Offset printing transfers the image first to a rubber blanket and then to the paper. Sheetfed and web offset printing are similar to letterpress printing. The inks used are similar to those used in letterpress printing but contain water-resistant vehicles and pigment. In web offset and gravure printing, the relative humidity in the pressroom should be kept constant, and the temperature should be selected for comfort or, at least, to avoid heat stress. It is important to maintain steady conditions to ensure the dimensional stability of the paper onto which the images are printed.

The pressroom for sheet multicolor offset printing has more exacting humidity requirements than other printing processes. The paper must remain flat with constant dimensions during multicolor printing, in which the paper may make six or more passes through the press over a period of a week or more. If the paper does not have the right moisture content at the start, or if there are significant changes in atmospheric humidity during the process, the paper will not retain its dimensions and flatness, and misregistering will result. In many cases of color printing, a register accuracy of 100 μm is required. Figure 3 shows the close control of the air relative humidity that is necessary to achieve this register accuracy. The data shown in this figure are for composite lithographic paper.

Maintaining constant moisture content of the paper is complicated because paper picks up moisture from the moist offset blanket

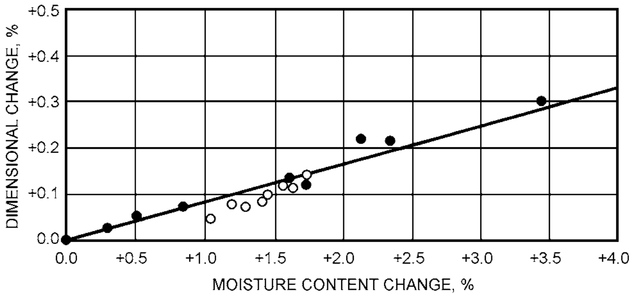

Fig. 3 Effects of Variation in Moisture Content on Dimensions of Printing Papers
(Weber and Snyder 1934)

during printing (0.1 to 0.3% for each impression). When two or more printings are made in close register work, the paper at the start of the printing process should have a moisture content in equilibrium with air at 5 to 8% rh above the pressroom air. At this condition, the moisture evaporated from the paper into the air nearly balances the moisture added by the press. In obtaining register, it is important to keep the sheet flat and free from wavy or tight edges. To do this, the relative humidity balance of the paper should be slightly above that of the pressroom atmosphere. This balance is not as critical in four-color roll-feed presses because the press moisture does not penetrate the paper quickly enough between colors to affect sheet dimensions or cause sheet distortion.

Recommended Environment

The Graphic Arts Technical Foundation recommends ideal conditions in a lithographic pressroom of 24 to 27°C db and 43 to 47% rh, controlled to ±1 K db and ±2% rh (Reed 1970). Comfort and economy of operation influence the choice of temperature. The effect of relative humidity variations on register can be estimated for offset paper from Figure 3. Closer relative humidity control of the pressroom air is required for multicolor printing of 1930 mm sheets than for 560 mm sheets with the same register accuracy. Closer control is needed for multicolor printing, where the sheet makes two or more trips through the press, than for one-color printing.

Ink drying is affected by temperature and humidity, so uniform results are difficult to obtain without controlling the atmospheric conditions. Printing inks must dry rapidly to prevent offsetting and smearing. High relative humidity and high moisture content in paper tend to prevent ink penetration, so more ink remains on the surface than can be quickly oxidized. This affects drying time, intensity of color, and uniformity of ink on the surface. Relative humidity below 60% is favorable for drying at a comfortable temperature. Higher relative humidity may cause severe paper distortion and significant damage to the final product.

The air conditioning for the pressroom of a lithographic plant should control air temperature and relative humidity, filter the air, supply ventilation air, and distribute the air without pronounced drafts around the presses. Using anti-offset sprays to set the ink creates an additional air-filtering load from the pressroom. Drafts and high airflow over the presses lead to excessive drying of the ink and water, which causes scumming or other problems.

The operating procedures of the pressroom should be analyzed to determine the heat removal load. The lighting load is high and constant throughout the day. The temperature of the paper brought into the pressroom and the length of time it is in the room should be considered to determine the sensible load from the paper. Figure 2 shows the time required for wrapped paper to reach room temperature. The press motors usually generate a large portion of the internal sensible heat gain.

Readings should be taken to obtain the running power load of the larger multicolor presses. The moisture content of the paper fed to the press and the relative humidity of the air must be considered when computing the internal latent heat gain. Paper is used that is in equilibrium with air at a relative humidity somewhat higher than that of the pressroom, so the paper gives up moisture to the space as it absorbs moisture during printing. If the moisture transfer is in balance, water used in the printing process should be included in the internal moisture load. It is preferable to determine the water evaporation from the presses by testing.

Air Conditioning

Precise multicolor offset lithography printing requires either refrigeration with provision for separate humidity control, or sorption dehumidifying equipment for independent humidity control with provision for cooling. The need for humidity control in the pressroom may be determined by calculating the dimensional change of the paper for each percent of change in relative humidity and checking this with the required register for the printing process.

Air conditioning of the photographic department is usually considered secondary in importance to that of the pressroom. Most of the work in offset lithography is done on film. Air conditioning controls cleanliness and comfort and maintains the size of the film for register work.

Air conditioning is important in the stripping department, both for comfort and for maintaining size and register. Curling of the film and flats, as well as shrinkage or stretch of materials, can be minimized by maintaining constant relative humidity. This is particularly important for close-register color work. The photographic area, stripping room, and platemaking area usually are maintained at the same conditions as the pressroom.

Dryers used for web offset printing are the same type as for web-fed letterpress. Drying is not as complex because less ink is applied and presses run at lower speeds (4 to 9 m/s).

6. ROTOGRAVURE

Rotogravure printing uses a cylinder with minute inkwells etched in the surface to form the printing image. Ink is applied to the cylinder, filling the wells. Excess ink is then removed from the cylinder surface by doctor blades, leaving only the ink in the wells. The image is then transferred to the paper as it passes between the printing cylinder and an impression cylinder.

In sheetfed gravure printing (as in offset printing), expansion, contraction, and distortion should be prevented to obtain correct register. The paper need not be in equilibrium with air at a relative humidity higher than that of the pressroom, because no moisture is added to the paper in the printing process. Humidity and temperature control should be exacting, like in offset printing. The relative humidity should be 45 to 50%, controlled to within ±2%, with a comfort temperature controlled to within ±1 K.

Gravure printing ink dries principally by evaporating the solvent in the ink, leaving a solid film of pigment and resin. The solvent is a low-boiling hydrocarbon, and evaporation takes place rapidly, even without the use of heat. The solvents have closed-cup flash points from –5 to 27°C and are classified as Group I or special hazard liquids by local code and insurance company standards. As a result, in areas adjacent to gravure press equipment and solvent and ink storage areas, electrical equipment must be Class I, Division 1 or 2, as described by the *National Electrical Code®* (NFPA *Standard* 70), and ventilation requirements (both supply and exhaust) are stringent. Ventilation should be designed for high reliability, with sensors to detect unsafe pollutant concentrations and then to initiate alarm or safety shutdown when necessary.

Rotogravure printing units operate in tandem, each superimposing print over that from the preceding unit. Press speeds range from 6 to 12 m/s. Each unit is equipped with its own dryer to prevent subsequent smearing or smudging.

A typical drying system consists of four dryers connected to an exhaust fan. Each dryer is equipped with fans to recirculate 2500 to 4000 L/s (at standard conditions) through a steam or hot water coil and then through jet nozzles. The hot air (55°C) impinges on the web and drives off the solvent-laden vapors from the ink. It is normal to exhaust half of this air. The system should be designed and adjusted to prevent solvent vapor concentration from exceeding 25% of its lower flammable limit (Marsailes 1970). If this is not possible, constant lower-flammable-limit (LFL) monitoring, concentration control, and safety shutdown capability should be included.

In exhaust design for a particular process, solvent vapor should be captured from the printing unit where paper enters and exits the dryer, from the fountain and sump area, and from the printed paper, which continues to release solvent vapor as it passes from one printing unit to another. Details of the process, such as ink and paper characteristics and rate of use, are required to determine exhaust quantities.

When dilution ventilation is used, exhaust of 500 to 700 L/s (at standard conditions) at the floor is often provided between each unit. The makeup air units are adjusted to supply slightly less air to the pressroom than that exhausted, to keep the pressroom negative with respect to the surrounding areas.

7. OTHER PLANT FUNCTIONS

Flexography

Flexography uses rubber raised printing plates and functions much like a letterpress. Flexography is used principally in the packaging industry to print labels and also to print on smooth surfaces, such as plastics and glass.

Collotype Printing

Collotype or photogelatin printing is a sheetfed printing process related to lithography. The printing surface is bichromated gelatin with varying affinity for ink and moisture, depending on the degree of light exposure received. There is no mechanical dampening as in lithography, and the necessary moisture in the gelatin printing surface is maintained by operating the press in an atmosphere of high relative humidity, usually about 85%. Because the tonal values printed are very sensitive to changes in the moisture content of the gelatin, the relative humidity should be maintained within ±2%.

Because tonal values are also very sensitive to changes in ink viscosity, temperature must be closely maintained; 27 °C ± 2 K is recommended. Collotype presses are usually partitioned off from the main plant, which is kept at a lower relative humidity, and the paper is exposed to high relative humidity only while it is being printed.

Salvage

Salvage systems remove paper trim and shredded paper waste from production areas, and carry airborne shavings to a cyclone or baghouse collector, where they are baled for recycling. Air quantities required are 2.5 to 2.8 m^3 per kilogram of paper trim, and the transport velocity in the ductwork is 23 to 25 m/s (Marsailes 1970). Humidification may be provided to prevent the buildup of a static charge and consequent system blockage.

Air Filtration

Ventilation and air-conditioning systems for printing plants commonly use automatic moving-curtain dry-media filters with renewable media having a rating of MERV 13 (ASHRAE *Standard* 52.2).

In sheetfed pressrooms, a high-performance final filter is used to filter starch particles, which require about a MERV 13 rating as well. In film processing areas, which require relatively dust-free conditions, high-efficiency air filters are installed, with a rating of MERV 14.

A different type of filtration problem in printing is **ink mist** or **ink fly**, which is common in newspaper pressrooms and in heatset letterpress or offset pressrooms. Minute droplets of ink (5 to 10 μm) are dispersed by ink rollers rotating in opposite directions. The cloud of ink droplets is electrostatically charged. Suppressors, charged to repel the ink back to the ink roller, are used to control ink mist. Additional control is provided by automatic moving curtain filters.

Binding and Shipping

Some printed materials must be bound. Two methods of binding are perfect binding and stitching. In **perfect binding**, sections of a book (signatures) are gathered, ruffed, glued, and trimmed. The glued edge is flat. Large books are easily bound by this type of binding. Low-pressure compressed air and a vacuum are usually required to operate a perfect binder, and paper shavings are removed by a trimmer. The use of heated glue necessitates an exhaust system if the fumes are toxic.

In **stitching**, sections of a book are collected and stitched (stapled) together. Each signature is opened individually and laid over a moving chain. Careful handling of the paper is important. This has the same basic air requirements as perfect binding.

Mailing areas of a printing plant wrap, label, and ship the manufactured goods. Operation of the wrapper machine can be affected by low humidity. In winter, humidification of the bindery and mailing area to about 40 to 50% rh may be necessary to prevent static buildup.

CHAPTER 22

TEXTILE PROCESSING PLANTS

Terminology 22.1
Fiber Making 22.1
Yarn Making 22.2
Fabric Making 22.3
Air-Conditioning Design 22.4
Energy Conservation 22.7

THIS chapter covers (1) basic processes for making synthetic fibers, (2) fabricating synthetic fibers into yarn and fabric, (3) relevant types of HVAC and refrigerating equipment, (4) health considerations, and (5) energy conservation procedures.

Most textile manufacturing processes may be placed into one of three general classifications: synthetic fiber making, yarn making, or fabric making. Synthetic fiber manufacturing is divided into staple processing, tow-to-top conversion, and continuous fiber processing; yarn making is divided into spinning and twisting; and fabric making is divided into weaving and knitting. Although these processes vary, their descriptions reveal the principles on which air-conditioning design for textile facilities is based.

1. TERMINOLOGY

The following is only a partial glossary of terms used in the textile industry. For more complete terminology, consult the sources in the Bibliography.

Air permeability. Porosity, or ease with which air passes through material. Air permeability affects factors such as the wind resistance of sailcloth, air resistance of parachute cloth, and efficiency of various types of air filtration media. It is also a measure of a fabric's warmness or coolness.

Bidirectional fabric. A fabric with reinforcing fibers in two directions: in the warp (machine) direction and filling (cross-machine) direction.

Calender. A machine used in finishing to impart various surface effects to fabrics. It essentially consists of two or more heavy rollers, sometimes heated, through which the fabric is passed under heavy pressure.

Denier. The mass, in grams, of 9000 m of yarn. Denier is a direct numbering system in which lower numbers represent finer sizes and higher numbers the coarser sizes. Outside the United States, the **Tex** system is used instead.

Heddle. A cord, round steel wire, or thin flat steel strip with a loop or eye near the center, through which one or more warp threads pass on the loom, so that thread movement may be controlled in weaving. Heddles are held at both ends by the harness frame. They control the weave pattern and shed as the harnesses are raised and lowered during weaving.

Lubricant. An oil or emulsion finish applied to fibers to prevent damage during textile processing, or to knitting yarns to make them more pliable.

Machine direction. The long direction within the plane of the fabric (i.e., the direction in which the fabric is being produced by the machine).

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Pick. A single filling thread carried by one trip of the weft insertion device across the loom. Picks interface with the warp ends to form a woven fabric.

Reed. A comblike device on a loom that separates the warp yarns and also beats each succeeding filling thread against those already woven. The space between two adjacent wires of the reed is called a **dent**. The fineness of the reed is calculated by the number of dents per 25.4 mm: the more dents, the finer the reed.

Selvage. The narrow edge of woven fabric that runs parallel to the warp. It is made with stronger yarns in a tighter construction than the body of the fabric, to prevent raveling. A **fast selvage** encloses all or part of the picks; a selvage is not fast when the filling threads are cut at the fabric edge after each pick.

Shuttle. A boat-shaped device usually made of wood with a metal tip that carries filling yarns through the shed in the weaving process.

Tex. The mass, in grams, of 1000 m of fabric. Used primarily outside the United States. *See also* **Denier**.

Warp. The set of yarn in all woven fabrics, running lengthwise and parallel to the selvage, interwoven with the filling.

2. FIBER MAKING

Processes preceding fiber extrusion have diverse ventilating and air-conditioning requirements based on principles similar to those that apply to chemical plants.

Synthetic fibers are extruded from metallic spinnerets and solidified as continuous parallel filaments. This process, called **continuous spinning**, differs from the mechanical spinning of fibers or tow into yarn, which is generally referred to as **spinning**.

Synthetic fibers may be formed by melt-spinning, dry-spinning, or wet-spinning. Melt-spun fibers are solidified by cooling the molten polymer; dry-spun fibers by evaporating a solvent, leaving the polymer in fiber form; and wet-spun fibers by hardening the extruded filaments in a liquid bath. The selection of a spinning method is affected by economic and chemical considerations. Generally, nylons, polyesters, and glass fibers are melt-spun; acetates dry-spun; rayons and aramids wet-spun; and acrylics dry- or wet-spun.

For melt- and dry-spun fibers, the filaments of each spinneret are usually drawn through a long vertical tube called a **chimney** or **quench stack**, within which solidification occurs. For wet-spun fibers, the spinneret is suspended in a chemical bath where coagulation of the fibers takes place. Wet-spinning is followed by washing, applying a finish, and drying.

Synthetic continuous fibers are extruded as a heavy denier tow for cutting into short lengths (called staple) or somewhat longer lengths for tow-to-top conversion, or they are extruded as light denier filaments for processing as continuous fibers. Oil is then applied to lubricate, give antistatic properties, and control fiber cohesion. The extruded filaments are usually drawn (stretched) both to align the molecules along the axis of the fiber and to improve the crystalline structure of the molecules, thereby increasing the fiber's strength and resistance to stretching.

Heat applied to the fiber when drawing heavy denier or high-strength synthetics releases a troublesome oil mist. In addition, the mechanical work of drawing generates a high localized heat load. If the draw is accompanied by twist, it is called **draw-twist**; if not, it is called **draw-wind**. After draw-twisting, continuous fibers may be given additional twist or may be sent directly to warping.

When tow is cut to make staple, the short fibers are allowed to assume random orientation. The staple, alone or in a blend, is then usually processed as described in the Cotton System section. However, tow-to-top conversion, a more efficient process, has become more popular. The longer tow is broken or cut to maintain parallel orientation. Most of the steps of the cotton system are bypassed; the parallel fibers are ready for blending and mechanical spinning into yarn.

In the manufacture of glass fiber yarn, light denier multifilaments are formed by attenuating molten glass through platinum bushings at high temperatures and speeds. The filaments are then drawn together while being cooled with a water spray, and a chemical size is applied to protect the fiber. This is all accomplished in a single process prior to winding the fiber for further processing.

3. YARN MAKING

The fiber length determines whether spinning or twisting must be used. Spun yarns are produced by loosely gathering synthetic staple, natural fibers, or blends into rope-like form; drawing them out to increase fiber parallelism, if required; and then twisting. Twisted (continuous filament) yarns are made by twisting long monofilaments or multifilaments. Ply yarns are made in a similar manner from spun or twisted yarns.

The principles of mechanical spinning are applied in three different systems: cotton, woolen, and worsted. The cotton system is used for all cotton, most synthetic staple, and many blends. Woolen and worsted systems are used to spin most wool yarns, some wool blends, and synthetic fibers such as acrylics.

Cotton System

The cotton system was originally developed for spinning cotton yarn, but now its basic machinery is used to spin all varieties of staple, including wool, polyester, and blends. Most of the steps from raw materials to fabrics, along with the ranges of frequently used humidities, are outlined in Figure 1.

Opening, Blending, and Picking. The compressed tufts are partly opened, most foreign matter and some short fibers are removed, and the mass is put in an organized form. Some blending is desired to average the irregularities between bales or to mix different kinds of fiber. Synthetic staple, which is cleaner and more uniform, usually requires less preparation. The product of the picker is pneumatically conveyed to the feed rolls of the card.

Carding. This process lengthens the lap into a thin web, which is gathered into a rope-like form called a **sliver**. Further opening and fiber separation follows, as well as partial removal of short fiber and trash. The sliver is laid in an ascending spiral in cans of various diameters.

For heavy, low-count (length per unit of mass) yarns of average or lower quality, the card sliver goes directly to drawing. For lighter, high-count yarns requiring fineness, smoothness, and strength, the card sliver must first be combed.

Lapping. In sliver lapping, several slivers are placed side by side and drafted. In ribbon lapping, the resulting ribbons are laid one on another and drafted again. The doubling and redoubling averages out sliver irregularities; drafting improves fiber parallelism. Some recent processes lap only once before combing.

Combing. After lapping, the fibers are combed with fine metal teeth to substantially remove all fibers below a predetermined length, to remove any remaining foreign matter, and to improve fiber arrangement. The combed lap is then attenuated by drawing rolls and again condensed into a single sliver.

Drawing. Drawing follows either carding or combing and improves uniformity and fiber parallelism by doubling and drafting several individual slivers into a single composite strand. Doubling averages the thick and thin portions; drafting further attenuates the mass and improves parallelism.

Roving. Roving continues the processes of drafting and paralleling until the strand is a size suitable for spinning. A slight twist is inserted, and the strand is wound on large bobbins used for the next roving step or for spinning.

Spinning. Mechanical spinning simultaneously applies draft and twist. The packages (any form into or on which one or more ends can be wound) of roving are creeled at the top of the frame. The unwinding strand passes progressively through gear-driven drafting rolls, a yarn guide, the C-shaped traveler, and then to the bobbin. The vertical traverse of the ring causes the yarn to be placed in predetermined layers.

The difference in peripheral speed between the back and front rolls determines the draft. Twist is determined by the rate of front roll feed, spindle speed, and drag, which is related to the traveler mass.

The space between the nip or bite of the rolls is adjustable and must be slightly greater than the longest fiber. The speeds of front

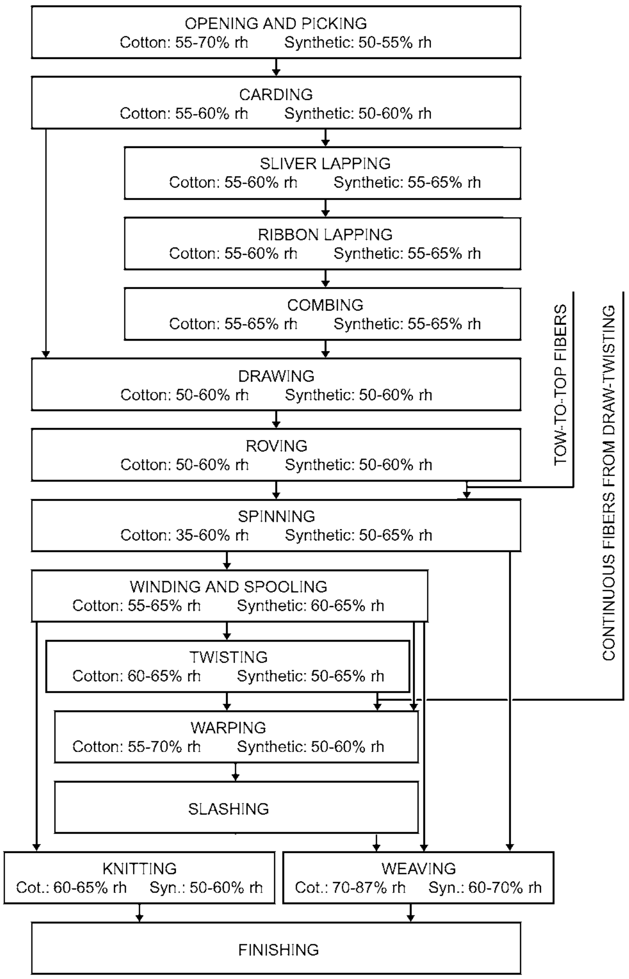

Fig. 1 Textile Process Flowchart and Ranges of Humidity

and back rolls are independently adjustable. Cotton spindles normally run at 8000 to 9000 rpm but may exceed 14 000 rpm. In ring twisting, drawing rolls are omitted, and a few spindles run as high as 18 000 rpm.

Open-end or turbine spinning combines drawing, roving, lapping, and spinning. Staple fibers are fragmented as they are drawn from a sliver and fed into a small, fast-spinning centrifugal device. In this device, the fibers are oriented and discharged as yarn; twist is imparted by the rotating turbine. This system is faster, quieter, and less dusty than ring spinning.

Spinning is the final step in the cotton system; the feature that distinguishes it from twisting is the application of draft. The amount and point of draft application accounts for many of the subtle differences that require different humidities for apparently identical processes.

Atmospheric Conditions. From carding to roving, the loosely bound fibers are vulnerable to static electricity. In most instances, static can be adequately suppressed with humidity, which should not be so high as to cause other problems. In other instances, it is necessary to suppress electrostatic properties with antistatic agents. Wherever draft is applied, constant humidity is needed to maintain optimum frictional uniformity between adjacent fibers and, hence, cross-sectional uniformity.

Woolen and Worsted Systems

The woolen system generally makes coarser yarns, whereas the worsted system makes finer ones of a somewhat harder twist. Both may be used for lighter blends of wool, as well as for synthetic fibers with the characteristics of wool. The machinery used in both systems applies the same principles of draft and twist but differs greatly in detail and is more complex than that used for cotton.

Compared to cotton, wool fibers are dirtier, greasier, and more irregular. They are scoured to remove grease and are then usually reimpregnated with controlled amounts of oil to make them less hydrophilic and to provide better interfiber behavior. Wool fibers are scaly and curly, so they are more cohesive and require different treatment. Wool, in contrast to cotton and synthetic fibers, requires higher humidities in the processes prior to and including spinning than it does in the processes that follow. Approximate humidities are given in Kirk and Othmer (2004).

Twisting Filaments and Yarns

Twisting was originally applied to silk filaments; several filaments were doubled and then twisted to improve strength, uniformity, and elasticity. Essentially the same process is used today, but it is now extended to spun yarns, as well as to single or multiple filaments of synthetic fibers. Twisting is widely used in the manufacture of sewing thread, twine, tire cord, tufting yarn, rug yarn, ply yarn, and some knitting yarns.

Twisting and doubling is done on a **down-** or **ring-twister**, which draws in two or more ends from packages on an elevated creel, twists them together, and winds them into a package. Except for the omission of drafting, down-twisters are similar to conventional ring-spinning frames.

When yarns are to be twisted without doubling, an **up-twister** is used. Up-twisters are primarily used for throwing synthetic monofilaments and multifilaments to add to or vary elasticity, light reflection, and abrasion resistance. As with spinning, yarn characteristics are controlled by making the twist hard or soft, right (S) or left (Z). Quality is determined largely by the uniformity of twist, which, in turn, depends primarily on the tension and stability of the atmospheric conditions (Figure 1). Because the frame may be double- or triple-decked, twisting requires concentrations of power. The frames are otherwise similar to those used in spinning, and they present the same air distribution problems. In twisting, lint is not a serious problem.

4. FABRIC MAKING

Preparatory Processes

When spinning or twisting is complete, the yarn may be prepared for weaving or knitting by processes that include winding, spooling, creeling, beaming, slashing, sizing, and dyeing. These processes have two purposes: (1) to transfer the yarn from the type of package dictated by the preceding process to a type suitable for the next and (2) to impregnate some of the yarn with sizes, gums, or other chemicals that may not be left in the final product.

Filling Yarn. Filling yarn is wound on quills for use in a loom shuttle. It is sometimes predyed and must be put into a form suitable for package or skein dyeing before it is quilled. If the filling is of relatively hard twist, it may be put through a twist-setting or conditioning operation in which internal stresses are relieved by applying heat, moisture, or both.

Warp Yarn. Warp yarn is impregnated with a transient coating of size or starch that strengthens the yarn's resistance to the chafing it will receive in the loom. The yarn is first rewound onto a cone or other large package from which it will unwind speedily and smoothly. The second step is warping, which rewinds a multiplicity of ends in parallel arrangement on large spools, called **warp or section beams**. In the third step, slashing, the threads pass progressively through the sizing solution, through squeeze rolls, and then around cans, around steam-heated drying cylinders, or through an air-drying chamber. A thousand kilograms or more may be wound on a single loom beam.

Knitting Yarn. If hard-spun, knitting yarn must be twist-set to minimize kinking. Filament yarns must be sized to reduce strip-backs and improve other running qualities. Both must be put in the form of cones or other suitable packages.

Uniform tension is of great importance in maintaining uniform package density. Yarns tend to hang up when unwound from a hard package or slough off from a soft one, and both tendencies are aggravated by spottiness. The processes that require air conditioning, along with recommended relative humidities, are presented in Figure 1.

Weaving

In the simplest form of weaving, harnesses raise or depress alternate warp threads to form an opening called a **shed**. A shuttle containing a quill is kicked through the opening, trailing a thread of filling behind it. The lay and the reed then beat the thread firmly into one apex of the shed and up to the fell of the previously woven cloth. Each shuttle passage forms a pick. These actions are repeated at frequencies up to five per second.

Each warp thread usually passes through a drop-wire that is released by a thread break and automatically stops the loom. Another automatic mechanism inserts a new quill in the shuttle as the previous one is emptied, without stopping the loom. Other mechanisms are actuated by filling breaks, improper shuttle boxing, and the like, which stop the loom until it is manually restarted. Each cycle may leave a stop mark sufficient to cause an imperfection that may not be apparent until the fabric is dyed.

Beyond this basic machine and pattern are many complex variations in harness and shuttle control, which result in intricate and novel weaving effects. The most complex loom is the **jacquard**, with which individual warp threads may be separately controlled. Other variations appear in looms for such products as narrow fabrics, carpets, and pile fabrics. In the **Sulzer weaving machine**, a special filling carrier replaces the conventional shuttle. In the rapier, a flat, spring-like tape uncoils from each side and meets in the middle to transfer the grasp on the filling. In the **water jet loom**, a tiny jet of high-pressure water carries the filling through the shed of the warp. Other looms transport the filling with compressed air.

High humidity increases the abrasion resistance of the warp. Weave rooms require 80 to 85% humidity or higher for cotton and up to 70% humidity for synthetic fibers. Many looms run faster when room humidity and temperature are precisely controlled.

In the weave room, power distribution is uniform, with an average concentration somewhat lower than in spinning. The rough treatment of fibers liberates many minute particles of both fiber and size, thereby creating considerable amounts of airborne dust. In this high-humidity area, air changes average from four to eight per hour. Special provisions must be made for maintaining conditions during production shutdown periods, usually at a lower relative humidity.

Knitting

Typical knitted products are seamless articles produced on circular machines (e.g., undershirts, socks, and hosiery) and those knitted flat (e.g., full-fashioned hosiery, tricot, milanese, and warp fabrics).

Knitted fabric is generated by forming millions of interlocking loops. In its simplest form, a single end is fed to needles that are actuated in sequence. In more complex constructions, hundreds of ends may be fed to groups of elements that function more or less in parallel.

Knitting yarns may be either single strand or multifilament and must be of uniform high quality and free from neps or knots. These yarns, particularly the multifilament type, are usually treated with special sizes to provide lubrication and to keep broken filaments from stripping back.

The need for precise control of yarn tension, through controlled temperature and relative humidity, increases with the fineness of the product. For example, in finer gages of full-fashioned hosiery, a 1 K change in temperature is the limit, and a 10% change in humidity may change the length of a stocking by 75 mm. For knitting, desirable room conditions are approximately 24°C db and 45 to 65% rh.

Dyeing and Finishing

Finishing, which is the final readying of a mill product for its particular market, ranges from cleaning to imparting special characteristics. The specific operations involved vary considerably, depending on the type of fiber, yarn, or fabric, and the end product usage. Operations are usually done in separate plants. In addition to normal heating, ventilation, and fog removal systems, these areas also require removal of hot, dusty, and toxic fumes from continuous ovens and tenters. Packaged chilling equipment is sometimes used to control temperatures of preshrink chemicals, dyes, and coatings that are applied to textiles and yarns before finishing. Some of these processes require corrosive-resistant materials and equipment.

Inspection is the only finishing operation to which air conditioning is regularly applied, although most of the others require ventilation. Finishing operations that use wet processes usually keep their solutions at high temperatures and require special ventilation to prevent destructive condensation and fog. Spot cooling of workers may be necessary for large releases of sensible, latent, or radiant heat.

5. AIR-CONDITIONING DESIGN

There are many diverse and special needs of specific areas of the textile process. Generally, a meeting with the owner's representative(s), local code officials, and the owner's insurance company is helpful in satisfying the particular requirements of the process, insurance companies, and local officials. HVAC engineers designing textile projects need to have a thorough understanding of the following HVAC system elements:

- Psychrometric process in spray systems
- Humidification and dehumidification
- Draft-free air distribution
- Fog control
- Water and air filters
- Dust collectors
- Industrial ductwork
- Large built-up air handlers
- Large water chillers
- Cooling towers
- Industrial piping systems
- Pumping
- Corrosion-resistant metallurgy
- Large centrifugal air compressors
- Programmable logic controllers and supervisory control and data acquisition (SCADA) systems
- Water treatment in open sump systems

Consultation with mechanical contracting companies experienced with building and installing textile-related systems provides great insight to these attributes. Thorough understanding of the processes to be conditioned; precise calculations; familiarity with codes, regulations, and current industry standards; as well as reasonable owner/engineer/contractor relationships and adherence to the owner's budget are necessary for successful projects.

Air washers are especially important in textile manufacturing and may be either conventional low-velocity or high-velocity units in built-up systems. Unitary high-velocity equipment using rotating eliminators, although no longer common, is still found in some plants.

Contamination of air washers by airborne oils often dictates the separation of air washers and process chillers by heat exchangers, usually of the plate or frame type.

Open-Sump Chilled-Water Systems

It is common practice to use open sumps in textile processing with air washer air-handling units. Open sumps present a unique problem for the removal of lint from the basins. Many systems return the air from spinning areas, and this air carries lint and free fibers from the spinning process. These fibers are typically not completely removed by central collectors (see Figure 3). In older facilities, the central collectors may be totally ineffective or nonexistent. A rotating drum filter is commonly used to remove lint fibers from the sumps of air washers to prevent clogging of spray nozzles and fouling of spray media. The rotating drum filters are semisubmerged in the sump and are fitted with a vacuum system that traverses the part of the drum that is exposed to air, removing the lint from the drum surface and transporting it through a high-pressure blower to a bag house, where water is separated and the lint collected for future disposal.

Many textile plants have an open sump for return of chilled water from the air washers (see A in Figure 2). The chilled-water pumps draw out of these sumps through a screened inlet, C, for return of chilled water to the chillers. In designing the inlet screen, care must be taken to avoid a configuration that might lead to pump cavitation. Rotating drum filters should also be considered for these sumps to prevent fouling of chiller tubes by lint that passes the screens. These sumps must be carefully sized to receive the volume of water contained in the system when the air washers are shut off and their sumps drain down.

Integrated Systems

Many mills use a refined air washer system that combines the air-conditioning system and the collector system (see the section on Collector Systems) into an integrated unit. Air handled by the collector system fans and any air required to make up total return air are delivered back to the air-conditioning apparatus through a central duct. The quantity of air returned by individual yarn-processing machine cleaning systems must not exceed the quantity of air-conditioning supply air. Air discharged by these individual suction systems is carried by return air ducts directly to the air-conditioning system. Before entering the duct, some of the cleaning system air

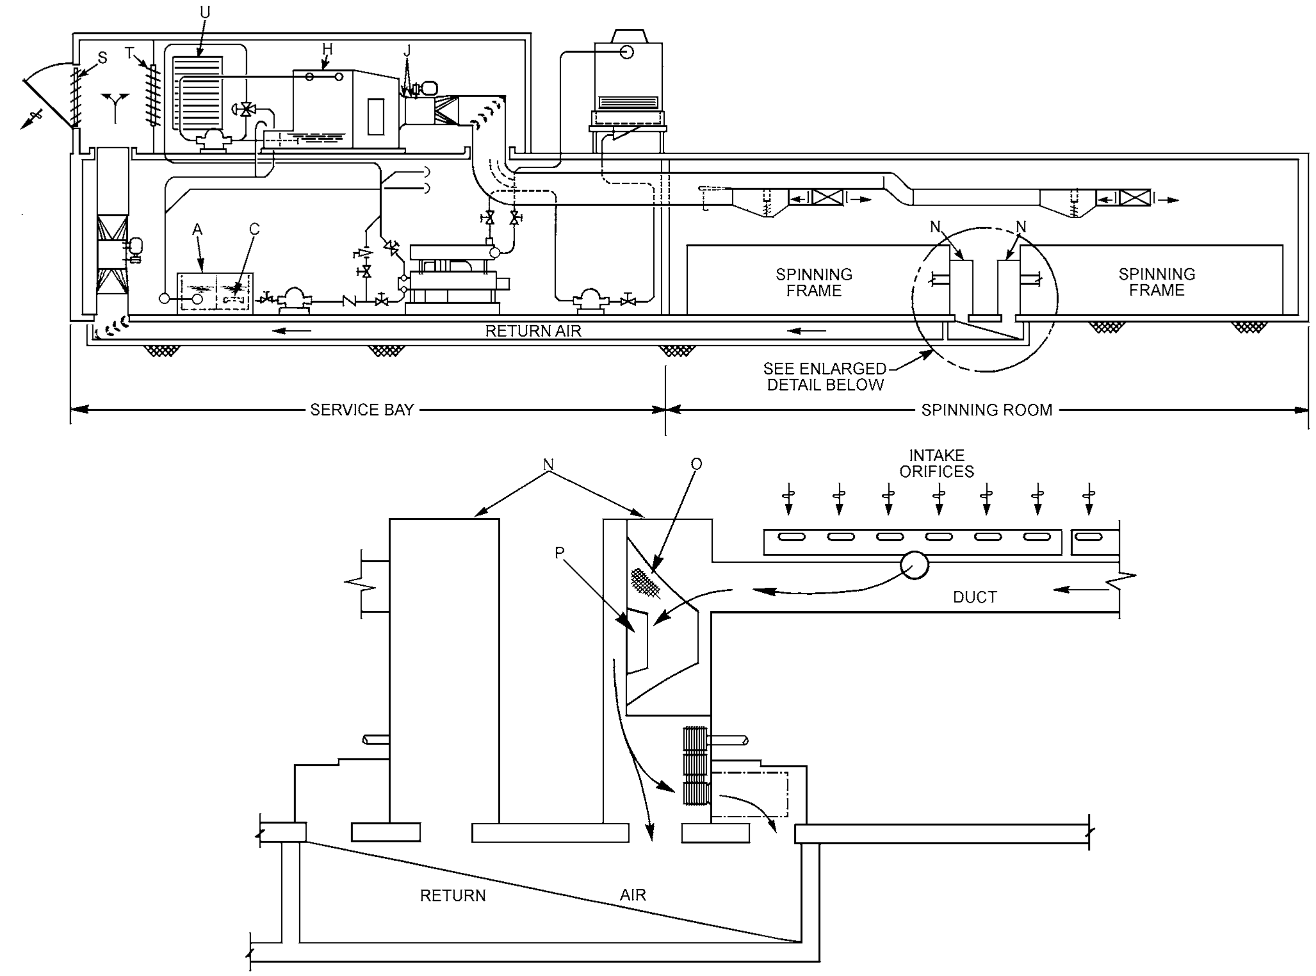

Fig. 2 Mechanical Spinning Room with Combined Air-Conditioning and Collector System

passes over the yarn-processing machine drive motor and through a special enclosure to capture heat losses from the motor.

When integrated systems occasionally exceed the supply air requirements of the area served, the surplus air must be reintroduced after filtering.

Individual suction cleaning systems that can be integrated with air conditioning are available for cards, drawing frames, lap winders, combers, roving frames, spinning frames, spoolers, and warpers. The following advantages result from this integration:

- With a constant air supply, the best uniform air distribution can be maintained year-round.
- Downward airflow can be controlled; crosscurrents in the room are minimized or eliminated; drift or fly from one process to another is minimized or eliminated. Room partitioning between systems serving different types of manufacturing processes further enhances the value of this integration by controlling room air pattern year-round.
- Heat losses of the yarn-processing frame motor and any portion of the processing frame heat captured in the duct, as well as the heat of the collector system equipment, cannot affect room conditions; hot spots in motor alleys are eliminated, and although this heat goes into the refrigeration load, it does not enter the room. As a result, the supply air quantity can be reduced.
- Uniform conditions in the room improve production; conditioned air is drawn directly to the work areas on the machines, minimizing or eliminating wet or dry spots.
- Maximum cleaning use is made of the air being moved. A guide for cleaning air requirements follows:

Pickers	1200 to 1900 L/s per picker
Cards	300 to 700 L/s per card
Spinning	2 to 4 L/s per spindle
Spooling	19 L/s per spool

Collector Systems

A collector system is a waste-capturing device that uses many orifices operating at high suction pressures. Each piece of production machinery is equipped with suction orifices at all points of major lint generation. The captured waste is generally collected in a fan and filter unit located either on each machine or centrally to accept waste from a group of machines.

