system. More hours at high dew point increase risks, but do not guarantee failure.

Experience (e.g., Harriman and Lstiburek [2009]; Harriman et al. [2001]) also shows that, at high indoor dew points, occupants are very likely to turn down the thermostat to gain comfort, which increases energy consumption. Again, these difficulties will be more problematic as the number of humid hours outdoors increases.

Climate. In cool climates or high-altitude locations with only a few hundred hours of outdoor dew points above 12.8°C and a few hundred hours of air conditioning, the risk of higher indoor dew points above may be relatively low. Any problems would usually take many years to develop, if they indeed ever happen. But in mixed or humid climates where there are many thousands of hours when the outdoor dew point is above 12.8°C and where the air-conditioning season (i.e., when building surfaces are chilled) is long, problems may develop in a few months or a few years.

Drying During Unoccupied Periods

When a building is unoccupied and the weather outdoors is humid, keep the air inside the building dry, so that in turn, the surfaces of walls, floors, ceilings, carpets, furnishings, and contents remain dry enough to prevent mold growth.

Until recently, humidity control during unoccupied periods has often been ignored, because the HVAC design and its operation are, logically, focused on providing the lowest-cost system that will maintain comfortable temperatures with acceptable humidity levels when people are in the building. However, it has become increasingly apparent that moisture and mold problems are associated with unoccupied periods during the summer in schools, military barracks, and university dormitories and also in seasonally occupied buildings such as vacation apartments and condominiums (Light 2017; Light et al. 2015; McMillan and Block 2005).

To avoid growing mold in buildings that are not occupied constantly, the HVAC designer (and the system operators) need to make decisions that keep the indoor air dry during unoccupied periods. As a minimum, design and operate the HVAC systems so that humid outdoor air does not flood into the building.

First, ensure that when the building is not occupied, toilet exhaust fans turn off, so that exhaust fan suction does not pull humid outdoor air into the building. Next, make sure that all outdoor air dampers close tightly (ideally automatically) during unoccupied periods, so that these do not act as holes that allow infiltration of humid outdoor air. Finally, provide equipment and controls that continue drying the indoor air, independent of the cooling set point. This last point is important, but is often not addressed because most HVAC designs rely on cooling equipment to remove humidity as well as removing sensible heat. Although most cooling systems are adequate to keep humidity under control when they are in full operation, it is important to keep in mind that during intermittent operation, cooling systems may not actually remove any humidity.

During unoccupied periods, the thermostat set point is generally raised to reduce energy costs. At the higher set point, the thermostat calls for cooling only rarely, because sensible cooling loads are much reduced. Also as a result of the lower loads, the sensible cooling is accomplished so quickly that the cooling equipment turns off before any significant amount of moisture is removed from the air (Shirey and Henderson 2004). There are several strategies available that can address this limitation of cooling systems while still keeping operational costs low when a building is not occupied.

First, make sure that the dehumidification loads are kept low, by halting ventilation and exhaust fans and closing dampers to keep outdoor air out of the building as discussed above. After those measures have been implemented, either add a separate dedicated dehumidifier to the system to recirculate dry air during unoccupied periods, or operate the cooling system components towards the goal of limiting the indoor air dew point rather than keeping the air cool.

Drying during unoccupied periods can be partly accomplished in existing buildings that do not have dedicated dehumidifiers by ensuring that operation of cooling equipment is restricted in two respects: raise the cooling set point temperature to 27°C or above, and only allow cooling equipment to operate between the hours of 12:00 noon and 3:00 PM. This strategy has two beneficial effects. It keeps indoor surfaces warm, which discourages moisture accumulation. Then, by restricting the number of hours the cooling equipment can operate to the hottest hours of the day, the system is forced to operate for long periods to drop the indoor air to the thermostat set point. Long periods of continuous cooling provide some amount of dehumidification, even without dedicated dehumidifiers.

When designing new buildings, a much more robust dehumidification design strategy is to provide the building with dedicated outdoor air systems (DOAS) so that all the outdoor air is dried and filtered before it enters the building. Then the DOAS unit can be converted to a dedicated, recirculating dehumidifier during unoccupied periods. This can be accomplished at very modest first cost by providing the DOAS unit with two additional components: a return air connection and dampers that can close off the ventilation air when the building is not occupied. With that arrangement, air from the space can be dried by the DOAS in response to a dew point controller. As the indoor space rises towards a dew point of 15°C, the DOAS unit turns on to dry and recirculate the indoor air. Figure 5 shows a diagram of such a configuration.

The suggestion to control the indoor air dew point, rather than its relative humidity, is based on the fact that at high dry-bulb temperatures, a relative humidity setting that might otherwise seem reasonable could allow an excessive amount of moisture to accumulate in surfaces. For example, at 30°C, a relative humidity of 65% represents a dew point of 22°C. At that level of absolute humidity, the relative humidity at the surface is above 80% for any material that has a temperature of 25°C or below. Chances are good that, in any building that has mechanical cooling, some surface will often be below 25°C, due to leaking cold supply air duct connections and less-than-optimal placement of supply air diffusers. In contrast, controlling the indoor air dew point to less than 15°C when the building is unoccupied provides more certain avoidance of moisture absorption into surfaces, especially if the indoor air temperature stays above 27°C.

Design for Dehumidification Based on Loads at Peak Outdoor Dew Point

Peak dehumidification loads occur when the outdoor dew point is at its highest level—not when the outdoor dry bulb temperature is at its peak. In absolute terms, the outdoor humidity is 30 to 35% higher at the peak dew point condition compared to the humidity load at the peak dry bulb condition.

Figure 7 shows the effect of this difference on the humidity loads of a medium-sized retail building that complies with the requirements of ASHRAE *Standard* 62.1-2016. When the humidity loads are calculated at peak outdoor dry-bulb temperature, the load calculation grossly understates the humidity load occurring when the outdoor air is at its local peak dew point. Note also that magnitude of this unexpected difference in humidity loads is usually greatest in continental climates (e.g., Beijing, Cincinnati) rather than coastal climates (e.g., Miami, Hong Kong). To avoid the risk of major shortcomings in the design of the dehumidification components, the designer should use the peak dew point values for dehumidification load calculations. Peak dew-point design values for more than 6000 weather locations are provided in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* and on the CD accompanying that volume.

Mastic-Sealed Duct Connections

To reduce the risk of problems from humid air infiltration into the building and the risks of problems from chilling hidden surfaces in building cavities, specify that all air system connections must be both mechanically fastened and covered with mastic that has been reinforced for long-term durability. Air sealing is equally important for all connections to air handlers and to air distribution components such as filter boxes, fans, cooling and heating coils, and variable-air-volume (VAV) boxes. Less obviously, the requirement to seal duct connections also extends to all joints in exhaust air duct work.

Air leakage into and out of duct connections has been responsible for many of the most expensive and difficult-to-repair mold problems in buildings. Leaking exhaust duct connections pull air from interstitial spaces, much of which is replaced by untreated outdoor air leaking in through construction joints in the exterior wall. The suction created by the exhaust fan ensures that this humid air infiltration is large, and in many cases, continuous. See Figure 1 for the results of this shortcoming in HVAC and architectural design.

The same thing happens when return air duct connections or plenums leak. The suction of the system creates local negative pres-

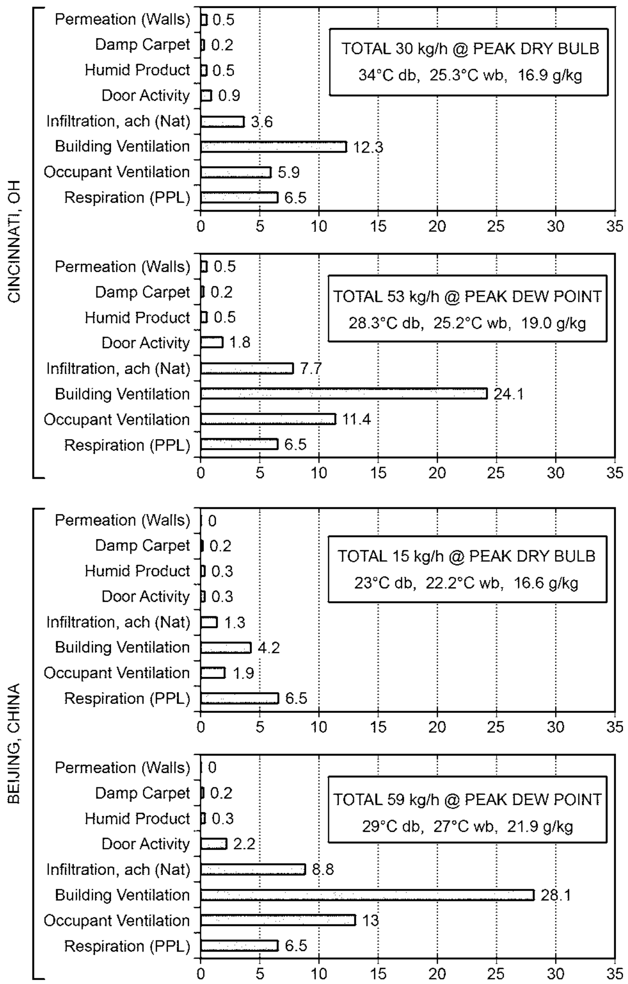

Fig. 7 Peak Dry-Bulb Versus Dew-Point Design: Retail Store Humidity Loads Based on ASHRAE *Standard* 62.1-2016

sures, which lead to humid air infiltration and subsequent moisture absorption by cool indoor surfaces.

On the positive-pressure side of the fan, any leaks mean that cold air escapes the duct, cooling surfaces behind walls, under floors, and above ceilings. Those cold surfaces can either condense moisture from humid air, or absorb moisture because their surface relative humidity is very high. Both problems result in mold.

The other problem with leaking connections and plenums is that they waste energy. In theory, if the leak is inside the thermal boundary, all the cooling energy stays indoors; in fact, if the cooling capacity is where it is not needed (e.g., in the attic, above the ceiling), the air-conditioning system must work harder and longer to get the needed cooling to the occupied zones. Thus, any air leaks waste fan capacity, fan power, and compressor energy.

In the past, vinyl or fabric-backed "duct tape" has often been used to satisfy a duct sealing requirement, but these materials have often proven inadequate over time. Field experience does not usually match the expectations set by the warranty of fabric or vinyl-based duct tape. Durability warranties are only for "properly applied" material in "properly designed" and "properly installed" joints. Apparently, it is more difficult to properly apply the duct tape than might be expected, because over time duct tape has proven to be unreliable. Connections that are mechanically fastened and sealed with either reinforced liquid-applied mastic or pressure-sensitive mastic carried on metal foil tape have not shown the same number or degree of problems.

According to measured data from field studies in California, Florida, New York, and Iowa, air leaks from duct connections waste between 25 and 40% of the annual energy needed to heat and cool the building (Cummings et al. 1996; Henderson et al. 2007; Wray 2006). Consequently, without airtight duct connections, the building is not likely to meet energy reduction targets no matter how efficient the heating and cooling equipment might appear from its ratings. Solving this problem is critical for reaching energy reduction targets: all air-side connections must be sealed with mastic, and unsealed plenums must not be used for either supply or return air systems.

Positive Building Pressure When Outdoor Dew Point Is Above 12.8°C

During occupied hours in the cooling season, risks of humid air infiltration can be reduced by providing more dry outdoor air to the building than the sum of the exhaust air. To reduce the risk of moisture problems during hot and humid weather, it is better to have any air leaks going out of the building. By providing a slight excess of dry ventilation and makeup air, most of the leakage will be from indoors to outdoors, so that air inside the exterior walls will be dry instead of humid. This keeps the building's materials from absorbing moisture, and the slight outward flow of dry air helps dry out rain leakage that sometimes finds its way into exterior walls.

In most buildings, it is not necessary maintain a specific, defined pressure difference between indoors and outdoors to reduce risks of moisture problems. It is usually enough to design and commission the system so that more air enters the building than is being exhausted. In the real world, it is nearly impossible to maintain a defined pressure difference at all points across the exterior wall at all times. The wind outdoors changes pressures on the exterior wall many times per second, and any system attempting to maintain a fixed difference across an exterior wall is likely to waste cooling, dehumidification, and fan energy by keeping the building overpressurized much of the time.