A collector in the production area may discharge waste-filtered air either back into the production area or into a return duct to the air-conditioning system. It then enters the air washer or is relieved through dampers to the outdoors.

Figure 2 shows a mechanical spinning room with air-conditioning and collector systems combined into an integrated unit. In this case, the collector system returns all of its air to the air-conditioning system. If supply air from the air-conditioning system exceeds the maximum that can be handled by the collector system, additional air should be returned by other means.

Figure 2 also shows return air entering the air-conditioning system through damper T, passing through air washer H, and being delivered by fan J to the supply duct, which distributes it to maintain conditions within the spinning room. At the other end of each spinning frame are unitary filter-collectors consisting of enclosure N, collector unit screen O, and collector unit fan P.

Collector fan P draws air through the intake orifices spaced along the spinning frame. This air passes through the duct that runs lengthwise to the spinning frame, passes through screen O, and is then discharged into the enclosure base (beneath the fan and screen). The air quantity is not constant; it drops slightly as material builds up on the filter screen.

Because the return air quantity must remain constant, and the air quantity discharged by fan P is slightly reduced at times, relief openings are necessary. Relief openings also may be required when the return air volume is greater than the amount of air the collector suction system can handle.

The discharge of fan P is split, so part of the air cools the spinning frame drive motor before rejoining the rest of the air in the return air tunnel. Regardless of whether the total return air quantity enters the return air tunnel through collector units, or through a combination of collector units and floor openings beneath spinning frames, return air fan R delivers it into the apparatus, ahead of return air damper T. Consideration should be given to filtering the return air prior to its delivery into the air-conditioning apparatus.

Mild-season operation causes more outdoor air to be introduced through damper U. This air is relieved through motorized damper S, which opens gradually as outdoor damper U opens, while return damper T closes in proportion. All other components perform as typical central station air-washer systems.

A system having the general configuration shown in Figure 2 may also be used for carding; the collector system portion of this arrangement is shown in Figure 3. A central collector filters the lint-laden air taken from multiple points on each card. This air is discharged to return air duct A and is then either returned to the air-conditioning system, exhausted outdoors, or returned directly to the room. A central collector filter may also be used with the spinning room system of Figure 2.

Air Distribution

Textile plants served by generally uniform air distribution may still require special handling for areas of load concentration.

Continuous Spinning Area. Methods of distribution are diverse and generally not critical. However, spot cooling or localized heat removal may be required. This area may be cooled by air conditioning, evaporative cooling, or ventilation.

Chimney (Quench Stack). Carefully controlled and filtered air or other gas is delivered to the chimneys; it is returned for conditioning and recovery of any valuable solvents present. Distribution of the air is of the utmost importance. Non-uniform temperature, humidity, or airflow disturbs the yarn, causing variations in fiber diameter, crystalline structure, and orientation. A fabric made of such fibers streaks when dyed.

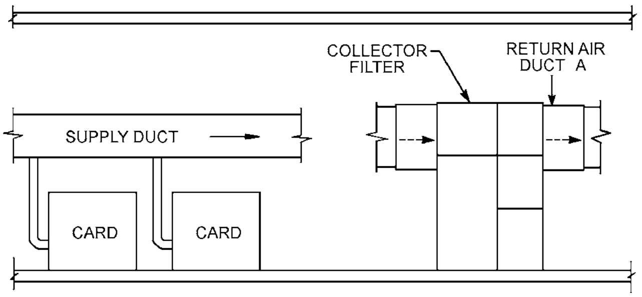

Fig. 3 Central Collector for Carding Machine

In melt spinning, the solvent concentration in the chimney air must be maintained below its explosive limit. Even with this provision, care is still required to prevent vapors from being ignited by a spark or flame. The air-conditioning system must be reliable, because interruption of the spinning causes the solution to solidify in the spinnerets.

Wind-Up or Take-Up Areas of Continuous Spinning. A heavy air-conditioning load is developed. Air is often delivered through branch ducts alongside each spinning machine. Low-velocity, low-aspiration diffusers must be sized to avoid agitating delicate fibers.

Draw-Twist or Draw-Wind Areas of Fiber Manufacture. A heavy air-conditioning load is developed. Distribution, diffusion, and return systems are similar to those for the continuous spinning take-up area.

Opening and Picking. Usually, opening and picking require only a uniform distribution system. The area is subject to shutdown of machinery during portions of the day. Generally, an all-air system with independent zoning is installed.

Carding. A uniform distribution system is generally installed. There should be little air movement around the web in cotton carding. Central lint collecting systems are available but must be incorporated into the system design. An all-air system is often selected for cotton carding.

In wool carding, there should be less air movement than in cotton carding, not only to avoid disturbing the web, but also to reduce cross-contamination between adjacent cards. This is because different colors of predyed wool may be run side by side on adjacent cards. A split system (i.e., separate systems for each card) may be considered for wool carding to reduce air movement. The method of returning air is also critical for achieving uniform conditions.

Drawing and Roving. Generally, a uniform distribution all-air system works well.

Mechanical Spinning Areas. A heavy air-conditioning load is generated, consisting of spinning frame power uniformly distributed along the frame length and frame driver motor losses concentrated in the motor alley at one end of the frame.

Supply air ducts should run across the frames at right angles. Sidewall outlets between each of the two adjacent frames then direct the supply air down between the frames, where conditions must be maintained. Where concentrated heat loads occur, as in a double motor alley, placement of a supply air duct directly over the alley should be considered. Sidewall outlets spaced along the bottom of the duct diffuse air into the motor alley.

The collecting system, whether unitary or central, with intake points distributed along the frame length at the working level, assists in pulling supply air down to the frame, where maintenance of conditions is most important. A small percentage of the air handled by a central collecting system may be used to convey the collected lint and yarn to a central point, thus removing that air from the spinning room.

Machine design in spinning systems sometimes requires interfloor air pressure control.

Winding and Spooling. Generally, a uniform distribution, all-air system is used.

Twisting. This area has a heavy air-conditioning load. Distribution considerations are similar to those in spinning. Either all-air or split systems are installed.

Warping. This area has a very light load. Long lengths of yarn may be exposed unsupported in this area. Generally, an all-air system with uniform distribution is installed. Diffusers may be of the low-aspiration type. Return air is often near the floor.

Weaving. Generally, a uniform distribution system is necessary. Synthetic fibers are more commonly woven than natural fibers. The lower humidity requirements of synthetic fibers allow the use of an all-air system rather than the previously common split system. When lower humidity is coupled with the water jet loom, a high latent load results.

Health Considerations

For detailed information on control of industrial contaminants, see Chapter 29 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Control of Oil Mist. When textiles coated with lubricating oils are heated above 93°C in drawing operations in ovens, heated rolls, tenterframes, or dryers, an oil mist is liberated. If the oil mist is not collected at the source of emission and disposed of, a slightly odorous haze results.

Various devices have been proposed to separate oil mist from the exhaust air, such as fume incinerators, electrostatic precipitators, high-energy scrubbers, absorption devices, high-velocity filters, and condensers.

Spinning operations that generate oil mist must be provided with a high percentage (30 to 75%) of outdoor air. In high-speed spinning, 100% outdoor air is commonly used.

Operations such as drum cooling and air texturizing, which could contaminate the air with oil, require local exhausts.

Control of Monomer Fumes. Separate exhaust systems for monomers are required, with either wet- or dry-type collectors, depending on the fiber being spun. For example, caprolactam nylon spinning requires wet exhaust scrubbers.

Control of Hazardous Solvents. Provisions must be made for the containment, capture, and disposal of hazardous solvents.

Control of Cotton Dust. Byssinosis, also known as brown or white lung disease, is believed to be caused by a histamine-releasing substance in cotton, flax, and hemp dust. In the early stages of the disease, a cotton worker returning to work after a weekend experiences difficulty in breathing that is not relieved until later in the week. After 10 to 20 years, the breathing difficulty becomes continuous; even leaving the mill does not provide relief.

The U.S. Department of Labor enforces an OSHA standard of lint-free dust. The most promising means of control are improved exhaust procedures and filtration of recirculated air. Lint particles are 1 to 15 μm in diameter, so filtration equipment must be effective in this size range. Improvements in carding and picking that leave less trash in the raw cotton also help control lint.

Noise Control. The noise generated by HVAC equipment can be significant, especially if the textile equipment is modified to meet present safety criteria. For procedures to analyze and correct the noise from ventilating equipment, see Chapter 49.

Safety and Fire Protection

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

Oil mist can accumulate in ductwork and create a fire hazard. Periodic cleaning reduces the hazard, but provisions should be made to contain a fire with suppression devices such as fire-activated dampers and interior duct sprinklers.

6. ENERGY CONSERVATION

The following are some steps that can be taken to reduce energy consumption:

- Applying heat recovery to water and air
- Automating high-pressure dryers to save heat and compressed air
- Decreasing hot-water temperatures and increasing chilled-water temperatures for rinsing and washing in dyeing operations
- Replacing running washes with recirculating washes where practical
- Changing double-bleaching procedures to single-bleaching where practical
- Eliminating rinses and final wash in dye operations where practical
- Drying by “bump and run” process
- Modifying drying or curing oven air-circulation systems to provide counterflow
- Using energy-efficient electric motors and textile machinery
- For drying operations, using discharge air humidity measurements to control the exhaust versus recirculation rates in full economizer cycles

CHAPTER 23

PHOTOGRAPHIC MATERIAL FACILITIES

Storing Unprocessed Photographic Materials 23.1
Processing and Printing Photographic Materials 23.1
Storing Processed Film and Paper 23.3

PROCESSING and storing sensitized photographic products requires temperature, humidity, and air quality control. Manufacturers of photographic products and processing equipment provide specific recommendations for facility design and equipment installation that should always be consulted. This chapter contains general information that can be used in conjunction with these recommendations. See Chapter 31 for information on general industrial ventilation.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. STORING UNPROCESSED PHOTOGRAPHIC MATERIALS

Virtually all photosensitive materials deteriorate with age; the rate of photosensitivity deterioration depends largely on the storage conditions. Photosensitivity deterioration increases both at high temperature and at high relative humidity and usually decreases at lower temperature and humidity.

High humidity can accelerate loss of sensitivity and contrast, increase shrinkage, produce mottle (spots or blotches of different shades or colors), cause softening of the emulsion (which can lead to scratches), and promote fungal growth. Low relative humidity can increase the susceptibility of the film or paper to static markings, abrasions, brittleness, and curl.

Because different photographic products require different handling, product manufacturers should be consulted regarding proper temperature and humidity conditions for storage. Refrigerated storage may be necessary for some products in some climates.

Products not packaged in sealed vaportight containers are vulnerable to contaminants. These products must be protected from solvent, cleanser, and formaldehyde vapors (emitted by particleboard and some insulation, plastics, and glues); industrial gases; and engine exhaust. In hospitals, industrial plants, and laboratories, all photosensitive products, regardless of their packaging, must be protected from x-rays, radium, and radioactive sources. For example, films stored 8 m away from 100 mg of radium require the protection of 90 mm of lead.

2. PROCESSING AND PRINTING PHOTOGRAPHIC MATERIALS

Ventilation with clean, fresh air maintains a comfortable working environment and prevents vapor-related complaints and health problems. It is also necessary for high-quality processing, safe handling, and safe storage of photographic materials.

Processing produces odors, vapors, high humidity, and heat (from lamps, electric motors, dryers, mounting presses, and high-temperature processing solutions). Thus, it is important to supply plentiful clean, fresh air at the optimum temperature and relative humidity to all processing rooms. ASHRAE *Standard* 62.1 specifies 5.0 L/(s·m^2) of exhaust for darkrooms in Table 6-4.

Air Conditioning for Preparatory Operations

During receiving operations, exposed film is removed from its protective packaging for presplicing and processing. **Presplicing** combines many individual rolls of film into a long roll to be processed. At high relative humidity, photographic emulsions become soft and can be scratched. At excessively low relative humidity, the film base is prone to static, sparking, and curl deformation. The presplice work area should be maintained at 50 to 55% rh and 21 to 24°C db. Room pressures should cascade downward from areas of higher air quality to areas of lower air quality (clean to dirty).

Air Conditioning for Processing Operations

Processing exposed films or paper involves using a series of tempered chemical and wash tanks that emit heat, humidity, and vapors or gases (e.g., water vapor, acetic acid, benzyl alcohol, ammonia, sulfur dioxide). Room exhaust must be provided, along with local exhaust at noxious tanks. To conserve energy, air from pressurized presplice rooms can be used as makeup for processing room exhaust. Further supply air should maintain the processing space at a maximum of 24°C dry bulb and 50 to 55% rh.

The processed film or paper proceeds from the final wash to the dryer, which controls the moisture remaining in the product. Too little drying causes film to stick when wound, whereas too much drying causes undesirable curl. Drying can be regulated by controlling drying time, humidity, and temperature.

The volume of supply air should be sufficient to achieve the design condition. Airflow should be diffused or distributed to avoid objectionable drafts. Apart from causing personnel discomfort, drafts can cause dust problems and disturb the surface temperature uniformity of drying drums and other heated equipment. Supply and return air openings should be properly positioned (1) for good mixing and dilution of the room air, (2) to ensure efficient removal of fugitive vapors, and (3) to avoid short-circuiting of supply air into return or exhaust air openings. For automated processing equipment, tempered outdoor air should be supplied from the ceiling above the feed or head end of the machine at a minimum rate of 70 L/s per machine (Figure 1). If the machine extends through a wall into another room, both rooms need to be exhausted.

An exhaust system should be installed to remove humid or heated air and chemical vapors directly to the outdoors (process streams typically must comply with regulations pursuant to the Clean Air Act). The room air from an open machine or tank area should be exhausted to the outdoors at a rate sufficient to achieve at least the vapor dilution levels recommended by the American Conference of Governmental Industrial Hygienists (ACGIH 2010). An exhaust rate higher than the supply rate produces a negative pressure and makes the escape of

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

vapors or gases to adjoining rooms less likely. Depending on the process chemistry, local exhaust hoods may be needed at uncovered stabilizer tanks or at the bleach fix tanks (Figure 1).

The exhaust opening should be positioned so that the flow of exhausted air is away from the operator, as illustrated in Figure 2. This air should not be recirculated. The exhaust opening should always be as close as possible to the source of the contaminant for efficient removal [see ACGIH (2010) for more information]. For a processing tank, the exhaust hood should have a narrow opening at the back of, level with, and as wide as the top edge of the tank.

Processing tanks are often covered to reduce evaporation of heated processing chemical solutions (approximately 38°C). Covers on photographic processing equipment and chemical storage tanks can effectively minimize the amount of gases, vapors, or mists that enter the work area. If the processing tanks are enclosed and equipped with an exhaust connection, the minimum room air supply and exhaust rates may be reduced compared to an open tank (Figure 3).

A sulfide-toning sink should have a local exhaust hood to vent hydrogen sulfide. However, sulfide toners are rarely used now except for some specialized art processing and archival microfilm processing. The exhaust duct must be placed on the side opposite the operator so that vapor is not drawn toward the operator's face.

Air distribution to the drying area must provide an acceptable environment for operators as discussed in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* and ACGIH (2010). Exposed sides of the dryer should be insulated as much as is practical to reduce the large radiant and convected heat gain to the space. Exhaust grilles above the dryer can directly remove much of its rejected heat and moisture. Supply air should be directed to offset the remaining radiant heat gain to the space.

Using processor dryer heat to preheat cold incoming air during winter conditions can save energy. An economic evaluation is necessary to determine whether the energy savings justify the additional cost of the heat recovery equipment.

A canopy exhaust hood over the drying drum of continuous paper processors extracts heat and moisture. It is important to follow the processing equipment manufacturer's recommendations for venting the dryer section of the processor. Whenever possible, dryer vents should be exhausted to the outdoors to prevent build-up of excessive temperature and humidity in the workplace.

When drying motion picture film, exhaust should draw off vapor from the solvent and wax mixture that is normally applied for lubrication.

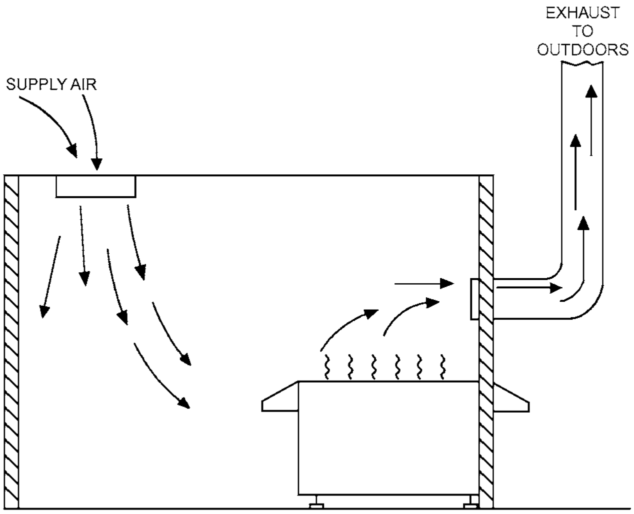

Fig. 1 Open Machine Ventilation

Air Conditioning for the Printing/Finishing Operation

In printing, where a second sensitized product is exposed through the processed original, the amount of environmental control needed depends on the size and type of operation. For small-scale printing, close control of the environment is not necessary, except to minimize dust. In photofinishing plants, printers for colored products emit substantial heat. The effect on the room can be reduced by removing the lamphouse heat directly. Computer-controlled electronic printers transport the original film and raw film or paper at high speed. Proper temperature and humidity are especially important because, in some cases, two or three images from many separate films may be superimposed in register onto one film. For best results, the printing room should be maintained at between 21 and 24°C and at 50 to 60% rh to prevent curl, deformation, and static. Curl and film deformation affect the register and sharpness of the images produced. Static charge should be eliminated because it leaves static marks and may also attract dust to the final product.

Mounting of reversal film into slides is a critical finishing operation requiring a 21 to 24°C db temperature with 50 to 55% rh.

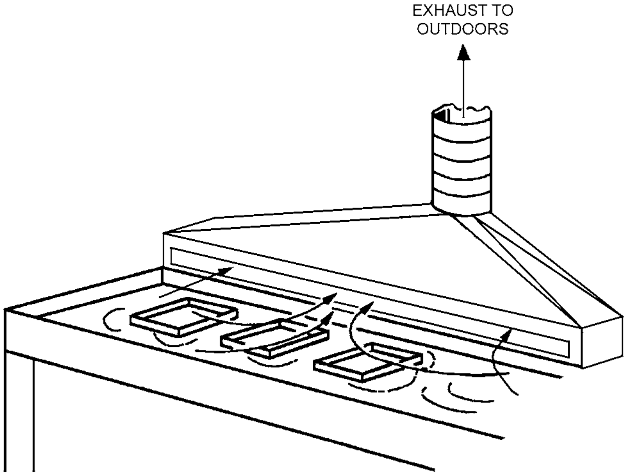

Fig. 2 Open-Tray Exhaust Ventilation from Processing Sink

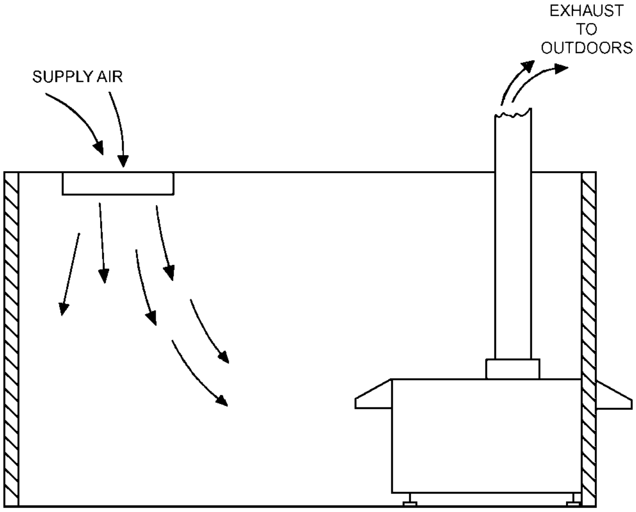

Fig. 3 Enclosed Machine Ventilation

Digital printing operations use equipment that generates significant heat. An exhaust system can be directly connected to the laser printer to remove heat at a flow rate specified by the equipment manufacturer. Sufficient room ventilation is required so that applicable occupational exposure limits are not exceeded and a favorable operating environment is maintained.

Particulates in Air

Air conditioning for most photographic operations requires 85% efficiency disposable bag-type filters with 30% efficiency prefilters to extend the bag filter life. In critical applications (such as high-altitude aerial films) and for microminiature images, filtering of foreign matter is extremely important. These products are handled in a laminar airflow room or workbench with 95% efficiency HEPA filters plus 30% efficiency disposable prefilters.

Other Exhaust Requirements

A well-ventilated room should be provided for mixing the chemicals used in color processing and high-volume black-and-white work. The room should be furnished with movable exhaust hoods that provide a capture velocity as defined in ACGIH's (2010) *Industrial Ventilation* for the worst-case scenario. Modern photographic minilabs often use canisters of premixed processing solutions, so no chemical mixing is necessary.

If prints are lacquered regularly, a spray booth is needed. Concentrated lacquer spray is both hazardous and very objectionable to personnel; spray booth exhaust must be discharged outdoors.

Processing Temperature Control

Low processing volumes are typically handled in minilabs, which are often installed in retail locations. Minilabs are usually self-contained and equipped with temperature controls, heaters, and pumps. Typically, the owner only has to connect the minilab to water, electricity, exhaust (thimble connection), and a drain.

Higher-volume processing is handled with processors that come from the manufacturer complete with controls, heat exchangers, pumps, and control valves designed for the process that the owner has specified. Electricity, hot water, cold water, drainage, and steam may be required, depending on the manufacturer, who typically provides the specifications for these utilities.

3. STORING PROCESSED FILM AND PAPER

Storage of developed film and paper differs from storage of raw stock, because the developed materials are no longer photosensitive, are seldom sealed against moisture, and are generally stored for much longer periods. Required storage conditions depend on (1) the value of the records, (2) length of storage time, (3) whether the films are on nitrate or safety base, (4) whether the paper base is resin coated, and (5) type of photographic image.

Photographic materials must be protected against fire, water, mold, chemical or physical damage, high relative humidity, and high temperature. Relative humidity is much more critical than temperature. High relative humidity can cause films to stick together, (particularly roll films, but also sheet films). High humidity also damages gelatin, encourages the growth of mold, increases dimensional changes, accelerates the decomposition of nitrate support, and accelerates the deterioration of both black-and-white and color images. Low relative humidity causes a temporary increase in curl and decrease in flexibility, but when the humidity rises again, these conditions are usually reversed. An exception occurs when motion picture film is stored for a long time in loosely wound rolls at very low humidities. The curl causes the film roll to resemble a polygon rather than a circle when viewed from the side. This **spokiness** occurs because a highly curled roll of film resists being bent in the length direction when it is already bent in the width direction. When a spoky roll is stored for a long time, the film flows permanently into the spoky condition, resulting in film distortion. Very low relative humidity in storage may also cause the film or paper to crack or break if handled carelessly.

Low temperature (–23 to 10°C) is desirable for film and paper storage if (1) the relative humidity of the cold air is controlled, and (2) the material can be sufficiently warmed (for 2 to 8 h) before opening to prevent moisture condensation. High temperature can accelerate film shrinkage, which may produce physical distortions and the fading of dye images. High temperature is also detrimental to the stability of nitrate film.

Film Longevity

The American National Standards Institute (ANSI *Standard* IT9.11) defines longevities of films with a life expectancy (LE) rating. The **LE rating** is the minimum number of years that information can be retrieved if the subject film is stored under long-term storage conditions. In order to achieve the maximum LE rating, a product must be stored under long-term storage conditions. Polyester black-and-white silver gelatin films have an LE rating of 500, and acetate black-and-white silver gelatin films have an LE rating of 100. No LE ratings have been assigned to color films or black-and-white silver papers. Medium-term storage conditions have been defined for materials that are to retain their information for at least 10 years.

Medium-Term Storage

Rooms for medium-term storage of safety base film should be protected from accidental water damage by rain, flood, or pipe leaks. Air conditioning with controlled relative humidity is desirable but not always essential in moderate climates. Extremes of relative humidity are detrimental to film.

The most desirable storage relative humidity for processed film is about 50%, although 30 to 60% is satisfactory. Air conditioning is required where the relative humidity of the storage area exceeds 60% for any appreciable period. For a small room, a dehumidifier may be used if air conditioning cannot be installed. The walls should be coated with a vapor retarder, and the controlling humidistat should be set at about 40% rh. If the prevailing relative humidity is under 25% for long periods and problems from curl or brittleness are encountered, humidity should be controlled by a mechanical humidifier with a controlling humidistat set at 40%.

For medium-term storage, a room temperature between 20 and 25°C is recommended. Higher temperatures may cause shrinkage, distortion, and dye fading. Occasional peak temperatures of 35°C should not have a serious effect. Color films should be stored below 10°C to reduce dye fading. Films stored below the ambient dew point should be allowed to warm up before being opened to prevent moisture condensation.

An oxidizing or reducing atmosphere may deteriorate the film base and gradually fade the photographic image. Oxidizing agents may also cause microscopically small colored spots on fine-grain film such as microfilm (Adelstein et al. 1970). Typical gaseous contaminants include hydrogen sulfide, sulfur dioxide, peroxides, ozone, nitrogen oxides, and paint fumes. If these fumes are present in the intended storage space, they must be eliminated, or the film must be protected from contact with the atmosphere.

Long-Term Storage

For films or records that are to be preserved indefinitely, long-term storage conditions should be maintained. The recommended space relative humidity ranges from 20 to 50% rh, depending on the film type. When several film types are stored within the same area, 30% rh is a good compromise. The recommended storage temperature is below 21°C. Low temperature aids preservation, but if the storage temperature is below the dew point of the outdoor air, the records must be allowed to warm up in a closed container before they are used, to prevent moisture condensation. Temperature and humidity conditions must be maintained year-round and should be continuously monitored.

Requirements of a particular storage application can be met by any one of several air-conditioning equipment combinations. Standby equipment should be considered. Sufficient conditioned outdoor air should be provided to keep the room under a slight positive pressure for ventilation and to retard the entrance of untreated air. The air-conditioning unit should be located outside the vault for ease of maintenance, with precautions taken to prevent water leakage into the vault. The conditioner casing and all ductwork must be well insulated. Room conditions should be controlled by a dry-bulb thermostat and either a wet-bulb thermostat, humidistat, or dew-point controller.

Air-conditioning installations and fire dampers in ducts carrying air to or from the storage vault should be constructed and maintained according to National Fire Protection Association (NFPA) recommendations for air conditioning (NFPA *Standard* 90A) and for fire-resistant file rooms (NFPA *Standard* 232).

All supply air should be filtered with noncombustible HEPA filters to remove dust, which may abrade the film or react with the photographic image. As with medium-term storage, gaseous contaminants such as paint fumes, hydrogen sulfide, sulfur dioxide, peroxides, ozone, and nitrogen oxides may cause slow deterioration of the film base and gradual fading of the photographic image. When these substances cannot be avoided, an air scrubber, activated carbon adsorber, or other purification method is required.

Films should be stored in metal cabinets with adjustable shelves or drawers and with louvers or openings located to facilitate circulation of conditioned air through them. The cabinets should be arranged in the room to permit free circulation of air around them.

All films should be protected from water damage due to leaks, fire sprinkler discharge, or flooding. Drains should have sufficient capacity to keep the water from sprinkler discharge from reaching a depth of 75 mm. The lowest cabinet, shelf, or drawer should be at least 150 mm off the floor and constructed so that water cannot splash through the ventilating louvers onto the records.

When fire-protected storage is required, the film should be kept in either fire-resistant vaults or insulated record containers (Class 150). Fire-resistant vaults should be constructed in accordance with NFPA *Standard* 232. Although the NFPA advises against air conditioning in valuable-paper record rooms because of the possible fire hazard from outside, properly controlled air conditioning is essential for long-term preservation of archival films. The fire hazard introduced by the openings in the room for air-conditioning ducts may be reduced by fire and smoke dampers activated by smoke detectors in the supply and return ducts.

Storage of Cellulose Nitrate Base Film

Although photographic film has not been manufactured on cellulose nitrate (nitrocellulose) film base for several decades, many archives, libraries, and museums still have valuable records on this material. Preserving the cellulose nitrate film will be of considerable importance until the records have been printed on safety base.

Cellulose nitrate film base is chemically unstable and highly flammable. It decomposes slowly but continuously even under normal room conditions. The decomposition produces small amounts of nitric oxide, nitrogen dioxide, and other gases. Unless the nitrogen dioxide can escape readily, it reacts with the film base, accelerating the decomposition (Carrol and Calhoun 1955). The rate of decomposition is further accelerated by moisture and is approximately doubled with every 6 K increase in temperature.

All nitrate film must be stored in an approved vented cabinet or vault. Nitrate films should never be stored in the same vault with safety base films because any decomposition of the nitrate film will cause decomposition of the safety film. Cans in which nitrate film is stored should never be sealed, because this traps the nitrogen dioxide gas. Standards for storing nitrate film have been established (NFPA *Standard* 40). The National Archives and the National Institute of Standards and Technology have also investigated the effect of a number of factors on fires in nitrate film vaults (Ryan et al. 1956).

The storage temperature should be kept as low as economically possible. The film should be kept at less than 50% rh. Temperature and humidity recommendations for the cold storage of color film in the following section also apply to nitrate film.

Storage of Color Film and Prints

All dyes fade in time. ANSI *Standard* IT9.11 does not define an LE for color films or black-and-white images on paper. However, many valuable color films and prints exist, and it is important to preserve them for as long as possible.

Light, heat, moisture, and atmospheric pollution contribute to fading of color photographic images. Storage temperature should be as low as possible to preserve dyes. For maximum permanence of images, materials should be stored in light-tight sealed containers or in moisture-proof wrapping materials at a temperature below freezing and at a relative humidity of 20 to 50%. The containers should be warmed to room temperature before opening to avoid moisture condensation on the surface. Photographic films can be brought to the recommended humidity by passing them through a conditioning cabinet with circulating air at about 20% rh for about 15 min.

An alternative is the use of a storage room or cabinet controlled at a steady (noncycled) low temperature and maintained at the recommended relative humidity. This eliminates the necessity of sealed containers, but involves an expensive installation. The dye-fading rate decreases rapidly with decreasing storage temperature.

Storage of Black-and-White Prints

The recommended storage conditions for processed black-and-white paper prints should be obtained from the manufacturer. The optimum limits for relative humidity of the ambient air are 30 to 50%, but daily cycling between these limits should be avoided.

A variation in temperature can drive relative humidity beyond the acceptable range. A temperature between 15 and 25°C is acceptable, but daily variations of more than 4 K should be avoided. Prolonged exposure to temperatures above 30°C should also be avoided. The degradative processes in black-and-white prints can be slowed considerably by low storage temperature. Exposure to airborne particles and oxidizing or reducing atmospheres should also be avoided, as mentioned for films.

Storage of Digital Images

A hard drive should only be used for temporary storage, because if that drive fails, the images could be lost forever. Digital files should be backed up on alternative media (e.g., CD-ROMs) for short-term storage. Because of rapid technological development, storage media systems in 10 to 20 years may not be compatible with current CD-ROMs. In addition, CDs are somewhat fragile and susceptible to damage and data loss if not handled properly. Digital images can be stored as photographic prints; these can last for generations when stored properly as described in the preceding sections.

CONSTRUCTION 24.42
COMMISSIONING 24.42
TRAINING AND DOCUMENTATION 24.42
OPTIMIZATION 24.43

THIS chapter presents best practices and advice on planning, designing, and implementing environmental strategies for long-term preservation of cultural heritage that also support access in an economically and environmentally responsible way. It aims to support a holistic approach, taking into consideration the types of collections, buildings, and environmental control systems that can sustain appropriate conditions for specific collections with their own climate histories. It acknowledges that any strategy will have to be an integral part of heritage preservation as a whole. The chapter is applicable to museums, galleries, nonresidential historic buildings, reference libraries, and archives, as well as to both new and existing structures. It is not designed for buildings with public access that only hold collections not intended for preservation, such as school libraries.

This chapter is primarily directed at HVAC engineers and facility managers involved with indoor climate control projects in cultural heritage institutions, including new construction and extensions, renovations and upgrades of existing systems, and the adjustment of climate control strategies towards sustainability. Because this chapter has been widely used by allied professionals in a much broader context, it informs all stakeholders involved in the decision-making process on designing and implementing environmental strategies for cultural heritage collections. These include, but are not limited to, engineers, architects, collection owners, cultural heritage administrators, collection managers, conservators, conservation scientists, curators and registrars.

The information in this chapter focuses on mechanical and, to a limited extent, nonmechanical approaches to the control of temperature, relative humidity, and indoor air quality. Tables and graphs are used to provide clear and easy access to specific information, but the underlying text is necessary to understand the full context.

1. TERMINOLOGY

The terminology used in this chapter derives from the professional conservation field and, except where noted, is taken from the website of the American Institute for Conservation of Historic and Artistic Works (AIC 2018).

Cultural property includes objects, collections, specimens, structures, or sites that have artistic, historic, scientific, religious, or social significance.

Tangible heritage includes buildings, historic places, and monuments, as well as objects and collections significant to the archaeology, architecture, science, or technology of a specific culture.

Intangible heritage, according to the United Nations Educational, Scientific and Cultural Organization (UNESCO), includes traditions or living expressions inherited and passed on within a culture, such as oral traditions, performing arts, social practices, rituals, festive events, knowledge, and practices concerning nature and the universe or the knowledge and skills to produce traditional crafts (UNESCO 2017a).

Digital heritage includes valued knowledge or expressions that have been created digitally, or converted into digital form from existing analogue resources (UNESCO 2017b).

Preservation is protection of cultural property through activities that minimize chemical and physical deterioration and damage and that prevent loss of informational content. The primary goal of preservation is to prolong the existence of cultural property.

Conservation is the profession devoted to preservation of cultural property for the future. Conservation activities include examination, documentation, treatment, and preventive care, supported by research and education.

Preventive care (also called **preventive conservation**) is mitigation of deterioration and damage to cultural property through the formulation and implementation of policies and procedures for the following: appropriate environmental conditions; handling and maintenance procedures for storage, exhibition, packing, transport, and use; integrated pest management; emergency preparedness and response; and reformatting/duplication.

2. KEY CONSIDERATIONS

2.1 HERITAGE

"Heritage is our legacy from the past, what we live with today, and what we pass on to future generations. Our cultural and natural heritage are both irreplaceable sources of life and inspiration" (UNESCO 2018).

Cultural heritage (tangible, intangible, and digital) is considered essential to the understanding and appreciation of humanity's diverse cultures and history. The importance of cultural heritage may be national, regional, or local, and it may have symbolic, aesthetic, cultural, social, historical, scientific, and monetary values that are frequently impossible to estimate. Thus, access to and preservation of cultural heritage is important and may even be legally mandated.

This chapter addresses preservation of tangible heritage: physical objects such as books and documents, works of art, historic tools and utilities, archaeological artifacts, specimens of natural history, examples of popular culture, products of various technologies, and historic buildings.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

2.2 CONTEXT

Objects are often held by various collecting institutions such as museums, galleries, historic buildings, libraries, and archives. These collections have different uses, depending on the institution's mission, and require specific management policies: in museums, the majority of a collection may be kept in storage with limited access, with a smaller portion on temporary or semipermanent display, often in showcases; in archives and libraries, almost all of the collections are in storage, from which they are pulled for research or exhibition; historic houses have most of their collections on permanent open display. Individual objects from collections may be on short- or long-term loan to another organization.

Collections may be housed in purpose-built buildings or existing buildings of historic significance; sometimes, the building may be as (or more) important than the collection it houses. Most collections have been housed in existing buildings with climate control ranging from nonmechanical strategies (e.g., thermal insulation, window shutters) to mechanical systems (e.g., localized dehumidifiers, full HVAC). As a result, collections have a specific climate history that should be taken into consideration when reviewing environmental strategies.

2.3 INTERNATIONAL STANDARDS

To facilitate loans, cultural heritage organizations often look to follow international guidelines on environmental control. It is therefore important to be aware of the shift in thinking about sustainable collection management that is having a major impact on standards and guidelines. The U.K. National Museum Directors' Conference (NMDC 2008) focused on a long-term, broad plan for minimizing excessive energy use in the care of collections, reducing museums' overall carbon footprint. In turn, the International Group of Organizers of Large-Scale Exhibitions (Bizot Group 2015) proposed a broader set of interim temperature and relative humidity guidelines for hygroscopic materials on loan, based on the NMDC proposal; their goal was to simplify international loans, reduce costs, and decrease the carbon footprint. This prompted the Association of Art Museum Directors (AAMD) to request input from the conservation community.

As a response, the international professional organizations International Institute for Conservation of Historic and Artistic Works (IIC) and International Council of Museums—Committee for Conservation (ICOM-CC) published a declaration on environmental guidelines (IIC/ICOM-CC 2014). It states

- "The issue of museum sustainability is much broader than the discussion on environmental standards, and needs to be a key underlying criterion of future principles.
- "Museums and collecting institutions should seek to reduce their carbon footprint and environmental impact to mitigate climate change, by reducing their energy use and examining alternative renewable energy sources.
- "Care of collections should be achieved in a way that does not assume air conditioning (HVAC). Passive methods, simple technology that is easy to maintain, air circulation and lower energy solutions should be considered.
- "Risk management should be embedded in museum management processes."

2.4 PRESERVATION AND RISK MANAGEMENT

Preservation of cultural heritage involves mitigating the impact of agents of deterioration (CCI 2018). It requires a trade-off among many factors and there is no single golden rule. Instead, risk management approaches are used to arrive at an appropriate solution (see the section on Overview of Risks). For example, creating an environment for preserving the collection that causes problems for the building in which it is housed is not acceptable.

It is possible to substantially slow deterioration caused by environmental agents of deterioration, thus fulfilling a major function of the collecting institution. However, doing so may conflict with another important function of cultural institutions: allowing public and scholarly access. Additionally, extremely tight control over all environmental parameters comes at a price few cultural institutions can justify or afford. Managing risk, not avoiding it altogether, is the objective.

Climate-induced risks should be seen in context and relation to other risks to the preservation of cultural heritage, such as natural and human-caused disasters. Frequently, it is not the greatest risk to a collection, and available funds may be spent more effectively elsewhere. Therefore, it is fundamental that an institution develops an overall preservation strategy, of which its climate control is an integral part, based on a comprehensive risk assessment. A climate-control strategy should complement mitigation plans for other risks and should not in itself create a greater hazard. Consequently, greater risk reduction can come from ensuring the reliability of the system, rather than controlling minor excursions from defined climatic ranges. Most threats to collection preservation, in fact, can be addressed by properly maintained housing and professional support.

2.5 SUSTAINABILITY

This chapter advocates environmental strategies and solutions for cultural heritage collections that support their access and preservation in a responsible way (i.e., that are sustainable economically, socially, and environmentally). It aims to inform strategies that sustain feasible climatic conditions for the foreseeable future and takes into consideration

- An organization's mission and resources
- The needs of the collection and its users
- Building type
- Local, regional, national, or international policies
- Suitable environmental systems

To design and implement appropriate climate control for a specific collection, it is important to involve all appropriate stakeholders, which can vary by institution but may include engineers, architects, facility managers, security staff, cultural heritage administrators, archivists, collection managers, conservators, conservation scientists, curators, and registrars. Administrators are responsible for fiscal and political decisions, whereas collection managers and conservators are responsible for providing access and care of the collection. Curators build the collection and design exhibitions. Registrars oversee the legal paperwork and administration related to collection management. Security staff is critical to safekeeping of the collection.