The purpose of the slight positive pressure is simply to keep most of the leakage going out rather than going in, most of the time. As long as that modest goal is achieved, and provided that the other risk reduction measures are installed, the exact amount of positive pressure does not really matter, and less is better. For example, 10% more air makeup than the total exhaust air is a long-standing rule of thumb, but with modern airtight buildings and airtight duct connections, 5% excess outdoor air is often sufficient.

To minimize energy waste, modern designs sometimes reduce both exhaust and ventilation air steams according to occupancy. The preferred way to do this is to interlock the DOAS system with the exhaust fans. As the exhaust fans reduce speed or turn off, reduce the airflow through the DOAS system, keeping the total outdoor air higher than the total exhaust air. This is often a more practical method than using pressure control. With a very small pressure difference as the target, the system would be constantly hunting (i.e., running the fan speeds up and down, attempting to provide just the right pressure difference).

Winter weather presents a different problem. In cold climates, major moisture and mold problems happen when humid indoor air is pushed into cold exterior walls. During the heating season, the humid air is now on the inside of the building rather than the outside. It is counterproductive to keep blowing warm, humid indoor air outward through the cold exterior enclosure, where it is likely to condense and create problems. Also, a great deal of energy is wasted by heating excess outdoor air to keep buildings under an arbitrary positive pressure during cold weather. Therefore, during the heating season, the airflow balance should target neutral building pressure with respect to the outdoors.

5. HEALTH-RELEVANT INDOOR DAMPNESS

Epidemiological investigators have shown clear and consistent associations between occupancy of damp indoor spaces and increased probability of significant adverse health effects such as development of new asthma, exacerbation of existing asthma, allergic rhinitis, and respiratory infections (Institute of Medicine 2004; Kanchongkittiphon et al. 2015; Kennedy and Grimes 2013; Mendell et al. 2011; Miller 2011; Miller and McMullin 2014; WHO 2009). Unlike some other health complications, illnesses triggered by damp indoor spaces are preventable.

Indicators of health-relevant indoor dampness in a building or space include either visible mold growth, damage from water or moisture, or musty/moldy/earthy odors. These indicators have each been clearly and strongly associated with increased probability of negative health effects for occupants, although no specific dampness thresholds have been established, and not all individuals are equally affected.

The term *mold growth* here refers to fungal colonization of building assemblies, finishing materials and coatings, or building contents. Growth reflects the fact that fungal spores have encountered adequate surface moisture on a suitable substrate to induce germination, and sufficient metabolic activity to develop colonies that can be seen with the unaided eye. Such visual evidence can include past growth that is currently dormant or dead, as well as currently active growth. Note that the presence of airborne fungal spores is not by itself evidence of growth in the space in question, nor is the presence of spores accumulated in surface dust. Fungal particles are quite common on indoor surfaces and air, even in well-maintained buildings. For example, one study quantified the number of discrete organisms that had characteristic DNA sequences of either bacteria or fungi in active, undamaged, and well-maintained university classrooms. (Qian et al. 2012). The researchers concluded that the typical bioburden imposed on the indoor air by the presence and movement of students resulted in resuspension and/or shedding of 37 million bacteria and 7 million fungi per person, per hour.

Quantitative metrics that can provide early warning of possible health risks from dampness include

- Persistent water activity levels above 0.85 at the surfaces of organic materials or coatings.
- Persistent moisture content above 15% wood moisture equivalent (WME) in organic materials, coatings, and untreated paper-faced gypsum board.
- Persistent moisture content above 80% equilibrium rh in concrete or masonry that is either coated or in contact with organic materials.
- Persistent indoor humidity above a dew point temperature of 15°C in buildings that are being mechanically cooled, or above a dew point temperature of 7°C in buildings that are being heated.

In this context, *persistent* means that the condition has become typical, extending for days or weeks at a time, rather than consisting of infrequent excursions of a few hours per week above these suggested thresholds, followed by a return to normal levels of dryness.

These thresholds are indicators of abnormal conditions that can ultimately lead to moisture accumulation and health-relevant indoor dampness. *Abnormal* here describes conditions that, although they may occur with some regularity in many buildings, are seldom (if ever) the basis of design for durable buildings and energy-efficient climate control systems.

Finally, keep in mind that these four suggested metrics and thresholds have not been documented to be indicators of health-relevant indoor dampness. They should be considered *early warnings* of possible health-relevant dampness at some future date. They do not provide quantitative validation of *current* health-relevant dampness.

6. MEASURING BUILDING DAMPNESS

6.1 WATER ACTIVITY

When moisture in a material is loosely bound, the moisture is more easily accessible to mold. Given equal temperature and nutrient value for any given mold type, the factor that most governs growth is not material moisture content, but rather how tightly that moisture is bound into the material's molecular structure. The concept of **water activity** provides a means of quantifying the biological growth potential of a damp material by measuring how tightly moisture is bound in a material. Consequently, it is the metric used by biophysicists and mycologists to define mold growth potential. It is the ratio of the water vapor pressure in the material to the water vapor pressure in the surrounding air, if that air were to be fully saturated at the same temperature as the material. (A useful engineering shorthand description is that water activity provides a measure of the bioavailability of water in a material. High values mean that water in the material is more easily accessible to bacteria and fungi. Lower water activity values mean that the material's moisture is more tightly bound and therefore less available to support fungal and bacterial growth.)

Water activity is measured most accurately by sealing the material in question into a small container, and then allowing the air inside that container to come into complete hygrothermal equilibrium with the material. The temperature of both air and material must be identical, and the air in the sealed container must have the same relative humidity as the air inside the pores of the material. After the hours or days necessary for both variables to reach simultaneous equilibrium, water activity of the material is measured by reading the relative humidity inside the sealed container. Water activity is reported as the decimal equivalent of the equilibrium relative humidity. For example, relative humidity measured at 80% after complete hygrothermal equilibrium inside the sealed container is reported as a material water activity of 0.80.

Water activity as low as 0.75 has allowed slow mold growth in an ideal laboratory environment of constant temperature and moisture, in a nutrient-rich and biologically accessible growth medium such as a Petri dish filled with malt extract agar. However, building materials are typically formulated to avoid mold growth. Also, in a building environment, damp areas usually benefit from a small amount of drying through normal HVAC system operation. Consequently, measured values of water activity below 0.75 usually indicate a low risk of mold growth, even in the most nutrient-rich building materials and coatings.

Measuring water activity in buildings can never be identical to measurements in a sealed container in a lab environment, because nothing is ever at complete hygrothermal equilibrium in buildings. Materials are always gaining and losing small amounts of both heat and moisture, even when there is no excessive dampness. Also, it is not practical to seal up entire installed building components into a tightly sealed small container, much less wait the days, weeks, or months necessary for such a sealed container's air and the material to reach identical temperature and relative humidity. When water activity measurements are made in a building, they are more accurately described as the **near-equilibrium surface water activity** rather than as the biophysically defined term of water activity. Given that water activity is abbreviated as A_w, to avoid confusion with the microbiological literature of the late twentieth century the building-relevant near-equilibrium surface water activity should be abbreviated as A_{ws}.

Surface water activity measurements are made in buildings by attaching a relative humidity sensor within a few millimetres of a target surface, and then covering both sensor and target location with a shield that isolates the two from direct contact with the surrounding air and any air movement. An ideal sensor attachment and shielding approximates the environment of the sealed container used in laboratory measurements while not impeding the lateral diffusion of heat and moisture within the material that occurs in any normal building environment.

6.2 MOISTURE CONTENT

Although moisture content and water activity are not the same thing, it is often true that when a material has a high moisture content, it may also have a high water activity. When water activity measurements are not available, moisture content measurements can provide a potentially useful quantitative indicator of relative dampness. It is important to remember, however, that there is usually a wide variation between moisture content readings taken in nearly the same location. There are two principal causes of this variation: different exact measurement location and different scales and measurement technologies of moisture meters.

Importance of Documenting Measurement Location

Figure 8 shows the variation in moisture content readings in the same material, in the same environment separated by a distance of less than 150 mm. Mold growth is apparent where the moisture content reading is above 20% wood moisture equivalent (WME). Just a few millimetres away, the same meter shows the moisture content to be less than 15% WME, and in that location, no mold growth is visible. This figure illustrates two key points about moisture content measurements: they can and do vary widely within a few millimeters, and small differences in measured moisture content can lead to big differences in mold growth rates.

Moisture Meter Distinctions

Different types of moisture meters use different measurement principles, and each manufacturer generally chooses to scale the measured values differently. Therefore a moisture content reading of 26% has no useful meaning until both the meter model and the

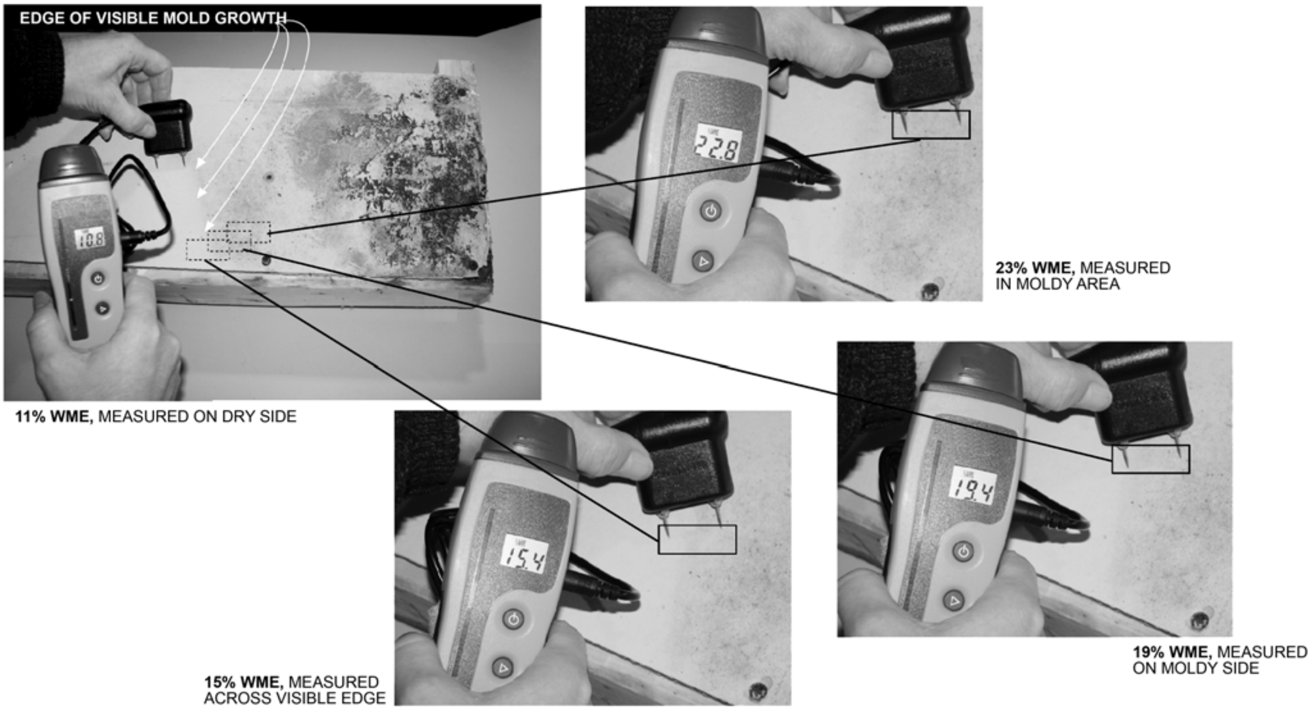

Fig. 8 Variation in Moisture Content and Mold Growth Across Short Distances

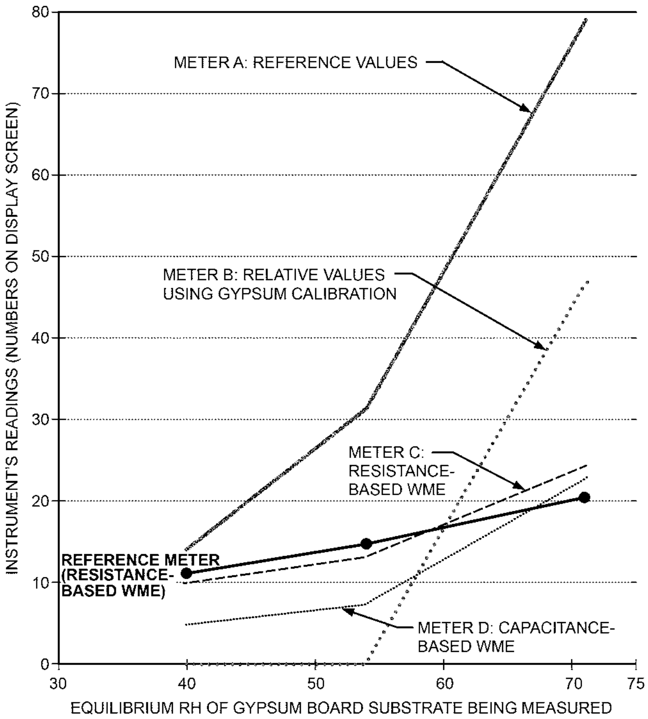

Fig. 9 Variation in Moisture Meter Readings on Same Material

meter's scale are defined. Figure 9 shows why this issue is important in assigning any level of concern based on readings from undefined moisture meters. It shows that readings from different meters provide very different values when connected to the exact same electrodes planted in the same material at the exact same moment. This