Therefore, a multidisciplinary approach is required to obtain a comprehensive overview of all aspects that impact an environmental management strategy, and some of this work should be carried out before an engineer is engaged in a project.

Cultural institutions frequently operate as nonprofit organizations on tight budgets with limited human and/or technical resources. Insisting on best-available technology for extraordinary humidity control or comprehensive pollutant filtration may endanger long-term fulfillment of the institutional mission.

From project inception, both the design objective and realistically available operation and maintenance resources must be considered. Having reliable monitoring data is crucial in the decision-making process. Before embarking on full mechanical control solutions, efforts should be made to use or integrate strategies that do not rely on mechanical control, including passive building solutions and non-

Fig. 1 Decision Diagram for Environmental Management Strategies in Museums, Galleries, Archives, and Libraries
(based on Taylor, forthcoming)

mechanical adjustments, which can successfully provide appropriate environmental control for the collection.

In accordance with the international call for reducing energy use and examining alternative renewable energy sources, solutions that can complement the local external climate should be explored first. These include building envelope improvements; integrated strategies that address preservation, access, and human comfort needs; hybrid systems (alternative energy sources); seasonal and diurnal adjustments; and enclosures providing microenvironments for individual or multiple objects.

3. CONTEXT AND PREDESIGN

Before an appropriate environmental management strategy can be developed, many contextual factors need to be considered. Cultural institutions vary not only in their geographic location and building morphology, but also in their purpose, mission, and the materials, condition, and needs of their collections. The values placed on different collections, their uses, and their expected lifetimes all influence an environmental management strategy.

This section addresses the process of developing sustainable environmental management strategies for different types of projects, from installing new or upgraded mechanical systems in new purpose-built or renovated structures, to more energy-efficient climate control strategies in existing situations. Although there are significant differences between new purpose-built museums and historic houses, the decision points are similar.

A schematic decision-making flowchart can be used to define the necessary, broad steps from strategic plan to evaluation (Figure 1). It is intended for both new and existing buildings with a range of environmental solutions. The diagram also accounts for situations where there may be no collection preservation problems or the environment is deemed appropriate, but there is a desire to reduce energy consumption. The components/steps in the diagram are described in the following text. Although the later steps outlined in Figure 1 are not within the scope of predesign, these sections describe considerations that can be addressed during the predesign phase.

Different projects require different amounts of time and resources for individual steps. For many cultural institutions, particularly those that have been operating for some time, relevant information such as collection surveys or significance assessments may already exist, reducing the time required for predesign. In all instances, however, decision making is a multidisciplinary activity involving a variety of stakeholders, whose role and level of involvement can change throughout the project. The list on the right-hand side of Figure 1 shows the expected level of participation for stakeholders at each step: if they are making decisions, if they should be consulted or be informed. If there is doubt, it is usually advisable to engage the stakeholders earlier in the process.

Table 1 Examples of Space Types in Museums, Galleries, Archives, and Libraries

	Collection	Noncollection
Public space	Changing exhibition galleries Permanent collection galleries Reserve/scholar collections Open storage Most reading/collection study rooms	Entrances/vestibules Atria Cafeteria Restaurants Shops Auditoria Education spaces Restrooms Coat/baggage rooms
Nonpublic space	Conservation laboratories Collection storage Workshops and mount-making areas Archive stacks Library stacks Quarantine areas Photography studios Digitization areas	Offices Crate storage (controlled relative humidity may be required) Mechanical/electrical rooms Data centers/IT rooms Food preparation areas Loading bays
Low-occupancy space*	Cool and cold storage Low oxygen storage Low-relative-humidity rooms Off-site storage (e.g., high-density library stacks)	General storage areas (sales shop inventory, event equipment, etc.)

*Occupancy in these spaces is for short periods, and meeting human comfort standards may not be required.

Notes:

(1) Collection spaces and adjacent noncollection spaces often require substantially different types of control. Providing barriers (e.g., doors, air curtains) to limit airflow and moisture vapor exchange between these spaces is usually necessary for successful control.

(2) As exhibition needs change and collections grow, it is common for noncollection areas to be repurposed for collection exhibition. It is important to keep this in mind when planning HVAC systems. A café or atrium may not require relative humidity control or special filtration, but if the space is repurposed to exhibit objects that require specialized environments (relative humidity control, etc.), retrofitting a system to provide the appropriate environment can be costly and disruptive.

(3) Objects may be displayed in noncollection spaces through careful object selection (e.g., statues in vestibules) or use of display cases with the necessary microclimate performance. Offices that display collection items, such as paintings, should apply the same preservation requirements as collection spaces. Classrooms or other education spaces may be used to house some collection objects for extended periods; if so, collection-appropriate environmental control may be required.

A design engineer may not be involved in the early stages of this process. All these steps, however, influence the choice and delivery of the environmental management strategy and include important information for considering appropriate goals and solutions. A new building may involve developing a strategic plan and mission before a building project is started, whereas an operating museum may engage an engineer to provide a solution to an identified problem or undesirable situation.

3.1 MISSION AND STRATEGY

The purpose of any cultural institution is central to all decisions, even if its influence is implicit. Almost all cultural institutions have a mission statement, even those where the building is yet to be constructed. An operating museum often has statements of significance for collections, which describe the reasons for their importance. The mission of the institution and how its heritage assets are valued determines how the assets should be preserved and what is understood as a risk. The values of a collection directly inform the impact of a hazard, and even how different kinds of damage are regarded. An archive values the informational assets of its collection, often allowing access to individual items by researchers, increasing the risks of damage caused by handling. A fine arts museum may value aesthetic appearances that are affected by minor damage. A library and a contemporary art museum will have different expectations of the lifetimes of their objects and how their values are embodied by the material. This concept is also addressed in the section on Context, under Key Considerations.

3.2 DETERMINE NEEDS

Although the collections are usually the principal focus for managing the environment in a cultural institution, the needs of occupants and of the building itself must be balanced (along with capital and operating costs). Historic buildings can often be more significant than the collections that they contain. The respective importance of these needs varies among institutions and even among spaces, and their requirements can conflict.

The differing needs of spaces in cultural institutions can be broken down into broad categories of use by considering whether they contain collections, people, or both. This also helps identify spaces that can often be more flexible in terms of control, because there are many areas in cultural institutions that do not house collections, are not open to the public, and have occupancy for short and limited periods. Table 1 shows the kinds of spaces found in cultural institutions and what their use could imply through a matrix of occupancy levels for collections (columns) and people (rows). Spaces that house both often require the most consideration. Given that needs often differ between people and collections, the matrix presents opportunities to emphasize certain needs. Although specifics may vary over time (e.g., long-term uses, short-term management of spaces that are unoccupied at night), Table 1 provides some guidance of where resources are best applied. The specific collection needs must further be addressed in context.

Collection needs vary considerably with the kinds of materials, combinations of materials in a single object, and how the objects were made. Even library collections comprise a mix of materials to consider. Information about different materials can require specialist knowledge from conservation or science experts, some of whom may be external to the institution.

Relevant information to determine collection needs includes

- Materials
- Construction/assembly
- Condition and vulnerability (see Tables 2 and 13)
- Current and intended uses of the collection

- Frequency and kinds of access
- Specific climate history (and movement of objects over time)

Relevant information to determine building needs includes

- Materials and construction
- Condition and vulnerability
- Current and intended uses of the building
- History and changes to the building

Relevant information to determine human needs includes

- Numbers of staff and visitors and their current and/or intended activities
- Current and intended uses of spaces
- Expected kinds of clothing (which can vary in historic properties)

For a new institution, data gathering may involve plans and blueprints, and collection policies, rather than assessments of specific collections, but information that can help determine needs can be found in a range of sources. In operating cultural institutions, a collection risk assessment and/or condition survey may have been carried out for the collection, which would include most of this information. Collection needs are described more comprehensively in the sections on Overview of Risks and Environmental Effects on Collections.

3.3 CURRENT ENVIRONMENT

Analyzing and understanding the past and current environmental conditions in and surrounding the buildings, and the interactions among climates, buildings, people, and collections, is essential to developing appropriate environmental management, even if no intervention is carried out in the cultural heritage institution. Information relevant to understanding the influence of the environment on the building, collection, and people includes climate zone and predicted climate change, site macrocontext and morphology, the building and its orientation, existing methods of environmental control, and monitoring data on each hazard (temperature, relative humidity, pollutants, and light) both indoors and outdoors. This often requires a year of data collection, particularly for seasonally affected parameters such as temperature and relative humidity. These data are collected regularly in cultural institutions, but the points of measurement, sampling interval, and reasons for monitoring should be reviewed. A building management system (BMS) may provide useful information about existing environmental management, particularly with respect to human comfort, but in general, climate monitoring should be independent from the system that is used to control climate, and it may be necessary for data to be gathered close to objects.

Other contextual factors to consider include staff, their roles, institutional policies, operating costs, and energy use, as well as an institution's budget. Each institution should seek to understand its pattern of energy consumption and recognize the most energy-intensive activities, which usually include lighting; appliance use; and mechanical ventilation, heating, and cooling. The sampling interval for monitoring energy use should be short enough (typically 1 h or less) to evaluate daily energy consumption patterns. Energy consumption should be evaluated according to existing national or international regulations, and compared with existing benchmarking systems or, if no benchmarks are available, with energy consumption in similar cultural institutions. For further discussion on environmental context, see the section on Climate Loads.

3.4 OVERVIEW OF RISKS

The impact of the environment on materials can only be understood when both the environmental conditions and material properties are known. By connecting preservation needs to materials' responses to environmental conditions, expected changes can be understood. Considering information about the institution's values and assets along with material change clarifies decisions about future risk and priorities. Synthesizing the impact requires an overview of which factors are most important and how the collections are affected by the building and people, and vice versa; mitigating risk to one aspect may increase risk to another. Integrating the information allows a comprehensive definition of the situation, because criteria vary between institutions: for example, historic houses may place more emphasis on preserving the building than a new museum might.

Understanding this impact allows comparison to other general risks (see Table 2). Developing this overview allows an institution to prioritize needs, allocate resources, and develop goals for the development of a strategy. Much of this information may already exist in the form of a risk assessment. For further discussion of collection risks, see the section on Overview of Risks.

3.5 ACCEPT OR MODIFY ENVIRONMENT

Once information has been gathered and synthesized, modifications to the environment may be considered. If the current environment is appropriate for the institution's identified needs, goals, and resources, the most appropriate decision can be to do nothing at the present time and continue monitoring. Other priorities in the institution may take precedence.

For an operating institution, changes to existing building management and/or modifications to the building envelope may be appropriate ways to address the identified risks or high energy consumption. Problems can be addressed without directly modifying the environment, by adjusting locations and activities such as changes in circulation patterns, use of selected spaces, and exhibition policies. Dividing collections by material type is a common measure, particularly in storage locations. When planning a new building, managing the risks most relevant to the institution's mission should be addressed early, with careful consideration of building morphology, envelope characteristics, and expected energy use, as recommended by the International Institute for Conservation of Historic and Artistic Works and the International Council of Museums Committee for Conservation (IIC/ICOM-CC 2014).

Environmental modification may involve direct intervention, either mechanical or nonmechanical; passive design measures are also available. There is no risk-free scenario, and any decision must take into account available resources and the impact on the institution as a whole, as well as overall environmental impact. Even after the initial diagnosis of risks, it is likely that this consideration may require further investment and expertise before a final plan can be developed.

Regardless of how big or small the expected changes to the environment or management, monitoring should be carried out to further investigate problems or check for simple solutions.

For related information, see the section on Preservation and Risk Management.

3.6 ANALYZE/PREDICT ACHIEVABLE ENVIRONMENTS AND IMPEDIMENTS

If it is decided that a comprehensive solution is required, further analysis (e.g., diagnostic monitoring, hygrothermal modelling of indoor spaces, deeper investigation of existing control methods) will be necessary. Assessing information already gathered indicates what environments can realistically be achieved in a given climate zone with existing control methods, or the expected impact of proposed changes in the building envelope or type of environmental control.

Comparing what environment can be achieved in the current or planned space with what is identified as necessary for collection preservation indicates the kind and level of intervention that is appropriate. This could include energy-saving options where a collection's sensitivity is lower than the tightest level of control that can be managed (see Tables 13A and 13B), or a new approach to environmental management in the institution. For new buildings, this step presents an opportunity to consider appropriate parameters and objectives for different needs in the proposed spaces based on their (potentially mixed) use.

The sections on Environmental Effects on Collections and on Design Parameters for Performance Target Specifications contain further discussion of environment and impediments.

3.7 SET PARAMETERS AND OBJECTIVES

Understanding what is required to sustain the collection over time, and to ensure access to and use of the collection, is essential. Knowing the resources necessary to accomplish this, as well as what is achievable with the building envelope, the environmental parameters can be agreed upon. The expected lifetime of a collection, or its desired rate of deterioration, can be reviewed at this point, which may require input from a conservation scientist. Many collections comprise a mix of materials with differing preservation qualities. If a collection largely comprises a limited range of materials, or if materials can be easily separated from one another, specific information about the responses of those materials to environmental conditions can be directly applied. If the collection has been in the same environment for a long time (usually longer than 10 years), it will have had time to acclimatize to those conditions. Tables 13A and 13B provide information on the expected implications (outcomes) of different kinds of climatic control for mixed collections.

These parameters also must take into account human comfort (see ASHRAE *Standard* 55-2017) and cost implications.

The sections on Environmental Effects on Collections and on Design Parameters for Performance Target Specifications contain further discussion of parameters and objectives.

3.8 DEVELOP OPTIONS

How the environment is managed (according to agreed-upon parameters and objectives) has multiple implications, not just for the collection and costs (financial and energy consumption), but also on facility operations. Even in small interventions, staff should have access to the information because simple measures can affect other activities, such as security or audience engagement events. A clear understanding of the resources available, including budget, staff roles, time, training, and space, is needed for control options to be developed and evaluated.

For a new building, the solution may be part of a larger, integrated approach. HVAC design options should first consider the building as a means of control (see Tables 12, 13A, and 13B).

For more details, see the section on Design Parameters for Performance Target Specifications, and ASHRAE *Guideline* 34-2018.

3.9 REVIEW OPTIONS AND SELECT

Many criteria may be involved in selecting the most appropriate approaches to environmental management. A method to determine consensus should be decided upon, and the key stakeholders for the project identified. All staff affected by environmental management should be consulted (or represented) in terms of how the options meet the chosen criteria. This is often best carried out through facilitated, recorded meetings where criteria are addressed systematically and transparently (Cassar 1995). Such processes present the opportunity to examine different perspectives and resolve apparent conflict through discussion. Results should be archived for future reference.

Criteria for evaluating approaches to environmental management may well go beyond collection preservation and cost, to include issues such as impact on historic building fabric and human comfort. For example, historic houses can be adversely affected by installation of mechanical systems. A cultural institution's mission statement can be a useful reference point to weigh the importance of criteria. This stage distills much of the information gathered earlier in a clear, digestible form for all stakeholders, so informed decisions can be reached collaboratively.

3.10 PREDESIGN PROGRAM BRIEF

This is an opportunity for owner's requirements to be defined before the solution is designed, including approach, scope, design team, and timeline. In some cases, a design engineer might not be engaged until after creation of the program brief.

While setting criteria for the design team, solutions outside the scope of the design team (e.g., housing objects in display cases or archival boxes) should be part of the overall project effort. This again allows project goals to be aligned with the institution's wider mission and other goals. A range of stakeholders already engaged in the process will be involved in planning and construction, so a clear shared vision helps the cultural institution work through the development.

3.11 DESIGN OF SOLUTION

Although design of the solution is discussed more comprehensively later in the chapter, some considerations can be addressed during predesign. All needs identified while developing the predesign program brief should be communicated, and a liaison with collection and building staff should be identified. The solution may not yet be designed, but if the general approach is known, decisions can be made about whether to move collections before work begins. Rehousing a collection requires considerable time, including measures for documentation (e.g., database, photography, radio-frequency identification [RFID]) and security, as well as environmental management. If the collections are not being moved, preparation for extra protection may be needed during an implementation phase. Depending on the approach, projected growth of the collection may also be a consideration during predesign.

3.12 PROCUREMENT AND CONSTRUCTION

Procurement and construction are discussed in more detail later in the chapter, but there are opportunities to prepare for this stage. A risk assessment may be required for the designed solution (especially if the collection is moving). Information from the context and predesign phases about the values of the collection and building is relevant and should be accessible. For larger projects, a dedicated collections professional responsible for oversight of collections preservation issues during construction may be engaged.

Cultural institutions often have historic buildings that are intended to last for a long time. The life cycle of materials, and any impact of the solution on historic values, should be understood by all parties.

3.13 START-UP AND COMMISSIONING

Commissioning and start-up are discussed later in the chapter. A commissioning agent should be identified and engaged during final predesign and early design stages, so they understand the underlying design goals and can be present through the process.

3.14 TRAINING AND DOCUMENTATION

Training and documentation are discussed later in the chapter, but the data gathering that has already occurred should be instructive to this process. Understanding and documenting current management and maintenance practices can help communicate in-house skills and expertise to the design team. Time during a project may need to be put aside for training, and a realistic understanding of institutional and staff capacity is required before implementing a design option. Staff changes over the time horizon of larger projects may also need to be considered.

Table 2 Agents of Deterioration: Potential Hazards in Managing Collection Environments

Agent	Comments
Physical forces	Handling, shock, and vibration can cause immediate or accumulative long-term damage to fragile objects. Risks often increase during construction work, when collections may have to be relocated or secured in situ. Mechanical systems may present a risk if vibration is transmitted through ductwork to works hung on adjacent walls or in particularly active air drafts. Vibration transmitted to objects may cause them to move, and to fall off of exhibit and/or storage shelves.
Thieves and vandals	Can be addressed by limiting access to mechanical systems to improve security.
Fire*	Fire (and its related methods of extinction) can result in serious damage or even total loss of building(s), collections, operations, and services. Fire prevention and control, aimed at reducing the risk of a fire occurring and minimizing its effects, should be given the highest priority possible. It is recommended that each HVAC system be integrated with a fire detection system, ensuring that the system is shut down in a fire alarm to limit the spread of fire, smoke, and soot.
Water*	Liquid water (including rain, flood water, or water from broken pipes) is often related to incidents and disasters, but also includes dampness resulting from condensation and rising damp in buildings. Liquid water is very destructive to collections: it can stain, deform, or even dissolve materials. Wet conditions can quickly germinate mold, fungi, and bacteria, creating hazardous conditions for human health.
Pests	Infestations primarily include insects devouring collections; mold, fungi, and bacteria also qualify as pests. Limitation measures include avoiding high relative humidity and warm conditions, maintaining overall cleanliness, and controlling indoor air quality and ventilation (which helps reduce temperature gradients and thus relative humidity).
Pollutants (or contaminants)	Includes outdoor-generated gaseous and particulate contaminants that infiltrate the building and indoor-generated gaseous pollutants. Sources and effects of pollutants are detailed in the section on Airborne Pollutants/Contaminants. Particulate filtration to control both coarse and fine particles and gaseous filtration is discussed in the section on Airborne Pollutant Control Strategies.
Light (or radiation)	Most materials undergo some form of permanent photochemical or photophysical change from exposure to radiation (i.e., visible, infrared [IR], and ultraviolet [UV] light), which is an inevitable consequence of display. Light damage is cumulative but relatively easy to control if addressed at architectural, design, and operational levels by eliminating ultraviolet radiation, minimizing infrared radiation, and limiting light exposure by decreasing illumination intensity or its duration.
Temperature	When temperature increases, damaging chemical processes accelerate. Any temperature change affects the absolute humidity in the air, resulting in changes in relative humidity. Relative humidity and temperature are often considered together when deciding on a climate control strategy, especially for susceptible classes of materials such as early synthetics (plastics), paper, and photography.* See the section on Temperature and Humidity for details.
Relative humidity	Each organic/hygroscopic material has a specific level of moisture content consistent with maximum chemical, physical, or biological stability. Relative humidity becomes a risk factor when it causes the moisture content in a material to be significantly too low or too high. Fluctuating relative humidity with large and prolonged variation in levels can also be damaging, specifically to objects of composite materials and/or restrained constructions. Inorganic (nonhygroscopic) materials can also be adversely affected by moisture in the air (e.g., corrosion of metals, salt efflorescence in porous materials). See the section on Temperature and Humidity for details.

*Fire and water are often associated with building and mechanical (design) malfunctions, such as power outages, electrical short circuits or water pipe failure (especially over spaces containing collections). These failures are infrequent but do happen, and it is important to remember that a single failure could ruin a significant portion of a collection. Every effort should be made to route water lines and other utilities away from areas that house collections. Building systems also rely on the infrastructure to provide utilities and communications. Where the infrastructure is not reliable or is of inadequate capacity, provisions should be made for temporary or alternative supply.

3.15 EVALUATE AND REVISE

This step is addressed later in the chapter, but data gathered at any early stage can help serve as a baseline for evaluating the solution, and should be documented and archived for future reference. This includes data on climate and pollution as well as energy costs. How environmental monitoring is carried out during predesign should inform continued monitoring beyond implementation of the solution.

4. OVERVIEW OF RISKS

A collection's longevity is directly influenced by the building's architecture, any climate control systems (nonmechanical or mechanical), and existing preservation procedures and protocols. These may positively mitigate the impact of risks or, alternatively, exacerbate them. Mechanical engineers need to consider the risks for collections even if they do not appear to relate directly to a building's mechanical systems. The hazards listed in Table 2 are called **agents of deterioration** in the conservation field and may affect collections. Note that there can be interactions between different agents of deterioration, and many hazards are created by several agents in conjunction with one another (CCI 2018). Assessments are often used to identify the potential impact or magnitude of a risk occurring.

Any climate control strategy should complement mitigation strategies for other risks and should not in itself create a greater hazard (e.g., when an energy supply fails, or when an active HVAC system spreads fire or soot if no automatic HVAC shutdown is provided).

Table 2 does not cover natural emergencies, which are often devastating and have effects beyond the institution. Institutions (should) have emergency response policies in place to deal with incidents, emergencies and disasters.

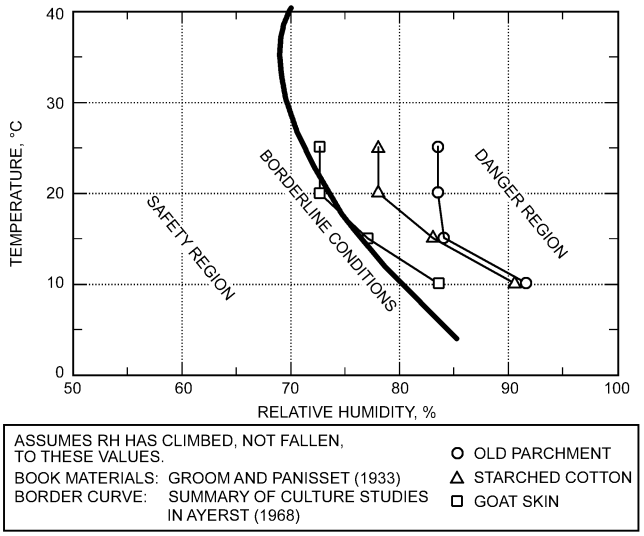

Fig. 2 Temperature and Humidity for Visible Mold in 100 to 200 days

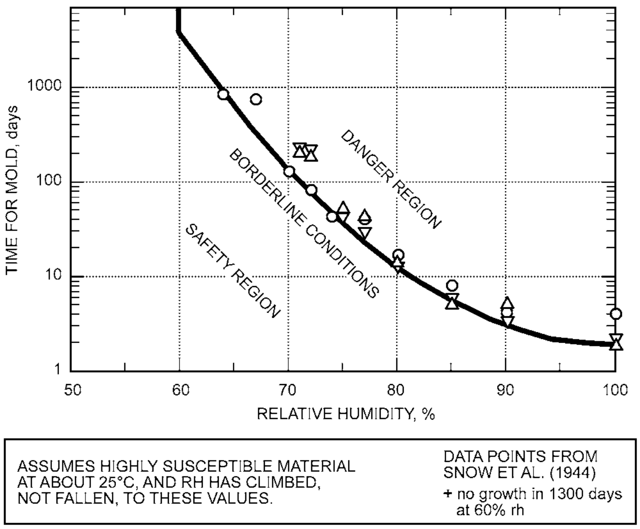

Fig. 3 Time Required for Visible Mold Growth

5. ENVIRONMENTAL EFFECTS ON COLLECTIONS

Providing specialized temperature and relative humidity control has been central to museum, gallery, archive, and library design since the nineteenth century, and numerous architectural and HVAC solutions have been explored. Luciani (2013) provides a detailed history of these engineering and architectural solutions throughout the twentieth century in North America and Europe. Until recently, temperature and relative humidity specifications were based on cautiously applied qualitative understanding (Michalski 2016), rather than quantitative understanding applied to decisions influenced by sustainability. This section summarizes the technical knowledge available to support current decisions, particularly when selecting or modifying targets.

5.1 BIOLOGICAL DAMAGE

High relative humidity levels and dampness accelerate mold growth on most surfaces. Of all HVAC-controllable environmental parameters, high humidity is the most important factor.

The most comprehensive mold data are from the feed and food literature. Fortunately, this provides a conservative outer limit to dangerous conditions. Mold on museum objects occurs first on surfaces contaminated with dust, sugars, starch, oils, etc., but can also occur on objects made of grass, skin, bone, and other feed- or food-like materials. Water activity is identical to and always measured as the equilibrium relative humidity of air adjacent to the material. This provides a better measure than the equilibrium moisture content (emc) for mold germination and growth on a wide variety of materials (Beuchat 1987). Figure 2 shows the combined role of temperature and relative humidity. A study by Groom and Panisset (1933) of the most vulnerable book materials concurs with the general trend of culture studies from Ayerst (1968) and comprehensive data on mold growth in buildings obtained by Sedlbauer (2001). Ohtsuki (1990) reported microscopic mold occurring on clean metal surfaces at 60% rh. The fungal DNA helix is known to collapse near 55% rh (Beuchat 1987), so a conservative limit for no mold ever, on anything, at any temperature, is below 60% rh. Chapter 26 suggests a similar lower boundary to avoid mold in food crops.

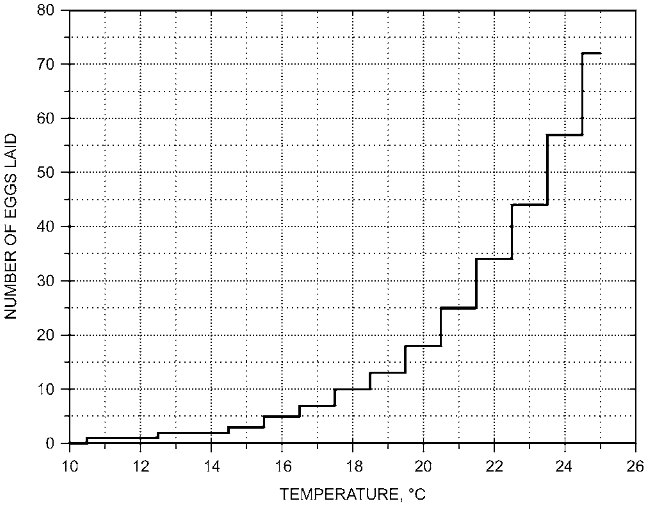

Fig. 4 Number of Eggs Laid by Webbing Cloth Moth (*Tieneola bisselliella*) as Function of Temperature

Snow et al. (1944) looked for visible mold growth on materials inoculated with a mixture of mold species. These are plotted in Figure 3, and follow the same trend reported by Hens (1993) for the European building industry for wall mold.

Figures 2 and 3 show practical dangers: growth in less than a summer season requires over 70% rh, and growth in less than a week requires over 85% rh. Care must be taken to avoid cold surfaces where condensation might occur, such as on windows and ductwork.

There are relatively few experimental data on the relationship between the risk of insect infestation and climate parameters (Strang 2012). Child (2007) and Pinniger (2001) suggest that, below 15°C, pests that can damage cultural heritage collections start to be sluggish and do not fly. Also, low relative humidity further limits pest risk because eggs and young larvae are sensitive to dehydration. Child (2007) reported that the furniture beetle (*Anobium punctatum*) require relative humidity levels above 60% to reproduce. A risk index quantifying the threat of pest infestation was proposed by Brimblecombe and Lankester (2013). As shown in Figure 4, the number of eggs laid by the webbing cloth moth depends on T according to the following relationship:

$$E = \int \left\{ 130 \exp \left[-\left(\frac{T^2}{30} - 30 \right) / 12 \right]^2 \right\}$$

5.2 MECHANICAL DAMAGE

Very low or fluctuating relative humidity or temperature can lead to mechanical damage of objects. The fundamental cause is the expansion and contraction of materials, combined with some form of internal or external restraint. Hygroscopic materials absorb moisture when relative humidity rises and desorb moisture when relative humidity falls, causing change in dimensions. Dimensional change caused by temperature change is more rapid, but much smaller than that caused by relative humidity in hygroscopic materials. When the dimensional change of a component in an object is restrained, the component is strained and stressed. Components can be fully restrained by another, stronger, immobile component; partially restrained when connected to a component with a different coefficient of expansion; or restrained within themselves when experiencing a gradient in moisture or temperature. Beyond a critical stress or strain point, irreversible deformation or fracture occurs.

Concerns about mechanical damage from temperature and relative humidity fluctuations have led to extremely narrow specifications, such as 21 ± 1°C and 50 ± 3% rh (LaFontaine 1979). These “best-available technology” specifications were based on the assumption that, because very large fluctuations could be seen to cause obvious damage, any size of fluctuation must bring some degree of damage. Revisions to this assumption, based on limited quantitative research, drove the first (1999) edition of this chapter. Recent research has further strengthened the need for a more flexible approach to climate control for museum collections.

The materials most sensitive to temperature and relative humidity fluctuations are all hygroscopic polymers, whether complex natural mixtures such as wood, paper, leather, or parchment, or processed products such as animal glue, oil paints, acrylic paints, or cellulose acetate. The stress or strain that causes fracture depends on the amplitude and rate of any temperature or relative humidity change. Low temperatures, fast rates of strain, and low relative humidity lead to brittle “glassy” behavior with small tolerable strains, whereas high temperatures, slow rates of strain, and high relative humidity lead to more “rubbery” behavior and large tolerable strains. The transition between these two behaviors occurs at the polymer’s **glass transition temperature**, which is a gradual change over a range that is typically10 to 20 K wide (Hagan 2017; Michalski 1991).

Some materials, such as paints, are in their flexible but tough state at room temperature. When temperature drops, these materials become increasingly brittle and fragile: artists’ acrylic and oil paints enter their glassy states in the range of 10 to 0°C (Daly Hartin et al. 2018; Hagan 2017; Mecklenburg and Tumosa 1991). In this temperature range, risk of fracture from small errors in handling greatly increases.

Other materials, such as animal glue, paper size, and photographic gelatin, are in their hard but strong state at room temperature. High relative humidity (>75% rh), however, pushes them into their rubbery state (sticky and weak) because of the plasticizing effect of moisture (Karpowicz 1989; Krzemien et al. 2016; Mecklenburg 1991; Michalski 1991). Wood can be more easily deformed over 75% rh; if constrained in a cabinetry joint, a wood component will be permanently deformed by high relative humidity. This leads to tensile fracture of the component if it is restrained during its return to a middle (or low) humidity.

Simple models of uniformly constrained material, combined with data on the mechanical properties of painting materials in particular, suggested that a fluctuation of approximately 15% rh was tolerable within the elastic limits of such materials (Erhardt and Mecklenburg 1994; Erlebacher et al. 1992; Mecklenburg and Tumosa 1991, 2005; Mecklenburg et al. 1998; Michalski 1991, 1993). More detailed research has since emerged: Jakieła et al. (2008) used numerical modelling of large pieces of wood, as used in sculptures, to show a tolerable fluctuation of 15% rh (in the 25 to 75% rh range). Tantideeravit et al. (2013) showed similar tolerance using finite element modelling for delamination in paint, as did Bratasz et al. (2015) for historic textiles. Overall, the last decade of work with more detailed material data and more complex models has confirmed that, for materials found in collections, uniformly constrained components tolerate fluctuations of at least ±10% rh, whereas fluctuations beyond 20% rh cause rapidly increasing risk of fracture.

Three large practical factors must be added to any simple model based on uniform restraint: stress relaxation, stress concentration, and proofed fluctuation.

Stress relaxation results from the shift over time from glassy to rubbery behavior. Wood will stretch more than twice as much across the grain before fracturing if the strain is applied slowly over 3 months rather than over the course of one day (Madsen 1975). Even highly pigmented oil paint (ground), which has only very gradual relaxation, experiences only half the stress of a 10 min event if that same strain is applied gradually over 3 months (Daly Hartin et al. 2018). This general tendency to relax to about half the stress when comparing cycles lasting hours to those lasting months is the justification for equating the risk from a seasonal adjustment of 10% rh to a short-term increment of 5% rh for Types A1 and A2 in Table 13A.

Stress concentration is well known to engineers, and can be described as the increase in local stress because of a flaw, groove, hole, or narrowing of the component. The fracture pattern (cracks starting at these weak points) is familiar to conservators. Stress concentration was used to help construct categories in Table 3. Objects that fit uniform restraint models are in the category of medium sensitivity (i.e., stress concentration of ~1); values around 2 indicate high sensitivity, and 3 and above are very high sensitivity. These include assemblies where a weak layer bridges a joint in strong components that either diverge or shear during relative humidity change. Low-sensitivity assemblies do not restrain any components (e.g., sheets of paper or thin wood free to expand and contract).

Proofed fluctuation is the phenomenon whereby restrained components that have already fractured because of an excessive fluctuation in the past will not fracture further until a fluctuation exceeds that historic “proofed” fluctuation (Michalski 1993, 2014). Consequently, higher-sensitivity objects in Table 3 move to lower sensitivity categories, and a collection’s sensitivity both diminishes and becomes less varied. Proofed fluctuation has become part of some standards (e.g., Ente Italiano di Normazione [UNI] *Standard* 10969) and has been refined to include **fatigue**: repetitive fluctuations must accumulate as many cycles as have already occurred before there is significant risk of new fracture (i.e., when partway along an *S-N* fatigue plot depicting stress *S* against the number of cycles *N* to failure, one must move significantly along the *N* scale to grow the fracture). Michalski (2014) created a graphic tool using *S-N* plots for estimating tolerable fluctuations, given a known history of fluctuations.

Proofed fluctuation implies that improved climate control beyond the historic pattern for a collection cannot be justified easily on the basis of mechanical risks, unless there is an active program of restoration of fractured objects, which erases proofed fluctuations. (Chemical and biological deterioration have no such limiting concept: they accumulate up to the point of total destruction.) Proofed fluctuation also clarifies the type of climate control risk that does warrant careful mitigation: the probability of extreme fluctuations beyond the proofed fluctuations (e.g., during HVAC system malfunction). The time span for judging reliability in museums is 100

Table 3 Sensitivity of Unproofed Objects to Relative Humidity Fluctuations[a]

Objects and Effects of Fluctuations	Low Sensitivity	Medium Sensitivity	High Sensitivity	Very High Sensitivity[b]
Flat sheets of paper, film, tape, leather, parchment, metal, with image or data layer. May delaminate, fracture, or distort permanently.	**Support layer with finely dispersed image/data layers.** Includes most single sheets of paper with print, halftones, line drawings, inks, washes. **Laminates with low differences in expansion.** Includes most case-bound books (not leather or parchment book covers). Most CDs. Commercial signs painted on metal.	**Layered structures with moderate strength, moderate differences in expansion.** Includes most photographs, negatives, and film. Most magnetic records. Thin, well adhered inks on parchment, such as deeds. Gouache on paper. Book bindings of vellum and/or wood. Gilded parchment, leather.	**Layered structures with poor strength, moderate to high differences in expansion.** Includes thick images on parchment. Globes. Thick oil-resin images on paper or cloth. Objects listed as medium vulnerability that have weakened substantially because of UV exposure, or aging already causing flaking.	**Large reactive (to fluctuations) sheets restrained at periphery**. Includes large paper sheets adhered to stretchers, 19th-century photos on fabric and stretchers. Large prints adhered at all four corners (usually tear near the point of restraint).
Wood or wood assemblies. May crack, split, delaminate, or distort permanently.	**Single wood components, or assemblies designed to eliminate stresses.** Includes floating panels in furniture or room paneling; tongue-and-groove planking nailed or bolted on edge only (e.g., wainscoting), wood boxes on farm machinery (unless jammed because of painting, warping), hollowed-out totem poles, wooden tool handles. **Assemblies with prior damage that allows stress release.** Includes most old tables where all screws and joints are loose, any panels already split.	**Wood assemblies with uniformly distributed stresses during fluctuations.** Includes most plain wood furniture with tight joints, no prior splits, most veneers and marquetry that cover a continuous piece below, such as most 18th- and 19th-century chests of drawers. Furniture made with plywoods, such as Victorian catalog pieces. Fluctuation to higher relative humidity may not always cause visible damage, because many joints/panels are invisibly crushed, but this makes them more likely to split during lower relative humidity. **Large wooden objects.** Outer layers are constrained uniformly by the inner core because of gradient in response to relative humidity change.	**Wood assemblies with concentration of stresses during fluctuations.** Includes veneer over corner joints, such as many wardrobe doors, Art Deco furniture. Fretwork applied wooden ornaments. Assemblies with bolts, nails, screws that hold both sides of a single plank. Many musical instruments.	**Wood assemblies with attached or inlaid metal, horn, shell, etc., that spans more than 10 mm across the wood grain.** Attachment or inlays may delaminate or buckle. Includes masks with adhered shell, 18th- and 19th-century fine furniture, clocks with inlays.
Pigmented coatings on a support: paintings, gilding, lacquer. May crack, delaminate, flake.	**Acrylic paintings on canvas.** Includes many paintings since 1960 (may move to medium sensitivity if a heavy glue size was used, or if adhesion between layers is poor).	**Rigid paint layers on canvas, in moderate to good condition.** Includes most oil paintings on canvas (may move to high sensitivity if weakened by water damage or great age). Definitely move to high sensitivity if stretched too tight, or tightened during high relative humidity. Note: fluctuation from low relative humidity is a much higher risk to paintings on fabric than from high relative humidity; however, over 85% rh may cause canvas shrinkage and flaking of the ground plus paint layers Includes oil paint, gilding on narrow spans of wood, gilt furniture, picture frames.	**Oil paint, gilding, on wide spans of wood, or paint on other organic rigid supports with weak adhesion.** Includes most panel paintings, wide gilded panels. If seams are flawed, with rigid fills, etc., then may become very high sensitivity. Miniatures on ivory, because of poor adhesion and undulations of some ivories. Heavy modern paintings on smooth side of fiber-board may delaminate because of weak adhesion.	**Paint layers bridging seams or flaws that concentrate stress**. Includes polychromes, painted furniture, painted architectural wood elements. Note that hairline cracks over joints of doors or painting frames are usually considered normal, but not those in heavily lacquered furniture.
Other organic objects.	**Woven organic materials without edge restraints.** Includes most basketry. Textiles such as blankets, flags, simple costumes.	**High crimp woven organic materials with edge restraints.** May tear during fluctuation to high relative humidity. Includes needlepoint fixed to a stretcher.	N/A	N/A
Organic materials with zero stress level at 100% rh.			Includes teeth, boats made from stretched leather on rigid construction. Crack when relative humidity drops below critical level (e.g., teeth below 50% rh).	
Other objects where ratcheting mechanism may exist.			Objects where small parts continuously dislocate and block expansion of object. Elephant tusk positioned downwards: small parts fall down gravitationally during low relative humidity period and block material expansion during rises of relative humidity.	