Fig. 10 Example of Documenting Both Values and Pattern of Moisture

is not a matter of meter accuracy, but rather because each moisture meter manufacturer designed both the measurement principle and the scale for different purposes, and each different material has different electrical characteristics that affect the meter reading.

Similar variability is also typical of water activity measurements in buildings, because of different means of attaching sensors to building assemblies. Consequently, the investigator concerned with assessing the extent of moisture and dampness in a building is well advised to

- Note the date and time, and document the exact location of readings using a camera (Figure 10)
- Record the manufacturer, model number, and measurement scale of the instrument used to make the measurements

Building owners, investigators, and those who read their reports should consider that observations and measurements made at a single moment, at a single location in a building are rarely representative of that entire building's behavior over the extended time frame and variability of normal building operations. Also, different types of building materials, building construction, and environmental exposures present quite different risks with respect to dampness. Consequently it is usually helpful to make repeated visual observations, interview building occupants, and take measurements in all suspect locations over a representative time frame of days or weeks to obtain the information to support robust conclusions about the causes and risks of dampness in a given building.

MODELING AND EVALUATING OCCUPANT-CENTRIC HVAC CONTROL SYSTEMS 65.8
Whole-Building Performance Simulation Programs 65.8

HUMANS generally spend 87% of their time in buildings, living and working (Klepeis et al. 2001). Understanding dynamic and diverse occupant comfort needs as well as occupant interactions with building systems is therefore crucial. Building design and operations must meet energy performance goals while providing healthy and productive living and working environments. At the same time, occupants also influence building performance (not just the other way around). For example, the International Energy Agency (IEA) Energy in Buildings and Communities (EBC) Programme Annex 53 (*Total Energy Use in Buildings: Analysis and Evaluation Methods)* identifies and evaluates occupant behavior as one of six key factors influencing energy use in buildings (IEA 2016).

Occupant actions such as adjusting a thermostat for comfort, switching lights on/off, using appliances, opening/closing windows, pulling window blinds up/down, and moving between spaces can significantly impact both energy use and occupant comfort. Depending on the building type, climate, and degree of automation in operation and controls, such behaviors can impact energy use by up to a factor of three for residential buildings (Andersen 2012), and result in an up to 80% increase or 50% decrease for single-occupancy offices (Hong and Lin 2013). One simulation study (Sun and Hong 2017) also estimated occupant behavior measures to have a 41% energy savings potential for office buildings.

Nevertheless, there is currently little integration of information about occupancy and occupant preferences in building control systems. Taking advantage of this information, energy use can be reduced with optimized scheduling of HVAC systems (Sun et al. 2014); herein, such scheduling is referred to as *occupant-centric building control*. Occupant-centric sensing and controls include detection or monitoring of occupant presence, movement, comfort level, interactions with building systems, and other environmental adaptations, as well as the operational strategies required to meet occupants' needs with respect to thermal, visual, and acoustic comfort, and indoor air quality.

Figure 1 demonstrates an occupant-centric control scheme in which occupancy information (e.g., presence, count, and activity) and indoor environmental parameters (e.g., temperature, humidity, and CO_2 concentration) are detected and transferred as a feedback signal to the control system. Control algorithms find optimal set points for zone parameters (e.g., temperature, illuminance, ventilation), accounting for occupant comfort models and feedback, and implement the chosen control action.

This chapter provides a technical overview of occupant-centric sensing and control, including data collection and modeling approaches. Focus is primarily on HVAC-related controls (e.g., where zone temperature is set based on real-time occupancy and/or comfort measurements); in many cases, such control schemes also incorporate predictions about future occupancy and/or comfort states. In previous applications, such occupant-centric HVAC control schemes have demonstrated significant energy savings potential (10 to 40%), while maintaining or improving occupant comfort outcomes (Ghahramani et al. 2014; Nagy et al. 2015; Williams et al. 2012).

1. COLLECTING REAL-TIME OCCUPANCY AND OCCUPANT COMFORT FEEDBACK

Occupant feedback to a building management system can be categorized as indirect, where the system passively monitors occupants and takes appropriate actions; direct, where occupants provide input to control the system; or a hybrid (Munir et al. 2013).

1.1 INDIRECT OCCUPANT FEEDBACK

Indirect occupant-centric control schemes use measured variables as proxies for real-time occupancy and/or occupant comfort data. Such variables may include infrared light, pressure, equipment power consumption (e.g., computers), control states (e.g., VAV damper position, door or window status), Wi-Fi network logs, and environmental measurements (e.g., volatile organic compound [VOC], CO, or CO_2 concentration; ultrasonic or audible sound; illumination; temperature; humidity). Statistical or physical models are used to uncover latent occupancy information in data and infer the presence and/or number of occupants in a zone.

Examples of indirect occupancy feedback schemes are found in Labeodan et al. (2015), where chair sensors are used in an office building to provide fine-grained occupancy information for demand-driven control applications; Ardakanian et al. (2016), where apparent zone-level occupancy is inferred from building automation system data and used to tune set points to real-time occupancy patterns; Goyal et al. (2015), which examines the relative benefits of rule-based and model-predictive control of commercial HVAC using real-time occupancy measurements from a passive infrared sensor; Agarwal et al. (2010), which uses a combined passive infrared and reed switch sensor to detect occupancy in an office and set back thermostat set points when no occupancy is detected; and Jin et al. (2015), where occupant counts are inferred through supply and return air CO_2 concentrations and used to drive a demand-controlled ventilation strategy.

For indirect comfort feedback, proxy measurements include outdoor temperature, which can be translated to group-level comfort predictions using the adaptive comfort standard, as well as indoor temperature, humidity, and air velocity, which can be paired with assumptions about typical occupant clothing and metabolic rate (Erickson and Cerpa 2012), or indirect measurements of such variables, (e.g., via respiratory sensors) to calculate predicted mean vote (PMV) (Fanger 1973).

Additionally, recent research suggests that measurements from wearable devices for skin temperature, perspiration rate, and heart rate may be used as proxies for individual-level occupant comfort,

The preparation of this chapter is assigned to MTG.OBB Occupant Behavior in Buildings

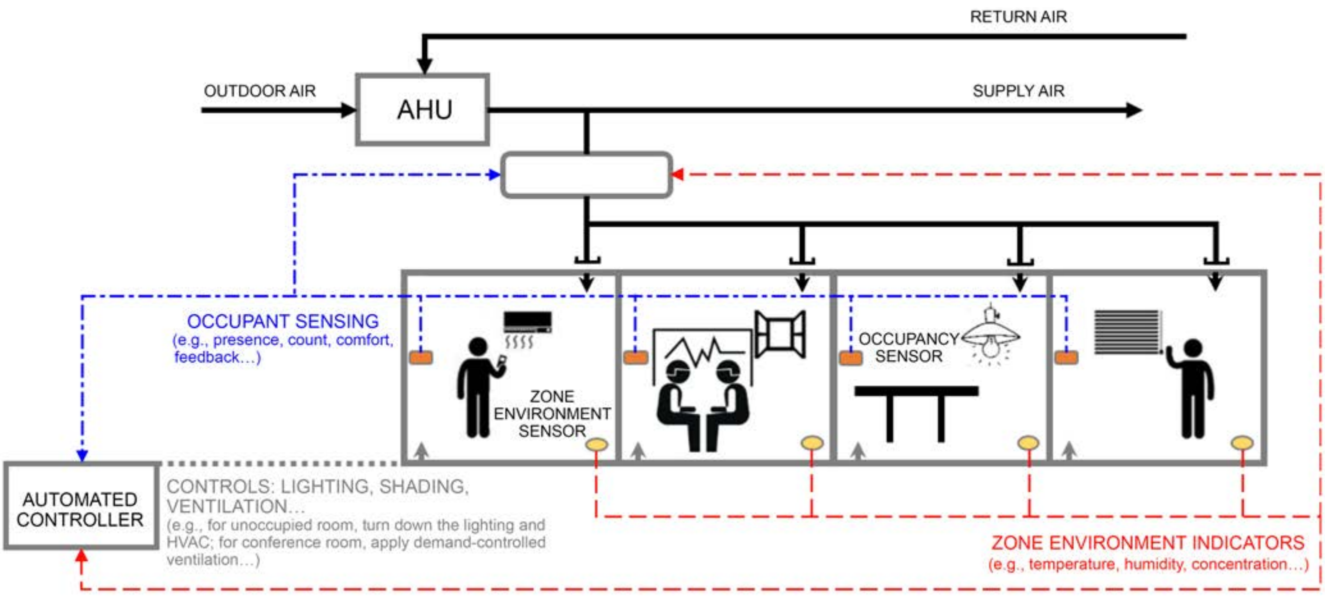

Fig. 1 Occupant-Centric Sensing and Control Scheme

though the accuracy and large-scale deployment potential of such techniques remain uncertain (Abdallah et al. 2016). Another study suggests that occupants' control interactions (e.g., interactions with personal comfort systems [Kim et al. 2018a, 2018b]) may also be effective predictors of individual-level comfort.

Examples of indirect comfort feedback schemes are found in Abdallah et al. (2016), where traditional environmental sensing data streams are fused with wearable sensing information to predict PMV; Klein et al. (2012), where occupant preferences and schedules are coordinated with building system device control using a multiagent framework; and Nagy et al. (2015), where set points for switching artificial lighting on and off are derived dynamically from statistical analysis of occupancy sensor data and occupant lighting control actions.

1.2 DIRECT OCCUPANT FEEDBACK

Direct occupant-centric control schemes require occupant input to determine real-time occupancy and/or occupant comfort. In the case of the former, direct feedback may include visual, infrared, or depth camera-based determination of occupant presence and/or count; radio frequency tagging of occupants; or detection of personal devices using Bluetooth beacons. Here, occupancy is determined through physical interaction with spaces and sensing instruments, rather than inferred through proxy variables (as in indirect feedback schemes).

Examples of direct occupancy feedback schemes are found in Newsham and Arsenault (2009), where a camera-based system for lighting and shading control was developed using an image subtraction technique; and Li et al. (2011), where a radio frequency identification (RFID)-based occupancy detection system estimates occupant counts across multiple spaces in real time, supporting demand driven HVAC operations.

Direct comfort-feedback schemes collect real-time occupant comfort input via survey interfaces on personal electronic devices such as smart phones, tablets, and computers. Such surveys typically ask an occupant to register their current environmental preference (e.g., cooler or warmer, darker or lighter, no change), feeding these preference votes back to the building management system to drive heating, cooling, and lighting adjustments. Various preference scales are suggested in existing literature, including the ASHRAE *Standard* 55 thermal sensation scale, the Bedford comfort scale, the McIntyre three-point preference scale, the binary thermal acceptability scale, and combinations or simplifications of these (Jazizadeh et al. 2014a; Zhang et al. 2015). In building zones with multiple occupants and preference votes, votes must be aggregated by the building management system before a control action can be determined. This aggregation may be achieved through simple averaging or with determination of a simple majority consensus (Shin et al. 2017). Alternatively, more sophisticated vote aggregation approaches may be used, such as when errors between each occupant's vote and a reference vote are summed across occupants and minimized by the attendant control strategy (Purdon et al. 2013) or votes are weighed differently according to occupant type (e.g., employee versus visitor) and vote history (Erickson and Cerpa 2012).

Direct comfort feedback schemes are characterized by the persistent requirement for occupant votes to change building operation; in the absence of these votes, control states remain unchanged from default schedules and unaffected by dynamic variables that might serve as proxies for occupant comfort, as previously discussed.

Examples of direct comfort feedback schemes are found in Chen et al. (2014), wherein a dynamic thermal sensation (DTS) model that incorporates real-time thermal sensation votes is used to optimize the control temperature of an experimental chamber; Purdon et al. (2013), where a model- and sensor-free control algorithm paired with real-time user comfort votes drives HVAC operation; and Pritoni et al. (2017), where student comfort votes collected and averaged every five minutes override thermostat set points, which, in one case, are allowed to slowly drift towards outdoor temperatures to yield energy savings.

1.3 HYBRID OCCUPANT FEEDBACK

Hybrid occupant-centric control schemes merge direct occupant feedback with indirect occupant measurements in order to minimize the burden of reporting for occupants and increase the accuracy and coverage of real-time occupancy and/or occupant comfort measurements. Hybrid approaches to both occupancy and comfort involve learning schemes in which direct input informs and trains models that use occupant proxy variables as inputs. Once trained, such models predict real-time occupancy and/or comfort, given changes

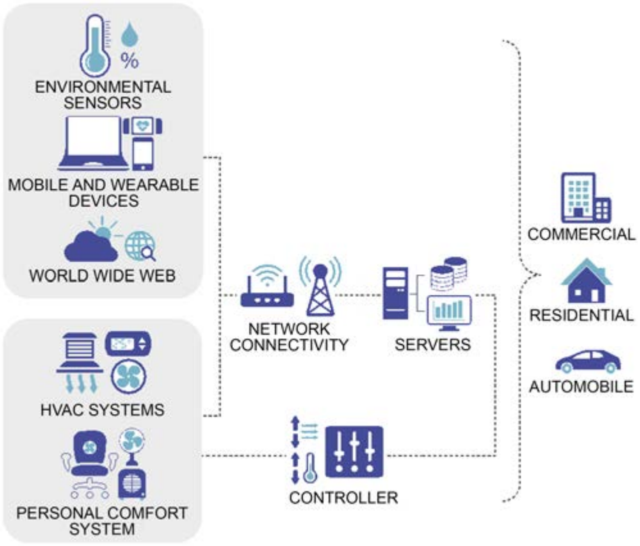

Fig. 2 System Architecture for Occupant-Responsive Environmental Control
(Adapted from Kim et al. [2018)])

in the proxy inputs and without the need for direct occupant input. In some instances, occupant inputs beyond the initial training period are used to update model input coefficients (Lee et al. 2017), while in others, control actions accommodate requests for changes while keeping model coefficients consistent (Ghahramani et al. 2014).

Several examples of hybrid occupancy and/or comfort feedback schemes are found in the existing literature, including Peng et al. (2017), where temperature setbacks are inferred based on occupancy profiles learned from historical (two to four weeks into the past) occupancy data collected by motion sensors; Jazizadeh et al. (2014a, 2014b), which fuse comfort votes and ambient temperature data, compute comfort profiles using a fuzzy rule-based descriptive and predictive model, and use the learned comfort profiles to control an HVAC system; Lee et al. (2017) and Sadeghi et al. (2017), which use a Bayesian approach to efficiently learn and update personalized thermal and lighting preference profiles, clustering occupants based on preferences; Kim et al. (2018a, 2018a), where several different machine learning approaches effectively predict individual-level thermal comfort, leveraging data on occupant interaction with personal comfort systems and other local environmental data; Ghahramani et al. (2014), which trains zone-level personalized comfort profiles and selects zone temperature set points based on an optimization of energy, comfort profile, air quality, and system performance; Winkler et al. (2016), which explores several HVAC control strategies that incorporate occupant thermal preferences learned from comfort voting feedback; and Daum et al. (2011), where user comfort votes are translated to probabilistic comfort profiles that serve as optimization functions for blind control.

Figure 2 provides a diagrammatic overview of an occupant-centric control system architecture that incorporates both direct and indirect occupant feedback. As shown in the figure, occupant data drawn from a variety of sources, including environmental and wearable sensors and mobile devices, are merged with data from the building management system and personal environmental control devices (Zhang et al. 2015) on control states and local environmental conditions. This figure pertains to HVAC control, but the same feedback loop applies to lighting, ventilation, and plug load control schemes. A more complete characterization of the types of sensing equipment available for occupant data collection is provided in the following sections.

1.4 STATE-OF-THE-ART OCCUPANT SENSING

A wide range of sensor types has been implemented in the field to collect information on occupants and their interactions (presence, actions, power consumption, etc.) with the built environment. This information establishes a foundation to study the physiological, psychological, and social aspects of occupant behavior. This section summarizes existing data acquisition technologies in terms of field applications and develops nine performance metrics for evaluation. The reviewed technologies focus on both occupant presence and interaction with the built environment, and are categorized into six major categories: threshold and mechanical, image-based, motion sensing, radio-based environmental, human-in-the-loop, and consumption sensing (Andreas et al. 2018).

Threshold and Mechanical Sensing. Threshold and mechanical sensors detect or change the acquired state of building components with which occupants frequently interact, such as windows or doors. Examples in this category include

- *Reed contacts*, which detect whether a door or window has been opened or closed
- *Door badges*, which an occupant must swipe to access a room
- *Piezoelectric mats*, which produce an electric signal when an occupant stands or walks on them
- *Infrared (IR) beams*, which produce a signal when the beam is blocked at the entrance.

Image-based Sensing. Image-based sensing collects objective and quantitative occupant data. The primary focus of image-based occupant detection technologies is to track people as they move through spaces (Erickson et al. 2014; Gade et al. 2012, 2013; Kamthe et al. 2009; Kumar et al. 2014). If errors can be excluded (such as accounting for noncovered areas in a space), image-based sensing can provide ground truth information for studies using other sensors (Dong and Lam 2011; Dong et al. 2015; Erickson et al. 2009; Hutchins et al. 2007; Lam et al. 2009; Li and Dong 2017; Meyn et al. 2009) and to study occupant interactions with building elements such as windows (Inkarojrit 2005; Konis 2012), blinds, and shades (Kapsis et al. 2013; Reinhart 2001), or occupant evacuation (Proulx and Reid 2006). The most advanced versions of image-based technology use detection algorithms running within the packaged visible light camera hardware to detect the direction and number of people traveling through a space (Wang and Fesenmaier 2013). Simpler approaches use visible light cameras to detect motion (Ding et al. 2011). Challenges associated with this data collection method include the analysis of visual information and ethical considerations.

Motion Sensing. Passive infrared (PIR), ultrasonic Doppler, microwave Doppler, and ultrasonic ranging sensors (Agarwal et al. 2010, 2011; Hnat et al. 2012; Yavari et al. 2013) are commonly used motion sensors. PIR is by far the most common. This sensor can be used for lighting control and to verify occupant presence models (Dong and Lam 2011; Dong et al. 2015; Yavari et al. 2013). PIR sensors are only accurate if mounted to achieve good coverage of the areas of occupancy. These sensors often under count because they require line of sight and become inactive when occupancy activity is low. The ultrasonic and microwave Doppler sensors measure frequency (the speed at which an object is moving toward or away from the sensor). Doppler sensors are technically advanced and have greater sensitivity than PIR sensors, yet are not commonly applied for building automation. They also tend to over count due to extreme sensitivity to smaller movements. Ultrasonic range sensors, meanwhile, measure the distance to objects and have been used to measure motion through doorway passing events (Hnat et al. 2012). Ultrasonic range sensors have moderate cost, and accuracy is only good if the mounting environment is free from ultrasonic noise and no nonhuman objects are moved through the doorway.

Radio Signal Sensing. Radio signals cover the range of electromagnetic wave frequencies from 10 kHz to 300 GHz (Misra and Enge 2011) and are sent from a transmitting node to a receiving node. The signal consists of a short series of pulses or a modulated radio signal. Radio signals can provide occupancy information such as user location, presence, count, identity, and movement (Martani et al. 2012). It is important to consider that radio signals transmitted through air are affected by humidity, the presence of other signals, and many other environmental factors that can have a significant impact on the accuracy of the sensing results. Different types of radio-based technologies have been standardized and commercialized and can be used for occupancy detection. Relevant radio technologies for occupancy detection include radio frequency identification (RFID), Wi-Fi/Bluetooth®, ultra-wideband (UWB), and global positioning system (GPS).

Human-in-the-Loop. The human-in-the-loop method requires humans to be involved in the measurement and collection of occupancy and/or comfort or behavior data. There are three approaches in this category. **Manual observations** cover the logging of data by a person directly sensing the information being relayed (e.g., counting the people walking through a hallway in person or watching a video recorded in a building and annotating the video with occupancy information). Manual observations are often used as the ground truth when evaluating the accuracy of other occupancy sensors. This method is costly because of the labor required, but can achieve high accuracy if it is possible to precisely define the task to ensure consistency in interpretation and recording. **Internet-based occupant data** cover various types of data provided by occupants and collected by applications such as social networks, calendars, or surveys. Although there are some privacy concerns associated with this approach (e.g., collecting sensitive information), many organizations already gather such data, which brings down the cost of occupancy sensing. Methods combining social networking and calendar data have been proposed for the estimation of cubicle occupancy (Ghai et al. 2012). **Device interactions** include occupant action data registered through interaction with control interfaces. Common interfaces include thermostats, light switches, and controls for motorized blinds. Wall thermostats and other modern control interfaces often contain programmable buttons to execute occupants' control decisions, such as increasing/decreasing temperature set points, turning on/off lighting, and adjusting the position of motorized blinds. Logging occupant manipulation of motorized blinds is a more common method of using sensors for monitoring blinds.

Consumption sensing. Consumption sensing derives information about occupant presence or behavior from measured water and energy consumption in buildings. The accuracy of such methods depends on the level of metering granularity, which ranges from one meter per building to one meter per receptacle/fixture. Better metering granularity can be obtained via algorithmic methods (i.e., nonintrusive load monitoring methods) that split total consumption into its individual components. The cost of such methods is directly related to the cost of installing relevant metering. Existing studies have shown that the power consumption of electric appliances in offices and homes has a very high correlation with usage of appliances (Dong et al. 2015) and occupancy status of the space (Zhao et al. 2014). More recently, smart water meters have been used for detailed monitoring, but the deployment of smart water meters is still far behind that of electricity meters (Ranjan et al. 2014; Xue et al. 2017).

Mixed Sensing. Due to the daily interactions between occupants and indoor environment (generation of heat, pollutants [e.g., CO_2, odor] and sound, opening and closing of windows, and lights being turned on and off), a single sensing technology often cannot cover the full range of occupant comfort/behavior and presence. A mixed sensing approach can be adopted, whereby various types of sensors are used together (sensor fusion). A typical example is an information technology enabled sustainability testbed (ITEST), developed by Dong and Lam (2011). This includes occupant sensing, data acquisition, data storage and management, and data processing. ITEST uses PIR and an array of sensors, including cameras and devices measuring total volatile organic compound (TVOC) concentration, CO_2, temperature, illuminance, relative humidity, and acoustics. Together, these detect and predict occupant presence and numbers in an office building (Dong and Lam 2011).