[a] Vulnerability assumes objects can fully respond to fluctuation. Objects in enclosures take many days or weeks to respond. See Table 8 for response time of objects.
[b] These objects are very rare: they break rules of craftsmanship and will have already failed unless relative humidity has never fluctuated since fabrication. Alternatively, these are objects that underwent overly interventive and inflexible restoration.

years. Catastrophes of mechanical damage to collections are usually caused by a system failure that causes novel conditions, compounded by a failure of rapid response (monitoring failure).

Two types of observational studies of historic objects in uncontrolled spaces are confirming these models: acoustic emission and visual evidence. Strojecki et al. (2014) applied acoustic emission to a 1785 wardrobe that was high sensitivity when new (veneer bridging many seams in structural wood components, some of which have fractured). It is on permanent display in a type D (see Table 13A) controlled museum (20 to 65% rh short term, 30 to 50% 30 day average), so it has been proofed to the building's historic climate pattern. A year of acoustic emission established that fracture because of fatigue is growing only very slowly, on the order of 13 mm/century. Given that the existing crack is at least 100 times longer, growth is decelerating. Bratasz and Vaziri Sereshk (2018) demonstrated an upper limit to craquelure growth as well, which they call "crack saturation". Ekelund et al. (2018) compared the current state of cracks in similar pieces of furniture to old photographs and established that current variations of at least ±20% rh and ±10 K did not increase visible damage. Oreszczyn et al. (1994) compared visible damage differences between collections in historic houses with "improved" climate control and those without, and saw none. Highly sensitive techniques for measuring distortions are giving similar evidence (Lasyk et al. 2012).

Overall, it is new (unproofed) or restored objects with erased proofed fluctuations that are more likely to be sensitive, not old (proofed) objects. The rare large fluctuations are the greatest risks, not the frequent and small ones. Very-long-term reliability and ease of rapid repair (before collections fully respond) are more important than trimming ripples in hourly climate data. The section on Temperature and Relative Humidity defines different levels of control of fluctuations (AA, A1, A2, B, C, and D). The most stringent level, AA control within ±5% rh, can only be justified if there are unproofed objects of very high sensitivity, if the small risk of fatigue fracture is unacceptable, and if all larger risks have been controlled. For many collections, either A1, A2, B, C, or D will provide suitable control of the remaining risks of fracture.

5.3 CHEMICAL DAMAGE

This section is not intended to replace the use of standards available for cold storage of collections, listed in Table 4. Standards consider not just the benefits of low temperature and low relative humidity, but also their side effects, their management, and critical procedures that are beyond the scope of this chapter. The ranges in Table 4 are not specific recommendations; rather, they only show the maximum range of conditions cited as various recommendations in each standard.

Both ISO *Standard* 18934 and the Image Permanence Institute (IPI; Adelstein 2009) provide definitions for four temperature terms: room, cool, cold, and either subzero (ISO) or frozen (IPI). This chapter uses *frozen* (although it unfortunately could imply that equilibrium moisture in hygroscopic materials goes through a phase transition and freezes like bulk water, which it does not.) IPI (Adelstein 2009) defines the first three terms by "anchor points" rather than ranges: 20°C, 12°C, and 4°C. These anchor points are used in Table 5.

Relative Humidity

The National Archives and Records Administration (NARA 2013) changed relative humidity control from a steady 45% rh to a permissible seasonal swing between 30% and 50% rh. They estimated a savings of $650 000 per year in utility costs as well as an increase of 20% in collection lifetime. This section enables quantitative answers to very common questions about sustainable variations on fixed standards: how much do benefits change with adjustments in temperature and relative humidity? How much does

Table 4 ISO Storage Standards for Collections that Use Cold Storage

ISO Number	Collections Covered	Range of Relative Humidity	Range of T
18911:2010	Photographic films (except nitrate)	20 to 50%	0 to 7°C
18920:2011	Photographic prints	30 to 50%	2 to 16°C
18923:2000	Magnetic tape	15 to 50%	2 to 16°C
18934:2011	Multiple media	30 to 50%	Room: 16 to 23°C Cool: 8 to 16°C Cold: 0 to 8°C Frozen –20 to 0°C

risk climb during high temperature and high humidity? Are seasonal adjustments possible for energy saving? What are the risks during retrieval? This section is also a reminder that not only archives, but all collections with low-stability objects listed in Table 5, can benefit from low temperature.

Lower temperature reduces the rate of all forms of chemical decay. For the most rapidly decaying organic materials (right-hand columns of Table 5), the dominant mechanism is acid hydrolysis, which increases strongly with the acidity of the material, and increases with moisture content (Zou et al. 1996). Moisture content, in turn, depends on relative humidity. The consensus is that the rate of decay (or its reciprocal, lifetime) is a product of an acidity factor, a temperature factor, and a relative humidity factor (which sometimes includes a correction dependent on temperature).

$$L = f(\mathrm{pH})\, f(T)\, f[\mathrm{rh}(T)] \tag{1}$$

where L is lifetime, in years.

For our purposes, acidity is a given, and only temperature and relative humidity can be controlled. The temperature function is an Arrhenius equation:

$$f(T) = C \exp\left(-\frac{E_a}{RT}\right) \tag{2}$$

where

C = constant, units of time
R = gas (Boltzmann) constant, 8.134E-3 kJ /mol·K
E_a = activation energy, kJ /mol
T = temperature, K

Michalski (2002) compiled data from reviews of activation energies (notably reviews by Nishimura [1996]) for paper, film, and photographic dyes, as well as further individual studies of magnetic media and the yellowing of varnish. More than three-quarters of all the studies of paper degradation, acetate film degradation, and dark fading of dyes fit within an E_a range of 80 to 120 kJ/mol. In Figure 5, this range is shown by the shaded area. Michalski (2002) further showed that this range of E_a can be derived with no consideration of a specific material, but simply by examining the kinetics of a chemical process that requires several decades to proceed at room temperatures. Thus, both data and theory suggest that this E_a range can be used to estimate the benefits of cold storage, and the risks from high temperature, for all organic materials suspected of being low or very low stability (Table 5). Michalski (2000, 2002) selected a middle value for mixed collections at 100 kJ/mol, shown by the heavy black line in Figure 5. For decay of polyester polyurethane (the weak link in magnetic media, and a popular material with artists in the late twentieth century) and for yellowing of natural resins, the activation energies fall slightly lower, 60 to 80 kJ/mol (between the shaded area and the dashed line in Figure 5.)

Data on the influence of relative humidity are much less extensive than those for temperature, and insufficient to select between differing models. Some authors assume that the true variable is moisture content (Strlic et al. 2015; Zou et al. 1996) and use a

Table 5 Classes of Chemical Stability

High Stability	Medium Stability	Low Stability	Very Low Stability
Wood, glue, linen, cotton, leather, rag paper, parchment, oil paint, egg tempera, watercolor media, gesso. Serviceable examples up to 3 millennia old exist, from dry burial or dry enclosures at ~20°C. These examples were protected from any acid exposure (e.g., air pollution from Industrial Revolution), and have never been damp. Skin, bone, and ivory of the woolly mammoth have survived intact for over 40 000 years while frozen.	Current best estimate for stable photographic materials (e.g., 19th century black-and-white negatives on glass, 20th century black-and-white negatives on polyester film) to remain usable as images with little or no change.	Acidic paper (e.g., newsprint, low-quality books, papers post-1850) and some film become brittle and brown, difficult to access. Acetate film shrinks, image layer cracks. Celluloid and many early plastics become yellow, crack, distort. Natural materials acidified by pollution (textiles, leather) weaken, may disintegrate.	So-called unstable materials. Typical magnetic media (e.g., video/audio/data tapes, floppy disks) begins to be unplayable. Least-stable photographic materials decay (e.g. color prints fade in the dark; poorly processed items yellow, disintegrate; cellulose nitrate yellows, disintegrates, faster when packaged in large amounts). Many elastic polymers, from rubber to polyurethane foams, become brittle, or sticky, or disintegrate. Some acrylic paints on some canvas supports yellow rapidly.

Lifetimes at Various Temperatures*

	High Stability	Medium Stability	Low Stability	Very Low Stability
60°C, heat treat, sun	~4 years +	~1 year	~6 months	2 months
30°C, hot room	~250 years +	~75 years	~25 years	~7 years
25°C, warm room	~500 years +	~150 years	~50 years	~15 years
20°C, room	**Millennia ~1000 years**	**A few centuries ~300 years**	**One human lifetime ~100 years**	**One human generation ~30 years**
12°C, cool	~3200 years +	~1000 years	~320 years	~100 years
4°C, cold	11 000 years +	~3300 years	~1100 years	~330 years
–20°C, frozen	750 000 years +	~225 000 years	~75 000 years	~22 500 years

Source: Modified from the tables "Chemical sensitivity of materials to room temperature" and "Approximate lifetimes of the materials at various temperatures" (Michalski 2018)
**Lifetime* defined here in terms of effects or utility described for each material listed in the top row. Lifetimes expressed in each row have considerable uncertainty, but relative improvement from top to bottom rows is certain.

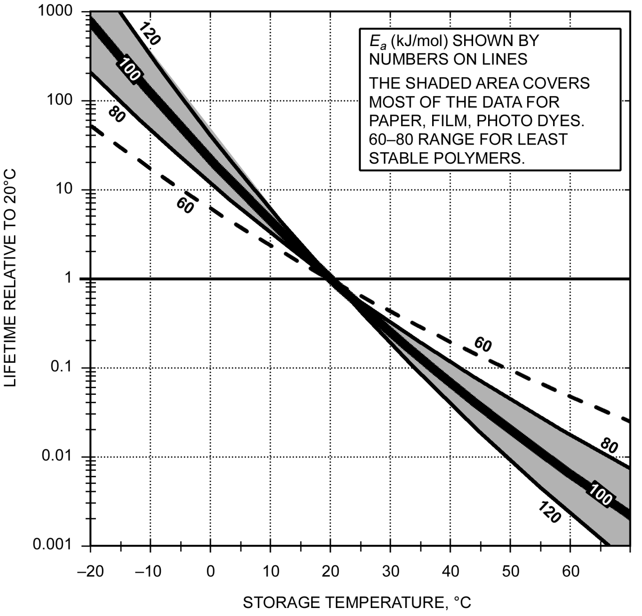

Fig. 5 Effect of Temperature on Lifetime for Various E_a

complex function of relative humidity that includes a temperature correction.

Three advisory tools are currently available: the preservation index (Reilly 1995), Michalski (2000), and Strlic et al. (2015). These tools can be used to derive equations for a lifetime (L_r) relative to the lifetime at room conditions 20°C, 50% rh. These equations have been used to plot lines of constant relative lifetime (also called **isoperms**) on the psychrometric chart in Figure 6. The following equations are all arranged with the temperature and relative humidity components separated for clarity, and with R separated so that E_a becomes explicit as the numerator above RT.

1. Preservation Index, derived principally from acetate film data, but considered applicable to all organic objects as listed in Table 5 (the equation derived from Table 1 in Reilly (1995) fits within 5%); available as a wheel calculator, and as a software tool, from Image Permanence Institute (IPI 2018).

$$L_r = 4.69 \times 10^{-17} \left\{ \exp\left[\frac{94.9}{RT}\right] \exp[\mathrm{rh}(0.02087T - 8.79)] \right\} \quad (3)$$

2. Michalski (2000) derived from a review of data on paper, film, dyes; considered applicable to all organic objects. (Equation (4) was used for a similar figure in previous editions of this chapter.)

$$L_r = 6.17 \times 10^{-19} \exp\left(\frac{100}{RT}\right)\left(\frac{1}{\mathrm{rh}}\right)^{1.3} \quad (4)$$

3. Strlic et al. (2015), derived from a review of data on paper; applicable primarily to paper and other cellulosic materials listed in Table 5.

$$L_r = 9.468 \times 10^{-21} \exp\left(\frac{119}{RT}\right) \exp\left\{ -36.72 \left[\frac{\ln(1 - \mathrm{rh})}{1.67T - 741.82}\right]^{\frac{1}{5.7688 - 0.012T}} \right\} \quad (5)$$

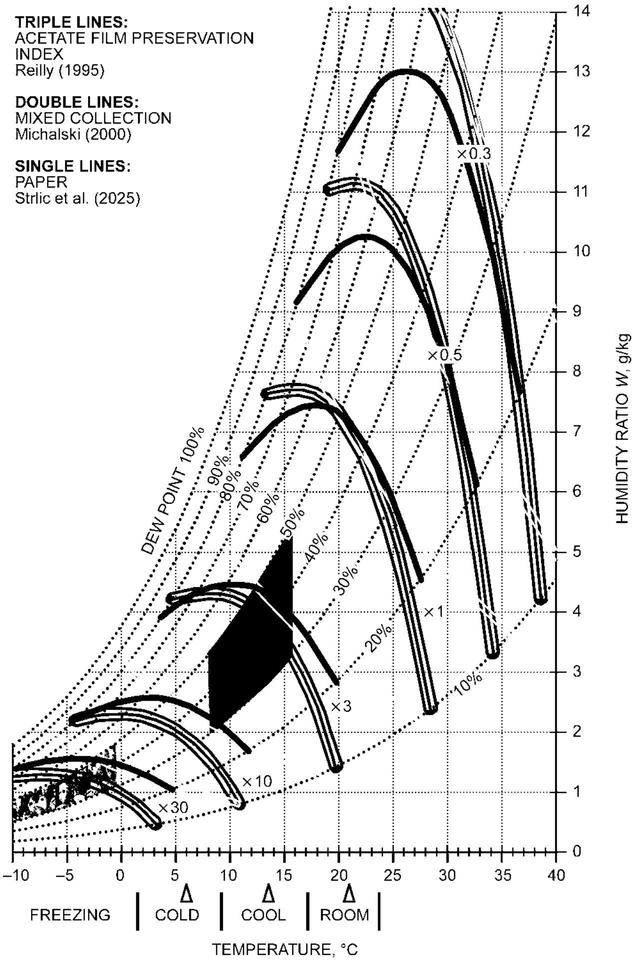

Fig. 6 Lines of Constant Lifetime (Isoperms) for Three Models

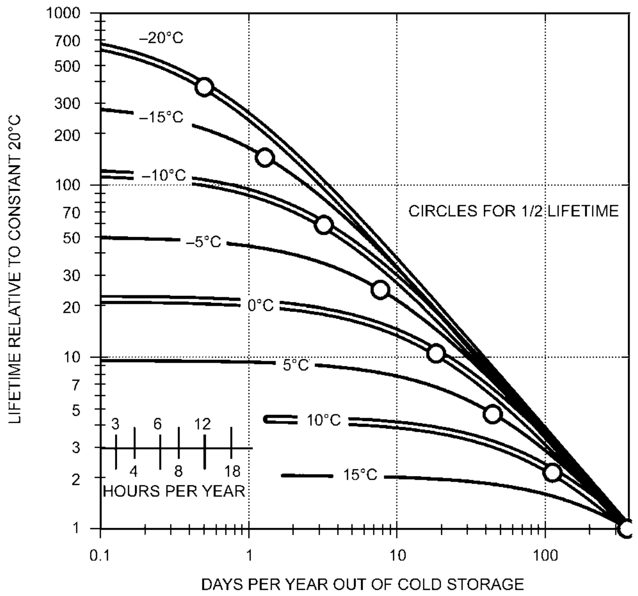

Fig. 7 Effect of Time Out of Cold Storage
(Based on Michalski [2000])

Between 20 and 60% rh, differences in the three models are negligible for practical purposes (Figure 6). Beyond this humidity range, the models diverge because of the different functions selected (exponential versus power law), but this is largely irrelevant because relative humidity extremes are usually avoided (mold risk at very high values, and mechanical risks at very low values). The small differences between models on the effect of very low temperature are not because of any differences in opinion about the function (Arrhenius), but on the value of E_a selected, which depends on the particular data set that each author emphasized: acetate film, mixed collections, or acidic paper. The E_as of all three models fit within the shaded area of Figure 5. Essentially, in the range of 20 to 60% rh and for high and low temperatures, any of the three models can be used and will provide the same practical answers.

Temperature

A common technical question beyond the scope of fixed standards is the impact on lifetime of out-of-spec events, or seasonal fluctuations. Estimates can assume a simple linear dependence on relative humidity: for instance, if half the year is at 30% rh and half at 60% rh, then the effective annual relative humidity is the average: 45% rh. Temperature dependence, however, is far from linear, and averages cannot be used. The derived equations are general and users can select a preferred E_a, but the graphs and worked examples assume the middle E_a value of 100 kJ/mol (the small differences of E_a of the three models do not make practical differences).

A common query concerns the effect of short periods at higher temperature. The reciprocal of Equation (2) can be used to find the average rate of decay of an object that is normally at a cooler temperature (T_c) but which is at a higher temperature (T_h) for a fraction f of the time. The result for net lifetime is

$$L_r(T_c) = \left\{ f + [(1-f)] \exp\left[\frac{E_a}{R} \left(\frac{1}{T_h} - \frac{1}{T_c} \right) \right] \right\}^{-1} \quad (6)$$

where

$L_r(T_c)$ = lifetime relative to a lifetime of 1 at T_c
f = fraction of time at hotter temperature
T_c = temperature in colder condition, K
T_h = temperature in hotter condition, K

There are two situations of interest: objects in cold storage that are occasionally retrieved to room temperature, and collections at room temperature that are occasionally exposed to high temperature. Figure 7 plots the relationship for retrieval from cold storage, and Table 6 provides worked examples.

There is no advantage to very low temperature cold storage if the object is retrieved frequently to room temperatures. Cold storage does not reverse the decay that progresses during warm periods. Temperatures for cold storage should be designed considering the expected retrieval pattern. Examples in Table 6 can be considered the break-even point, where the retrieval pattern has cut the potential of the cold temperature by one-half. Lower-temperature storage will not significantly improve remaining lifetime, unless retrieval time also diminishes.

Figure 8 plots the loss of lifetime from chemical risk during periods of high temperatures as compared to room temperature (20°C). An annual accumulation of about 30 days at 40°C cuts lifetimes at 20°C in half. Using high temperatures (e.g., 60°C for pest control should not exceed a total of 6 hours per year (or 60 hours each 10 years) to maintain 90% of normal lifetime; this is a reasonable trade-off for reducing the risk of massive insect damage.

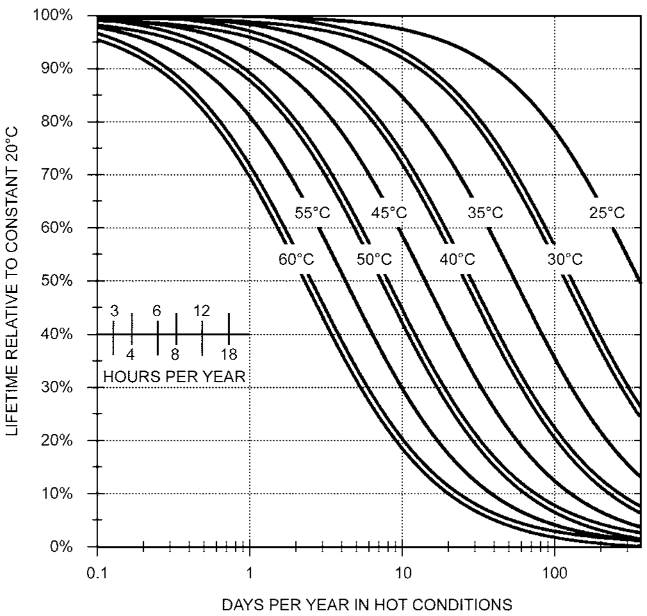

Fig. 8 Reduced Lifetime Caused by Occasional Hot Conditions
(Based on Michalski [2000])

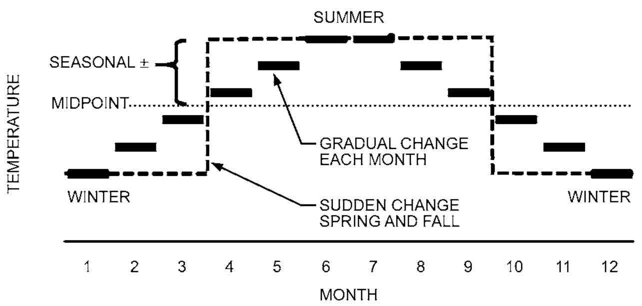

Fig. 9 Seasonal Patterns Used for Sudden and Gradual Changes

Table 6 Object Lifetime and Effects of Time Out of Storage

	20°C	10°C	5°C	0°C	–5°C	–10°C
Relative lifetime compared to 20°C	1	4.4	9.6	21.6	50	120
Lifetime for very low stability objects, years	30	132	298	650	1500	3600
Time out of storage causing 50% loss		107 days/y	42 days/y	18 days/y	7.5 days/y	3.1 days/y
Lifetime remaining		66 y	150 y	325 y	750 y	1800 y

A seasonal swing in temperature can allow energy savings, especially in climates with cold winters. Its benefit to collections with low chemical stability is much more important than the smaller risks from annual temperature fluctuation. Because of the exponential dependence of lifetime on temperature, summer adjustments must be balanced by even larger winter adjustments. If one assumes a typical annual schedule (Figure 9) of two winter months at the lowest temperature, two summer months at the highest temperature, and four months of adjustments through the two swing seasons, then the correction between the midpoint temperature and the effective annual temperature for calculating lifetime is given by Figure 10.

Table 7 Examples of Corrections to Temperature Midpoint

Seasonal ±	Correction	Equal to Constant 10°C	Equal to Constant 20°C
5 K gradual	–1 K	9 ± 5°C	19 ± 5°C
8 K gradual	–2 K	8 ± 10°C	18 ± 10°C
5 K sudden	–2 K	8 ± 5°C	18 ± 5°C
8 K sudden	–4 K	6 ± 10°C	16 ± 10°C

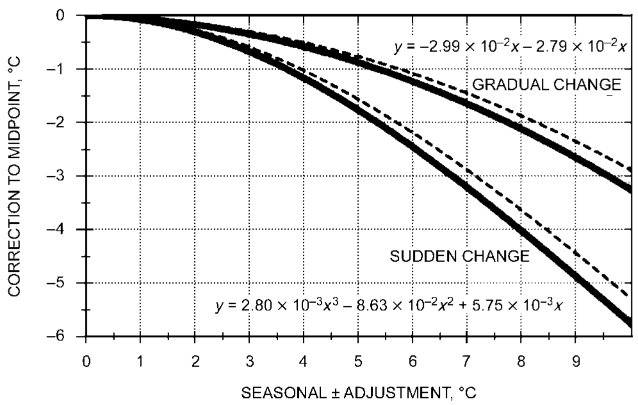

Fig. 10 Correction to Temperature Midpoint Caused by Seasonal Adjustment

The correction alters slightly with the midpoint temperature (the solid lines are for near 0°C, and the dashed lines for near 20°C), but for cautious estimates at any temperature, use the solid lines. Table 7 provides several worked scenarios. For example, when the seasonal adjustment reaches ±5 K or more, almost all aging occurs during the summer months, and winter simply becomes a dormant period in comparison.

Retrieval from cold storage raises the question of whether to build a transition space, and what procedures to use for acclimatization. Two risks are mitigated by a transition space: condensation during retrieval (the major risk) and direct mechanical effects of the temperature change (usually minor). A transition space adds complexity to cold storage construction and operation. In smaller installations, it also represents a large fraction of “lost” storage. The greatest risk of condensation is during reentry to warm conditions or during failure of the cooling system, so it is essential that objects in cold storage always be inside moisture proof packaging or bags, and that these packages not be opened until the object has reached room temperature. This packaging reduces the need for tight control of relative humidity fluctuations in cold storage, because response times are many days or weeks (see Table 8). When moving from extreme cold storage (–20°C), small amounts of condensation can still form inside packages, such as film cans (Padfield 2002) and larger wrapped plastic objects, causing irreversible blanching of some plastics (Shashoua 2004, 2005, 2008) Despite these side effects, cold storage remains the only option for preserving low-chemical-stability materials (Shashoua 2014). Detailed advice for retrieval of paper, film, and magnetic media is available in the ISO standards listed in Table 4.

5.4 CRITICAL RELATIVE HUMIDITY

At a specific critical relative humidity, minerals may hydrate, dehydrate, or deliquesce. When part of a salt-containing porous stone, a corroded metal, or a natural history specimen, these minerals cause disintegration of the object. Distinct critical relative humidity values are known for dozens of minerals in natural history collections (Waller 1992). Pyrites, which are contaminants of most

Table 8 Hygric Half-Times (near 20°C)

Time Range	Objects or Enclosed Objects	Design Implications
A year or more $>10^8$ s	Wooden objects at least 12 mm thick if wrapped in heavy-gage polyethylene (200 µm), with perfect seams. **Enclosures:** Paintings on canvas, paper, or photographs with several layers of matboard (or buffer) framed with glass front and impermeable backing board, perfect seals except for single pressure equalization pinhole, ~15 years. If acrylic sheet, 4 mm, ~11 months (Michalski 2005).	Risk only emerges if annual average space relative humidity is unacceptable to enclosed object.
$\sim10^7$ s Weeks to months	Large uncoated wood objects, 100 mm across the grain, 760 mm along end grain, 100 days. Books, exposed only on fore edge, tightly compressed ~25 days, if loosely compressed ~ 11 days (Derluyn et al. 2007). Bigourdan (2012) gives ~18 days, unspecified hardcover book, exposed all sides. **Enclosures:** Spools of 35 mm film inside metal can, 60 days (Adelstein et al. 1997). Paintings on canvas, paper or photographs with several layers of matboard (or buffer) framed with glass front and impermeable backing board, but gaps of 0.1 mm at top and bottom, 30 days. (Michalski 2005).	Hourly and daily relative humidity fluctuations create negligible risk. Seasonal space adjustments smoothed out. System loss lasting less than a week creates little risk.
$\sim10^6$ s Days to a week	Old panel painting, back "waterproofed," ~15 days (Stilwell and Knight 1934). Spools of 35 mm film, no can, 4 days (Adelstein et al. 1997). Uncoated wood slab, 22 mm across grain, 160 mm along end grain. Most wooden cabinetry when empty. Ivory, uncoated, handheld ~25 mm cylindrical (Lafontaine and Wood 1982). **Enclosures:** Paintings on canvas, paper, or photographs with several layers of matboard (or buffer) framed with glass front and impermeable backing board, but gaps of 0.5 mm at top and bottom (Michalski 2005). Hackney (1990) measured at most 6 days with glass frame and coated backing board; gaps must have determined performance. Archive box, paperboard or polypropylene, no holes, full, ~2 days (Batterham and Wignell [2008], estimated from measured damping of external daily fluctuation of ×4.)	Hourly and daily relative humidity fluctuations create little risk. System loss lasting several days can create high risk.
$\sim10^5$ s A day	Uncoated wood slab, 8 mm across the grain, 130 mm along end grain. Ivory, uncoated, handheld ~25 mm cylindrical (Lafontaine and Wood 1982). **Partial enclosures:** Paintings on canvas with continuous paint layer and impermeable backing board applied to frame (Di Pietro and Ligterink 1999).	Hourly relative humidity fluctuations create little risk. System loss lasting all day can create high risk.
$\sim10^4$ s Hours	Bare acrylic paint, medium-thick layer. Bare oil paint, alkyd paint, thin layers. Uncoated wood, wood fiber boards, leather, skin, 3 mm thick.	Hourly relative humidity fluctuations or system loss can create risk.
$<10^3$ s Few minutes or less	Single sheet of paper, 4 min (Kupczak et al. 2018b). Includes book pages that are fanned open. Thin sheet of parchment, ivory. Thin layers of watercolor paint, gouache. Feathers, fur, hair. Lightweight textiles, costumes. Gelatin layer of photographic print or film. Sized canvas used for paintings.	Relative humidity fluctuation or system loss of only a few minutes can create risk. (Museums rarely display these objects unenclosed.)

Note. All plates considered exposed both sides unless noted otherwise. Adelstein et al. (1997) and Bigourdan (2012) reported 90% response times, converted here to halftimes by ×0.3 assuming exponential decay. Derluyn et al. (2007) measured a 50 mm square experimental book, closed on all sides but fore edge. Their times have been adjusted to a more realistic 100 mm depth, so ×4 (square law) is applied. Estimates from Michalski (2005) based on material data plus enclosure leakage equations. Wood objects and furniture based on Figures 11 and 12. Others are based on calculations using Equation (7) for a plate and diffusion coefficients from the literature.

fossils, disintegrate if held above 60% rh (Howie 1992). Bronze, one of the most important archaeological metals, has a complex chemistry of corrosion, with several critical relative humidity values. This variety means there is no universal safe relative humidity; particular conditions should be achieved for specific artifacts with local cabinets or small relative-humidity-controlled packages (Waller 1992). The only generalization is that any relative humidity above 75% is dangerous.

Rapid corrosion above 75% rh occurs for two reasons: increased surface adsorption of water, and contamination by salts. Water adsorption on clean metal surfaces climbs rapidly from 3 molecules or less below 75% rh to bulk liquid layers above 75% rh (Graedel 1984). This phenomenon is aggravated by most surface contaminants, as shown in studies of the role of dust on clean steel corrosion. The most common contaminant of museum metals, sodium chloride, dissolves and liquefies (deliquesces) above 76% rh.

Glass collections, objects with glass bead decoration, and stained glass may contain a type of historic glass that is very sensitive to incorrect relative humidity because of deliquescence of unstable constituents. A stable 40% rh is recommended. See van Giffen et al. (2018) for detailed recommendations on climate control for various types of historic glass.

Response Times of Artifacts

Approximate thermal response times of objects are familiar from common experience, and their calculation is described in Chapter 25 of the 2017 *ASHRAE Handbook—Fundamentals*. This section focuses on the response time that is much less familiar to most engineers, but much more important to preservation science: hygric response times.

Table 8 provides hygric half-times for common objects and enclosed objects in cultural institutions. Where direct measurements are available, these have been cited; other estimates are based on calculations. Lower temperatures greatly increase all these times (Adelstein et al. 1997); conversely, higher temperatures shorten them. Response times at least double for each drop of 10 K: for example, ×2 for cool conditions, ×4 for cold, ×8 or more for freezing storage.

The hygric half time of a plate (a shape that applies to many cultural objects, or that provides an upper bound to cylinders, cubes, spheres, etc) is given by Crank (1979) as

$$T_{1/2} = 0.049\frac{L^2}{D} \tag{7}$$

where

$T_{1/2}$ = half-time of enclosure system, s
L = thickness of plate (or sheet), m
D = diffusion coefficient, m^2/s

Some estimates in Table 8 are based on Equation (7) and diffusion coefficients found in the literature on polymers. An object with a surrounding moisture barrier (coating or enclosure) can be simplified as a series of two resistances to moisture flow. Figure 11 was generated using this approach, with wood data from Siau (2012) for medium-density wood near 50% rh. When barriers provide useful resistance (upper lines in each plot in Figure 11), the plots have a slope of 1 (linear). When coatings provide negligible resistance (e.g., the boundary layer of air in a calm room), the slope changes to the square law of Equation (7). There is only a slight curve as thickness drops to 1 mm across the grain. As Kupczak et al. (2018b) show, the contribution of the boundary layer of air, though measurable, is far from rate determining even for a single sheet of paper. In practical terms, although thinner objects (e.g., a violin, ivory miniature, paper sheet) respond more quickly, they benefit greatly from even simple coatings or enclosures, whereas massive objects do not.

Figure 12 was generated using the same series resistances model, but using leakage equations for an enclosure found in Michalski (1994). The horizontal plateaus are in the region where crack leakage is insignificant, and the wood coating dominates halftime. The slopes are the region where leakage (infiltration) dominates, and the knees indicate which size cracks are worth blocking.

The humidity half-time of a leaky enclosure with a hygroscopic material (objects or additional buffers) can be expressed in terms of the fraction of the enclosure volume filled with the buffering material (Michalski 1994):

$$T_{1/2} = 0.69\frac{V_h \alpha \rho}{V_e N C_{ws}} \tag{8}$$

where

$T_{1/2}$ = half-time of enclosure system, s, h, or days (depends on leakage units)
V_h = volume of hygroscopic material, m^3
V_e = volume of enclosure, m^3
α = hygric capacity (slope of moisture isotherm) kg/kg
ρ = bulk density of hygroscopic material, kg/m^3
N = leakage, air changes per s, per h, or per day
C_{ws} = concentration of water in air at saturation, kg/m^3

The critical role of leakage N for enclosed objects can be seen in Table 8 for paintings or works on paper in a sealed glass frame (increasingly used by major galleries, especially for loaned paintings.) Depending on tiny differences in crack width, performance can change by orders of magnitude. This is because of the key role of infiltration in determining N, and the fact that infiltration varies with the cube of crack width (laminar flow) (Michalski 1994).

Equation (8) can be reduced to an estimate for materials such as paper, wood, leather, and dense fabrics near room temperature (20°C), where $C_{ws} = 0.0173$ kg/m^3. Using a conservative density of $\rho \approx 600$ kg/m^3 and a conservative hygric capacity of $\alpha \approx 0.05$, then

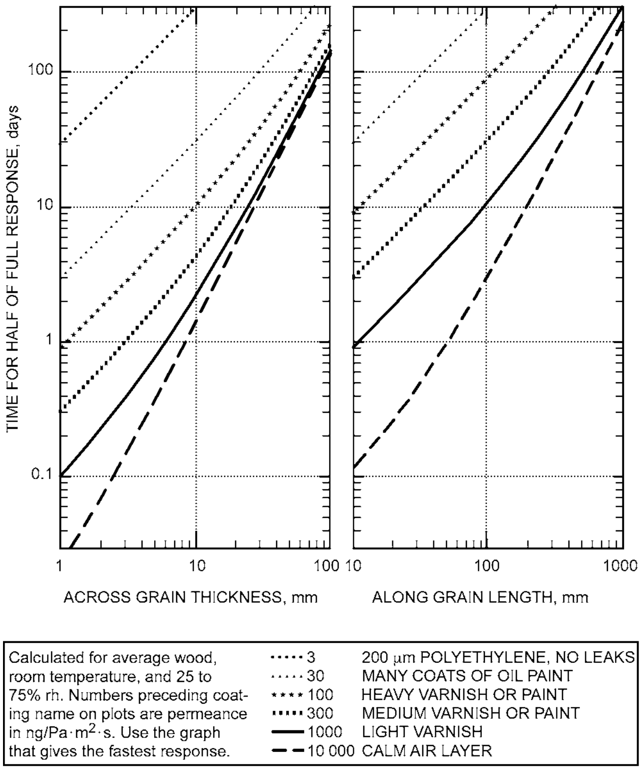

Fig. 11 Calculated Humidity Response Times of Wooden Artifacts

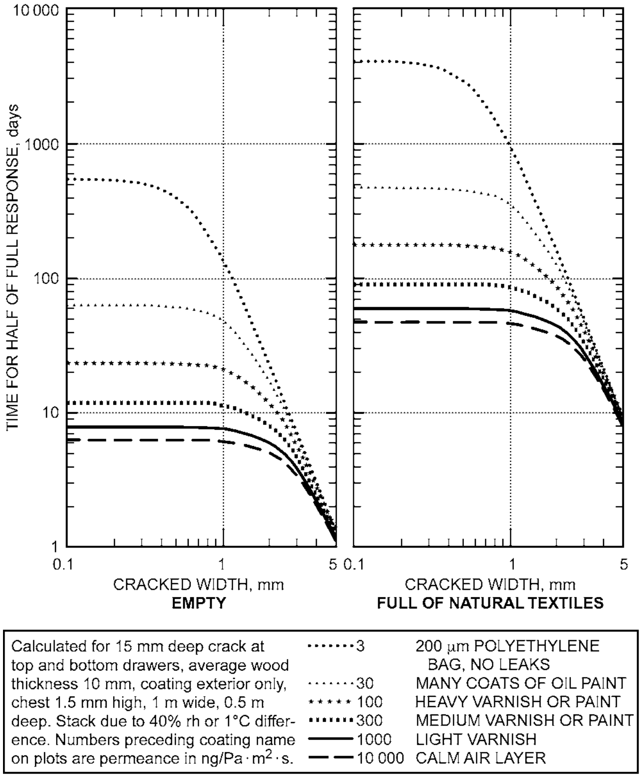

Fig. 12 Interaction of Air Leakage, Wood Coating, and Textile Buffering on Response of Wooden Chest of Drawers

$$T_{1/2} \sim 0.69\frac{V_h \alpha\rho}{V_e N} \quad (9)$$

A leakage rate of 1 air change per day (acd) is considered a suitable design target for airtight museum display cases (Thickett et al. 2007), so an enclosure half full of wood or paper (V_h/V_e = 1/2) would give a half-time of 600 days. In practical terms, very tight enclosures are rarely very full enclosures (although wrapping large wooden objects in heavy-gage, perfectly sealed polyethylene can achieve this). Half-full enclosures are generally cabinets or crates, and they leak closer to 1 air change per hour (ach), which still provides a 25 day half-time. A tight display case of 1 ach rarely has more than 10% of its volume filled with hygroscopic material, resulting in half-times up to 120 days. In practice, it is difficult but not impossible to design and maintain very low infiltration.

An inevitable concern with enclosures is the humidity fluctuation driven by a thermal fluctuation. This worry first emerged in the 1960s for works of art in shipping crates, but Toishi (1959) showed that if a sealed crate contained hygroscopic material, it would stabilize its relative humidity despite drops from room temperature to freezing and back. Stolow (1966) provided complete data and equations for the counter-intuitive finding that, with natural hygroscopic materials, case humidity even drops slightly when temperature drops (the opposite of empty enclosures) because of the slight downward shift of moisture isotherms at lower temperature. Thomson (1964) showed that the transition point between relative-humidity-controlled enclosures and empty-enclosure behavior for hygroscopic materials such as wood occurred at about 1 kg/m^3, and humidity control was fully in place by 10 kg/m^3 (about 2% full by volume). Later authors examined further side effects such as mixed thermal/hygric dimensional response in wood (Richard 2007) and condensation in air pockets during cold storage retrieval (Padfield 2002; Shashoua, 2005, 2008) but the general consensus is that such occasional side effects do not outweigh the benefits (Richard 2007; Shashoua 2014).