Performance Metrics for Occupancy Sensing Technologies

The following performance metrics, shown in Table 1, are developed based on review of current sensing technologies and adapted from Andreas et al. (2018).

Cost. The total cost of deploying an occupant sensing technology. The cost encompasses several elements, such as hardware, installation and integration, and operation.

Power Type. The manner in which a sensing technology is powered (such as external or self-powered).

Data Storage. Data storage options provided by a given sensing technology. Internal storage uses an onboard device. If data from the sensor(s) is stored on a server or a distributed environment (networking), details of that architecture should be reported.

Deployment Type. Any description of an occupant detection technology should specify how it is deployed, including three key components: type of building, type of room(s), and specific deployment.

Sensing Range. Where applicable, an occupant sensing technology should be tested to find the maximum (and if relevant, minimum) range, as well as the area or view angle that it can cover.

Data Sensed. Data can be divided into five categories: presence, count, people tracking, state, and actions. Most technologies are only concerned with one type of data at a time. This distinction is the most critical for occupant sensing technology and should be precisely and clearly noted.

Collection Style. The collection method of an occupant detection technology should be reported, distinguishing between periodic (taking a sample at a fixed time period) and event-based (taking a sample when triggered).

Accuracy and Failure. Where possible, the absolute accuracy should be reported, compared to a manual observation or other relevant methods. In addition, any report on a new technology or deployment area should consider potential situations of sensor failure, such as failure due to environmental conditions, system failures, or inaccuracies.

Demonstrated Control Applications. Demonstration level of an occupant action and presence detection technology can be evaluated by two main factors: the number of papers reporting on it and whether or not it is commercially available.

2. INTEGRATING OCCUPANT FEEDBACK INTO HVAC CONTROL SCHEMES

Traditional Control Methods for HVAC Systems

Traditionally, a building automation system (BAS) provides a centralized management system to control heating, ventilation, air conditioning, lighting, safety, and security, to achieve occupant comfort and efficient building operation (Carlson and Giandomenico

Table 1 Overview of Occupancy Sensing Technologies and Their Performance Metrics

			Power Type		Data Storage		Deployment Type		Sensing Range		Data Sensed							Demonstrated Control Applications

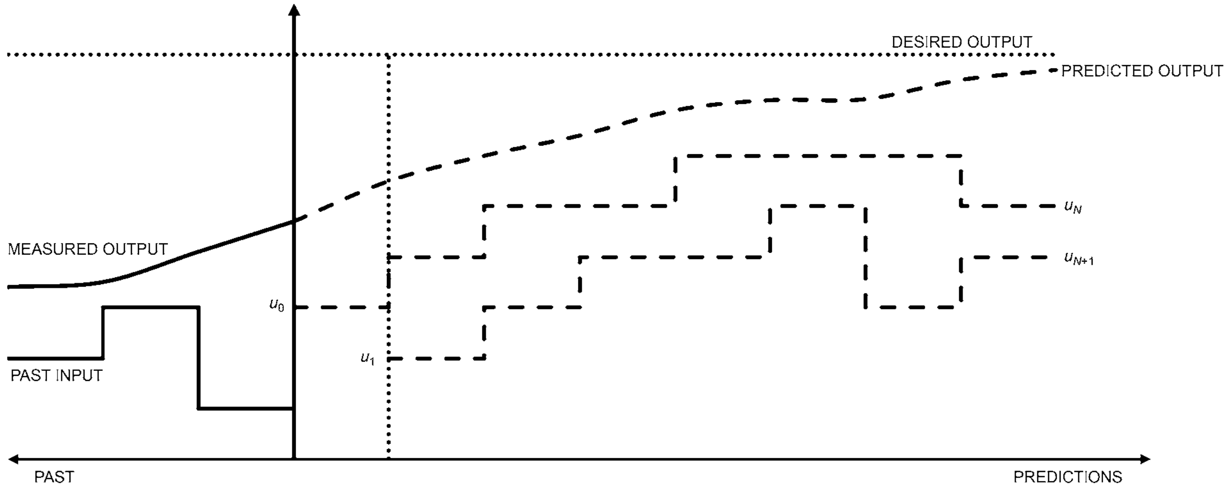

Fig. 3 Receding Horizon Control Actions
(Adapted from Mirakhorli and Dong [2016])

1991). Most control methods used in traditional BAS can be divided into two main categories: supervisory and local controllers. Supervisory (high-level) controllers define set points for local controllers to achieve cost-efficient thermal comfort without violating system constraints (Wang and Ma 2008). Local (low-level) controllers manage each low-level hardware component of the system to achieve their functions.

The low-level category can be divided further into the subcategories of sequencing and process control. Sequencing control turns each component on and off, while process control brings each component state to desired values. Over the past few decades, different supervisory control methods have been developed, including PID, optimal, model predictive control (MPC), robust, nonlinear, and adaptive controllers (Naidu and Rieger 2011a, 2011b). Optimal and model predictive control methods are known for their attractive energy savings potential; MPC and robust controllers are recognized for their capability in dealing with model uncertainties and disturbances (Gang et al. 2015). Among all these controllers, PID and on/off controllers are most popular, due to their simplicity and ease of implementation.

Occupant-Driven Rule-Based HVAC Controls

Occupancy measurements have commonly been integrated into building controls for lighting and HVAC systems (Bourgeois et al. 2006; Erickson et al. 2009; Hoes et al. 2009; Roetzel et al. 2010). Typically, a motion or PIR sensor is installed in a space to indicate whether the space is occupied or not. If the space is occupied, lighting is turned on and the temperature set point is aligned with the daytime preference temperature. Otherwise, lighting is turned off and the temperature set point goes to setback mode. Such occupancy-driven rule-based HVAC controls have demonstrated significant energy savings in both simulation case studies and field experiments. For example, PIR sensors were installed for two weeks in ten offices to measure occupancy presence and then a simulation study carried out to show that 10 to 15% energy savings in VAV boxes can be achieved. Erickson et al. (2011) found that 42% energy saving is achieved using an occupancy-driven rule-based controller, compared to use of a baseline controller that does not know occupancy information in advance. Ding et al. (2016) demonstrate 35.9% energy saving in simulation using a Markov-model-trained occupancy prediction for cooling control.

Most of the time, overtime work in companies is not accounted for. There are some studies that attempt to model the number of occupants in the building after regular working hours in commercial buildings (Sun et al. 2014). Gunay et al. (2015) models occupancy arrival and departure in commercial buildings with data from PIR sensors, with a resulting 10 to 15% energy saving in an EnergyPlus simulation.

In addition to the temperature set-point controls, occupancy measurement is also used for room ventilation control. Yuan and Perez (2006) introduce an algorithm to preventilating each room based on occupied status of neighboring rooms and demonstrate 6.1 to 19.7% energy savings compared to a traditional control. Specifically, each unoccupied room is preconditioned if a neighboring room is occupied.

2.1 MODEL PREDICTIVE CONTROL (MPC)

MPC is a method to design control sequences based on a prediction of future inputs to best optimize an objective function considering system constraints. It references a physical model of the system, system inputs, and potential disturbances (e.g. outdoor weather, occupancy, solar gain) to predict future system states (e.g., indoor temperature) and implement the most efficient control action (García et al. 1989; Hazyuk et al. 2012). Figure 3 provides a simple illustration of how MPC projects the control sequence over a prediction horizon determined by an online optimization. The control time step ranges from minutes to days. Because the MPC is typically running online in a real-time environment, there is a trade-off between controller time-step required by the online optimization and the precision of the optimizer. Typically, MPC for building systems is formulated as an optimization problem, defined by Equations (1) to (4), to minimize energy consumption. At each time step, the controller is asked to determine new values for the control variable at the current time step. For these equations, f is the objective function where the total energy consumption or cost is defined. x represents the system states (e.g. indoor temperature), u is control inputs, and w is the disturbances to the system (e.g., occupancy schedules). g is a function representing system dynamics and computes states x over the prediction horizon.

$$\min_u \sum_{t=1}^{N} f(u_t, x_t, w_t) \tag{1}$$

$$\text{s.t. } x_{t+1} = g(u_t, x_t, w_t) \qquad t = 1, \ldots, N \tag{2}$$

Table 2 Optimization Methods and Related Software for Solving Occupancy-Based MPC Problem

Objective Functions

The goal of an MPC design is commonly defined as optimizing whole-building energy consumption, overall system efficiency, operation cost, greenhouse gas emissions, occupant thermal comfort, indoor temperature set point, or utility bill cost. Sometimes, multiobjective functions are defined, such as energy consumption and weighted zone temperature by occupied status (Dobbs and Hencey 2014), CO_2 emission along with overall cost (West et al. 2014), or PMV and energy cost (Cigler et al. 2012).

Constraints

One of the most commonly used constraints for building HVAC control is occupant thermal comfort. There are two main approaches to introduce this constraint to the overall optimization problem. The first approach sets predicted mean vote/predicted percentage dissatisfied (PMV-PPD) and temperature bounds (Biyik et al. 2014; Freire et al. 2008; Gao and Keshav 2013). In addition, a data driven Wiener-logistic comfort model has been used as a constraint to a stochastic and deterministic MPC problem to optimize energy use and occupant comfort (Chen et al. 2015). To reduce computational complexity, the nonlinear PMV formulation is often linearized (Cigler et al. 2012). Other constraints include limitation of a physical system, equipment efficiency, system states, and uncertainties in future weather forecasting, internal heat gains, and occupant behavior.

Optimization Method

Building system control is well known for its nonlinearity and discontinuity. As a result, the commonly used gradient-based optimization algorithms have difficulty solving the problem. Metaheuristic evolutionary algorithms such as genetic algorithm (Ascione et al. 2014; Xu et al. 2009) and particle swarm optimization (Zou et al. 2010) have been implemented to solve the building system MPC optimization problem. Linear programming (Gwerder and Tödtli 2005), mixed integer programming, dynamic programming, and quadratic programming have also been implemented. Table 2 summarizes optimization methods and software used by different studies in building thermal model predictive control with occupancy.

Building and HVAC Model

The thermal network model (RC model) is a common physics-based model used in occupant-driven MPC design. In this model, heat transfer between the building envelope and outdoor conditions is modeled as thermal resistance and capacitance with thermal storage capacities. Zone heat transfer is modeled with capacitors, representing thermal storage. Among thermal network models, the three-resistance-two-capacitance model (3R2C model) is the most widely implemented.

Occupant-Driven MPC-Based HVAC Controls

In an occupant-driven, rule-based HVAC scenario, occupant measurements are fed back into an HVAC control system to save energy during unoccupied periods while maintaining thermal comfort. However, a preferred temperature is often not guaranteed upon occupancy arrival. Therefore, a predictive HVAC control is needed. In this case, occupancy information is first predicted (based on past measurements) for the future time steps that are aligned with the MPC prediction horizon. Meanwhile, future model disturbances (e.g., weather) are also predicted for the same time steps. Then, the MPC optimizes the objective function and provides a control sequence.

In recent years, over 100 papers have been published describing different approaches, methods, and energy saving results from occupancy-based HVAC control (Mirakhorli and Dong 2016). Almost all these studies focus on better temperature set-point controls for air-handling units (AHU) and variable-air-volume (VAV) boxes. In particular, there is a report from Pacific Northwest National Laboratory (PNNL) on occupancy-based VAV box control for 0.4 billion m^2 commercial buildings (6% of total commercial floor space) in different climate zones, showing an energy saving opportunity for energy savings of up to 23% through control of VAV airflow based on room occupancy sensors (Zhang et al. 2013). Only approximately 14 studies have implemented the developed control algorithm and verified actual energy savings (Mirakhorli and Dong 2016). Xu et al. (2009) demonstrate up to 12% energy saving considering number of occupants, while minimizing energy use and maintaining air quality and occupant comfort in a multizone building. They found that use of model predictive control just to minimize temperature deviation from the comfort zone can result in a higher air quality compared to that achieved with a conventional controller. Goyal et al. (2013) consider four HVAC control methods that have been contrasted for complexity and performance: a baseline controller (1) with and (2) without occupancy measurements, (3) optimal control with occupancy measurement, and (4) MPC with occupancy prediction. Among all approaches, MPC with occupancy prediction results in greater energy saving and fewer occupant comfort violations.

There are a few experimental studies on occupancy-based MPC. For example, a seven day experiment was conducted with a three-story building, testing the rule-based controller using occupancy measurements (Brooks et al. 2014). A network of wireless sensors (PIR, CO_2, temperature, and humidity) was used for occupancy measurements, and a baseline schedule with setback rules was used to control zones' temperature. This exercise resulted in an average of 37% energy savings on the testing AHU for one floor. Another experiment was conducted in a solar decathlon house during both the heating (two months) and cooling (one week) seasons. In this experiment, local weather forecasting and occupancy presence predictions were used to minimize total building energy use. This study shows nonlinear model predictive control allowing 30 and 17.8% energy savings during the heating and cooling experiments respectively, in contrast with the use of scheduled temperature set points (Dong and Lam 2014).

Occupancy Prediction

Prediction of the future occupancy status or even number of occupants in a room is a necessary to implement occupancy-based MPC. The first arrival and last departure time of an occupant for a single occupied office is of especial interest (Li and Dong 2017, 2018; Lu et al. 2010). Markov chain models can be used to predict occupancy based on previous occupancy measurements (Dong and Lam 2014; Dong et al. 2010; Page et al. 2008). In most cases, the number of occupants in the room cannot be observed directly. Hence, the occupancy presence or number is the hidden state, and the sensor data or system output is the observable state for a hidden Markov model (Dong and Lam 2011). There are also studies that compare the ability of neural network, support vector machine, and hidden Markov models to detect the number of occupants in a building (Dong et al. 2009; Lam et al. 2009; Li and Dong 2018).

Comfort-Driven MPC-Based HVAC Controls

Although there are a few studies that focus on personalized thermal-comfort-driven HVAC control through learning individual preference (Ghahramani et al. 2015; Kim et al. 2018a) and RGB video images (Jazizadeh and Jung 2018), comfort-driven MPC studies are not common.

3. MODELING AND EVALUATING OCCUPANT-CENTRIC HVAC CONTROL SYSTEMS

Modeling and evaluation of occupant-centric HVAC control systems require the integrated simulation of three components: (1) the thermal dynamics of building envelope, lighting, and plug loads; (2) the dynamics of HVAC systems; and (3) the stochastic occupant behaviors of presence, movement, and interactions with building systems. Whole-building performance simulation (BPS) programs (e.g., EnergyPlus) can realize the overall simulation of the building envelope and energy systems, and occupant behaviors and interactions, as well as the HVAC controls. Complex HVAC control strategies may be simulated using separate modules coupled with whole-building BPS programs, using tools like Building Controls Virtual Test Bed (BCVTB) (Wetter et al. 2011) or through cosimulation of functional mockup units (Nouidui et al. 2013, 2014). Finally, dedicated modeling tools such as obFMU (Hong et al. 2016), Occupancy Simulator (Chen et al. 2018), and the Buildings Occupants Modelica package (Wang et al. 2018) can be used to cosimulate stochastic occupant behaviors.

3.1 WHOLE-BUILDING PERFORMANCE SIMULATION PROGRAMS

Whole-building performance simulation programs, such as EnergyPlus (DOE BTO 2017), ESP-r (Hand 2015), IDA-ICE (EQUA 2017), DeST (Yan et al. 2008), and TRNSYS (2012), are widely applied to evaluate the performance of building technologies and energy systems, with the aim of reducing energy use and associated greenhouse gas emissions. However, the functionalities of modeling the occupant behavior and HVAC controls among BPS tools are generally inconsistent and lack flexibility for user customization (Cowie et al. 2017; Crawley et al. 2008). For instance, schedules of casual gains from occupants are generally used, or control of window opening may be applied based on temperature set points. There are minor variations between programs (e.g., some are limited to hourly resolutions whilst others can handle subhourly resolution; some have provision for control in aspects others do not). Yet, input requirements and functionality are broadly similar across programs. In particular, occupant behavior is typically represented in current BPS programs via oversimplified static schedules or fixed rules. This leads to deterministic and homogeneous simulation results that do not fully capture the stochastic nature, dynamics, and diversity of occupants' energy behavior in buildings.

Cowie et al. (2017) provide an overview of the stochastic occupant modeling capabilities in current BPS programs. BPS programs such as EnergyPlus provide generalized model input functionality, allowing users to program or customize models or control logics through the interface (without requiring recompilation of the BPS programs) in a proprietary language. Some BPS programs (e.g., EnergyPlus, ESP-r) allow cosimulation with stand-alone external programs to model occupant behaviors (see subsequent section). Although some BPS programs include built-in stochastic modeling capabilities, these functionalities are inconsistent across programs. Addressing this gap, cosimulation platforms centralize functionality, allowing models to be implemented in a consistent way among different BPS programs (Cowie et al. 2017). However, the success of this approach depends on the ability of BPS programs to exchange data with this platform, which in turn requires a cosimulation standard that is adopted by as many BPS programs as possible. Such progress could potentially be stimulated by the existence of such a cosimulation platform, because this would provide a demonstrable contribution to the functionality of BPS programs.

HVAC Control Modeling

Most whole-building BPS programs can model the dynamic performance of HVAC systems, but system types, configurations, and control strategies are usually predefined or lack flexibility for users to customize. To address the limitations of whole-building BPS programs in modeling HVAC control, a cosimulation approach can be adopted. The approach integrates separate HVAC modeling modules or tools with the whole-building BPS programs through cosimulation technique, using tools such as the BCVTB (Wetter 2011), a software environment that serves as middleware, connecting different simulation programs to exchange data during the time integration. The HVAC modules can be implemented in various software languages including MATLAB and Modelica (Wetter et al. 2014), an equation-based object-oriented programming language. For BPS programs implementing the functional mockup interface (Nouidui et al. 2013) such as EnergyPlus and ESP-r, direct cosimulation is possible with HVAC modules or tools implemented as functional mockup units (Nouidui et al. 2014).

The main task of a traditional HVAC control system is to maintain temperature and indoor air quality within a desired comfort range while minimizing energy use. Current mainstream HVAC control practice depends on the choice of predefined dead-band values, which involves a significant amount of tedious tuning. In fact, this tuning has become increasingly challenging with the rising complexity of the modern HVAC systems, particularly with regard to the uncertain characteristics of occupancy and occupant behavior. However, with the decreased costs and advances in data processing, storage and computing, it becomes feasible to adopt an occupant-centric control approach to overcome such inherent issues in HVAC controls.

Occupant Behavior Modeling

As aforementioned, BPS programs use varying and nonstandardized input syntaxes to represent OB models (Hong et al. 2017). Cowie et al. (2017) conducted a comprehensive review to identify and compare approaches to representing and implementing OB models in eight of the most widespread BPS programs in the engineering and simulation community. For OB model implementation in BPS programs, four approaches were used: (1) direct user input or control using BPS input syntax (all eight BPS programs), (2) user functions or custom code (EnergyPlus, DOE-2, and IDA-ICE), (3) built-in OB models (DeST and ESP-r), and (4) cosimulation with dedicated OB software tools such as obFMU (EnergyPlus and ESP-r). Generally, current BPS programs use diverse approaches to represent and implement OB models, which hinder the exchange, reuse, and comparative analysis of OB models. There is a significant need for a common ontology (data dictionary) and data model to standardize the representation of OB models and enable their flexibility and exchange; and a modular software implementation of OB models adopting the common data model and enabling a robust and an interoperable integration with multiple BPS programs.

Occupant models are grouped into three types:

- *Adaptive behavior models* (e.g., opening or closing windows to maintain thermal comfort or indoor air quality)
- *Nonadaptive behavior models* (e.g., turning on/off computer monitors)
- *Occupancy models*

The adaptive behavior models have typically been developed as weekly schedules, Bernoulli models, and discrete-time or discrete-event Markov models. Bernoulli models predict the likelihood of a building component (with which occupants frequently interact) for a given circumstance (e.g., the percentage of lights switched on at a given outdoor illuminance). Markov models predict the likelihood of an adaptive action as a function of explanatory variables (e.g., the probability of a light switching on in the next time step in a discrete-time Markov model, or at the next arrival in a discrete-event Markov model). Nonadaptive behavior models include weekly schedules, survival models, or occupancy schedules from a similar building. Survival models for nonadaptive behaviors predict the lifetime of an occupant action or the state of a building component with which occupants interact (e.g., the lifetime of blind positions before they are changed). Occupancy models can take the form of weekly schedules, discrete-time Markov models predicting the timing and frequency of arrivals and departures, and survival models predicting the duration of an uninterrupted occupancy/vacancy period.

Occupancy modeling aims to determine the occupants' presence either as the occupancy status at the space level or as the number of occupants in a space or the entire building. Typical approaches use Markov chains or inverse transform sampling. Numerous window opening models have been introduced as input for BPS programs. Markov chains, generalized linear models, generalized linear mixed effects models, and Bayesian networks have been used to model window openings in residential and office buildings. Window shading models are less common and use logistic or linear regression and Markov chains. Models of occupants' light switching behavior have mostly focused on small offices and residential buildings. The typical approach is to use Markov chains and Poisson processes. The relatively few statistical models for thermostat use behavior in homes and offices rely on Markov chains and discrete Weibull distributions. In most models of appliance use, the switch-on times of the appliances are determined via Monte Carlo simulation. The models often rely on Markov chains, and many occupant behavior models use data that have been aggregated over dwellings, offices, or occupants. As a result, the models may fail to capture details of individual occupants and the diversity amongst them. It is suggested that behaviors of switching on lights, closing blinds, and opening/closing windows are most accurately represented with discrete-time or discrete-event Markov models. On the other hand, survival models adequately characterize occupant plug-in equipment use, blind opening, and light switch-off behaviors (Yan et al. 2017).

To address the limitations of whole-building BPS programs in modeling occupant behaviors, a cosimulation approach can be adopted that enables BPS programs to cosimulate with dedicated occupant behavior modeling modules or tools, as mentioned. A suite of occupant behavior modeling tools are now available for such cosimulation, including (1) obXML, (2) obFMU, (3) Occupancy Simulator, and (4) Buildings.Occupants. These tools help standardize the input structures for occupant behavior models, enable the collaborative development of a shared library of occupant behavior models, and allow for a rapid and widespread integration of occupant behavior models in various BPS programs. This ultimately improves the simulation of occupant behavior and the quantification of its impact on building performance.