5.5 AIRBORNE POLLUTANTS/ CONTAMINANTS

Sources

From the outdoors, different-sized particles can infiltrate museums. Gaseous outdoor pollutants such as nitrogen dioxide and ozone can also penetrate buildings, including modern HVAC-equipped construction, when gas filtration is not present to remove them. Within buildings, sources of airborne pollutants include institutional activities such as food preparation, service vehicles in the loading dock, and renovation (e.g., preparation of new exhibitions). Construction products such as wood, paints, adhesives, and sealants, especially by-products formed by chemical curing or solvent release, can be important sources of gaseous pollutants. Collections themselves can be sources of pollutants that can affect other objects nearby; examples include archival materials such as cellulose nitrate and acetate films, as well as acidic papers. Collections made of natural organic materials such as leathers, fur, and wood elements can also release harmful volatile compounds. The metabolism of staff and visitors further contributes to airborne pollutants, and introduces coarse particles from skin cell shedding and clothing. It is important to understand that the impact of gaseous pollutants varies according to the sensitivity of each material (i.e., acetic acid corrodes lead but is harmless to silver; silver is very sensitive to hydrogen sulfide, but lead is minimally affected). In other words, the potential damage is very specific to each pollutant/material system and the damage caused to objects by pollutants is usually cumulative, irreversible, and disfiguring. Table 9 presents a list of objects sensitive to various pollutants and pollutant sources.

Impact

Dust deposition is a general problem for all collections. More precisely, dust deposition impacts objects' aesthetic appearance and affects conservation considerations (e.g., cleaning frequency, risk involved during treatments). Coarse dust is relatively easy to remove from robust surfaces such as flat glasses or metals, but difficult to remove from fragile surfaces such as feathers. Particles generated by people are not usually removed by HVAC filters. Fine particles such as black soot pose a particular challenge. This is a typical problem for museums in the vicinity of high-volume diesel vehicle traffic. Special conservation skills are needed to remedy this situation, but there are cases where the soot cannot be removed (e.g., soot entrenched in the cracks of an ivory sculpture, soot in fragile textiles that may be significantly physically damaged by cleaning treatment).

The deterioration process caused by airborne pollutants can be enhanced in the presence of water vapor. This has a relevant impact on objects both in a direct and indirect way. In the presence of high relative humidity, many processes of deterioration accelerate. An example of an indirect effect that is greatly affected by high relative humidity, especially above 75% rh, is the increase in corrosion rates of many metals by pollutants. For example, formaldehyde does not corrode lead at 75% rh, but corrosion can occur at higher humidities (Thickett 1997). Water vapor can directly affect some materials (e.g., cellulose papers, cellulose acetate, nitrate plastic films) by hydrolysis. With just moisture in the cellulose, deterioration is slow, but increases when acids are present. This reaction is called **acid catalyzed hydrolysis**. Over time, the acids present as by-products of cellulose degradation increase, which further speeds up the reaction (Dupont et al. 2007; Zou et al. 1996). To maximize preservation of objects affected by pollutants, it is usually better to keep relative humidity low, particularly for metal objects. However, the environment must be compatible with the appropriate humidity range established for preservation of organic or composite collections. Oxygen in the indoor environment also may react with objects. Natural rubber is particularly known to degrade by oxidation, and many colorants are vulnerable to fading in the presence of oxygen and light.

Some work has been done to quantify the impact of pollutants on various materials, based on the concept of the **lowest observable adverse effect dose (LOAED)**. This dose is derived using the reciprocity principle: if a critical adverse effect is observed on an object after 1 month at 1000 parts per billion (ppb) of a pollutant, the same damage could occur after 10 months at 100 ppb. When extensive data exist for a pollutant/material system, a **no observable adverse effect level (NOAEL)** can be determined with some confidence. After studying the effect of acetic acid on (untarnished and pure) lead at different concentrations and relative humidity levels for a year, Tétreault et al. (1998) established a NOAEL for the acetic acid/lead system at 430 μg/m^3 or 170 ppb. Extensive sets of LOAED and some NOAEL data have been compiled by Tétreault (2003).

Note that concentrations of gaseous pollutants can be reported in either volumetric units (ppb), which are temperature and pressure dependent, or in gravimetric units (μg/m^3), which are temperature and pressure independent. To standardize reporting for volumetric units, the Compressed Air and Gas Institute (CAGI 2012) recommends using standard conditions of 20°C and 100.0 kPa. IAQ in Museums and Archives (IAQ 2016) provides an online concentration converter for major pollutants.

In general, there are three scenarios where objects can be at risk in museums:

- **Outdoor pollutant infiltration** is a problem in polluted areas where unprotected objects in rooms are exposed to outdoor pollutants that were not adequately blocked at the building level (envelope and filtration). Soot deposition and tarnishing of silver and copper by reduced sulfur compounds are common damage

Table 9 Airborne Pollutants: Sources and High-Vulnerability Materials

Airborne Pollutants	Indoor and Outdoor Sources	Effects on Materials
Aldehydes (RCHO)	Formaldehyde: formaldehyde-based resin in wood products, solid wood, paints and adhesives, natural history wet specimen collections, permanent press fabrics. Acetaldehyde: paints, adhesives, solid woods. Low-molecular-weight aldehydes can be transformed into their respective carboxylic acids in presence of strong oxidant such as peroxides released by oil-based paints or any paint films formed by oxidative polymerization.	Formaldehyde: Corrosion of lead at high relative humidity (>75%).
Amines (RNR)	Ammonia (NH3): alkaline-type silicone sealants, concrete, emulsion adhesives and paints, household cleaning products, visitors, animal excrement, fertilizer and inorganic process industries, underground bacterial activities. If combined with sulfate or nitrate compounds, it can form ammonium salts. Cyclohexylamine (CHA), diethylamino ethanol (DEAE), and octadecylamine (ODA): corrosion inhibitor in humidification systems, some vapor corrosion inhibitors.	Ammonia: blemishes on ebonite and efflorescence on cellulose nitrate. Other amines: thought to be responsible for blemishes on paintings and corrosion of bronze, copper, and silver.
Carboxylic acids (RCOOH)	Acetic acid (CH3COOH): acid-type silicone sealants (acetoxy cure), degradation of organic materials and objects such as cellulose acetate-based objects (vinegar syndrome) and wood products, most paints, flooring adhesives, human metabolism, linoleum, microbiological contamination of air-conditioning filters, oil-based paints, photographic developing products, some "green" cleaning solutions. Formic acid (HCOOH): degradation of organic materials, oil-based paints, wood products. Fatty acids (RCOOH): burning candles, cooking, flooring adhesives, human metabolism, linoleum, lubricant in HVAC systems, microbiological activities from air-conditioning or on objects, objects made of animal parts (including skins, furs, insect collections), oil-based paints, papers, paper and wood products, vehicle exhaust.	Acetic and formic acids: corrosion of copper alloys, cadmium, lead, magnesium, and zinc; efflorescence on calcareous materials (e.g., shells, corals, limestones, calcium-based fossils); fading of some colorants; efflorescence on soda-rich glass objects; lowering degree of polymerization of cellulose. Fatty acids: blemishes on paintings; corrosion of bronze, cadmium, and lead; ghost images on glass; yellowing of papers and photographic documents.
Nitrogen oxide compounds (NO_x)	Nitric oxide (NO): agricultural fertilizers, fuel combustion from vehicle exhaust and thermal power plants, gas heaters, and photochemical smog. Nitrogen dioxide (NO_2): degradation of cellulose nitrate and same sources as for NO, but mainly from oxidation of atmospheric NO. Nitric acid (HNO_3) and nitrous acid (HNO_2): oxidation of NO_2 in the atmosphere or on a material's surface, and the degradation of cellulose nitrate.	Deterioration of paper, fading of some artists' colorants, enhance the deterioration effect of SO_2 on leather and on metals.
Oxidized sulfur gases (SO_2 and H_2SO_4)	Sulfur dioxide (SO_2): degradation of sulfur-containing materials and objects such as proteinaceous fibers, pure pyrite or mineral specimens containing pyrite sulfur dyes, sulfur-vulcanized rubbers, petroleum refineries, pulp and paper industries, combustion of sulfur-containing fossil fuels. Sulfuric acid (H_2SO_4): oxidation of SO_2 in the atmosphere or on a material's surface.	Acidification of paper, corrosion of copper, fading of some artists' colorants, weakening of leather.
Ozone (O_3)	Electronic arcing, electronic air cleaners, electrostatic filtered systems, insect electrocuters, laser printers, photocopy machines, UV light sources, photochemical smog.	Fading of some artists' colorants, dyes, and pigments; oxidation of organic objects with conjugated double bonds such as rubber; oxidation of volatile compounds into aldehydes and carboxylic acids.
Particles (fine and coarse)	General: aerosol humidifier; burning candles; concrete; cooking; laser printers; renovations; spray cans; shedding from clothing, carpets, packing crates, etc. (due to abrasion, vibration, or wear); industrial activities; outdoor building construction; soil. Ammonium salts: reaction of ammonia with SO_2 or NO_2 in indoor or outdoor environments or on solid surfaces. Biological and organic compounds: microorganisms, degradation of materials and objects, visitor and animal danders, construction activities. Chlorides: sea salt aerosol, fossil combustion. Soot (organic carbon): burning candles, fires, coal combustion, vehicle exhaust.	General: abrasion of surfaces (critical for magnetic media), discoloration of objects (especially critical for those with surfaces with interstices [pores, cracks, or micro-irregularities] that entrap dust), may initiate or increase corrosion processes due to their hygroscopic nature. Ammonium salts: corrosion of copper, nickel, silver, and zinc; blemishes on varnished painting and furniture with natural resins and on ebonite; white deposit on object surface; lowering of the degree of polymerization of cellulose. Chlorine compounds: increase of rate of metal corrosion. Soot: discoloration of porous surfaces (painting, frescoes, statues, books, textiles, etc.), increased rate of metal corrosion. Carbon and metallic elements such as iron and magnesium can lower the degree of polymerization of cellulose.
Reduced sulfur gases (S^-)	Carbon disulfide (CS_2): polysulfide-based sealants; fungal growth; rotting organic matter in oceans, soils, and marshes. Carbonyl sulfide (OCS): degradation of wool, coal combustion, coastal ocean, soils, and wetlands, oxidation of carbonyl disulfide. Hydrogen sulfide (H_2S): arc-welding activities, mineral specimens containing pyrite, sulfate-reducing bacteria in impregnated objects excavated from waterlogged sites, polysulfide sealants, vulcanized rubbers, visitors, fuel and coal combustion, marshes, ocean, petroleum and pulp industries (kraft process), vehicle exhaust, volcanoes.	Corrosion of bronze, copper, and silver; discoloration of silver photographic images; darkening of lead pigments.

Source: Adapted from Tétreault (2003).

observed under those conditions. An assessment must be done to decide if better control should be carried out at the building level or if some objects should be placed in enclosures such as display cases, glazed frames, or storage containers. For protection against pollution and for security reasons, many small objects are placed in display cases, and paintings can be placed in glazed frames, but not all items on exhibition or in storage can be enclosed.

- With **pollutants generated in small enclosures**, products used to build the enclosure and the objects themselves can release volatile compounds (typically carboxylic acids and reduced sulfur gases), which can react with the objects housed within. Their concentrations can remain high for a long period if they cannot be exfiltrated or sorbed adequately. The best preventive solution is to carefully select construction products and to evaluate objects' potential emissions. If problematic products or objects cannot be removed from the enclosure, the second-best approach is usually to reduce the pollutant concentration in the enclosure by increasing the air exchange rate. However, an assessment is needed to determine which degree of airtightness is most suitable. The assessment must consider the concentration of pollutants in the room and in the enclosure, as well as the nature of both the pollutants and objects in the enclosure.
- **Indoor-generated pollutants** are similar to off-gassing in enclosures, but at a room scale. Objects displayed in a room with insufficient ventilation and with a high load of emissive materials can be at risk if pollutant concentrations become significant. Sources in the room can be products such as wood and paint, collections made of natural organic materials, and emissions from human activities such as cooking, renovation, or burning incense in religious buildings. Indoor pollutants can also affect people in the space, and the relation between air pollution and the health and comfort of building occupants is the focus of indoor air quality (IAQ) guidance, such as ASHRAE *Standard* 62.1. Possible solutions for minimizing the impact of indoor pollutants are to increase the ventilation, and to consider gas filtration systems or enclosures.

More information on the issue of pollutants in museums and historical buildings can be found in Anaf et al. (2015), Bellan et al. (2000), Bonacina et al. (2015), Grau-Bové and Strlic (2013), Grzywacz (2006), Hatchfield (2002), Lloyd et al. (2007), Mleczkowska et al. (2016, 2017), Nazaroff et al. (1993), Paterakis (2016), Pretzel (2003), and Tétreault (2003, 2017, 2018).

6. DESIGN PARAMETERS FOR PERFORMANCE TARGET SPECIFICATIONS

6.1 CLIMATE LOADS

Climate loads include above- and below-grade liquid water loads from rainfall; thermal loads from conduction, convection, and radiation; thermal and moisture vapor loads from infiltration (especially when driven by stack effect); and vapor transport through permeable envelope assemblies.

ASHRAE *Standard* 169-2013 provides a methodology for defining climatic regions based on thermal and moisture characteristics using nine thermal zones (0 to 8: extremely hot to subarctic), based on heating and cooling degree days, and three moisture zones (A, B, or C: humid, dry, or marine) calculated using precipitation and temperature data. The climate zone classification is useful for differentiating climate regions when considering envelope performance. Table 10 and Figure 13 indicate climate zones for typical cities and geographic locations throughout the world. Figure 14 provides a higher-resolution map of climate zones in the United States. ASHRAE *Standard* 169-2013 provides an extensive list of locations and their climate zone classification.

ASHRAE *Standard* 169-2013 also provides comprehensive location-specific climate data for calculations of loads for system and envelope design. *Engineering Weather Data*, published by the National Climate Data Center of the National Oceanic and Atmospheric Administration (NOAA 1997), includes informative graphics for visualizing seasonal variations in data, but the dataset is older. When using statistical climate data for design, consider not only maximum and minimum design conditions, but also the potential variability of thermal and moisture conditions in a given season; for example, in zones 3A, 4A, and 5A, thermal and moisture loads may change rapidly during spring and autumn. In some climate zones, seasonal dehumidification may not be coincident with large sensible cooling loads; thus, systems may have to be designed for dehumidification independent of cooling.

Bulk moisture from precipitation, especially wind-driven rain, can be a significant moisture load on envelopes above grade. Depending on soil type and site management of stormwater runoff from roofs and at-grade surfaces, rain can also affect moisture loads on subgrade portions of the building. However, even in climate zones classified as dry (B), infrequent but high-intensity rain events can result in significant short-term moisture loads on the building and soil.

The design service life and envelope durability of purpose-built museum buildings may be as long as 100 years. Design for climate loads on building envelopes should consider projections for climate change and their impact on future thermal, moisture, and bulk moisture loads on the building, consistent with the design service life of a building, its envelope assemblies, and environmental management systems.

6.2 BUILDING ENVELOPE

The building envelope mediates exchange of thermal energy and moisture between the interior and the exterior environments, both above and below grade. Above grade, the building envelope typically consists of wall assemblies, wall closure assemblies such as windows and doors, and roof assemblies. Below grade, the building envelope consists of foundation wall assemblies and floor assemblies in contact with soils.

The envelope mediates movement or transport of water, air, water vapor, and thermal energy. Flows that are not effectively mediated by the envelope result in thermal and moisture loads that must be addressed by mechanical systems; unmediated loads have implications for energy efficiency.

Performance Requirements. Envelope performance needed to effectively and efficiently perform the four control functions (water [bulk moisture], air, water vapor, and thermal energy) depends on the exterior climate and desired interior conditions. Table 11 lists the types of climate control recommended for collections preservation and identifies the envelope performance needed to achieve that control in different climate zones. For a given combination of control type and climate zone, the necessary envelope performance for each function is identified as *controlled*, *moderated*, or *optional*. Table 12 provides examples of typical envelope features or assemblies that correspond to these terms. Table 11 also includes considerations that should be addressed in design and for some combinations of exterior climate and interior type of control, and identifies whether hygrothermal analysis of the envelope is needed, recommended, or optional for the different combinations of type of control and climate zone. Hygrothermal analysis using dynamic transient modelling is preferred, but static-equilibrium analysis may be sufficient in some instances.

(ASHRAE *Standard* 169-2013)

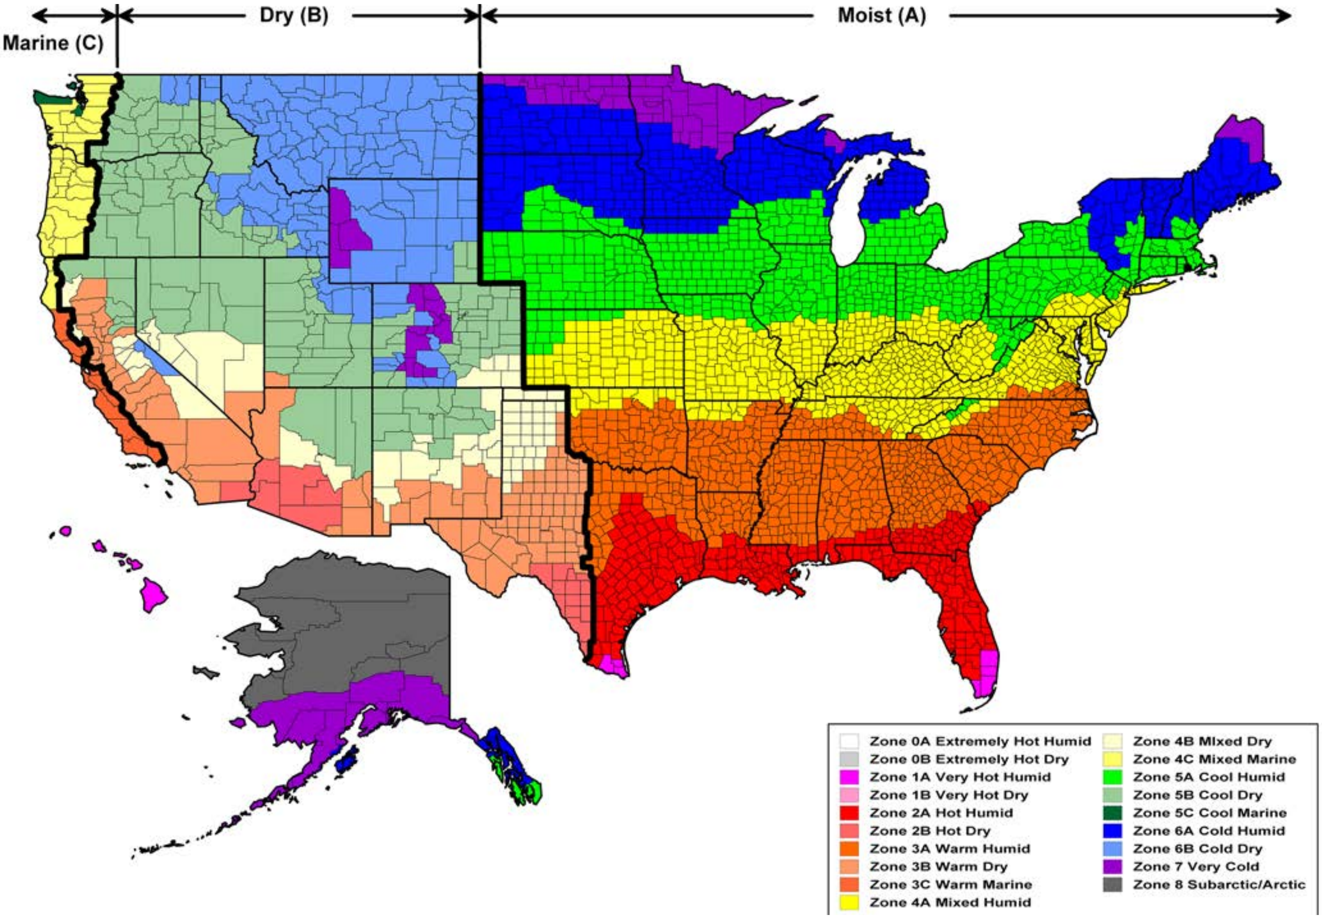

Fig. 14 Climate Zones in United States
(ASHRAE *Standard* 169-2013)

Table 10 Climate Zone Classifications for Select World Cities

Climate Zone	Type	Location	Climate Zone	Type	Location	Climate Zone	Type	Location
0A	Extremely hot, humid	Recife (Brazil)	3A	Warm, humid	Sydney (Australia)	5A	Cool, humid	Toronto (Canada)
		Bombay (India)			Shanghai (China)			Berlin (Germany)
		Manila (Philippines)			Atlanta (United States)			Chicago (United States)
0B	Extremely hot, dry	Ahmedabad (India)	3B	Warm, dry	Athens (Greece)	5B	Cool, dry	Rio Gallegos (Argentina)
		Niamey (Niger)			Tehran (Iran)			Taiyuan (China)
		Riyadh (Saudi Arabia)			Los Angeles (United States)			Denver (United States)
1A	Very hot, humid	Hanoi (Vietnam)	3C	Warm, marine	Nairobi (Kenya)	5C	Cool, marine	Esquel (Argentina)
		Mombasa (Kenya)			Cape Town (S. Africa)			Corum (Turkey)
		Miami (United States)			San Francisco (United States)			Bremerton (United States)
1B	Very hot, dry	Luxor (Egypt)	4A	Mixed, humid	Beijing (China)	6A	Cold, humid	Oslo (Norway)
		Lahore (Pakistan)			Paris (France)			St. Petersburg (Russia)
		Dakar (Senegal)			Philadelphia (United States)			Minneapolis (United States)
2A	Hot, humid	Sao Paulo (Brazil)	4B	Mixed, dry	Kabul (Afghanistan)	6B	Cold, dry	Chifeng (China)
		Haifa (Israel)			Adelaide (Australia)			Bozeman (United States)
		Dallas (United States)			Albuquerque (United States)	7	Very cold	Ulaanbaatar (Mongolia)
2B	Hot, dry	Cairo (Egypt)						Anchorage (United States)
		Lima (Peru)	4C	Mixed, marine	Brussels (Belgium)			
		Phoenix (United States)			Santiago (Chile)	8	Subarctic	Yellowknife (Canada)
					Portland (United States)			Fairbanks (United States)

Design Considerations. Interior environmental requirements for buildings containing collections are typically more stringent than those for human health and thermal comfort, particularly for relative humidity. Depending on the differences between the exterior and interior conditions, there may be large differences in temperature and moisture vapor across the building envelope. The resultant thermal, pressure, and moisture gradients between the exterior climate and the collections spaces have implications for envelope performance.

In new buildings, high-performance building envelopes address thermal and moisture gradients with layered sequences of functionally specific materials such as air barriers, thermal insulation, and vapor retarders/barriers. Older building envelopes typically used thick assemblies of fewer materials, consistent with contemporary expectations for envelope performance, building occupancy, and use. Many existing museum buildings constructed in the mid to late 20th century may have envelope assemblies similar to current high-performance envelopes, but the quality of materials, design details, or construction/installation may compromise their performance.

Furthermore, many collections are housed in existing buildings that are considered significant cultural heritage in their own right; these are not limited to historic buildings, and can include architecturally significant buildings of the late 20th century. The building envelope of historic or architecturally significant buildings is likely to be considered character defining, and changes or alterations to the envelope may be subject to preservation criteria. ASHRAE *Guideline* 34-2018 provides useful information on improving the energy performance of historic building envelopes.

An existing building envelope's performance possesses both strengths and liabilities for environmental management for collections. It may have high thermal mass and moisture capacity that can buffer interior and exterior fluctuations of thermal energy and moisture; these passive, or nonmechanical, aspects of envelope performance can be beneficial during extreme weather events or when mechanical systems are disabled.

Many older building envelopes have poor air control performance, especially at envelope penetrations around windows and doors, as well as the windows and doors and their operable elements. In older buildings originally designed for natural ventilation, intentional stack effect in large stair halls and through skylights above galleries may exacerbate high exchange rates through windows and doors, even when the assemblies have been upgraded.

Vapor control performance of existing wall and roof assemblies is typically inadequate for the differences between exterior and interior moisture vapor that must be maintained for some collections. Steep moisture gradients across envelope assemblies can drive moisture transport, with consequential damage to the building. Examples of damage in masonry or concrete wall assemblies include migration of soluble salts, freeze-thaw cycling, coatings failures or condensation. In wall assemblies with wood, damage may occur from moisture saturation and microorganism activity. Vapor control performance can be difficult to incorporate in an existing building envelope. As a result, depending on the climate zone, vapor control performance of an existing envelope may define the interior relative humidity level that can be safely maintained without risk of damage to the envelope.

When improved vapor control is necessary in an existing building, it may be appropriate to enclose the collections space with a new vapor-controlled interior partition, separated from the interior face of the exterior wall by a substantial air space. This approach, often called **box-in-box**, effectively cascades the total moisture gradient across multiple assemblies, decreasing the moisture gradient across the exterior wall assembly, and can effectively resolve air control issues. This approach may be applied to roof and ceiling assemblies when necessary.

In any case, identification of effective performance improvements for existing building envelopes must be based on evidence

Table 11 Type of Control, Climate Zone, and Typical Envelope Performance Necessary

	Liquid Water Loads (Table 12)		Hygrothermal Loads (Table 12)	Necessary Envelope Performance (Table 12)				Design Considerations
Type of Control	**Rain Exposure (Moisture Zone)**	**Source Moisture**	**International Climate Zone(s)**	**Thermal Flows**	**Air Leakage and Stack Effect**	**Moisture Vapor**	**Hygrothermal Analysis**	**Comments**
AA Precision control	All	●	All	●	●	●	■	Building envelope should be separated from interior enclosure of collections space.
A1, A2 Precision control with seasonal changes	All	●	5A, 5B, 5C and colder	●	●	●	■	Building envelope should be separated from interior enclosure of collections space.
	All	●	4A, 4B, 4C	◉	◉	◉	❖	
	All	●	3A, 3B, 3C and warmer	●	●	●	■	Building envelope should be separated from interior enclosure of collections space.
	All	●	6A, 6B, and colder	●	●	●	■	
B Limited control with seasonal changes	All	●	5A, 5B, 4A, 4B, 3A, 3B	◉	◉	◉	□	
	All	●	5C, 4C, 3C	◉	○	○	□	
	All	●	2A, 2B and warmer	◉	●	◉	❖	
	All	●	All B	◉	◉	○	□	Where diurnal temperature differences are large, insulation may be needed to prevent high relative humidity at night caused by cooling.
C Prevent relative humidity extremes	All	●	5C, 4C, 3C	◉	○	○	□	
	All	●	All other zones	◉	◉	◉	□	Moderated or controlled envelopes can eliminate or substantially reduce size of HVAC equipment.
D Prevent very high relative humidity	All	●	All B	◉	○	○	□	Where diurnal temperature differences are large, insulation may be needed to prevent high relative humidity at night caused by cooling.
	All	●	5C, 4C, 3C	○	○	○	□	
	All	●	All other zones	◉	◉	◉	□	Moderated or controlled envelopes can eliminate or substantially reduce size of HVAC equipment.
Cool store	All	●	All	●	●	●	❖	Specialized collections enclosures separate from the exterior building envelope are typically used. Where cooling loads are low (e.g., climate zone 6 and colder) and in some subgrade locations, specially designed exterior envelopes can achieve this performance without a separate interior enclosure.
Cold or "frozen" store	All	●	All	●	●	●	❖	Specialized collections enclosures separate from the exterior building envelope are typically used.
Relative humidity controlled below critical value	All	●	All	●	●	●	❖	Vapor control is a priority in moisture zones A and C, and thermal control is typically needed to maintain relative humidity stability below critical values.

Legend:
Moisture and hygrothermal loads: ● Controlled ◉ Moderated ○ Optional
Hygrothermal analysis: □ Necessary ❖ Recommended □ Optional

Table 12 Examples of Typical Envelope Assemblies or Features

Loads	Minimum Performance	Examples
Liquid water loads	●	**Source moisture control** is typically achieved by intercepting and diverting rain and surface and subgrade water away from above- and below-grade parts of building envelope. Examples: roof drainage systems; surface water drainage systems, including swales and piped systems; drainage planes in above-grade walls; subgrade drainage systems consisting of waterproofing, drainage planes on subgrade walls and under slabs, and subgrade piping.
Thermal flows	●	**Controlled thermal flows** are typically achieved by building envelopes that meet current ASHRAE *Standard* 90.1 requirements for building envelopes.
	◉	**Moderated thermal flows** are typically satisfied by • *Climate zones 4 and higher*: building envelopes with robust wall construction and thermal mass, retrofitted insulation, storm windows, or insulated glazing and insulated ceiling planes in the uppermost story attics in climates zones 4 and higher. • *Climate zones 3 and lower*: radiant barriers in attics or a double roof with a ventilated cavity. • *Climate zones 5 and lower*: summer solar gain through glazing may be moderated by low window-to-wall ratios, or by fixed or operable features such as *brise soleil*, roller shades, shutters, or blinds.
	○	Controlled or moderated thermal flow measures provide benefits but may not be necessary.
Air leakage and stack effect	●	**Controlled air leakage** is typically achieved by building envelopes that meet current ASHRAE *Standard* 90.1 requirements for building envelopes. **Controlled stack effect** is typically achieved by minimizing number of open communicating stories or by mechanical destratification among floors. **Moderated air leakage** is typically satisfied by limiting overall air intrusion. Examples include: air barriers in walls and in the ceiling plane of uppermost stories, weather-stripping of door and window openings, vestibules or buffer spaces at heavily used entry points.
	◉	**Moderated stack effect** is typically limited by not more than two open communicating stories plus air leakage improvements. If building pressurization is used, interior pressure should be slightly negative during heating and humidification and slightly positive during cooling and dehumidification.
	○	Controlled or moderated measures provide benefits but may not be necessary.
Moisture vapor	●	**Controlled moisture vapor flows** are typically achieved by building envelopes that meet current ASHRAE *Standard* 90.1 requirements for building envelopes.
	◉	**Moderated moisture vapor flows** are typically satisfied by building envelopes with robust envelope construction and limited vapor permeability, such as thick masonry walls. For less robust envelope construction, such as stud-framed walls or wood-framed ceilings in the uppermost stories and wood-framed floors over crawlspaces and basements, a vapor retarder may be needed.
	○	Any controlled or moderated measures provide benefits but may not be necessary.

Note: See also Chapter 64 for moisture management in buildings.

from documentary research and physical investigation of the envelope, and can be often informed by environmental monitoring and hygrothermal analysis.

6.3 TEMPERATURE AND RELATIVE HUMIDITY

This section explains the structure and use of Tables 13A and 13B, which list a set of options (rows) and their characteristics (columns). The tables are not meant to be a simple recipe box. They quantify and codify many options that will be judged by the criteria in Figure 1: the preservation needs of the collection, occupants' needs, capability of the current building envelope, feasibility of a new envelope, and long-term costs and sustainability of HVAC systems. It is an iterative process, exploring and reconciling inevitable conflicts.

Firstly, climate loads and envelope performance, as discussed previously, must be understood. A very common error in cultural institution HVAC specifications is a disconnect between the design specifications and what the envelope (and budget) can support over time.

With awareness of envelope limitations, select the Type of Collection and Building (column 1) that most closely matches the current project. Table 13A applies to general requirements of mixed permanent collections, and Table 13B applies to specialized spaces for specific materials: loans, low-temperature storage, and collections with critical relative humidity requirements.

Within the Type of Collection and Building selected (column 1), examine the Collection Benefits and Risks summarized in the far-right column. For Table 13B, this is usually a straightforward decision: only one option (or various degrees of cold) either is or is not feasible with the project budget in terms of high-performance envelope and HVAC.

Table 13A concerns more common situations, but is more complex.

For the type of collection and building selected (column 1) examine the collection benefits and risks summarized in the various options of the far-right column (only one option is described for the simplest type of building, control type D). If the collection contains only one type of object, or if the most important objects are of one type, then a more precise analysis of benefits and risks can be made using information in the section on the Environmental Effects on Collections.

For each option considered, analyze as well as possible the (1) benefits to the collections, (2) remaining risks to the collections, and (3) costs in terms of the building and HVAC system required. For the latter, it is necessary to understand columns 3 to 6. There are four components to a specification: long-term outer limits, annual averages, seasonal adjustments, and short-term fluctuations and space

Table 13A Temperature and Relative Humidity Specifications for Collections in Buildings or Special Rooms

Type of Collection and Building	Type of Control	Long-Term Outer Limits[a]	Annual Averages	Seasonal Adjustments from Annual Average[b]	Short-Term Fluctuations plus Space Gradients[c]	Collection Benefits and Risks[d]
Museums, Galleries, Archives and Libraries in modern purpose-built buildings or purpose-built rooms **Temperature at or near human comfort**	**AA** Precision control, no seasonal changes to relative humidity	≥35% rh ≤65% rh ≥10°C ≤25°C	For permanent collections: historic annual average of relative humidity and temperature. In public display areas, human comfort temperatures can apply.	No change to relative humidity Increase by 5 K; Decrease by 5 K	±5% rh, ±2 K	Mold germination and growth, and rapid corrosion avoided. No risk of mechanical damage to most artifacts and paintings. Some metals, glasses, and minerals may degrade if rh exceeds a critical value. Chemically unstable objects deteriorate significantly within decades at 20°C, twice as fast each 5 K higher.
	A1 Precision control, seasonal changes in temperature and relative humidity	≥35% rh ≤65% rh ≥10°C ≤25°C		Increase by 10% rh. Decrease by 10% rh. Increase by 5 K; Decrease by 10 K	±5% rh, ±2 K	Mold germination and growth, and rapid corrosion avoided. No mechanical risk to most artifacts, paintings, photographs, and books; small risk of mechanical damage to high-vulnerability artifact. (Current knowledge considers the specifications A1 and A2 as causing the same low risk of mechanical damage to vulnerable collections. Slow seasonal adjustment of 10% rh is estimated to cause the same mechanical risk as rapid fluctuations of 5% rh, because of significant stress relaxation occurring within three months of a slow transition.)
	A2 Precision control, seasonal changes in temperature only	≥35% rh ≤65% rh ≥10°C ≤25°C		No change to relative humidity. Increase by 5 K; Decrease by 10 K	±10% rh, ±2 K	Chemically unstable objects deteriorate significantly within decades at 20°C, twice as fast each 5 K higher.
Museums, galleries, archives, and libraries needing to reduce stress on their building (e.g., historic house museums), depending on climate zone[e]	**B** Limited control, seasonal changes in relative humidity and large seasonal changes in temperature.[f]	≥30% rh ≤70% rh ≤30°C	For permanent collection: historic annual average of relative humidity and temperature.	Increase by 10% rh Decrease by 10% rh Increase by 10 K Decrease by up to 20 K	±10% rh, ±5 K	Mold germination and growth, and rapid corrosion avoided. Chemical deterioration halts during cool winter periods No risk of mechanical damage to many artifacts and most books. Tiny risk to most paintings, most photographs, some artifacts, some books. Moderate risk to high-vulnerability artifacts. Objects made with flexible paints and plastics that become brittle when cold, such as paintings on canvas, need special care when handling in cold temperatures. Chemically unstable objects deteriorate significantly within decades at 20°C, twice as fast each 5 K higher.
	C Prevent relative humidity extremes (damp or desiccation) and prevent high temperature extremes.	≥25% rh ≤75% rh ≤40°C[g]	Within 25% to 75% rh year-round. Temperature usually below 25°C		Not continually above 65% rh for longer than *X* days.[h] Temperature rarely over 30°C	Chemical deterioration halts during cool winter periods. Mold germination and growth, and rapid corrosion avoided. Tiny risk of mechanical damage to many artifacts and most books; moderate risk to most paintings, most photographs, some artifacts, some books; high risk to high-vulnerability artifacts Even greater care is needed than provided in B when handling objects made with flexible paints and plastics that become brittle when cold, such as paintings on canvas. Chemically unstable objects deteriorate significantly within decades at 20°C, twice as fast each 5 K higher.
Collections in open structured buildings, historic houses	**D** Prevent very high relative humidity (dampness)	≤75% rh	Relative humidity reliably below 75% rh		Not continually above 65% rh for longer than *X* days.[h]	Chemically unstable objects deteriorate significantly within decades at 20°C, and twice as fast each 5 K higher. Conversely, cool winter season can extend their life. Mold germination and growth, and rapid corrosion avoided. High risk of sudden or cumulative mechanical damage to most artifacts and paintings because of low-humidity fracture; but avoids high-humidity delamination and deformations, especially in veneers, paintings, paper, and photographs.

Table 13B Temperature and Relative Humidity Specifications for Collections in Buildings or Special Rooms

Type of Collection and Building	Type of Control	Specifications	Collection Benefits and Risks
Temporary exhibit space and unpacking space for loaned objects	Conditions will be stipulated in loan agreements[i]	Conditions will be agreed between lender and borrower. Based on the historic climate to which the object is accustomed, and a risk assessment of the borrower's environment and that of the transit process. Solutions to protect objects from climate shock should first be found in the creation of microclimates (showcases, glazing, etc., potentially using buffering).[e,i]	Benefits and risks are assessed by the lender, and contractual specifications based on this assessment. Often, assessment is highly risk averse, precautionary. For the borrowing institution, the benefits are increased access to popular objects by visitors; risks are monetary and reputational damage if climate control does not meet conditions outlined in the loan contract.
Chemically unstable organic materials in modern purpose-built buildings or purpose-built rooms[j]	**Cool**	8 to 16°C, 30 to 50% rh As defined in ISO *Standard* 18934:2011. IPI (Adelstein 2009) uses an anchor of 12°C.	The benefit of low temperature storage is extended lifetime of objects that will be lost within a generation or two at room temperature. See the section Chemical Damage for details on quantifying the benefits. Biological damage is also much reduced. The risks are the many side-effects of such systems: high humidity or condensation during malfunctions, water exposure. Objects must be packaged appropriately to reduce risk of condensation during retrieval, and a transition space with intermediate climate may be required. Hourly, daily, and even longer humidity fluctuations do not affect most properly packaged objects at low temperatures.[e]
	Cold	0 to 8°C, 30 to 50% rh As defined in ISO-18934:2011. IPI (Adelstein 2009) uses an anchor of 4°C.	
	Frozen	–20 to 0°C, 30 to 50% rh As defined in ISO *Standard* 18934:2011 and Adelstein (2009)	
Unstable metal or glass in modern purpose-built buildings or purpose-built rooms	**Relative humidity controlled to avoid a critical relative humidity of a salt or hydrate**	Many different critical relative humidities for various materials. See the section on Critical Relative Humidity for details and sources of information.	