Tools

obXML (Hong et al. 2015a, 2015b) is an XML schema that standardizes the representation and exchange of occupant behavior models for building performance simulations. It builds on the drivers-needs-actions-systems (DNAS) ontology to represent energy-related occupant behavior in buildings. *Drivers* comprise environmental and other contextual factors that stimulate occupants to fulfill a physical, physiological, or psychological need. *Needs* include the physical and nonphysical requirements of occupants that must be met to ensure satisfaction with the environment. *Actions* are the interactions with systems or activities that occupants can perform to achieve environmental comfort. *Systems* refer to the equipment or mechanisms in the building that occupants may interact with to restore or maintain environmental comfort. A library of obXML files, representing typical occupant behavior in buildings, was developed from the literature (Belafi et al. 2016). These obXML files can be exchanged between different BPS programs, different applications, and different users. Figure 4 includes the four key elements of the obXML schema and their subelements, showing the DNAS ontology.

obFMU (Hong et al. 2016) is a modular software component represented in the form of FMUs, enabling its application via cosimulation with BPS programs using the standard functional mockup interface. It reads the occupant behavior models represented in obXML and functions as a solver. A variety of occupant behavior models are supported by obFMU, including (1) lighting control based on visual comfort needs and availability of daylight, (2) thermostat setpoint adjustment, (3) HVAC system on/off control based on occupants' thermal comfort needs, (4) plug load control based on occupancy, and (5) window opening and closing based on indoor and outdoor environmental parameters. obFMU has been used with EnergyPlus and ESP-r via cosimulation to improve the modeling of oc-

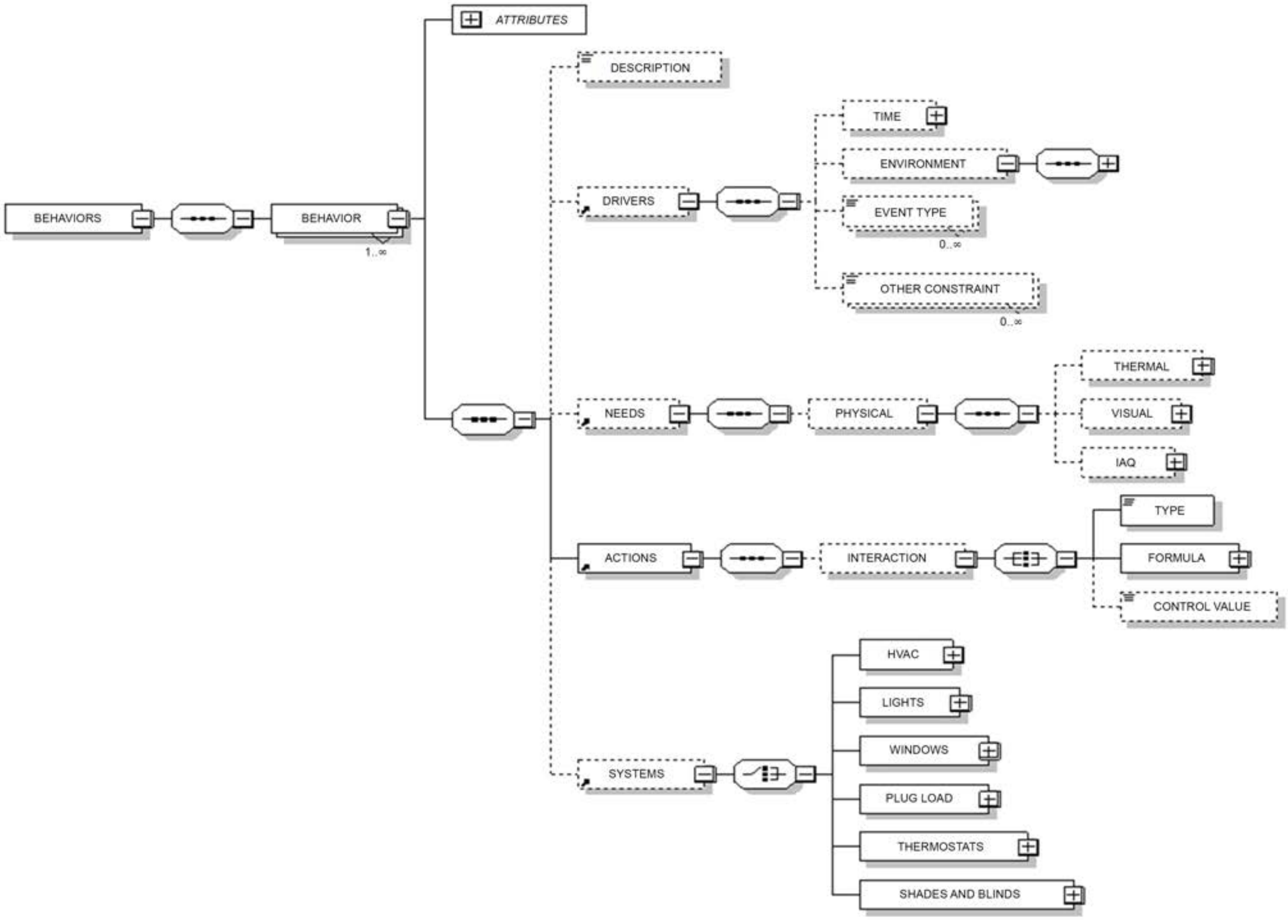

Fig. 4 obXML Schema

cupant behavior. Figure 5 shows the workflow of cosimulation using obFMU and EnergyPlus.

Occupancy Simulator. Occupancy Simulator (Chen et al. 2018; Luo et al. 2017) is a web-based application running on multiple platforms to simulate occupant presence and movement in buildings. The application can generate subhourly occupant schedules for each space and for individual occupants in the form of CSV files and EnergyPlus IDF files for building performance simulations. Occupancy Simulator uses a homogeneous Markov chain model (Feng et al. 2015; Wang et al. 2011) and performs agent-based simulations for each occupant's presence and movement. A hierarchical input structure is adopted, building on the input blocks of building, space, and occupant type, to simplify the input process while allowing flexibility for detailed information capturing the diversity of space use and individual occupant behavior. Users can choose to see simulated occupancy results for an individual space or the whole building.

Buildings.Occupants. To simulate the continuous and dynamic interaction between occupants and building systems, Buildings. Occupants, an open source occupant behavior package in Modelica (Wang et al. 2018), can be used. The Buildings.Occupants package, as part of the Modelica Buildings Library, supports fast prototyping by seamlessly integrating occupant behavior models with Modelica models from existing libraries for building dynamics. Additionally, the structure of the package has been designed to allow for flexible implementation of user-defined models by tuning the parameters and calling functions defined in the BaseClasses package. The Buildings.Occupants package includes reported occupant behavior models in the literature that are more commonly used and well documented in terms of the data source, mathematical equation, independent variables, parameter values, etc. The models are categorized into subpackages based on the building types and systems. There are 34 occupant behavior models for office and residential buildings that are included in the first release of the Buildings.Occupants package. Included in the office building models are eight on windows operation, six on window blind operation, four on lighting operation, and one on occupancy.

CHAPTER 66

CODES AND STANDARDS

THE codes and standards and other publications listed here represent practices, methods, or standard published by the organizations indicated. They are useful guides for the practicing engineer in determining test methods, ratings, performance requirements, and limits of HVAC&R equipment. Copies of these publications can be obtained from most of the organizations listed in the Publisher column, from Global Engineering Documents at **global.ihs.com**, or from Techstreet at **techstreet.com**. Addresses of the organizations are given at the end of the chapter.

Selected Codes and Standards Published by Various Societies and Associations

Subject	Title	Publisher	Reference
Air Conditioners	Commercial Systems Overview	ACCA	ACCA Manual CS-1993
	Residential Equipment Selection, 2nd ed.	ACCA	ANSI/ACCA 3 Manual S®-2014
	HVAC Quality Installation Specification	ACCA	ANSI/ACCA 5 QI-2015
	Technician's Guide & Workbook for Quality Installations	ACCA	ACCA 2015
	Laboratory Methods of Testing Air Terminal Units	ASHRAE	ANSI/ASHRAE 130-2016
	Non-Ducted Air Conditioners and Heat Pumps—Testing and Rating for Performance	ISO	ISO 5151:2017
	Ducted Air-Conditioners and Air-to-Air Heat Pumps—Testing and Rating for Performance	ISO	ISO 13253:2017
	Guidelines for Roof Mounted Outdoor Air-Conditioner Installations	SMACNA	SMACNA 1997
	Heating and Cooling Equipment	UL/CSA	ANSI/UL 1995-2011/C22.2 No. 236-11
	Performance Standard for Split-System and Single-Package Central Air Conditioners and Heat Pumps	CSA	CAN/CSA C656-14
	Energy Performance Rating for Large and Single Packaged Vertical Air Conditioners and Heat Pumps	CSA	CAN/CSA C746-2017
Gas-Fired	Commercial Systems Overview	ACCA	ACCA Manual CS-1993
	Residential Equipment Selection, 2nd ed.	ACCA	ANSI/ACCA 3 Manual S-2014
	Home Evaluation and Performance Improvement	ACCA	ANSI/ACCA 12 QH-2018
	Technician's Guide & Workbook for Home Evaluation and Performance Improvement	ACCA	ACCA 2014
	Gas-Fired, Heat Activated Air Conditioning and Heat Pump Appliances	CSA	ANSI Z21.40.1-1996/CGA 2.91-M96 (R2017)
	Gas-Fired Work Activated Air Conditioning and Heat Pump Appliances (Internal Combustion)	CSA	ANSI Z21.40.2-1996/CGA 2.92-M96 (R2017)
	Performance Testing and Rating of Gas-Fired Air Conditioning and Heat Pump Appliances	CSA	ANSI Z21.40.4a-1998/CGA 2.94a-M98 (R2017)
Packaged Terminal	Packaged Terminal Air-Conditioners and Heat Pumps	AHRI/CSA	AHRI 310/380-2017/CSA C744-2017
Room	Room Air Conditioners	AHAM	ANSI/AHAM RAC-1-2015
	Method of Testing for Rating Room Air Conditioners and Packaged Terminal Air Conditioners	ASHRAE	ANSI/ASHRAE 16-2016
	Method of Testing for Rating Room Air Conditioner and Packaged Terminal Air Conditioner Heating Capacity	ASHRAE	ANSI/ASHRAE 58-1986 (RA14)
	Method of Testing for Rating Fan-Coil Conditioners	ASHRAE	ANSI/ASHRAE 79-2015
	Energy Performance of Room Air Conditioners	CSA	CAN/CSA C368.1-14
	Room Air Conditioners	CSA	C22.2 No. 117-1970 (R2016)
	Room Air Conditioners, Ed. 7	UL	ANSI/UL 484-2014
Unitary	Commercial Systems Overview	ACCA	ACCA Manual CS-1993
	Residential Equipment Selection, 2nd ed.	ACCA	ANSI/ACCA 3 Manual S-2014
	Unitary Air-Conditioning and Air-Source Heat Pump Equipment	AHRI	ANSI/AHRI 210/240-2017

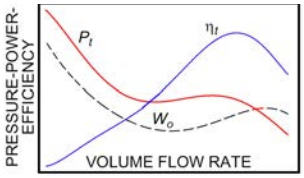
Additions and Corrections

The following presents additional information and technical errors found between June 15, 2016, and March 29, 2019, in the I-P editions of the 2016, 2017, and 2018 *ASHRAE Handbook* volumes. Occasional typographical errors and nonstandard symbol labels will be corrected in future volumes. The most current list of Handbook additions and corrections is on the ASHRAE web site (www.ashrae.org).

The authors and editor encourage you to notify them if you find other technical errors. Please send corrections to: Handbook Editor, ASHRAE, 1791 Tullie Circle NE, Atlanta, GA 30329, or e-mail hkennedy@ashrae.org.

2016 HVAC Systems and Equipment

p. 21.3, Table 1. The performance curve for propeller fans should be as follows:



p. 24.7, Fig. 13. The correct SI graphic is on p. A.2.

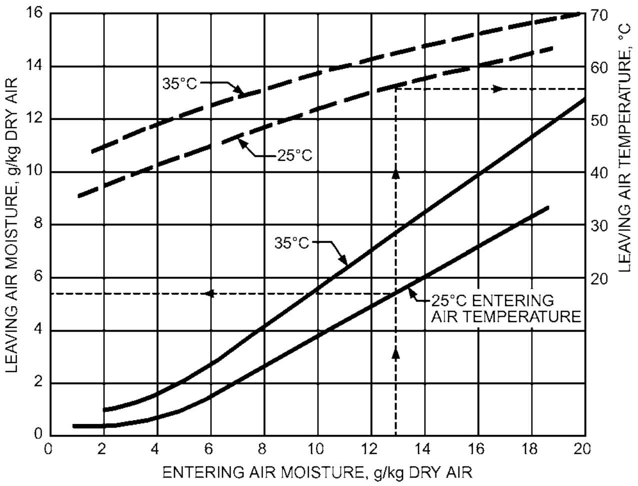


Fig. 13 Typical Performance Data for Rotary Solid Desiccant Dehumidifier
(from 2016 HVAC Systems and Equipment*, p. 28.7)*

p. 38.37, Eq. (24). Remove "x" from end of equation.

2017 Fundamentals

p. 1.9, Eq. (23). Following the equation, add the following text: "where μ is degree of saturation *W*/*Ws*, dimensionless."

p. 4.3, Table 2, 1st equation for hollow sphere. In the denominator, change the + to a –.

p. 4.20, Table 9. For Eq. (T9.10) for horizontal cylinder, the range should be $10^{-6} < \text{Ra} < 10^{13}$.

p. 4.21, Example 11. In list item number 1, the equation should be $t_f = (t_s + t_\infty)/2$.

p. 11.13, 2nd col. Change "*Guideline* 27" to "proposed *Guideline* 27P."

p. 14.12, Examples 7 and 8. In Example 7, in the equation for $E_{t,r}$, change "+ cos(68.62°)" to "– cos(90°)" and the result to 87.9 W/m². In Example 8, in the equation for $E_{t,r}$, change "cos(68.64°)" to "cos(30°)" and the result to 11.8 W/m².

p. 14.14, 2nd col., 3rd paragraph from bottom. Change "6.3 K" to "3.6 K."

p. 17.13, Infiltration and Ventilation. In the equation in the second sentence, change 1.1 to 1.4.

p. 18.5, Table 2. Under Health Care Facilitites, the value for medical supply rooms should be 7.96.

p. 18.21, Eqs. (24) and (25). In Eq. (24), change $Z_{i,0}$ to $X_{i,0}$. The following paragraph should read "Equation (24) shows the need to separate $X_{i,0}$ because the contribution of current surface temperature to conductive flux cannot be collected with the other historical terms involving that temperature." In Eq. (25), change $T_{si_{i,j}}$ to $T_{so_{i,j}}$.

p. 18.39, 1st col, definitions. The mention of Figure 18 of Chapter 34 of the 2011 *ASHRAE Handbook—HVAC Applications* should refer to that figure in the 2015 edition.

p. 18.49, calculations for q_{i1} to qi_{24}. The corrected equations are as follows:

$$q_{i,1} = (0.44)(5.57)(23.2 - 23.9) = -1 \text{ W}$$
$$q_{i,2} = (0.44)(5.57)(22.8 - 23.9) = -3$$
$$q_{i,3} = (0.44)(5.57)(22.4 - 23.9) = -4$$
$$q_{i,4} = (0.44)(5.57)(22.1 - 23.9) = -4$$
$$q_{i,5} = (0.44)(5.57)(21.9 - 23.9) = -5$$
$$q_{i,6} = (0.44)(5.57)(22.6 - 23.9) = -3$$
$$q_{i,7} = (0.44)(5.57)(25.2 - 23.9) = 3$$
$$q_{i,8} = (0.44)(5.57)(29.0 - 23.9) = 12$$
$$q_{i,9} = (0.44)(5.57)(32.7 - 23.9) = 21$$
$$q_{i,10} = (0.44)(5.57)(35.9 - 23.9) = 29$$
$$q_{i,11} = (0.44)(5.57)(38.6 - 23.9) = 36$$
$$q_{i,12} = (0.44)(5.57)(40.8 - 23.9) = 41$$
$$q_{i,13} = (0.44)(5.57)(50.2 - 23.9) = 64$$
$$q_{i,14} = (0.44)(5.57)(59.8 - 23.9) = 87$$
$$q_{i,15} = (0.44)(5.57)(65.9 - 23.9) = 102$$
$$q_{i,16} = (0.44)(5.57)(67.6 - 23.9) = 107$$
$$q_{i,17} = (0.44)(5.57)(64.3 - 23.9) = 98$$
$$q_{i,18} = (0.44)(5.57)(55.4 - 23.9) = 77$$
$$q_{i,19} = (0.44)(5.57)(39.5 - 23.9) = 38$$
$$q_{i,20} = (0.44)(5.57)(27.6 - 23.9) = 9$$
$$q_{i,21} = (0.44)(5.57)(26.6 - 23.9) = 6$$
$$q_{i,22} = (0.44)(5.57)(25.6 - 23.9) = 4$$
$$q_{i,23} = (0.44)(5.57)(24.7 - 23.9) = 2$$
$$q_{i,24} = (0.44)(5.57)(23.9 - 23.9) = 0$$

p. 21.23, Example 8, Solution. At end of second paragraph, text should read, "in this case, 350 mm."

p. 22.22, Table 21. For the >305 mm nominal row, under ≤2000 Variable Flow/Variable Speed in m/s, delete the "13.0"

COMPOSITE INDEX

ASHRAE HANDBOOK SERIES

This index covers the current Handbook series published by ASHRAE. The four volumes in the series are identified as follows:

S = 2016 HVAC Systems and Equipment

F = 2017 Fundamentals

R = 2018 Refrigeration

A = 2019 HVAC Applications

Alphabetization of the index is letter by letter; for example, **Heaters** precedes **Heat exchangers**, and **Floors** precedes **Floor slabs**.

The page reference for an index entry includes the book letter and the chapter number, which may be followed by a decimal point and the beginning page in the chapter. For example, the page number F30.6 means the information may be found in the 2017 HVAC Fundamentals volume, Chapter 30, beginning on page 6.

Each Handbook volume is revised and updated on a four-year cycle. Because technology and the interests of ASHRAE members change, some topics are not included in the current Handbook series but may be found in the earlier Handbook editions cited in the index.

medium- and high-temperature systems, S15.7
nonchemical (physical), A50.13, 15
once-through systems, A50.20
open recirculating systems, A50.21
scale control, A50.5
sprayed-coil units, A50.21
steam and condensate systems, A50.19
terminology, A50.23
thermal storage, S51.6
Water use and management (*See* **Energy and water use and management**)
Water vapor control, A45.6
Water vapor permeance/permeability, F26.12, 17, 18
Water vapor retarders, F26.6
Water wells, A35.30
Weather data, F14
Weatherization, F16.18
Welding sheet metal, S19.12
Wet-bulb globe temperature (WBGT), heat stress, A32.5
Wheels, rotary enthalpy, S26.9
Whirlpools and spas
Legionella pneumophila control, A50.15
service water heating, A51.25
Wien's displacement law, F4.12
Wind. (*See also* **Climatic design information; Weather data**)
data sources, F24.7
effect on
chimneys, S35.3, 33
smoke movement, A54.5
system operation, F24.8
pressure, F24.4
Wind chill index, F9.23
Windows. (*See also* **Fenestration**)
air leakage, F15.53
solar gain, F15.14, 19
U-factors, F15.4, 7, ; F27.7
Wind restraint design, A56.15
minimum design wind load, A56.16
Wineries
refrigeration, R39.9
temperature control
fermentation, R39.9
storage, R39.10
wine production, R39.8
Wireless sensors, A63.7
Wood construction, and moisture, F25.10
Wood products facilities, A27.1
evaporative cooling, A53.15
process area, A27.2
storage, A27.2
Wood pulp, A27.2
Wood stoves, S34.5
WSHP. *See* **Water-source heat pump (WSHP)**
Xenon, R47.18
Zeolites, R18.10; R41.9; R47.13; S24.5. (*See also* **Molecular sieves**)

Comment Page

ASHRAE publications strive to present the most current and useful information possible. If you would like to comment on chapters in this or any volume of the *ASHRAE Handbook*, please use one of the following methods:

- Fill out the comment form on the ASHRAE website (www.ashrae.org)
- E-mail the editor at mowen@ashrae.org
- Cut out this page and fax it to the editor at 678-539-2187, or mail it to

Handbook Editor
ASHRAE
1791 Tullie Circle, NE
Atlanta, GA 30329-2305 USA

Please provide your contact information if you would like a response. (Personal identification information will not be used for any purpose beyond responding to your comments.)

ویدیو – انیمیشن های اطفا، اعلام حریق، تهویه وتخلیه دود (رایگان)

برای مشاهده هر یک از ویدیوهای زیر کافیست بر روی عنوان آن آموزش کلیک نمایید تا به صفحه ویدیو و آموزش آن عنوان هدایت شوید.

انیمیشن ویدیو

- اطفا حریق آبی
  - سیستم اطفا لوله خشک اسپرینکلر
  - سیستم اطفا لوله تر اسپرینکلر
  - سیستم اطفا پیش عملگر
  - سیستم اطفا واترمیست
  - سیستم اطفا سیلابی
- سیستم اطفا فوم
- تجهیزات اطفا حریق – تجهیزات هشدار دهنده
- تجهیزات اطفا حریق- اسپرینکلر
- سیستم اطفا آشپزخانه صنعتی
- سیستم اطفا آیروسل
- سیستم اطفا دستی
- سیستم اطفا گازی
  - سیستم اطفا FM200 , NOVEC, Inert Gas (IG)
  - سیستم اطفا CO_2
- سیستم تهویه و تخلیه دود
- سیستم اعلام حریق
  - آدرس‌پذیر
  - متعارف

تهران . خیابان سعدی شمالی .خیابان مرادی نور . پلاک ۳۱ . واحد ۱
۰۲۱ – ۷۷۶۸۶۹۶۶ – ۰۹۳۵۴۷۴۳۹۱۳
WWW.EDUFIRE.IR

آموزشگاه ادوفایر
EDUFIRE

آموزش استاندارد

- آموزش استاندارد NFPA 13
- آموزش استاندارد NFPA 14
- آموزش استاندارد NFPA 20

آموزش نرم‌افزار

- اتواسپرینک
- پایروسیم
- پث‌فایندر

دانلود استاندارد

- ترجمه استاندارد NFPA 30,14,13,10
- تمامی استانداردهای NFPA & FM
- ترجمه استاندارد NFPA 1037

محصولات

- اتواسپرینک ۲۰۱۳ و ۲۰۱۹ به زبان فارسی برای اولین بار در ایران
- آلارم کد ۲۰۱۹ به زبان فارسی برای اولین بار در ایران
- اطفا حریق آبی
- پایپ‌نت (ماژول اسپرینکلر)
- کانتم
- اعلان حریق

دوره‌های حضوری

- آموزش اتواسپرینک
- آموزش آلارم‌کد
- آموزش پایروسیم
- آموزش کانتم + اگزاست
- آموزش اطفا آبی +پمپ + بازدید از کارگاه
- آموزش اطفا گازی
- آموزش اطفا فوم
- آموزش مبحث سوم مقررات ملی
- آموزش اعلام حریق F&G
- آموزش اعلام حریق آدرس‌پذیر
- آموزش اعلام حریق متعارف
- دوره آمادگی آزمون آتش‌نشانی (برق، مکانیک، عمران، معماری)

آموزشگاه ادوفایر
EDUFIRE

دوره های آموزشی

ارائه تخفیف جهت خرید نرم افزارها

ارائه کد تخفیف جهت شرکت در دوره های آموزشی

EDUFIRE.IR

کد آموزشی	عنوان دوره	مدت
کد آموزشی ۱۰۱	طراحی اطفاء حریق آبی با نرم افزار AutoSPRINK۲۰۱۹	۱۶ ساعت
کد آموزشی ۱۰۲	طراحی اعلام حریق Addressable Conventional	۱۶ ساعت
کد آموزشی ۱۰۳	مبانی و شناخت پمپ بوسترپمپ‌های آبرسانی و آتش نشانی به همراه **بازدید از خط تولید**	۱۶ ساعت
کد آموزشی ۱۰۴	طراحی تهویه و تخلیه دود همراه با آموزش نرم‌افزار Contam	۱۶ ساعت
کد آموزشی ۱۰۵	طراحی سیستم اعلان آدرس پذیر همراه با آموزش نرم افزار AlarmCAD	۱۶ ساعت
کد آموزشی ۱۰۶	طراحی اطفاء حریق فوم	۱۶ ساعت
کد آموزشی ۱۰۷	طراحی اطفاء حریق و آشنایی با ضوابط سازمان آتش نشانی	۱۶ ساعت
کد آموزشی ۱۰۸	طراحی اطفاء حریق گازی FM200 & NOVEC CO_2	۱۶ ساعت
کد آموزشی ۱۰۹	آموزش مبحث سوم مقررات ملی ساختمان	۳۲ ساعت
کد آموزشی ۱۱۰	طراحی با نرم افزار Pyrosim	۱۶ ساعت
کد آموزشی ۱۱۱	آمادگی آزمون آتش نشانی مکانیک – برق عمران – معماری	۱۶ ساعت
کد آموزشی ۱۱۲	طراحی استخر، سونا و جکوزی	۱۶ ساعت