Notes for Tables 13A and 13B:

[a]Long-term limits apply to combination of selected annual average plus selected seasonal adjustments. See Figure 15 for examples on a psychrometric chart.
[b]Rate of seasonal adjustments in relative humidity set point should not exceed the short-term fluctuation limit each 30 days, and the rate for temperature adjustment should not exceed the short-term fluctuation limit each 7 days (e.g., for A1, a seasonal adjustment can be no faster than 5% rh change per 30 days and 2 K change per 30 days.
[c]Short-term fluctuation means any fluctuation shorter than the times specified in footnote b for rate of seasonal adjustment (i.e., 30 days for relative humidity fluctuations, 7 days for temperature fluctuations). Space gradient refers to the differential in relative humidity or temperature between any two locations where objects are permitted to be placed in the controlled space (designers can specify out-of-limit locations, such as a specific distance to exterior walls and supply vents).
[d]See Table 3 for examples of objects in each sensitivity category, and Table 5 for lifetimes of objects at various temperatures.
[e]Microclimates (enclosures, packaging) can achieve the same relative humidity control as type AA or A in a much less controlled space (e.g., B, C, or D), and with much greater long-term reliability. See the section on Response Times of Artifacts.
[f]Long-term risk (≥10 years) of mechanical damage because of relative humidity fluctuations is dominated by the probability of extreme events such as system overload or failure in winter. Control type B with high reliability is less risk to collections than AA or A with poor reliability.
[g]An upper temperature limit is provided for a mixed collection that may contain objects with waxy materials that deform irreversibly beginning at ~40°C. This limit is set more cautiously for type B control, 30°C than type C control.
[h]From Figure 3, mold germination becomes very slow, but not impossible, in the range of 75 to 65% rh.
[i]In general, professional guidance currently refers to Bizot, which stipulates outer limits of 40 to 60% rh, and 16 to 25°C throughout the year. Ratified as of 2016 by ICOM-CC, IIC, AIC, AAMD, NMD, BM, and Bizo. See Michalski (2016) for details.
[j]See Table 5.

gradients. Rather than defining a specification and then estimating the benefits and risks, Tables 13A and 13B consider practical categories of benefit and risk, and then define the range of specifications consistent with those benefits and risks.

Column 3 (long-term outer limits) specifies the boundaries beyond which risk climbs unacceptably for many mixed collections (in broad agreement with recent guidelines such as BSI PAS *Standard* 198:2012). The upper limit of relative humidity is based on mold risk (see the section on Biological Damage). The lower limits of relative humidity and temperature are based on mechanical risk, such as the probability of fracture of organic materials (see the section on Mechanical Deterioration). The upper limit of temperature is based on the risk of chemical decay, which climbs exponentially with increase in temperature (see the section on Chemical Deterioration). These generalized limits for mixed collections do not replace a thorough determination of the specific vulnerabilities of specific collections based on information in the section on the Environmental Effects on Collections, alongside consultation with conservators and scientists. For example, a (clean) stone sculpture collection is not at risk from high summer relative humidity or high temperature (pollution and vandalism are more likely risks).

Column 4 (annual averages) assumes design for permanent collections, not loans. To minimize mechanical risk, and to reduce energy costs and building stress, annual averages can be set at local historic annual averages, to which the collection has mechanically acclimatized. In public display areas, a range of human comfort temperatures can apply, but cannot be set beyond the long-term outer limits.

Columns 5 (seasonal adjustments) and 6 (short-term fluctuations) are similar to older versions of this table, although some ranges are now wider. Seasonal adjustments are constrained by the long-term outer limit, although short-term fluctuations are allowed to extend beyond this limit. For a discussion of dual set-point control as a means to achieve these parameters, see the section on Controls Design.

Figure 15 shows the interrelation of the four specification components and the role of long-term outer limits for an example of control type A1. The long-term outer limit (35 to 65% rh, 10 to 25°C is defined by the solid-line box. For this project, the annual average is 21°C and 42% rh, shown by the black dot; seasonal adjustments are ±10% rh, +5 K, and –10 K, although application of these seasonal adjustments is constrained by the upper temperature and lower humidity limits of the long-term outer limit. This combination of annual average and seasonal adjustment is shown by the dashed-line box. Short-term fluctuations of ±5% rh and ±2 K are added, and the

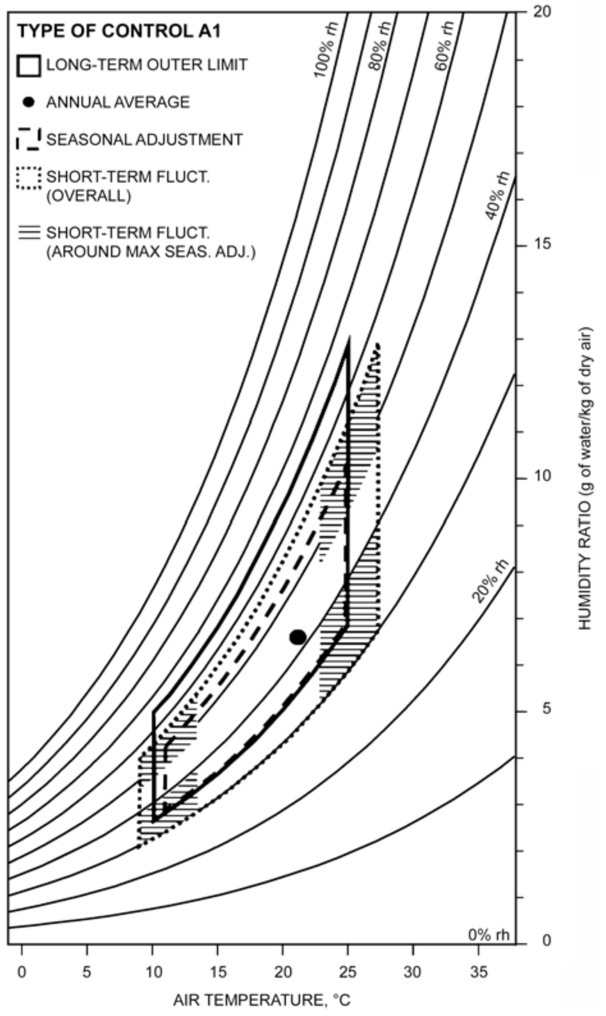

Fig. 15 Psychrometric Depiction of Control Type A1

total range is defined by the dotted-line box. The sections of the dashed-line box that go beyond the long-term outer limits are permissible because they represent short-term fluctuations.

To remain within the bounds of mechanical risk defined for each type of control, it is essential that the annual average be both historically accurate and consistent into the indefinite future. The example in Figure 15, for example, allows short-term relative humidity to drop to 30% because the historic annual average was claimed to be an unusually low 42% rh. At the same time, however, selecting this annual average does not allow short-term humidity to go above 57% rh in summer. Estimates of mechanical risk for each type of control are based on the total range of relative humidity values over many years. If, next year, the annual average setting is changed to 50% rh to justify a summer high of 65% rh, A1 control can no longer be claimed. In a project where historic averages are unknown, select annual averages that are consistent with future needs (e.g., sustainability) or a known critical relative humidity for part of the collection. Given the fixed boundary of the long-term outer limits, the maximum seasonal adjustments are available only for annual averages near the middle of this bounded area.

6.4 AIRBORNE POLLUTANT CONTROL STRATEGIES

In the past, recommendations for maximum pollutant concentrations allowed in museums and archives were based on levels that only limited numbers of major institutions could achieve, and that were measurable with commercial monitors or with sensitive analytical methods (Mathey et al. 1983; NARA 2002; NRC 1986). In the 1980s, little information existed on the impact of some pollutants, such as acetic acid and nitrogen dioxide. As a precaution, “use best available technology’ was the stated advice for those pollutants. This expression became popular and, consequently, many institutions requested it as specification, or requested very low limits of pollutant concentrations without justification. Those low limits were often hard to achieve and maintain. Apart from the cost, it also raised the issue of sustainability. In practice, target levels for pollutants were often simply neglected or ignored.

A common analytic method for measuring specific gaseous pollutants uses **diffusive samplers**. A chemical compound in a diffusion tube absorbs a specific pollutant for a fixed amount of time, typically 3 weeks. After the sampling, collected pollutants are sent to a laboratory for analysis. This method can detect most pollutants of interest for museums with good limits of detection (Grzywacz 2006). Particulate matter of different aerodynamic diameters can be measured with precision using a cascade impactor (Krupinska et al. 2013). However, unlike monitoring of temperature and relative humidity, measuring different pollutants is expensive and many museums will avoid doing it unless there is serious doubt about the actual concentration of some pollutants or damage is reported on an object. Qualitative and semiquantitative tests include pH testing, which gives an indication of the acidity level (Tétreault 1992); coarse particle deposition on glass or sticky slides (Lloyd et al. 2007); and metal corrosion electronic sensors or metal coupons, which give information on the corrosiveness of the environment (Coughlin 2011; Thickett et al. 2013). Detection limits of some of these tests can be an issue, as can the fact that they may fail to detect the most harmful compounds for the collection. Test results cannot easily be transposed to specific pollutant concentrations. Even with quantitative measurements, monitoring has some limitations. Not all rooms and enclosures are usually tested, and measurements at a specific location and time may provide limited information: pollutant concentrations can vary based on parameters such as changing seasons, crowd density, space gradients, product aging, and HVAC system adjustments. Measuring pollutant concentrations in a new building before its official opening will not give the same results as a building filled with collections, visitors, and older enclosures. It is best to consider a global preventive strategy before starting a monitoring campaign without being sure the results will provide the proper answer.

Table 14 offers a control strategy for pollutants based on a cost benefit scale and on the reduction of uncertainties of the risk evaluation. The table has three levels of control, and makes recommendations based on the building and enclosure; additional considerations are discussed for each level of control.

- **Basic level:** recommended dust filter performance at least equal to that recommended for office spaces (typically minimum efficiency reporting value [MERV] 11) or as specified by an accreditation program such as the U.S. Green Building Council’s (USGBC) LEED Indoor Environmental Quality credit (EQc) 5.1 (MERV 13) (ASHRAE *Standard* 52.2-2017). If appropriate, enclosures should be well sealed to prevent infiltration of pollutants present in the room. Consultation with conservation professionals can provide information on the global strategy for pollutant control, advise on which objects are typically at risk in museums, and provide guidelines for proper selection of products when building enclosures. The goal of the basic level is to avoid or minimize the most common short- and medium-term damage caused by pollutants in museums and archives, at reasonably low costs.
- **Intermediate level**: dust filtration efficiency should be higher than for the basic level (Tétreault 2003). Qualitative or semiquantitative monitoring is suitable in the new installation (rooms and enclosures), as well as some testing of products before use. Some deeper

Table 14 Strategies for the Control of Airborne Pollutants

Level of Control	Building with HVAC system	Display Cases and Storage Cabinets/Boxes	Considerations
Basic			
Basic control of fine particles and avoiding common problems in enclosures.	- Provide basic fine-particulate filtration such as that recommended for office space regulation or for LEED certification (EQc 5.1). - Locate HVAC fresh air intake away from pollutant sources and keep windows closed.	- In closed spaces containing objects, select and use materials recommended by conservation professionals.[a, b] - Ensure airtightness of enclosure (to prevent external pollutant infiltration) if there are no significant amounts of pollutants generated by objects or materials (see Table 9).	- Identify objects (e.g., lead, silver, soda-rich glasses, cellulose papers, calcareous objects) that may be at high or moderate risk from pollutants (see Table 9). - Address pollutants by using a systematic approach: avoid, block, dilute, and sorb.[c]
Intermediate			
Improved control of fine particles and reduced uncertainty and risk of damage in enclosures.	- Use medium-efficiency fine-particulate filtration or select filter performance based on outdoor concentration provided by local authority. - Seal concrete and wooden surfaces (walls, floor, shelves, etc.).	- Test or investigate materials and objects to identify those that contain harmful compounds.[b,c] - Monitor enclosed environment with low-cost monitoring techniques (risk of low sensitivity).[c,d]	- Consider adjusting relative humidity and temperature levels, which often affect pollutants' reactions on objects.
Advanced and special cases			
Optimal control of airborne pollutants in room; better quantification of preservation performance, which allows optimal strategies for improvement.	- Use high-efficiency fine-particulate filtration or select filter performance based on risk analysis result. - Use gas-phase filtration media if outdoor pollutants in surrounding environment or indoor-generated pollutants are an issue.	- Estimate or measure airtightness of enclosure.[e] - Options for special needs: positive air pressure,[c] gas sorbent,[c] anoxia system.[f]	- Maximal average pollutant concentrations for a general collection (excluding moderate- and high-risk objects) should stay below 1000 μg/m³ (400 ppb) for acetic acid; 1 μg/m³ (0.7 ppb) for hydrogen sulfide; and 10 μg/m³ for nitrogen dioxide (5 ppb), ozone (5 ppb), and fine particles. These limits should prevent low-level damage to objects for at least 1 year.[c] Controlling these key pollutants makes it very likely that other pollutants will be controlled as well.
	- Quantitatively monitor[d] concentration of key pollutants and compare against suggested limits or with institutional targets. - Do risk analysis of outdoor, room, and enclosure pollutant concentrations and determine most efficient solutions for minimizing impact of pollutants on specific objects or on collection in general. Adjust institutional target if necessary.		

[a]Tétreault (2017), [b]Hatchfield (2002), [c]Tétreault (2003), [d]Grzywacz (2006), [e]Calver et al. (2005), [f]Maekawa (1998).

investigation can be done to identify vulnerable objects and to determine whether emissions from the collections themselves can be a risk to other objects. This will not necessarily improve conservation of the collection from pollutants, but it reduces uncertainties related to the conservation strategies in place. The strategy can be adjusted, if needed, in the light of the results.

- **Advanced level:** quantitative measurements should be taken of the airborne pollutants (gases and fine particles) outside the institution as well as in some rooms and enclosures containing very significant and vulnerable objects. This can be done for a new installation, during renovations, or as needed. The maximum pollutant concentrations allowed can be based either on the limits in Table 14 for a general collection, or on the target for the general collection and/or for some objects established by the institution. Conservation professionals can help assign pollutant target concentrations aligned with the institution's preservation policy. Quantitative measurement of the air exchange rate for enclosures that need a high airtightness is also recommended. Knowing the airtightness also helps determine the quantity of silica gel or any sorbent needed for an optimal climate control in the enclosure.

Measuring particle and gaseous pollutant concentrations and airtightness of enclosures can provide better confidence on the strategy in place, and can support a proper risk analysis for the overall collection or for specific objects (Krupinska et al. 2013). Local environmental data, obtained from different levels of government agencies, can provide useful information on the outdoor climate. This analysis can help determine the filtration performance needed for rooms and for enclosures holding specific objects or collections. If the room is well controlled, leakage from enclosures may not be an issue. However, if it is difficult to achieve adequate control in the room, then the collection can be better protected inside enclosures. Unfortunately, not all objects can be placed in enclosures (e.g., because of size or access). The length of exhibition/exposure allowed can also be adjusted based on the results of the risk analysis.

For very vulnerable or/and significant objects, some special features can be considered for optimal preservation: positive-air-pressure enclosures (preventing dust infiltration in leaky cases), enclosures with gas sorbents (to reduce the amount of undesired gases generated inside or infiltrated), and low-oxygen enclosures (to minimize oxidative reactions, including photo oxidation). See Table 14 for references.

6.5 CONTROL STRATEGIES FOR OBJECTS WITH HIGH VULNERABILITY TO POLLUTANTS

Some objects tend to be more vulnerable to inadequately controlled environments. Those objects need special considerations that HVAC professionals should be aware of. A conservation professional can also assist with developing preservation strategies.

Silver

Silver is very sensitive to reduced sulfide compounds, mainly hydrogen sulfide (H_2S) and, to some extent, carbonyl sulfide (COS). Sulfur sources are many: the outdoors, from people in the room, and from products and collections inside enclosures. It is usually best to keep silver objects in airtight enclosures with no sulfur-emitting products. Consult the combustion section in the safety material sheet (SMS) for specific products to see if they contain sulfur compounds; products that contain sulfur compounds should be avoided. It is also wise to confirm the absence of sulfur compounds in the product by running a spot test, such as the lead acetate test, Oddy test, or equivalent (Robinet and Thickett 2003; Tétreault 2003). The same strategy can be applied for the preservation of copper. The LOAED for H_2S for silver is 0.10 μg/(m^3·yr) (0.071 ppb/yr) and 1.0 μg/(m^3·yr) (0.71 ppb/yr) for copper (Tétreault 2003). Complete dryness will not stop tarnishing, but will minimize it.

Lead

The most harmful vapor to lead is acetic acid. Lead is not usually at risk of corrosion in a room but may be in enclosures. Any organic-acid-emitting products or objects should be avoided. Lead may never be safe in the presence of wood, painted wood products, or freshly applied sealants or adhesives. The worst situation would be having lead present in a freshly painted enclosure with paint formed by oxidative polymerization (e.g., oil based paint). Polymerization releases aldehydes, organic acids, and peroxides. Those peroxides can convert aldehydes into organic acids (Raychaudhuri and Brimblecombe 2000; Tétreault 2011). Enclosing lead objects in a display case freshly sealed with acetoxy-cured silicone also puts the lead at high risk of corrosion. A relative humidity kept below 35% prevents corrosion by organic acids above the NOAEL (170 ppb).

Calcareous Objects

Calcareous objects (e.g., limestone, ceramics, shells) can react with organic acid vapors, especially when contaminated by chloride or nitrate salts (Halsberghe et al. 2005) in highly humid environments. No data exist to quantitatively assess these objects' vulnerability. As a precaution, it is best to minimize the presence of acid-emitting products or objects in the enclosure as well as relative humidity and temperature fluctuations, and if possible, lower the relative humidity to prevent salt dissolution, reaction, and migration.

Sodium- and Potassium-Rich Glasses

Some historical glasses degrade slowly in the presence of water vapor, resulting in alkali leaching, which can form crystalline corrosion compounds on the surface or modify the structure of the glass. The presence of formic and acetic acids accelerate the leaching (Robinet 2006). These types of glass should be displayed or stored near 40% rh with very little fluctuation (Koob 2006). See van Giffen et al. (2018) for detailed recommendations on climate control for glass. **Enclosures should not contain products that can emit organic acids.**

Colorants

Many colorants (organic pigments and dyes) are known to be sensitive to photooxidation and/or to hydrolysis (Reilly 1998). In addition, some colorants are affected by gaseous pollutants. The most sensitive colorants to nitrogen dioxide, sulfur dioxide, and ozone are curcumin, dragon's blood, aigani, realgar, iron ink, enju, basic fuschin, Brilliant green, pararosaniline, indigo, madder lake, Persian lake, and saffron (Cass et al. 1989; Whitmore and Cass 1989; Williams et al. 1993). Yellow dyes from photographic prints have been found to be affected by acetic acid (Fenech et al. 2010). Artworks with vulnerable colorants should not be displayed long term without protective enclosures, and photograph prints should not be enclosed with products that may release organic acids.

Cellulose Papers

For many decades, sulfur dioxide was thought to be the most damaging pollutant for paper. As its concentration in the environment decreased over the years, it was found that nitrogen dioxide was the main problem for paper. Fine particles and ozone also affect unprotected paper (Bartl et al. 2015; Gurnagul and Zou 1994). At the room level, displaying art on paper without protection (e.g., glazed framing, display cases) is not recommended. However, formic and acetic acid emitted by various organic materials can affect cellulose, but in the presence of aldehydes, the damage is found to be reduced (Tétreault et al. 2013). As a precaution, however, avoid acid-emitting products.

For paper in books, most damage (yellowing, embrittlement) by outdoor and indoor pollutants tends to remain on the margins of the paper sheets, with very slow diffusion into the book. Many archivists will accept some limited deterioration of the pages' edges. If stack or single-sheet papers are framed or protected in airtight boxes, gas filtration in archives and libraries may not be required. The cellulose is best preserved against acid-catalyzed hydrolysis by keeping the relative humidity and temperature as low as possible.

Cellulose Acetate Films

Cellulose acetate films degrade by acid-catalyzed hydrolysis, and acetic acid is the by-product released (Reilly 1993). It is best to preserve films from the 1950s and 1960s in cool or cold rooms (see Table 13B). In ambient conditions, degraded films should ideally be stored in special ventilated cabinets to avoid the risk of damage to other collections. Otherwise, consider enclosing the films in airtight enclosures with moisture sorbents to prevent the ingress of high humidity in the storage area (Nishimura 2015).

Cellulose Nitrate Films

As with any cellulosic material, cellulose nitrate (CN) films degrade by acid-catalyzed hydrolysis, releasing nitrogen oxides. Old CN films, produced mainly from 1896 to 1952, are unstable and must be kept absolutely below 38°C, above which there is a high risk of self-ignition. CN films should be removed from the collection and properly stored according to NFPA *Standard* 40, which provides detailed information on the ventilation requirements. However, it is best to preserve these films in cold rooms (see Table 13B).

Other CN objects (such as faux tortoise shell) do not degrade to the same magnitude as films, but to avoid the risk of damage from nitrogen oxide emissions to other collections, CN objects should be stored either in well-ventilated rooms or in special ventilated cabinets (Coughlin and Seeger 2008). A room with a high load of CN items must also comply with local regulations for explosive and combustible substances.

Difficult-to-Clean Objects

All objects are susceptible to particle deposition, but cleaning of particles is difficult or even impossible for some objects. During handling and cleaning, there is also a risk of physical damage. Example objects include those with powdery pigments or surfaces (e.g., some painted ethnographic objects, butterfly wings); physically fragile objects (e.g., insect collections, filamentous mineral specimens); objects in which fine particles could become lodged in microcracks or interstices (e.g., ivories, painted objects with cracks); and objects with sticky surfaces (e.g., some deteriorated plastics, some polyethylene-glycol-treated wooden waterlogged objects). For these objects, it is best to display and store them in airtight enclosures or in cases with a positive-pressure system. If enclosure is not an option, it is recommended to maintain a minimum distance between visitors and fragile objects: for example, a distance of 1.5 to 2 m reduces dust deposition by 50 to 75% (Lloyd et al. 2007). This distance prevents deposition of coarse particles on objects, but has limited effect on fine particles because of their longer suspension time.

7. CONTROLS DESIGN

Although control technologies for mechanical systems in cultural heritage institutions are similar to those used in the rest of the HVAC field, the control philosophies and logic that determine daily operation of systems that condition collections areas can, and typically should, be quite different. A common criticism of collections environments is the amount of energy required to maintain preservation standards and narrow environmental requirements, especially in structures (historic or otherwise) not designed for that level of control. Updated standards (see the section on Key Considerations) paired with an increased understanding of heritage risk (see the section on Overview of Risks) and how collections materials respond to changes in air conditions (see the section on Environmental Effects on Collections) allow for improved approaches to control and operation (see the section on Design Parameters for Performance Target Specifications) that better achieve sustainability goals while providing appropriate preservation conditions for a variety of materials. Applicable standards as well as preservation and sustainability expectations will have been identified during predesign (see the section on Context and Predesign); outcomes of this process may include selecting a nonmechanical solution to manage the collection environment. If a mechanical solution is required or selected, the control and mechanical design must apply the predesign outcomes, including any design parameters for preservation and sustainability. As mechanical systems move from design and construction into a commissioning/continuous commissioning phase, control and operation should be revisited to assess both achievement of the appropriate environmental conditions as well as energy consumption at individual stages of operation; this combination of appropriate environmental preservation conditions while only using the minimum energy consumption necessary is key to long-term optimal, sustainable operation.

In any cultural heritage application, moisture management and control are almost universally the most critical, difficult, and potentially costly processes to achieve. Moisture's role in determining the overall psychrometric properties of any environment, as well as its central role in most forms of collection degradation, make dehumidification and humidification control primary aspects of the holistic building and system operation. Temperature control, though important for both comfort and preservation, is generally the easier control process, and must be managed to maintain appropriate relative humidity at a given moisture content. To facilitate communication with collections professionals, designers and technicians should be prepared to discuss moisture control in the terms with which the client is most familiar and that map well with collections preservation metrics. Relative humidity is typically the best variable for analyzing risk from deterioration processes that depend on sorbed moisture in objects (see the section on Environmental Effects on Collections). Dew point can also be a useful representation of moisture content, especially for discussions of building envelope performance and deterioration (e.g., window and wall condensation), risks during retrieval of objects from cold storage, or entry of loaned objects during winter. Humidity ratio and enthalpy should be clearly defined when used in communication among the broader design team.

Any controls design should clearly define both the control ranges for temperature and relative humidity and the logical process that governs the operation of the relevant equipment. The sequence of operation should be available as a plain-language document that serves as a master reference for institutional staff (collections and facilities) and guidance to outside contractors (designers, programmers, etc.) for controls or equipment upgrades. This master document should be updated as optimization or other changes in operation dictate.

7.1 PHILOSOPHY

As noted previously, environmental tolerances for cultural heritage collections have largely been redefined through updated science, field observations of environmental impacts on collections, and greater awareness of sustainability considerations. Most collections environments can operate safely within a broader range of temperature and relative humidity conditions than previously understood, leading to new methods and approaches for equipment control and operation to achieve preservation and sustainability goals. Certain environments (e.g., exhibitions with loaned materials governed by an agreement) may still require a narrow band of control, but many collections environments can safely include seasonal adjustments and allow short-term fluctuations without causing damage.

The result is a more complex discussion from the controls design perspective. Information shared and developed during predesign should form the basis of the control philosophy, which should be formalized in a written sequence of operation that provides the logical relationships for how equipment achieves the intended operation. It is critical to recognize that the design sequence of operation is only a model of what is expected to happen: it is likely, even preferable, that the sequence of control will be adjusted during commissioning and optimization. Actual energy loads in the space may be different from models, and it is difficult to predict the effects of collections materials, which may effectively function as heat and moisture sinks in the room environment. Where ratios of hygroscopic material volume to air volume are significant enough, collections may actually buffer environmental changes. Kupczak et al. (2018a) show that, at high ratios, paper collections can reduce fluctuations and energy costs.

Design of temperature and relative humidity controls in cultural heritage settings have traditionally identified a single set point with a dead-band range, and the system works to achieve those set points year-round. With expanded humidity ranges and the use of seasonal temperature control in collections environments, single-point control is no longer the most efficient method. For temperature, occupied collection spaces (where human comfort needs may dictate a narrow range of temperatures throughout the year) are still appropriate candidates for single set-point control. However, low-occupancy collections spaces (e.g., storage) may see both preservation and energy benefits from seasonal temperature adjustments; designs should consider using dual heating/cooling set points or minimum/maximum conditions for seasonal control. Any collections environment, occupied or unoccupied, may benefit from dual relative humidity set points defining where humidification and dehumidification are enabled.

Controls design has two goals:

- Achieving appropriate equipment operation and process management to create and maintain the collection preservation environment defined during predesign
- Using only as much energy as necessary to achieve the desired conditions

Though many cultural heritage institutions or buildings may appear similar on the surface, individual factors such as the following usually require highly individualized controls and equipment designs to match the unique situation (see the section on Context and Predesign):

- Collection type and preservation needs
- Outdoor climate
- Building envelope performance
- Degree of mechanical intervention intended
- Occupancy of collections spaces
- Prioritization of preservation and energy usage
- Institutional capital, operational, and utilities budgets

These factors also heavily influence optimization: similarly constructed buildings and preservation environments (e.g., many offsite library/museum storage facilities) commonly optimize differently for preservation and energy based solely on geographic location and exterior environments, even when many other variables are the same.

7.2 ZONING

An air-handling zone refers to the group of spaces that an air-handling unit (AHU) serves in a building. Zoning in cultural heritage facilities can be broken down into four simple groups, each with different requirements for control. Generally, regardless of zoning, system control should be based on some combination of sensors placed in the collection space; return air sensors can be used as a reference point, but should not be used as the control point in cultural heritage applications. The four typical zoning configurations are as follows.

One AHU to One Space. Desirable for fine environmental control. Control should be based on a temperature/relative humidity (T/RH) sensor in the collection space. Control from return air sensors may not accurately represent what occurs in the space.

One AHU to Many Spaces. Best when spaces are used for the same purpose, have similar criteria for interior space conditions, and have similar interior and exterior thermal and moisture loads. Mixed zones (i.e., collections and noncollections) generally lead to suboptimal preservation conditions or energy use. In collections or mixed occupied collections zones, each individual space should have a T/RH sensor. Control can be based on either high/low readings from individual spaces that will enable a process, or on a zone average of readings from all space sensors. Using a zone average for control can lead to parts of the zone being out of the defined operational parameters, especially in rooms with an external wall or roof exposure. These areas may require either mitigation of the load or air rebalancing for correction. If high/low readings are used, conditions in other subzones must be monitored to ensure that they do not go out of specification. Using a blended return air sensor may lead to inaccuracy or control issues, depending on where return air is being pulled from within the zone.

Many AHUs to One Space. Used in large footprints, most commonly in storage, large galleries, or reading rooms. This strategy is especially useful if different parts of the space are exposed to different loads over a 24 h period (e.g., solar exposure). Control should be based on subzones in the space with individual T/RH sensors: control from return air sensors may not accurately represent what occurs in the space. In this configuration, control and sensor placement should be considered carefully to limit the potential for units to operate suboptimally; for example, the average room condition may register as acceptable, though individual units are performing dissimilar operations (e.g., one system is cooling and the other heating).

Many AHUs to Many Spaces. Typically found in large, multilevel footprints (e.g., multilevel library/archives storage); especially useful if different parts of the space are exposed to different loads over a 24 h period (e.g., solar exposure). Control should be based on subzones in the spaces with individual T/RH sensors, because control from return air sensors may not accurately represent what occurs in the space. For this configuration, carefully consider control and sensor placement to limit the potential for units to operate suboptimally; for example, the average room condition may register as acceptable, though individual units are performing dissimilar operations (e.g., one system is cooling and the other heating).

Zone design, adjacencies, and other aspects of functional organization should be part of early predesign discussions to optimize design for preservation and energy usage, as well as to rightsize systems for efficient initial capital investment.

Table 1 describes building space types in typical cultural heritage facilities, and should inform decisions of physical zoning and control. Ideally, an HVAC zone should consist of physical spaces that require similar environmental control. For many cultural heritage institutions, there are three general environmental zones to consider:

- **Occupied noncollection spaces** where human comfort is typically the priority. They require outdoor air and temperature control, but little moisture control (only for human comfort). These concerns may not be as pertinent for noncollection spaces that are typically unoccupied.
- **Occupied collection spaces** require outdoor air during occupied periods, human comfort temperatures, and moisture control for collection preservation. Systems may dehumidify and humidify based on climate zone (see Table 10 and Figures 12 and 13). Examples include galleries, reading rooms, and collection workspaces, and may constitute a large percentage of the building footprint. *Note*: a common issue is whether to treat certain offices as collection spaces. This should be considered carefully, not only for the added capital and operating cost, but also for risks to the collection if offices are not so treated and are nonetheless used for collections display or storage.
- **Storage environments** (typically unoccupied collection spaces) require temperature and moisture control that is optimized for long-term preservation. Outdoor air may be reduced or eliminated entirely, based on occupancy or other requirements. Depending on the institution, examples include typical low-occupancy storage environments (e.g., library and archives stacks), or truly unoccupied collection spaces (e.g., cold or low-oxygen storage).

Mechanical systems and buildings function best when AHUs and zones are logically divided according to purpose. System and controls designs should avoid mixing collection and noncollection spaces wherever possible and resist the tendency to accept downstream sub-zone controls (e.g., VAV/reheat designs) as immediate solutions to zoning issues. Such designs will invariably be less energy efficient over time, and commonly lead to problems maintaining conditions for the preservation environment as human comfort will take priority.

7.3 BASIC PROCESSES

Cultural heritage facilities perform four basic psychrometric processes on a moving airstream to control internal environments using mechanical intervention (Figure 15):

- **Heating:** raising sensible or dry-bulb temperature, as preheat, reheat, or heating for downstream temperature control. May be accomplished by various equipment, ranging from direct and indirect fired heaters to electric, hot-water, or steam coils. In certain settings, heating may be by nonforced-air systems, using other convection or radiant technologies.
- **Cooling:** decreasing sensible or dry-bulb temperature, commonly for downstream temperature control but occasionally as precooling ahead of some components (e.g., energy wheels) for increased efficiency. Typically accomplished either by direct-expansion (refrigerant-based) cooling or by chilled-water or glycol coils.
- **Dehumidification:** reducing moisture content for the specific purpose of maintaining a safe range of relative humidity at a given temperature condition. Equipment varies from common subcool/reheat coil designs, to various configurations of desiccant or energy wheels, whether as components in a larger air handler design or as a stand-alone package unit.
- **Humidification:** increasing moisture content to attain a minimum relative humidity condition in a downstream space, typically in arid or seasonally dry or cold climates. Humidification can be performed by isothermal (steam) or adiabatic (evaporative) systems, and may be located at the primary unit or in downstream ductwork.

The sequence of operation should clearly identify the logic of when each process occurs; for example, that humidification begins once the space drops below 35% rh, or that sensible cooling and sensible heating cannot be engaged at the same time.

7.4 OUTDOOR AIR AND VENTILATION

Outdoor Air

Introducing outdoor air into interior environments typically increases sensible and latent system loads and serves as the primary source of particulate and gaseous filtration loads. In collections spaces, where the primary goal is maintaining the appropriate interior temperature and relative humidity conditions, outdoor air quantities should be restricted to the minimum necessary for occupancy based on local code. For nonoccupied collections spaces and spaces with periods of zero and nonpeak occupancy (e.g., galleries, reading rooms, workspaces during closed periods), designs should incorporate means of further reducing outdoor air volumes, even to fully closed, based on actual need. CO_2 sensors and modulating dampers can help automate this process, and may allow for flexibility with certain code requirements. Particular consideration of outdoor air requirements should be given to spaces housing materials that may emit hazardous substances (e.g., radon) or require specific outdoor air volumes because of fire code.

Air-Side Economizers

Economizer controls, typically intended for energy-savings/free-cooling of interior environments, should generally be avoided in cultural heritage applications. Dry-bulb temperature and enthalpy controls may allow inappropriate levels of moisture (either too wet or too dry) into the airstream, increasing latent loads for dehumidification and humidification compared to the return airstream. Although dry-bulb temperature and dew-point controls can be programmed to allowable conditions, they generally offer reduced energy benefit compared to other energy-reduction strategies because, generally, most outdoor environments align with both temperature and dew-point requirements only for short periods. Economizers also increase risks to interior environment maintenance: control failure or mechanical failure of outdoor air dampers on ductwork sized to allow for 100% of the system volume can quickly create significant environmental issues. Air-side economizers should not be used unless (1) bin analysis or other study shows outdoor air moisture content to be favorable for an economical number of hours, and (2) favorable outdoor air can be reliably selected by the control system by combined dry-bulb temperature and dew point comparisons.

Pressurization

Positive air pressurization has been frequently used in cultural heritage facilities to minimize incursion of external loads into controlled collections environments. However, this practice often increases energy consumption, and in some cases increases the risk to the building envelope, particularly in historic structures. With improved envelope design and appropriate zoning and adjacency design, positive air pressurization is no longer an absolute requirement in cultural heritage settings. Neutral pressurization is typically an appropriate goal; avoid negative air pressurization. In multiple-story buildings, stack effect (discussed later) creates unavoidable pressurization in upper floors; airflow design should not exacerbate this problem. Positive pressurization is typically created through a combination of outdoor air and duct design, with supply air ducts sized for greater volumes than the return air. Designs for pressurization in cultural heritage facilities should allow for equal volumes of supply and return air to the downstream zone to facilitate recirculation modes (no outdoor air) without pressurization consequences because of duct sizing. Modulating dampers on the outdoor and return airstreams as well as using adjustable return and supply air grilles can allow for balancing adjustments.

Natural Ventilation for Preservation

In some circumstances, natural ventilation may be necessary for interior moisture control and/or inhibition of mold growth. Historic structures with limited mechanical intervention may benefit from controlled natural ventilation on a scheduled basis (e.g., diurnal or seasonal operation) or may require either mechanized or passive ventilation for emergency situations or disaster recovery. The goal of ventilation is one of the following:

- Move out moisture that has originated inside the building (e.g., rising damp)
- Raise temperature of spaces containing a cold surface causing high relative humidity (e.g., a slab floor) or a high-mass wall without solar exposure
- Reduce stratification of spaces containing a small, localized cold surface

These operations may be enabled by a high-limit relative humidity sensor in the space, time scheduled, or (for disaster recovery or power outages) manually activated.

Air Change Rates

Air change rates in cultural heritage institutions are not constant values, and should vary based on zone usage and occupancy, with other specific factors (e.g., events spaces, fabrication or paint shops, conservation labs, off-gassing collections materials) accounted for as necessary. The operational goal after optimization is to run the system with the minimum air volume/change rates necessary to maintain the desired environmental conditions while providing for occupancy and protecting against microenvironments. Proper envelope, airflow design, and duct layout should minimize potential microenvironments; environmental data logging in conjunction with control sensors can alert staff to potential issues. Initial design may use air change rates recommended for particular zone types (office, laboratory, classrooms, etc.) but should include variable-frequency drives (VFDs) or variable speed drives (VSDs) that can control air volume/change rates based on occupancy patterns, established needs, and other factors. Collections storage zones generally require lower air change rates unless extenuating factors (e.g., off-gassing materials, issues with microenvironments) dictate otherwise.

Stack Effect

Stack effect can have significant implications for control in cultural heritage settings, particularly in multistory structures and high-ceilinged spaces (ranging from modern high-bay storage environments to historic structures that may incorporate historic frescoes and murals). Differences in temperature (and, to a lesser extent, moisture) between interior and exterior environments can result in density gradients that induce air movement and exchange, drawing unconditioned outdoor air into the building and often causing issues with airflow, microenvironments, and overall system operation. Stack effect may reverse depending on the exterior and interior conditions: when cooling indoors, upper areas may be negatively pressurized relative to outdoors, drawing warm air into the structure, while lower parts of the building may be positively pressurized. The reverse is true when heating indoors. This is particularly problematic in structures with limited envelope integrity and limited or poor zone design. Where this effect is noted, if envelope improvements are not an option, pay particular attention to airflow design and balancing to combat preservation risks (typically from high-temperature and high-relative-humidity microenvironments).

Stratification

Interior thermal stratification can occur even in buildings with excellent envelope integrity. It is caused by the displacement of warm air by more dense cool air. This can occur independently of interior/exterior pressure differentials and, like stack effect, can create issues in preservation environments because of microenvironments and poor environmental controls throughout multistory or high-ceilinged spaces. Common problems include high temperatures (which can increase rates of chemical decay) near ceilings and on upper levels, and issues with high relative humidity and potential mold risk because of cooler temperatures near floor level, especially in areas with poor air circulation. Proper zoning, airflow design, duct layout, and balancing can reduce stratification. For storage and cool environments, overhead diffusers and floor-level returns generally are preferable; occupied spaces (offices, galleries, etc.) may use floor-level or overhead diffusers. Ceiling or circulation fans may be used as low-impact solutions for improved air mixing and reduced stratification.

7.5 SPECIAL CLIMATIC CONSIDERATION

Humidistatically Controlled Heating

This specialized approach has limited application and must include safety controls, but is sometimes the only option that can handle envelope limitations in cold climates. In this approach, the heating system is controlled by a humidistat rather than a thermostat (LaFontaine and Michalski 1984); cold, damp air is heated until the relative humidity drops to a predetermined safe range, typically below mold germination conditions. Where interior temperatures drop consistently below 10°C, it solves the problem of humidity in a building that does not have an adequate envelope. Humidity-controlled heating does not provide human comfort in winter, but many small museums, historic buildings, and reserve collection buildings may be largely unoccupied during this period. A high-limit thermostat is necessary to stop overheating during warm weather, and a low-limit thermostat may be used if water pipe freezing is a concern. This approach has been used in Canada (LaFontaine 1982; Marcon 1987), the United States (Conrad 1994; Kerschner 1992, 2006), and in many historic buildings in Britain. Maekawa and Toledo (2001) successfully applied humidistatic control in hot, humid climates to minimize mold growth.

Some cautions apply. Foundations in a previously heated building may heave if the ground is waterlogged before freezing. Improving drainage, insulating the ground near the footings, and heating the basement reduce this risk. Problems have occurred in buildings with dense object storage and a very low infiltration rate, such as a specially sealed storage space (Padfield and Jensen 1996); a very slow supply of dehumidified air to the space can be helpful.

This approach is cost effective in seasonal museums (especially for low-mass wood-frame buildings) in colder climates such as the northern United States and Canada, and in maritime regions. Application in hot and humid environments should be judiciously considered, typically where mechanical dehumidification is impractical. Humidistatically controlled heating may be applied where the imminent risk of mold growth outweighs other degradation risks, and should be balanced with the increased risk of chemical decay because of elevated temperatures. In many circumstances, improved air circulation or natural ventilation for air circulation may be a preferred first step for mold avoidance.

Note: humidistatically controlled heating may be used in place of stand-alone dehumidifiers. As described in the following section on Dehumidification, stand-alone dehumidifiers and air conditioners pose a particular threat to cultural heritage collections because of the inherent risk of flooding and electrical fire in the local collections zone; their use should be judicious, and only when the building/space is occupied.

Hot and Humid Environments

Control of mechanical operations in hot and humid environments (whether constant or seasonal) depends largely on the level of mechanical intervention selected. From a control perspective, moisture management (both relative humidity and moisture content/humidity ratio) is the critical process, and may be achieved through various mechanical means, including dehumidification, cooling with secondary dehumidification (as in typical direct expansion/refrigerant-based window, residential, and package air conditioners), ventilation, and, less commonly, humidistatically controlled heating. In most applications, the primary preservation goal is to restrict mold growth and other biological risks, with mechanical damage (particularly in seasonally humid/dry climates) and chemical decay typically secondary concerns.

Envelope capability heavily influences both control design and equipment selection. Where the structure has a modern, purpose-built envelope that can limit sensible and latent loads, temperature control and the limitation of chemical decay may be the first design priority. For most historic, renovated, and/or repurposed structures, control design for collections zones should primarily be based on space relative humidity. Designs should consider a specific ventilation control (whether integrated into the primary system, or as a separate system) that can also be manually enabled in the event of limited power availability or long-term power outages, where generator capacity may only be capable of providing circulation without temperature or humidity control. In mechanical designs where redundancy or back-up power may not be available, control and system designers should also consider advocating for passive strategies, including single-side, cross, or stack ventilation, as a way to provide airflow and limit mold growth during equipment failures or power outages.

Additional information on environmental management in hot and humid climates is presented by Harriman (2009) and Maekawa et al. (2015).

7.6 INTERIOR CONSTRUCTION

Interior construction decisions in multizone buildings can significantly affect the ability to successfully control interior environments. Early during predesign and design, it is essential to share information about partitioning, solar load, and spaces in which collections will be exhibited or stored. Beyond exterior envelope performance, architects and engineers must consider interior zone separations, which may include thermal and vapor barriers between collections and noncollections zones. Zone design should strive to keep spaces on the same mechanical zone contiguous to one another, with interior construction designed to minimize air and vapor flow between the zone and adjacent spaces. Beyond thermal and vapor barriers in interior walls, ceilings, and floors, strategies should include

- Insulated, fire-rated doors
- Door seals, gaskets, and sweeps
- Sealing any penetrations, with overall penetrations kept to a minimum
- Ducted return rather than plenum design

These practices are also commonly required for any environmental zone/space using clean-agent fire suppression systems.

8. CONTROL EQUIPMENT

Hardware and software choices in control design should be based on the best application for the institution/building in question, and vary from basic, direct single-point thermostat/humidistat control of a residential-style heating and air conditioning system to larger building automation (BAS) or building management systems (BMSs) intended to manage multiple air and water systems throughout a building or site. Rather than detailing the structure of the control system, the following factors should be considered in the design of any controls system for a cultural heritage setting.

8.1 HARDWARE

Sensors

Selection. Selection of temperature and relative humidity sensors (thermostats, humidistats) should consider accuracy, initial calibration, and response time. Sensors for cultural heritage applications generally trend toward the more accurate, with ranges of ±0.2 K and ±2% rh or better. As a guideline, response time should be within 1 min for temperature, and less than 2 min for relative humidity (BSI 2010). Reducing project costs by reducing relative humidity sensor reliability and accuracy is a false economy that will compromise operational accuracy and place the collection at risk. Dew-point sensors, though initially expensive, are much less likely to suffer from calibration drift.

Calibration. Design and initial commissioning typically assume newly purchased hardware and represent the best-case operational accuracy for the system. Institutional staff should be provided with guidance for eventual replacement or recalibration to provide continued accuracy in operation. Note that field recalibration rarely achieves the same level of accuracy as factory recalibration (if available) or new equipment.

Location. Typical sensor placement is based on control points, with occasional reference data (e.g., discharge air conditions, space or return air conditions, outdoor air conditions). Generally, primary control sensors should be located in the collections spaces; each collections space should have at least one sensor associated with the control system. As environmental optimization in cultural heritage has increased in popularity, institutional staff may desire greater transparency in operation, with data available from multiple points to assess the performance of individual system components. Sensor locations may now consist of an expanded list of reference points, beyond typical control points, and may include

- Outdoor air
- Return air
- Mixed air
- Cooled air
- Heated/reheat air
- Humidified air
- Discharge/supply air after downstream equipment

Designers should work with institutional staff to understand future informational needs and determine appropriate sensor locations.

Stand-Alone Data Loggers. Many cultural heritage institutions use stand-alone digital data loggers to monitor a collection's environment for preservation purposes. These devices have the advantage of flexible deployment throughout a mechanical zone (close to the collection, or in areas of suspected microenvironments) compared to hard-wired control sensors, which, because of access, location, calibration, etc., may not always provide an accurate representation of what the collection experiences. Stand-alone data loggers are often equally as accurate as BAS/BMS sensors and may have the advantage of more regular calibration. Use of data loggers and data comparison should be discussed during predesign; ideally, data from both systems (data loggers and BAS/BMS) should be used to assess environmental performance and to identify potential issues with either set of equipment. Some institutions may still use hygrothermographs to record environmental data; however, without continuous maintenance and frequent calibration by trained personnel, these units are prone to large measurement errors and are generally no longer recommended for use in the cultural heritage field.

CO_2 Sensors. Consider using CO_2 sensors as a control mechanism in settings where there are opportunities to control outdoor air intake beyond a set volume. In storage environments and collections spaces that are only lightly occupied or that are occupied on a fixed schedule, there may be significant opportunities to reduce heat, moisture, and filtration loads by minimizing outdoor air quantities when fresh air requirements are flexible.

Variable-Frequency Drives

Now common for both fans and pumps, VFDs or VSDs should be included on most systems larger than residential/light commercial equipment; small drives are regularly found on rooftop and other package systems. As control equipment, their uses vary; drives may respond to differential pressure or to downstream damper control in a variable-air-volume system or, more critical in collections-centric zones, can be used for optimal part-load fan operation or soft stops/starts as part of programmed shutdowns.

8.2 SOFTWARE

BAS/BMS systems may be proprietary or open source, and selection typically depends on the institution's level of on-site expertise: some institutions do controls programming in house, whereas many use outside contractors. Engineers should work with institutional staff to determine the likely level of staff interaction with the system, and should select a product accordingly. Other considerations may include a preexisting contractor or product at a site, and the availability of qualified controls contractors in a given geographic area. All systems should ideally allow for

- **Data trending:** retention of historical data from multiple points, including sensor readings, damper positions, motor speeds and status, and other information. Trends should allow for a minimum of one year's worth of stored data.
- **Data export:** export of data to open file formats (e.g., plain text, CSV) that can be imported into other programs for storage or analysis.
- **Alarms and notifications:** contact to multiple individuals, including staff in both facilities and collections, by email, text, or other means.
- **Remote access:** ability to manage or adjust building/system operation from off site, through a virtual private network or other secure connection.
- **Read-only access:** for nonfacilities or controls staff who use the BAS/BMS interface to monitor environmental conditions or system operation.
- **End-user control** (as desired): most institutions with on-site facilities staff should be able to adjust space temperature and relative humidity set points, create operation schedules, have access to an emergency shutdown function, and be able to set new data trends.

9. SYSTEM DESIGN AND SELECTION

System and equipment selection varies greatly from institution to institution. In addition to the factors of control philosophy that influence control design discussed under the Controls Design section, system and equipment selection must consider additional input that may be determined during predesign, including

- Institutional staffing and in-house mechanical expertise
- Physical configurations and limitations for mechanical equipment
- Influence or requirements of historic structures and envelopes
- Maintenance (preventive and reactive) practices and budgets
- Availability of qualified technicians and contractors
- Availability of onsite utilities, including water, electric, natural gas, renewable power
- Preexisting equipment (e.g., chillers, boilers, perimeter systems, ductwork) that may influence equipment and design choices

In system upgrades or renovation projects, a combination of these factors may significantly predetermine the type of equipment selected, although not necessarily its capacity or control. In new construction, the designer may have far greater flexibility in selection.

Three key principles should be considered during system design and equipment selection:

- **Design for purpose:** cultural heritage design parameters may be significantly different from standard engineering designs for occupied spaces, ranging from frozen environments to narrow bands of relative humidity control for specific spaces. The first goal of any design must be to achieve the required preservation conditions for various building zones. These conditions are determined during predesign and may require further discussion/refinement, depending on design option. Integrated design should strive to find the most appropriate holistic design solution possible for a structure that (for new construction) may have more than five distinct environments managed by multiple air or water systems, plants with multiple chillers and boilers operating to different capacities, and the possibility of significant downstream equipment.
- **Design for operability:** design of mechanical systems for cultural institutions is often an exercise in the balance of cost, capability, and, in particular, technology. Ideally, system designs should be operated, maintained, and repaired by the organizational staff or local contractors; regardless of its efficiency or potential, technology whose repair requires two weeks of lead time from a contractor many hours away will be unsustainable. In many applications, simple designs with clear roles of components and clear control logic are more favorable than the latest complex technologies and subsystems. Possibly except for the largest institutions with significant facilities infrastructure, cultural heritage is rarely the best proving ground for new or untested technologies. Redundancy may be significant and affordable in certain applications (e.g., humidification), but limited by capital budgets in others; resiliency must be considered in every design, often as an understanding of the holistic building system (systems, envelope and structure, siting, etc.).
- **Design for longevity:** though all equipment has limitations on its useful lifespan, equipment selection for cultural heritage should focus on designs and equipment that provide the longest service life possible. Many cultural heritage facilities are part of nonprofit or educational institutions whose capital budget planning may be on a longer cycle than other organizations. Installing package units with a 15 year service life expectancy for an institution whose budget cycle will not allow additional capital investment for another 20 years creates a potential 5 year gap where operation and maintenance of appropriate preservation conditions may be a struggle. These discussions should be included during predesign and design, and engineers should clearly communicate the potential lifespan limitations of different equipment options to the institutional staff.

9.1 ENERGY AND OPERATING COSTS

Energy and operating costs of mechanical systems are primarily a function of the amount of energy work being done for a certain number of hours, commonly analyzed on a monthly or annual basis. With large portions of buildings requiring greater moisture control than many other applications, total energy consumption by cultural institutions can appear inflated compared to noncultural applications while still being comparable to similarly purposed buildings and, at least over the past 20 to 30 years, generally expected by the cultural heritage profession.

Energy work related to cultural heritage should first focus on achieving the desired environmental conditions with the least energy expenditure possible. Sometimes, predesign identifies limitations to the potential preservation environment driven by estimated energy costs; these instances require some compromise to achieve the best preservation condition achievable with the projected energy/utilities budget. Initial capital investments made to reduce recurring annual energy costs may be considered, and continuous commissioning and optimization can identify opportunities for energy reduction without altering preservation quality.

Energy Audits

During predesign, projects for existing buildings should consider an energy audit based, at minimum, on existing systems and their typical operation. Predesign teams may also consider comprehensive energy audits for the entire building, to identify the influence of additional energy factors (e.g., lighting) not addressed in a mechanical study. Data from the audit should be analyzed for evidence of excessive operation, with these findings informing future system design. After construction, institutions may perform periodic energy audits to inform continuous commissioning or optimization processes.

Life-Cycle Cost Analysis (LCCA)

Applied to mechanical systems, LCCA is the assessment of the whole cost of the potential installed system over its estimated lifespan. This exercise, which can be applied on a whole-building scale, greatly assists in selecting the most appropriate design solution when several options appear viable. Typically, LCCA for systems should include estimates of

- Capital costs: purchase and installation
- Energy costs, whether using fossil fuels or renewables
- Operation, maintenance, and repair costs
- Component replacement costs, where system components (coils, motors, humidifiers, downstream equipment, etc.) may be replaced without changing the primary cabinet or system

LCCA studies should carefully identify the variables being compared, especially regarding differences in systems versus differences in environmental conditions. For example, comparative analysis of potential system designs that achieve the same environmental conditions (e.g., water-based subcool/reheat versus direct expansion cooling and electric reheat) is different from comparing LCCA for a water-based subcool/reheat system designed for either 20°C/50% rh or a 18°C/40% rh.

Energy Efficiency

Energy efficiency may be achieved either through direct equipment efficiency (e.g., more efficient coils or compressors) or through operational efficiencies, such as airflow control, outdoor air control, and strategies for nonpeak operation. In general, system designs should include the most efficient equipment selections possible given budget and institutional infrastructure. Potential operational efficiencies, which are highly dependent on performance and use of the final populated space, should be accounted for through flexible operational design (e.g., VFDs, modulating dampers and valves, programmable thermostats in smaller applications) and tested during continuous commissioning or optimization work before adoption.

Lighting and Daylighting

Lighting and daylighting, as they pertain to system design and operation, have several components to consider. Light-emitting diodes (LEDs) are increasingly common choices for collections environments in both new construction and renovation, and unlike other lights (fluorescent, incandescent, halogen) have comparatively little impact on overall system operation and design. Although LED fixtures do produce heat, the quantities are considerably smaller. Engineers should consult with lighting designers regarding lighting choices, their potential heat output, and what load must be accounted for in design calculations. Renovations of systems serving existing environments using a variety of heat sources should consider a lighting audit to determine existing thermal loads from space or exhibit lighting.

Daylighting is often proposed, especially for noncollections areas. Generally, daylighting should be avoided for all storage environments and avoided, or severely limited, for most exhibition spaces. Preservation assessment for possible light impact on collections should be conducted in conjunction with any lighting design. Ayres et al. (1990) noted that daylighting is always a net energy penalty. If used, the daylighting aperture should be minimized, and avoided as much as possible in and over collection areas. For lower risk of leaks and better-managed lighting, clerestories are preferred over skylights. In applications where daylighting is unavoidable (e.g., historic structures), light-reducing and blackout shades and UV filters can reduce exposure of collections to both visible light and ultraviolet wavelengths, as well as reduce potential heat gain.

Hybrid (Load-Sharing) HVAC Systems

As detailed in Chapter 6 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, hybrid HVAC systems use multiple means of heat transfer to control a specific environment. Most commonly, this involves collocating radiant and forced-convection systems. Most of the sensible loads are assigned to radiant panel systems, whereas latent loads and the remaining sensible loads are assigned to forced-convection systems. Decoupling the HVAC functions primarily into sensible and latent heat transfer components allows the designer to select better function-oriented HVAC components and ensure higher accuracy and precision in control, potentially at lower energy expenditure. Application has been limited in collections environments; where the approach is used, in-floor radiant may be the most appropriate application because of the potential for microclimates against radiant wall panels in exhibition and storage environments. One key detractor for application in cultural heritage is the possible higher cost of installation and maintenance of dual systems.

Historic structures, house museums, and recent buildings can present a similar scenario from a legacy perspective when institutions seek to combine modern forced-air cooling and dehumidification with original hydronic systems using radiators or a perimeter heat loop for either a portion or the whole of the sensible heating load. The heat transfer mode remains the same (both systems operate by convection), but the operational challenge is similar to that with other hybrid heating system designs: management and control of a hydronic system in conjunction with forced-air control. Balance and efficient operation can be excessively difficult to achieve; new construction, with opportunities for insulated glazing and perimeter forced air zones, can generally avoid using dual hydronic and forced-air systems.

Dual Fuel and Multiple Energy Sources

Dual-fuel and multiple-energy-source systems are typically seen in residential or light-commercial applications, often as a package unit that incorporates both fuel and electric heat depending on demand. Application of these units in cultural heritage is relatively limited, but as new technologies develop, other multiple-energy-source systems have begun to emerge, particularly for smaller applications and heating/dehumidification side. Water heating may use recovered waste heat from various applications or use solar thermal collectors, with a traditional boiler for back-up; the hot water can then be used for heating, reheat for dehumidification, or regeneration for a desiccant system. Variants on hybrid designs, especially with renewable energy sources, may be particularly applicable in design situations where regular utilities are limited (e.g., well-water or tank fuel-storage systems) or the cost of certain forms of energy is prohibitively high.

Maintenance and Ease of Operation

As discussed previously, maintenance, accessibility, and ease of operation and repair are critical components of any proposed mechanical design. System design should enable both preventive and reactive (i.e., breakdown) maintenance by either existing institutional staff or an identified contractor in the local area. Specialized equipment with no local maintenance or repair support should be carefully considered for potential benefit versus risk because of lack of maintenance, and alternative options should be explored. For large projects in larger cities, code-required staffing for the plant should be considered; sometimes, smaller reciprocating chillers can be used at night to preclude the licensed engineer needed to operate larger chillers. Specific aspects to consider as part of design review may include

- **Accessibility of the primary unit and individual components.** Package units should have adequate clearance on all sides for maintenance, repair, and cleaning. For larger air handlers, access doors should provide access to all sections, and before and after all downstream equipment; installation should be careful not to block these with piping or ductwork. Valves and dampers must be accessible for preventive maintenance and repair. Above-ceiling units should be limited if possible because of access issues, and ideally should not be located in collections areas because of leak and access risks.
- **Exterior equipment (rooftop, ground-level pad, etc.) versus interior mechanical rooms.** Exterior equipment installations typically suffer in longevity, especially in salt-air environments. Where possible, equipment installations should be indoors, with adequate air exchange and access.
- **Clear component labeling.** Piping and ductwork should be clearly labeled with its purpose and direction of flow, as should primary airflow on the unit and all sections. Basic flow schematics should be available for all air handlers and hydronic systems. This practice should also be applied in construction with clear labeling of piping, ductwork, and airflow.
- **Identification and labeling of manual shutoffs.** Primary shutoff points (electrical disconnects, manual valves) should be easy to locate and clearly labeled.
- **Availability of drains and fire suppression.** Floor drains should be local to equipment, and fire suppression (whether a central system or handheld) should be available.

Effects of maintenance activities on the collection must always be considered. For example, testing or accidental activation of a smoke removal system can radically change the collection environment. Tools and ladders in gallery and storage areas are a threat to the collection, and special precautions must be taken. Contaminated air conveyance components (e.g., mold growth and other build-up) can contribute to pollution levels, lead to premature component failure, and affect heat transfer efficiency, resulting in higher utility costs. Regular inspection and cleaning are an important part of preventive maintenance.

9.2 DESIGN ISSUES

Zoning/Functional Organization

As discussed in the section on Zoning (under Controls Design), three general environmental zones must be considered not only for control but also for system layout and design: noncollections spaces, occupied collections spaces, and unoccupied collection storage environments. Efficient operation is typically best achieved when each of these zones is served by mechanical systems dedicated to that particular environment; this approach avoids unnecessary energy usage (e.g., significant dehumidification for a noncollections zone) and improves the likelihood of maintaining environmental control.

The design engineer should be involved from the start of project planning to ensure that space layout does not present unnecessary problems. For both functional organization and design efficiency, spaces in similar environmental zones should be kept physically contiguous, with the occupied collections zone and the unoccupied storage environments adjacent to one another. This allows not only for efficient ducting, but also for efficient interior wall (thermal and vapor barrier) construction. Appropriate zoning should minimize the necessity for downstream subzone equipment (VAV/reheat, subzone humidification) in most occupied and unoccupied collections zones.

Activities that pose a potential threat to collections environments (food areas, loading docks, fabrication and rough shops, maintenance and housekeeping, etc.) should be kept away from collections zones, with exhaust from these areas located away and downwind from any fresh air intakes for collections systems and the rest of the building. One key exception to this practice may be relative-humidity-controlled crate storage, which may share a zone with occupied collections areas. Loading docks should ideally be positively pressurized, and shared walls with collections zones should be carefully designed to mitigate any potential energy transfer, whether from a load perspective or to reduce risk of condensation or other issues. Where possible, a separate loading dock may be specified for cleaner transfer of collections materials and crates, with direct access to crate storage and collections intake work areas.

System Design and Envelope Performance

System designs that call for interior moisture control, whether humidification or dehumidification, must carefully consider the likely performance of the existing or designed envelope for both thermal insulation and vapor transfer. These issues are commonly discussed for exterior envelopes, but the same issues can exist with excessive thermal or vapor differentials across interior walls.

Thermal insulation/barriers should be adequate to moderate heat transfer through the structure, with particular attention paid to thermal bridges (e.g., wall studs, floor/wall junctions, roof/wall junctions) that may be sources of heat gain/loss or potential condensation points.

Vapor incursion or loss occurs by two primary paths: air leakage/gaps and diffusion. Air leakage or gaps speed heat transfer, but may be defeated for thermal loads with positive pressurization. Vapor carried by air cannot be fully mitigated pressurization: it slows the process by slowing air transfer, but vapor flow and equilibration between interior and exterior spaces continue independently based on vapor, rather than air, pressure. The differential between interior and exterior vapor pressures also drives diffusion (movement of water vapor through permeable materials) from areas of higher vapor pressure to lower. Diffusion manifests differently depending on exterior climates and interior environments. When exterior moisture conditions are higher than interior conditions, whether typically or seasonally, vapor may move inward, especially during dehumidification, adding to system load and causing efflorescence or other damage on interior surfaces. During humidification, vapor is typically forced outward through the envelope, and may limit the possible control of the interior environment and damage the structure's exterior. Diffusion in either direction, combined with interior wall temperatures, can cause significant structural damage ranging from mold growth in warm environments to structural failure in situations of repetitive freeze/thaw cycles.

Windows, doors, and skylights can pose risks as potential condensation points, as well as points of heat transfer. Repetitive condensation on doors and windows places that element at risk, and the potential transfer of that moisture to the wall or floor can lead to issues ranging from mold and wood rot to cracking and masonry damage because of freeze/thaw.

Older structures, especially those with historic significance, can be particularly problematic, especially in projects that propose indoor moisture control. Where envelope performance is in question, the first step is to reassess environmental goals: considering either higher or lower relative humidity ranges to minimize differences in vapor pressure or, in cold climates, lowering temperature to raise relative humidity rather than using mechanical humidification. If specific conditions are necessary for long-term preservation, alternatives for containment of preservation environments should be considered, such as

- Microenvironments (cabinetry, certain housing solutions, small-scale freezing)
- Offsite, purpose-built storage, which may provide better environmental control with better energy efficiency
- Limited envelope upgrades in part of the structure, often called **box-in-box** solutions, where interior surfaces are built in to provide room for installation of thermal and vapor barriers

Reliability and Resiliency

Designs should include some way to manage the interior environment during periods of interrupted operation, such as maintenance, equipment failure, power outages, and disasters.

Redundancy and back-up equipment may be applicable in the largest of cultural heritage applications, but capital cost, load cycling for long-term operability, and limited availability of physical space are all factors against redundancy as a typical practice. Rather, discussion commonly turns to reliability and resiliency as risk mitigation strategies for interrupted operation. Better understanding of collection equilibration times to environmental changes and improved building and envelope construction often mean that collections, particularly storage areas, may be able to hold appropriate environmental conditions for longer periods than previously understood. The design team should discuss scenarios, with designs reflecting potential response to events to minimize downtime. Spare equipment may be kept on site to allow for timely repairs, modulating outdoor air dampers may be set to fail closed to minimize infiltration, and in certain environments architectural and systems allowances may be made to provide natural ventilation in long-term disaster or recovery scenarios.

Stand-alone generators may be part of this strategy, but their design and siting should be reviewed carefully for load capacity, accessibility, weight restrictions (for rooftop applications), fuel availability, and locations of fuel storage tanks, which pose their own significant disaster risk.

Loads

Accounting for design capacities for both sensible and latent energy is critical in cultural heritage applications and collections environments. Though common when specifying some systems types such as four-pipe subcool/reheat and desiccant designs, adequate latent capacity is often disregarded with two-pipe and standard package unit designs, resulting in environments that may be able to maintain temperature control, but commonly see relative humidity conditions rise beyond safe limits as exterior temperatures climb and cooling capacity is dedicated to the sensible load.

Certain specific load characteristics of cultural heritage buildings should be considered in system design. Occupancy patterns can vary widely among zones. Noncollections zones and occupied collections zones tend to have high occupancy only at certain times, which may include events outside of normal operating hours. Some gallery occupancies are as high as 1 m^2 per person, but unoccupied storage zones may have 100 m^2 per person or less. Systems should be designed to handle maximum loads as well as the more common part loads. Many engineers design to 2 m^2 per person because part of the room is never occupied. In zones where spaces are extensively used for receptions, openings, and other high-traffic activities, even higher density assumptions may be justified. Continual and close dialogue between the designer and the institution is critical. Where possible, especially in renovation projects, designers should request actual gate counts and event attendance to solidify load estimates.

Lighting loads vary widely by space and by time of day. For some applications, the most common driver of cooling load in a museum is display lighting, particularly where incandescent, halogen, fluorescent, or metal-halide bulbs are still used. The engineer should ensure that estimated lighting loads are realistic. Lighting typically varies from 20 to 85 W/m^2 for display areas; figures as high as 160 W/m^2 are sometimes requested by lighting designers, but are rarely needed. With growing awareness of damage caused by light, display areas for light-sensitive objects should have low illumination levels and associated low lighting power densities. The proliferation of LEDs has minimized many of the heat load concerns.

Shelving, Storage Cabinetry, and Compact Storage

Designers should be actively involved in discussions about collections storage designs, which can have significant impact on space airflow and the potential for microclimates. As a general rule, storage solutions fall into four categories for their interaction with the overall room environment:

- **Stationary library or museum shelving:** aisle widths and varying shelf heights generally allow for adequate airflow throughout the footprint. High-density storage environments with standard shelf heights spaced for storage efficiency may greatly restrict airflow between stacks while still allowing airflow through the aisle.

  - Airflow should be parallel to or above the stack orientation; perpendicular airflow will be blocked by the first stack, risking microenvironments and poor circulation throughout the stack.
  - Proximity of diffusers: diffusers less than 1 m from shelving may expose collections to dangerously high relative humidity microenvironments that can induce mold germination, particularly during dehumidification operations.
- **Compact library and museum storage (including sliding art racks):** minimized footprints, minimal gaps when closed, and narrow spaces between racks can greatly reduce airflow through the assembly. Compact shelving often contains a mix of storage assemblies, including shelving, open bins, flat-files, and cabinets.

  - Diffusers must be above the compact assembly and configured for side supply to throw air across the top of the assembly to ensure adequate dispersal.
  - Carriages should be designed with spacers to allow a 40 to 60 mm gap between carriages when closed, to allow air movement within the assembly.
  - Density of materials and tightly closed carriages can behave as a sealed package that tends toward developing microenvironments.
  - For large art rack installations, airflow should be parallel to rack orientation. Perpendicular airflow will be blocked by the first rack, risking microenvironments and poor circulation throughout the installation.
  - Proximity of diffusers: diffusers less than 1 m from shelving may expose collections to dangerously high relative humidity microenvironments that can induce mold germination, particularly during dehumidification.
- **Storage cabinetry (standard):** comes in various configurations, including flat file storage. These generally restrict airflow, but may include vent ports to allow for minimal air exchange, vapor equilibration, and off-gassing;
- **Storage cabinetry (gasketed):** comes in various configurations but is specifically gasketed to minimize air exchange and provide microenvironments or buffering for relative humidity conditions; may be maintained with silica desiccant.

In all applications, designers must advocate for sufficient spacing for airflow between storage furniture and exterior walls. Poor airflow can lead to high temperature or high relative humidity microenvironments, particularly near exterior walls with inadequate thermal resistance.

Integrating HVAC with Design of Exhibit Cases, Closed Cabinets, and Packaging

As discussed in the section on Response Times of Artifacts, the hygric response time of an enclosure containing hygroscopic materials will almost always exceed 24 h and can reach many months. This is analogous to the thermal mass (flywheel) effect of a building, but with hygric response times typically an order of magnitude longer. Design of sustainable and reliable building humidity control should take advantage of the hygric flywheels filling the building, not fight them. Feeding HVAC supply air into cases, though often proposed, usually results in very erratic conditions inside the cases since the moisture and thermal loads of the cases are a tiny fraction of the room loads. Barrette (1985) describes the failure of a system using AHUs attached to very large display cases at the Metropolitan Museum, and their (successful) decision to adopt "passive" relative humidity control instead.

When the annual average relative humidity of the space is suitable for the object or collection, a completely passive approach is best. Many objects can adapt to a stable relative humidity somewhere between 35 and 60%, and the annual average relative humidity inside many buildings (with HVAC) in many climates is also in this range. The role of the enclosure is to smooth out relative humidity fluctuations. If the only fluctuations are hourly or daily, and the enclosures are more than half full of hygroscopic materials, then ordinary enclosures (e.g., metal storage cabinet full of paper files, photographic materials in impermeable packaging) can perform well enough. If the fluctuations are seasonal, or the enclosure has only a small fraction of its volume filled, then achieving an adequate response time requires special attention to seal details and probably additional humidity buffers (Tétreault and Bégin 2018). The key to achieving long response times is reducing enclosure leakage (Michalski 1994; Thickett et al. 2007). Measuring and specifying acceptable case leakage is well established in museums (Thickett et al. 2007).

When the annual average relative humidity is not acceptable for the object or collection, routine intervention becomes necessary. The most reliable intervention is using a removable humidity buffer, typically silica gel. When the enclosure drifts to an unacceptable relative humidity, the (reusable) buffer is removed and replaced with one that has been equilibrated (reconditioned) to the desired relative humidity. This technique has been used to maintain middle, very low, or very specific relative humidity conditions in display cases (Thomson 1986), shipping crates (Richard et al. 1991), boxes with mineral specimens (Waller 1992), and film packages in cold storage (McCormick-Goodhart 2003). This method provides resilience: if the reconditioning process is abandoned (not unusual), all high risks from incorrect relative humidity are still mitigated as long as the annual average does not exceed 65% rh. Tétreault and Begin (2018) provide a recent manual on the application of silica gel buffers for museums.

Active mechanical control systems for relative humidity alone have been made for museum enclosures, especially display cases. These can be very small commercial units hidden in a single case, or designs for a larger package that feeds many cases via small-diameter tubes (Shiner 2007). Often these are used as short-term solutions to a loan requirement. For permanent collections, experience shows that the key factor for long-term success is that the units have a known parts and maintenance provider, and that they are adopted and maintained by facilities staff, not by the conservation or exhibits staff alone.

9.3 SPECIALIZED SPACES

Cold/Frozen Storage Vaults

Cold or frozen storage vaults extend the life of materials particularly sensitive to chemical deterioration (e.g., cellulose acetate, color photographic materials), or those that require cold/frozen conditions for their own stability as well as the potential threat they pose to other collections materials (e.g., cellulose nitrate). Design environmental conditions (see Table 13B) for cold/frozen environments typically require dehumidification beyond what can be achieved by chilled-water or glycol-mix systems. Direct expansion (DX) systems, though common as the primary equipment for cold/frozen environments in other industries, are typically only used for sensible cooling in these environments for cultural heritage. Dehumidification is handled as a separate process, typically via desiccant equipment, which achieves the preservation requirement for cold temperatures at controlled relative humidity conditions.

Design and construction of frozen vaults, in particular, should be carefully considered from a space need perspective: many cultural heritage institutions have only limited quantities of media that require frozen storage. For smaller collections, storage needs may be met with stand-alone solutions such as frost-free freezers. Depending on intended usage patterns, frozen storage may not be the best solution (see Table 6).

Cellulose nitrate is classified as a hazardous material; beyond preservation requirements, consult NFPA *Standard* 40-2019 and local fire codes for safe storage and disposal requirements. Smaller quantities can potentially be safely managed with approved cabinetry; vaults that hold larger quantities have specific construction requirements, including fire-rated walls and explosion venting.

Antechambers may be necessary in certain applications, especially where vault temperatures are colder than the typical ambient dew point (whether seasonal or year-round). The antechamber microenvironment should allow the object to fully equilibrate to a temperature higher than the final environment's dew point, with relative humidity in the safe range for the media. Some collection packaging practices may eliminate the necessity of the antechamber; application varies by institution and should be discussed during predesign.

Conservation Laboratories

Detailed discussion of HVAC design for laboratories can be found in Chapter 17. Further details on containment, collection, and removal of airborne contaminants such as particulates, vapors, and hazardous gases can be found in Chapter 33.

9.4 PRIMARY ELEMENTS AND FEATURES

Figure 16 shows the basic components of a cultural heritage HVAC system, and their typical order along the airstream. A few aspects of this order are different from many other applications: the cooling coil precedes the heating coil, to allow dehumidification followed by reheat; and the fine filter is last in line, to capture particulates created by any of the preceding components. A desiccant dehumidifier is common in cool and cold storage systems that need relative humidity control. The following sections outline details, as well as the many variations on this system.

Air Volumes

Air volume design in most cultural heritage applications should account for varying needs; individual functional zones may have volume requirements that change based on occupancy, space usage, loads, and other factors. In all cases, the design goal should be to provide the appropriate volume required to meet the need, without expending energy on work applied to volumes that are unnecessary. Collections zones should have supply and return air ductwork designed to equal volumes to allow for recirculation without risk of

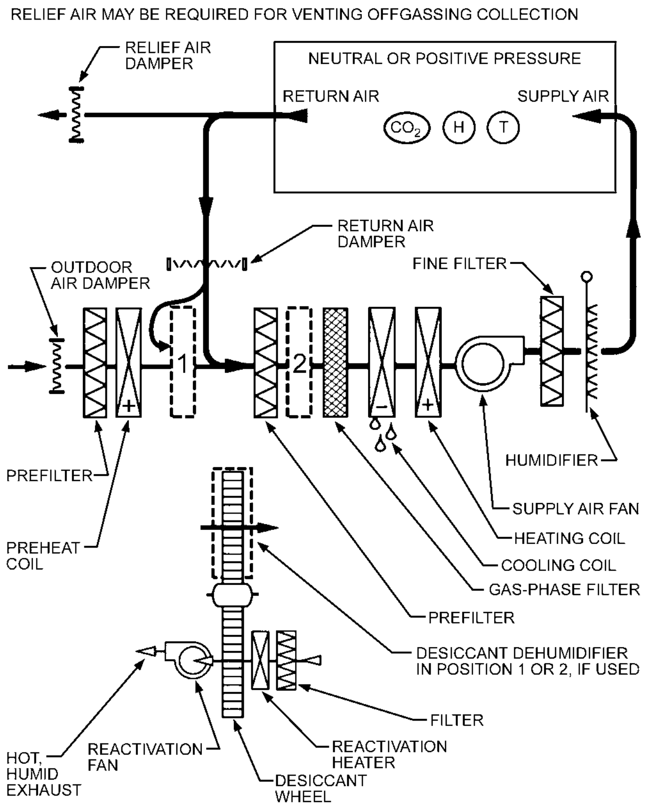

Fig. 16 Basic Components of HVAC System for Museums, Galleries, Archives, and Libraries

negative pressurization during low-occupancy, minimal outdoor air operation. Diffusers with adjustable outlets should be selected to allow appropriate zone balancing. The specific application of constant-volume and variable-air-volume designs is discussed in the section on System Types.

Fans

Every forced-air convection system, ranging from air-handling units to computer room air-conditioning (CRAC) systems and fan-coil units (FCUs), has at least a supply fan; depending on total air volumes, physical extent of the zone, outdoor air and exhaust design, etc., return fans may also be required. For institutions with the appropriate infrastructure, fan-wall/fan-array designs have distinct advantages over single-fan designs, including ease of motor maintenance/replacement and improved redundancy/resiliency. In either single-fan or fan-wall solutions, each motor should typically be equipped with a VFD; for systems with both supply and return fans, designers should ensure that VFDs are installed on both motors.

Fans may also be required for processes separate from the primary mechanical design. Ceiling and other circulation fans can be very effective for mitigating stratification and microenvironments, and some designs, especially in historic structures, should include fans for natural ventilation or other purposes.

Heating Equipment

Equipment for sensible heating in cultural heritage applications varies widely; direct-fire solutions are occasionally applied to storage warehouses and as components in desiccant regeneration, and indirect-fire systems, ranging from residential-type systems used in many historic structures to roof-top package systems, are common in smaller applications. Heat pumps may appear in smaller structures in hot environments, and electric heat can be applied in various settings, as the primary heat source or as a downstream component. Coil-based designs are most common in larger cultural heritage applications, and may be served with hot water or steam from boilers or a central plant. Heat generation systems can vary, including steam and oil with converter, modular boilers, and scotch marine boilers. Downstream reheat coils (common in VAV systems, but may exist without) most commonly use hot water or electricity.

Locations of heat application can vary; preheat may be required to protect downstream coils from freezing. For cultural heritage institutions, heat should typically be applied downstream of a cooling coil to allow for dehumidification. Reheat coils as part of downstream VAV configurations are typically best used for increased sensible temperature control. If used as the sole source of reheat, the capacity of downstream in-duct coils should be carefully considered and sized appropriately.

Cooling Equipment

The most common equipment for sensible cooling is coil based, including DX (refrigerant) systems, chilled water, and glycol. Evaporative cooling, common in arid regions, can be difficult to apply in cultural heritage settings because of reduced sensible temperature and moisture control. Designs using evaporative systems should carefully consider performance during any wet/rainy seasons; alternative design or additional equipment may be required for dehumidification. Ice storage systems with glycol may be an option in larger applications with appropriate infrastructure.

Cooling coils are commonly used for both sensible cooling and dehumidification in a subcool/reheat configuration. Location of cooling should typically allow for both sensible temperature control and dehumidification, with the cooling coil located upstream of the heating coil.

Screw compressors are recommended to generate chilled water at 2°C for use in chilled-water coils, which generally have copper fins and tubes.

Humidification

Humidification should be provided by clean steam or deionized water introduced in the air system. Evaluate the moisture source for risks of pollutants; building/plant steam should typically be avoided as a source for humidification, unless used to generate clean steam via a steam-to-steam heat exchanger. Often, steam used in closed loops to heat is treated with compounds (especially amines) that can pose a risk to the collection (Volent and Baer 1985). Systems should be selected and designed to prevent standing pools of water, and should follow good humidification design (see Chapters 1 and 22 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*).

Humidification equipment varies based on the application. In all applications, deionized or reverse osmosis water (based on institutional needs and availability) are preferred, whether for isothermal or adiabatic systems. Isothermal is generally more common, especially in year-round or seasonally cold environments, and steam is commonly generated via steam-to-steam heat exchangers or electronic steam humidifiers. Adiabatic systems (i.e., evaporative pan humidifiers, spray-coil wetted-element systems, pressurized-water atomizers, ultrasonic humidification) are more common in warmer climates. All materials in humidification equipment should be selected to minimize mold growth and degradation of system components.

Humidification should typically be located downstream of cooling and heating coils, and preferably in the primary air-handling unit. Mechanical design for cultural heritage is often more concerned with controlling humidity than temperature. The averaging effect of a common mixed-return air and common humidifier on a central system is preferred, but downstream zone humidifiers may be necessary to boost relative humidity because of specific environmental requirements or loads. If local low humidity conditions exist, try to identify and correct the cause of the condition before applying further mechanical solutions. Duct installations, whether on a common supply or in downstream subzone applications, should follow design requirements for absorption and be provided with drainage from the ductwork. Downstream humidifiers should not be located above collections areas; if it cannot be avoided, the ductwork approaching and downstream of the humidifier should be fitted with an additional catch pan with a drain and water alarm beneath the duct to provide protection for the collection. Widely different conditions in zones using the same air handler can be difficult to maintain and inefficient. If possible, different zone conditions should have the same absolute moisture content, using zone reheat to modify space humidity for different relative humidity requirements.

Designers should review maintenance requirements for humidifiers with institutional staff or contractors; electronic steam humidifiers and systems using building water can require particularly intensive maintenance to maintain design conditions and remain operable. Humidification in structures with limited envelope capacity should be carefully considered, and typically avoided.

Dehumidification

Dehumidification is the single most critical mechanical process for many cultural heritage institutions, and should be a central focus of most system designs. The required environmental conditions often determine the means of dehumidification. Sebor (1995) suggests the following typical approaches to more aggressive dehumidification:

- **Low-temperature chilled water**, usually based on a glycol solution, offers familiar operation and stable control but requires glycol management.
- **DX refrigeration** tends to be better for small systems and has lower capital costs, but generally is less reliable, requires more energy, and may require a defrost cycle.
- **Desiccant dehumidifiers** can be effective if properly designed, installed, and maintained. Economy of operation is very sensitive to the cost of the regeneration heat source. Active desiccants are typically preferred in collections settings and have become common features in cool/cold environment designs. Liquid desiccant systems eliminate (1) the need to cool the air below the dew point, and (2) reheat, both of which are very important cost factors for sustainability. Note that the possible application of liquid desiccant systems to collection environments should be carefully discussed with collections/preservation staff because of the potential risk of any aerosolized desiccant media coming in contact with collection materials.

Subcool/reheat designs, typically using cooling and heating coils, can generally achieve dew-point conditions as low as 2 to 3°C, depending on the chilled water/glycol temperature. Lack of dehumidification capacity may originate with design assumptions or equipment selection, or may be caused by issues including compromises in the cooling medium temperature, inadequate reheat, dirty or blocked coils, and poor flow or valve control.

Desiccant dehumidification, most commonly used for low dew points necessary in cold/frozen environments, is now being applied for dew-point control in some applications at 4°C and higher. Desiccant technology (typically a silica-gel rotary wheel design) can be installed as part of the primary system or as a separate component that feeds into the main air handler. For zones with minimal latent loads, or in designs using a high volume/percentage of outdoor air, designers may choose to focus on dehumidification of the outdoor airstream, rather than on the mixed air. For smaller applications and systems, package desiccant systems may be put in line with outdoor or return air. Dehumidification systems should be additions to a typical cooling system; they cannot maintain comfort conditions by themselves. For collections requiring cool, dry conditions, a desiccant system may be required. Chapter 24 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* has further information on desiccants.

Note: stand-alone dehumidifiers, common in residential and smaller applications, are not recommended for use in cultural heritage settings except in emergency scenarios. Risks to collections (e.g., electrical fires, flooding from basin overflow) generally outweigh benefits. If stand-alone dehumidifiers are used in collections environments, it should only be during occupied hours, with units emptied and unplugged before staff leave.

Outdoor Air

Outdoor air should typically be limited to the minimum necessary in cultural heritage applications. Intakes should have modulating dampers balanced with return air dampers on the system. Siting of the physical intake is critical; potential locations should be evaluated for various factors, including pollutants (e.g., vehicles, equipment, kitchen exhaust), prevailing wind directions, and sources of moisture/particulates (e.g., sprinklers, landscaping). In most applications, outdoor air intakes should fail closed on a shutdown or power outage, with the ability to manually adjust the damper if natural ventilation is required.

Preheat, precooling, or dehumidification may be best applied to the incoming outdoor airstream, increasing operational efficiency.

Ductwork

Ductwork selection varies by application; sheet metal, flexible fiberglass (flex duct), cloth, and others can be appropriate duct choices. Fiberboard is typically not recommended for cultural heritage institutions because of the potential for media breakdown over time.

All supply air ductwork should be insulated on the exterior, but return air ductwork should be insulated on the exterior if the difference between the duct condition and the ambient space is enough to make condensation possible. All duct joints, both in the duct itself and in the insulation, should be sealed against air leaks. Interior ductwork insulation/lining is not recommended in cultural heritage applications because of the potential for trapping moisture and the eventual breakdown into particulates that can deposit in collections areas. Where external insulation is not possible, or there are significant sound attenuation needs, interior duct lining may be considered if it meets hospital and health care facility standards: fiber free, closed cell, antimicrobial coated, low-VOC certified, and moisture and mold resistant. These sections must be clearly labeled on design drawings and should be discussed with institutional staff regarding ongoing maintenance and eventual replacement.

9.5 FILTRATION

Design

Particulate filtration is essential for removal of contaminants that could foul the HVAC system, as well as particles that might degrade or deface collections being preserved. For this reason, particulate filtration is addressed here in two steps: prefiltration and fine-particulate filtration.

Physical location of the filtration stages affects HVAC system performance, energy use, and ultimately protection of collections. In **upstream filtration**, all filtration is placed upstream of the cooling/heating and fans in system. All filters are essentially prefilters, even though fine-particle filtration may be present in the HVAC system. When all filters are upstream, it is common practice to stack filters, with a MERV 7 or 8 prefilter on a MERV 14 or 15 fine particle filter in the same section. This is done to preserve the life of the fine-particle filter. However, evaluate whether the cost of energy outweighs the savings of the fine-filter life: most collection areas are fairly clean environments. Eliminating the prefilter can be a very effective improvement to airflow and energy savings.

In **upstream/downstream filtration**, prefiltration is installed upstream of the cooling/heating and fan components and final filters downstream of all mechanical equipment. This more effective approach prevents a failure of HVAC components from fouling the ductwork and preservation areas downstream. In this case, it is important to filter at a minimum of MERV 11 for any chilled-water systems to prevent microbial fouling of the coils. MERV 7 or 8 is at best only 50% effective in this particle size category, and does not provide the protection needed against biofilm growth.

Performance

Prefiltration is required to prevent fouling in cooling coils and dust build-up in the fan, ductwork, or other HVAC components. It also protects and prolongs the functional service life of gas-phase filters and fine-particle filters. These fouling-size particles and microbes tend to be between 2 and 6 μm and accumulate into biofilms on coils and other wet areas in HVAC systems. MERV 7 or 8 filters by definition will not protect HVAC systems from this particle challenge and should be replaced by a minimum of MERV 11.

In some cases, prefiltration for HVAC system protection is the only filtration in a collection area. If this is the case, MERV 13 is recommended.

Fine-particulate filtration protects artifacts and collections in the facility. These **accumulation-size** particles fall in the MERV E-1 range of particles (0.3 to 1 μm). Removal efficiencies of a minimum of 85% of the E-1 range are sufficient for preservation of most collections. MERV 15 filters by definition are minimum 85% in the E-1 range, and minimum 90% in both the E-2 (1 to 3 μm) and E-3 (3 to 10 μm) ranges.

Some collections may require efficiencies higher than MERV 15 for long-term preservation. Options include microenclosures with minimal airflow and separate filtration, or HEPA (99.97% at 0.3 μm) filtration for the entire common area. Whenever HEPA filtration is used as the final filtration, seriously consider upgrading the prefiltration to protect the life of the HEPA filters.

Framing systems should be able to seal the air filters without bypass air leakage in housings and unit access doors. System designs with positive locking mechanisms for filters are beneficial, as is using gaskets rather than framing components on filters.

High-voltage electrostatic air cleaners should be used with caution because of their potential to generate ozone, which can damage collections (see Table 9).

Outdoor air infiltration of gaseous pollutants, materials off-gassing in new construction, and similar off-gassing of furnishings may put some collections at risk. Sensitive collections, such as those containing some metals and alloys, film, various papers and low-fired ceramics, should be carefully enclosed or controlled by an active **gas-phase filtration** system, depending on which method is most appropriate for reaching the desired preservation target (see the section on Control Strategies for Objects with High Vulnerability to Pollutants).

The primary compounds of concern include hydrogen sulfide, nitrogen dioxide, ozone, sulfur dioxide, and undesired volatile organic compounds, all of which are removable with molecular filtration. The specific sorbent must be chosen for the various gaseous contaminants indigenous to the facility, because removal and retention properties are not all the same. Some gases are easily removed with activated carbon, whereas others may require treated sorbents or beds. Using potassium-permanganate-treated media is not recommended because of the risk from the highly oxidative dust to collections and space surfaces.

Service life of molecular filtration media should be carefully evaluated. Much service life testing has focused on the potential mass removal capacity of the sorbent when immersed in a challenge chemical; although this information may be useful, its ability to remove pollutants from an airstream may not be achievable even though the sorbent is not spent.

If a molecular filtration system is used, some gas-filter designs require dusting filters downstream, because the aging gas filters can release dust that can affect the HVAC system and collection.

Gas-phase filtration system design should also consider institutional staffing and preventive maintenance practices; infrastructure must be able to support timely media replacement, in both labor and material cost. Consider gaseous contaminant monitoring and analysis before fully adopting gas-phase filtration; designers may choose to include the gaseous filter section in the design, but wait to install media until need has been determined.

9.6 SYSTEM TYPES

The type of HVAC system used is critical to achieving environmental goals; appropriate types may vary by zone based on use. In any cultural heritage application, proper airflow filters the air, controls moisture and relative humidity, adjusts temperature for either collection needs or human comfort, and inhibits mold growth and oxidation.

For any design, maintenance access and minimizing risk to the collection from disruptions and leaks from overhead or decentralized equipment are primary considerations. Water or steam pipes over and in collection areas present the possibility of leaks, as do air-handling units. Some systems can provide full control without running any pipes to the zones, but others require two to six pipes to each zone, which often must be run over or in collection areas and are, unfortunately, the pipes most likely to leak. Leaks and maintenance can prevent effective use of spaces and result in lost space efficiency.

Central air-handling stations keep filtration, dehumidification, humidification, maintenance, and monitoring away from the collection. The investment in added space and expense of the more elaborate duct system provide major returns in reduced disruption to the collection spaces and a dramatically extended service life for the distribution system. Where existing duct systems can be reused, renovating the existing system is economical, with most renovations confined entirely to the mechanical rooms. Duct distribution systems that are heavy on downstream equipment (e.g., terminal reheat, dual-duct, variable-air-volume) may require a new duct system and terminal equipment as part of a renovation, incurring major expense from demolishing the old ducts, installing the new duct system, and reinstalling architectural finishes.

Variable-Air-Volume and Constant-Volume

Air volume design can depend on several factors, including

- Sensible and latent loads in a space
- Collection degradation
- Practical airflow based on system design

In most cultural heritage applications, variable-air-volume (VAV) systems, in single-zone or multizone configurations, are appropriate.

Note: multizone VAV systems should not be used to serve multiple functional zones. Rather, the approach should be to account for varying loads within the same functional zone. (See the sections on Zoning and on Zoning/Functional Organization)

Multizone VAV has the distinct advantage of providing better temperature and relative humidity control to individual subzones with different sensible loads; both multi- and single-zone VAV design can achieve significant energy-savings in climates with diurnally or seasonally variable sensible and latent loads. Single-zone VAV designs in cultural heritage typically vary air volumes and occasionally sensible reheat temperatures; cooling coils, if used for dehumidification, most often have a single leaving air set point.

Constant-volume system designs may be necessary in certain scenarios. Some geological collections can emit radon, and may require constant volume and increased air change rates. Interior zones (e.g., storage rooms surrounded by a perimeter zone and with limited outdoor air) and some climates may experience essentially the same latent and sensible loads constantly, limiting the effectiveness of VAV designs. Even in these cases, initial designs should consider the inclusion of at least a VFD: actual air volume requirements may be different than design modeling, and the VFD allows adjustment of the optimal volume, even if the system operates at a constant volume moving forward.

For small volumes and applications, such as some cold/frozen storage vaults, constant volume (CV) may be the most practical design, whether based on equipment airflow requirements or simply because a VAV design offers no noticeable preservation or energy advantage.

Institutional capabilities and infrastructure must inform air volume and airflow designs. VAV control and equipment can quickly add to control/operational complexity and maintenance requirements; consider staff capabilities and/or the availability of qualified contractors before finalizing the design.

VAV or CV Reheat

A reheat system can present problems if improperly applied. In many institutions, terminal reheat with steam or hot-water coils located near or over collection spaces causes chronic problems from steam and water leaks. Subzone humidification control guidance often suggests placing the humidifier downstream from the terminal reheat coil; if the reheat coil is located near or over collection spaces, preventive maintenance on humidifiers further complicates the maintenance requirements. Reheat systems for collections zones are most effective when reheat coils and humidifiers are installed entirely within the mechanical space, instead of at the terminal end, feeding through what is effectively a multizone distribution system.

Multizone Systems

A multizone air handler with sufficient dehumidification capacity at the primary unit, zone reheat, and zone humidification can be a stable and relatively energy-efficient solution. However, multizone systems without individual zone reheat and zone humidification have proved problematic for many institutions, requiring retrofit of zone equipment for stable humidity control. With proper layout and complementary equipment, a multizone system can reduce the amount of reheat and be very energy efficient. Multizone systems should consider dehumidification in the outdoor airstream or upstream of the heating coil to ensure that sufficient dehumidification is available to the entire airstream. Note that multizone designs are still best applied to spaces with similar dehumidification requirements; mixing collections and noncollections spaces in the same multizone design typically leads to inefficiency and difficulty maintaining space conditions. Future renovation or changes in space usage can significantly impact design viability, again leading to issues with efficiency and management of the preservation environment.

Dual-Duct Systems

As with multizone systems, dual-duct designs can work well in cultural heritage if zoning is carefully considered. Downstream mixing boxes must be controlled and maintained to guard against overcooling and the resultant high-relative-humidity conditions. A critical consideration for dual-duct designs is a separate dehumidification coil upstream of both the hot and cold decks. This separate cooling coil, distinct from the one in the cold deck, is used during dehumidification demand. Air can be cooled to dew point even if it eventually flows through the hot deck. Without this feature, moist return air or outdoor air could be warmed in the hot deck and delivered back to the room without being dehumidified. An alternative is to locate a single cooling coil upstream of both decks, or in the outdoor air.

Fan-Coil Units

Fan-coil units have been problematic when placed in and above collection areas. Fan-coil units expand and decentralize maintenance, requiring maintenance in collection areas and a net increase in overall facility maintenance. Because they cool locally, they need condensate drains, which can leak or back up over time. As all-water systems, they require four pressurized-water pipes to each unit, increasing the chance of piping leaks in collection areas.

Fan-Powered Mixing Boxes

Fan-powered mixing boxes are usually inappropriate for cultural heritage facilities. Although fan-powered mixing boxes can help ensure air circulation to suppress mold growth, they do not allow effective air filtration for particles and gases. These fans also increase local maintenance requirements and present an added fire risk. If they include reheat, there is an added risk from leaks (with water or steam reheat) or fire (with electric reheat).

10. CONSTRUCTION

(This section is based, with permission, on Maekawa et al. [2015].)

The system design is physically realized through the procurement, construction and installation of equipment. Conformance with the design intent and the owner's project requirements (OPR) is confirmed through various methods, including review and acceptance of the contractor's technical submittals for materials and equipment to be supplied; in-factory acceptance of complex equipment before shipment; qualification and certification of tradespersons for certain critical installation activities such as welding; and field observation and inspection of equipment and systems during installation.

Construction quality, including cleanliness of systems during construction, is critical; all incomplete piping and ductwork should be kept closed or sealed during installation to prevent introducing dust and debris.

11. COMMISSIONING

(This section is based, with permission, on Maekawa et al. [2015].)

Start-up, testing, and balancing are performed once an environmental management system is installed. Preparation includes the following:

- **Design conformance:** The installed system must be checked for conformance with the design intent and the owner's project requirements. Specifically, the leaktightness of air and hydraulic systems must be verified by pressure testing; pump and fans checked for proper rotation; valves and control devices checked for correct actuation/response; and the electrical continuity and proper polarity of electrical wiring and connections must be confirmed. Sensors, instrumentation, and control devices must be checked for correct calibration and signal/response.
- **Cleaning:** Hydraulic systems must be flushed clean using start-up strainers, and air systems operated with construction filters; both operations must continue until cleanliness requirements are met, as indicated by the amount of construction-related debris and particulates captured in the strainers and filters.
- **Start-up:** Operation of each piece of equipment must be initiated in accordance with a start-up procedure provided by the equipment manufacturer. It is essential to adhere to the manufacturer's start-up procedures, because the manufacturer's warranty period begins with the initial power-up of equipment; failure to follow start-up instructions can void the warranty.

On completion of preliminary testing, cleaning, and start-up of individual components, equipment, and assemblies, the start-up sequence and shut-down sequences for the entire system must be verified before the system can be operated. After successful system start-up and shut-down, the system can be balanced for operation and construction commissioning can occur, as follows:

- **Balancing:** The balancing phase consists of measuring system air and fluid flows, making adjustments, and balancing the flows to match design flow rates. This may require adjusting airflow using dampers in ducts and/or pulleys or belts at the fans. Similarly, water flow rates in hot- or chilled-water systems must be measured, adjusted, and balanced. Both cooling and reheating capacities may also need to be adjusted by refrigerant compression or by regulation of cooling or heating fluid flow rates, to produce design heating, cooling, or dehumidification. Electrical loads from equipment must also be verified.
- **Construction commissioning:** After testing and balancing, construction commissioning occurs, during which system performance is checked against the owner's performance requirements and verified. In climates with wide ranges of thermal and moisture loads over four seasons, performance verification may take up to 12 months; in climates with more consistent thermal and moisture loads throughout the year, performance verification might be accomplished in 6 months.

12. TRAINING AND DOCUMENTATION

(This section is based, with permission, on Maekawa et al. [2015].)

The facilities staff at the building where the environmental management system is installed should be familiar with the owner's performance requirements and knowledgeable about design intent, operation, maintenance, and basic troubleshooting of the system. In-house knowledge of the OPR helps protect the collections, minimize unnecessary service calls, maintain system operation within performance specifications, and avoid premature failures. After system start-up, testing, and full commissioning, the facilities staff and building maintenance personnel must be trained in the operation and maintenance of the environmental management system. Training should start with the fundamentals of the system's design intent, followed by explanation of the contents of the operations and maintenance manual prepared for the system. Training should also include

- Hands-on practice by facilities staff with each of the necessary service/maintenance operations and control systems adjustments
- Basic trouble-shooting procedures for the system
- Operation of the monitoring features of the environmental management system and early identification of performance issues

Complete documentation of the environmental management from inception through start-up is a product of the commissioning process and is provided to the facility owner. The system documentation should include the OPR, design intent of the environmental control system, design documents, performance specifications, technical submittals, inspection reports, calibration records, testing and balancing reports, a detailed sequence of operation, start-up and shut-down procedures, a maintenance schedule for each of the system's components, and simple diagnostic and/or troubleshooting procedures.

13. OPTIMIZATION

(This section is based, with permission, on Maekawa et al. [2015].)

Operation of any environmental management system requires a program of preventive maintenance, ongoing performance monitoring, and periodic performance assessment and evaluation for overall effectiveness in collections conservation and in energy use.

If changes in operational parameters, collections conditions, or energy efficiency are noted, the current system's performance should be revisited as per the steps described in the Context and Predesign section, including

- Define realistic and achievable objectives and criteria; resolve competing objectives
- Identify possible environmental management strategies
- Evaluate and select the preferred strategy or strategies

CHAPTER 25

ENVIRONMENTAL CONTROL FOR ANIMALS AND PLANTS

DESIGN FOR ANIMAL ENVIRONMENTS 25.1
Cooling and Heating 25.4
Ventilation 25.5
Ventilation Management 25.5
Recommended Practices by Species 25.7
DESIGN FOR PLANT FACILITIES 25.10
Greenhouses 25.10
Plant Growth Environmental Facilities 25.16
Other Plant Environmental Facilities 25.21

THE design of plant and animal housing is complicated because many environmental factors affect the production and well-being of living organisms. Designers should consider that equipment must repay costs through improved economic productivity. Engineers, likewise, must balance costs of modifying the environment against potential economic losses incurred through plants or animals kept in a less than ideal environment.

Thus, design of plant and animal housing is affect by financial considerations, in addition to concern for the well-being of workers and animals, and regulations on pollution, sanitation, and health assurance.

1. DESIGN FOR ANIMAL ENVIRONMENTS

Typical animal production plants modify the environment, to some degree, by housing or sheltering animals year-round or for parts of a year. The degree of modification is generally based on the expected increase in production. Animal sensible heat and moisture production data, combined with information on the effects of environment on growth, productivity, and reproduction, help designers select optimal equipment. Detailed information is available in a series of handbooks published by the MidWest Plan Service. These include *Mechanical Ventilating Systems for Livestock Housing* (MWPS 1990a), *Natural Ventilating Systems for Livestock Housing and Heating* (MWPS 1989), and *Cooling and Tempering Air for Livestock Housing* (MWPS 1990b). ASAE *Monograph* 6, Ventilation of Agricultural Structures (Hellickson and Walter 1983), also gives more detailed information.

Design Approach

Environmental control systems are typically designed to maintain thermal and air quality conditions within an acceptable range and as near the ideal show as is practicable. Equipment is usually sized assuming steady-state energy and mass conservation equations. Experimental measurements that heat and moisture production by animals is not constant and that there may be important thermal capacitance effects in livestock buildings. Nevertheless, for most design situations, the steady-state equations are acceptable.

Achieving the appropriate fresh air exchange rate and establishing the proper distribution within the room are generally the two most important design considerations. The optimal ventilation rate is selected according to the ventilation rate logic curve (Figure 1).

During the coldest weather, the ideal ventilation rate is that required to maintain indoor relative humidity at or below the maximum desired, and air contaminant concentrations within acceptable ranges (Rates A and B in Figure 1). Supplemental heating is often required to prevent the temperature from dropping below optimal levels.

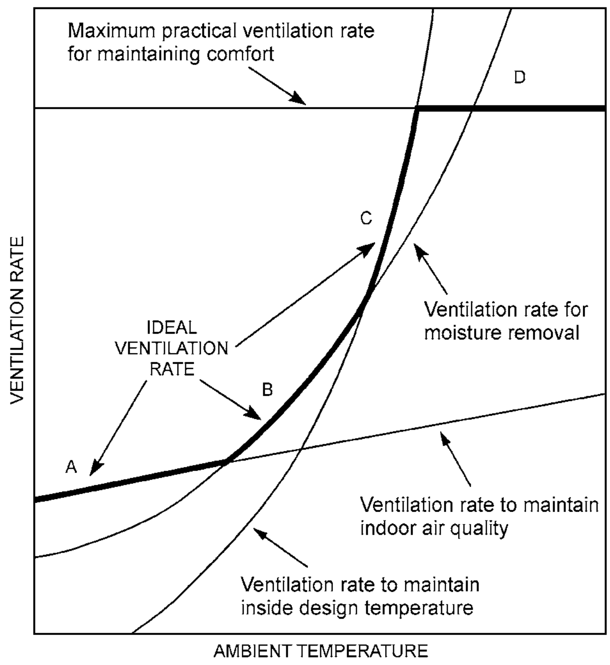

Fig. 1 Logic for Selecting Appropriate Ventilation Rate in Livestock Buildings
(Adapted from Christianson and Fehr 1983)

In milder weather, the ventilation rate required for maintaining optimal room air temperature is greater than that required for moisture and air quality control (Rates C and D in Figure 1). In hot weather, the ventilation rate is chosen to minimize the temperature rise above ambient and to provide optimal air movement over animals. Cooling is sometimes used in hot weather. The maximum rate (D) is often set at 60 air changes per hour (ach) as a practical maximum.

Temperature Control

The temperature in an animal structure is computed from the sensible heat balance of the system, usually disregarding transient effects. Nonstandard buildings with low airflow rates and/or large thermal mass may require transient analysis. Steady-state heat transfer through walls, ceiling or roof, and ground is calculated as presented in Chapters 25 to 27 of the 2017 *ASHRAE Handbook—Fundamentals*.

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

Mature animals typically produce more heat per of unit floor area than do young stock. Chapter 10 of the 2005 *ASHRAE Handbook—Fundamentals* presents estimates of animal heat loads. Lighting and equipment heat loads are estimated from power ratings and operating times. Typically, the designer selects indoor and outdoor design temperatures and calculates the ventilation rate to maintain the temperature difference. Outdoor design temperatures are given in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*. The section on Recommended Practices by Species in this chapter presents indoor design temperature values for various livestock.

Moisture Control

Moisture loads produced in an animal building may be calculated from data in Chapter 10 of the 2005 *ASHRAE Handbook—Fundamentals*. The mass of water vapor produced is estimated by dividing the animal latent heat production by the latent heat of vaporization of water at animal body temperature. Spilled water and evaporation of fecal water must be included in the estimates of latent heat production within the building. The amount of water vapor removed by ventilation from a totally slatted (manure storage beneath floor) swine facility may be up to 40% less than the amount removed from a solid concrete floor. If the floor is partially slatted, the 40% maximum reduction is decreased in proportion to the percentage of the floor that is slatted.

Ventilation should remove enough moisture to prevent condensation but should not render the relative humidity so low (less than 40%) as to create dusty conditions. Indoor relative humidity for winter ventilation is usually designed to be between 70 and 80%. The walls should have sufficient insulation to prevent surface condensation at 80% rh inside.

During cold weather, ventilation needed for moisture control usually exceeds that needed to control temperature. Minimum ventilation must always be provided to remove animal moisture. Up to a full day of high humidity may be allowed during extremely cold periods when normal ventilation rates could cause an excessive heating demand. Humidity level is not normally the controlling factor in mild or hot weather.

Air Quality Control

Contaminants. High moisture levels can also aggravate contaminant problems. The most common air contaminants in animal buildings are particulate matter (PM) and gases. In animal buildings, particulate matter originates mainly from feed, litter, fecal materials, and other animal substances. Particulates include solid particles (or dust), liquid droplets, and microorganisms, can be deposited deep within the respiratory system. Particulates carry allergens that cause discomfort and health problems for workers in animal housing facilities. They also carry much of the odors in animal housing facilities, for potentially long distances from the facilities. Consequently, particulates pose major problems for animals, workers, and neighbors. Particulate levels in swine buildings have been measured to range from 1 to 15 mg/m^3. Dust has not been a major problem in dairy buildings; one two-year study found an average of only 0.5 mg/m^3 in a naturally ventilated dairy barn. Poultry building dust levels average around 2 to 7 mg/m^3, but levels up to 18 to 29 mg/m^3 have been measured during high activity.

The most common gas contaminants are ammonia, hydrogen sulfide, other odorous compounds, carbon dioxide, and carbon monoxide. Ammonia, which results from decomposition of manure, is the most important chronically present contaminant gas. Typical ammonia levels measured have been 7 to 37 mg/m^3 in poultry units, 0 to 15 mg/m^3 in cattle buildings, 4 to 22 mg/m^3 in swine units with liquid manure systems, and 7 to 37 mg/m^3 in swine units with solid floors (Ni et al. 1998a). Up to 150 mg/m^3 have been measured in swine units in winter. Ammonia should be maintained below 18 mg/m^3 and, ideally, below 7 mg/m^3.

Maghirang et al. (1995) and Zhang et al. (1992) found ammonia levels in laboratory animal rooms to be negligible, but concentrations could reach 45 mg/m^3 in cages. Weiss et al. (1991) found ammonia levels in rat cages of up to 260 mg/m^3 with four male rats per cage and 50 mg/m^3 with four female rats per cage. Hasenau et al. (1993) found that ammonia levels varied widely among various mouse microisolation cages; ammonia ranged from negligible to 380 mg/m^3 nine days after cleaning the cage.

Hydrogen sulfide, a by-product of microbial decomposition of stored manure, is the most important acute gas contaminant. During normal operation, hydrogen sulfide concentration is usually insignificant (i.e., below 1 mg/m^3). A typical level of hydrogen sulfide in swine buildings is around 200 to 500 μg/m^3 (Ni et al. 1998b). However, levels can reach 280 to 460 mg/m^3, and possibly up to 1.4 to 11 g/m^3 during in-building manure agitation.

Odors from animal facilities are an increasing concern, both in the facilities and surrounding areas. Odors result from both gases and particulates; particulates are of primary concern because odorous gases can be quickly diluted below odor threshold concentrations in typical weather conditions, whereas particulates can retain odor for long periods. Methods that control particulate and odorous gas concentrations in the air also reduce odors, but controlling odor generation at the source appears to be the most promising method of odor control.

Barber et al. (1993), reporting on 173 pig buildings, found that carbon dioxide concentrations were below 5400 mg/m^3 in nearly all instances when the external temperature was above 0°C but almost always above 5400 mg/m^3 when the temperature was below 0°C. The report indicated that there was a very high penalty in heating cost in cold climates if the maximum allowed carbon dioxide concentration was less than 9000 mg/m^3. Air quality control based on carbon dioxide concentrations was suggested by Donham et al. (1989). They suggested a carbon dioxide concentration of 2770 mg/m^3 as a threshold level, above which symptoms of respiratory disorders occurred in a population of swine building workers. For other industries, a carbon dioxide concentration of 9000 mg/m^3 is suggested as the time-weighted threshold limit value for 8 h of exposure (ACGIH 1998).

Other gas contaminants can also be important. Carbon monoxide from improperly operating unvented space heaters sometimes reaches problem levels. Methane is another occasional concern.

Control Methods. Three standard methods used to control air contaminant levels in animal facilities are

1. Reduce contaminant production at the sources
2. Remove contaminants from the air by air cleaning
3. Reduce contaminant concentration by dilution (ventilation)

The first line of defense is to reduce release of contaminants from the source, or at least to intercept and remove them before they reach workers and animals. Animal feces and urine are the largest sources of contaminants, but feed, litter, and animal bodies are also a major source of contaminants, especially particulates. Successful operations effectively collect and remove all manure from the building within three days, before it decomposes enough to produce large quantities of contaminants. Removing ventilation air uniformly from manure storage or collection areas helps remove contaminants before they reach animal or worker areas.

Ammonia production can be minimized by removing wastes from the room and keeping floor surfaces or bedding dry. Immediately covering manure solids in gutters and pits with water also reduces ammonia, which is highly soluble in water. Because adverse effects of hydrogen sulfide on production begin to occur at 30 mg/m^3, ventilation systems should be designed to maintain hydrogen sulfide levels below 30 mg/m^3 during agitation. When manure is agitated and removed from the storage, the building should be well ventilated and all animals and occupants evacuated to avoid potentially fatal concentrations of gases.

For laboratory animals, changing the bedding frequently and keeping the bedding dry with lower relative humidities and appropriate cage ventilation can reduce ammonia release. Individually ventilated laboratory animal cages or placing cages in mass air displacement units reduce contaminant production by keeping litter drier. Using localized contaminant work stations for dust-producing tasks such as cage changing may also help. For poultry or laboratory animals, the relative humidity of air surrounding the litter should be kept between 50 and 75% to reduce particulate and gas contaminant release. Relative humidities between 40 and 75% also reduce the viability of pathogens in the air. A moisture content of 25 to 30% (wet basis) in the litter or bedding keeps dust to a minimum. Adding 0.5 to 2% of edible oil or fat can significantly reduce dust emission from the feed. Respirable dust (smaller than 10 μm), which is most harmful to the health and comfort of personnel and animals, is primarily from feces, animal skins, and dead microorganisms. Respirable dust concentration should be kept below 0.23 mg/m^3. Some dust control technologies are available. For example, sprinkling oil at 5 mL/m^2 of floor area per day can reduce dust concentration by more that 80%. High animal activity levels release large quantities of particulates into the air, so management strategies to reduce agitation of animals are helpful.

Methods of removing contaminants from the air are essentially limited to particulate removal, because gas removal methods are often too costly for animal facilities. Some animal workers wear personal protection devices (appropriate masks) to reduce inhaled particulates. Room air filters reduce animal disease problems, but they have not proven practical for large animal facilities because of the large quantity of particulates and the difficulty in drawing particulates from the room and through a filter. Air scrubbers can remove gases and particulates, but the initial cost and maintenance make them impractical. Aerodynamic centrifugation is showing promise for removing the small particulates found in animal buildings.

Ventilation is the most prevalent method used to control gas contaminant levels in animal facilities. It is reasonably effective in removing gases, but not as effective in removing particulates. Pockets in a room with high concentrations of particulate contaminants are common. These polluted pockets occur in dead air spots or near large contaminant sources. Providing high levels of ventilation can be costly in winter, can create drafts on the animals, and can increase the release of gas contaminants by increasing air velocity across the source.

Disease Control

Airborne microbes can transfer disease-causing organisms among animals. For some situations, typically with young animals where there are low-level infections, it is important to minimize air mixing among animal groups. It is especially important to minimize air exchange between different animal rooms, so buildings need to be fairly airtight.

Poor thermal environments and air contaminants can increase stress on the animals, which can make them more susceptible to disease. Therefore, a good environmental control system is important for disease prevention.

Air Distribution

Air speed should be maintained below 0.25 m/s for most animal species in both cold and mild weather. Animal sensitivities to draft are comparable to those of humans, although some animals are more sensitive at different stages. Riskowski and Bundy (1988) documented that air velocities for optimal rates of gain and feed

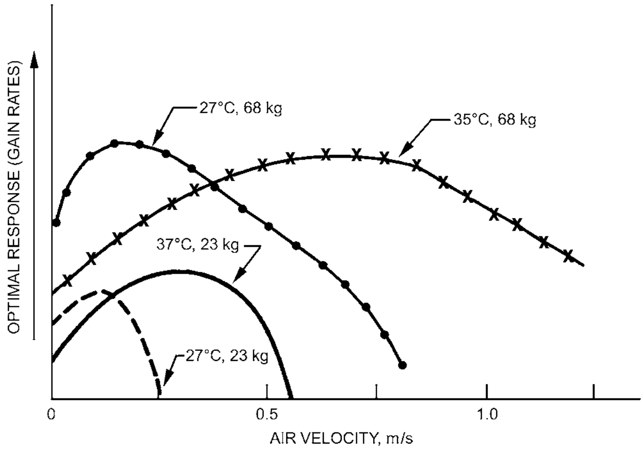

Fig. 2 Response of Swine to Air Velocity

efficiencies can be below 0.13 m/s for young pigs at thermoneutral conditions.

Increased air movement during hot weather increases growth rates and improves heat tolerance. There are conflicting and limited data defining optimal air velocity in hot weather. Bond et al. (1965) and Riskowski and Bundy (1988) determined that both young and mature swine perform best when air speed is less than 1 m/s (Figure 2). Mount and Start (1980) did not observe performance penalties at air speeds increased to a maximum of 0.76 m/s.

Degree of Shelter

Livestock, especially young animals, need some protection from adverse climates. On the open range, mature cattle and sheep need protection during severe winter conditions. In winter, dairy cattle and swine may be protected from precipitation and wind with a three-sided, roofed shelter open on the leeward side. The windward side should also have approximately 10% of the wall surface area open to prevent negative pressure inside the shelter, which could cause rain and snow to be drawn into the building on the leeward side. These shelters do not protect against high temperature or high humidity.

In warmer climates, shades often provide adequate shelter, especially for large, mature animals such as dairy cows. Shades are commonly used in Arizona; research in Florida has shown an approximate 10% increase in milk production and a 75% increase in conception efficiency for shaded versus unshaded cows. The benefit of shades has not been documented for areas with less severe summer temperatures. Although shades for beef cattle are also common practice in the southwestern United States, beef cattle are somewhat less susceptible to heat stress, and extensive comparisons of various shade types in Florida have detected little or no differences in daily mass gain or feed conversion.

The energy exchange between an animal and various areas of the environment is illustrated in Figure 3. A well-designed shade makes maximum use of radiant heat sinks, such as the cold sky, and gives maximum protection from direct solar radiation and high surface temperature under the shade. Good design considers geometric orientation and material selection, including roof surface treatment and insulation material on the lower surface.

An ideal shade has a top surface that is highly reflective to solar energy and a lower surface that is highly absorptive to solar radiation reflected from the ground. A white-painted upper surface reflects solar radiation, yet emits infrared energy better than aluminum. The undersurface should be painted a dark color to prevent multiple reflection of shortwave energy onto animals under the shade.

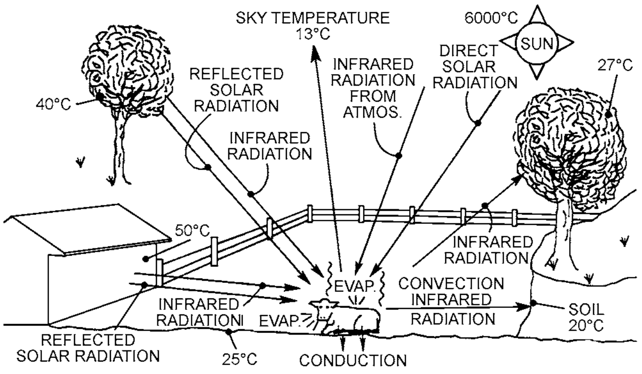

Fig. 3 Energy Exchange Between Farm Animal and Surroundings in Hot Environment

1.1 COOLING AND HEATING

Air Velocity

Increasing air velocity helps to facilitate the cooling of mature animals. It is especially beneficial when combined with skin wetting evaporative cooling. Mature swine benefit most with air velocities up to 1 m/s; cattle around 1.5 m/s; and poultry around 3 m/s. Air velocity can be increased with air circulation fans that blow air horizontally in circular patterns around the room, paddle fans that blow air downward, or tunnel cooling that moves air horizontally along the length of the building.

Evaporative Cooling

Supplemental cooling of animals in intensive housing conditions may be necessary during heat waves to prevent heat prostration, mortality, or serious losses in production and reproduction. Evaporative cooling, which may reduce ventilation air to 27°C or lower in most of the United States, is popular for poultry houses, and is sometimes used for swine and dairy housing.

Evaporative cooling is well suited to animal housing because the high air exchange rates effectively remove odors and ammonia, and increase air movement for convective heat relief. Initial cost, operating expense, and maintenance problems are all relatively low compared to other types of cooling systems. Evaporative cooling works best in areas with low relative humidity, but significant benefits can be obtained even in the humid southeastern United States.

Design. The pad area should be sized to maintain air velocities between 1.0 and 1.4 m/s through the pads. For most pad systems, these velocities produce evaporative efficiencies between 75 and 85%; they also increase pressures against the ventilating fans from 10 to 30 Pa, depending on pad design.

The building and pad system must be airtight because air leaks caused by the negative-pressure ventilation reduce airflow through the pads, and hence reduce cooling effectiveness.

The most serious problem encountered with evaporative pads for agricultural applications is clogging by dust and other airborne particles. Whenever possible, fans should exhaust away from pads on adjacent buildings. Regular preventive maintenance is essential. Water bleed-off and the addition of algaecides to the water are recommended. When pads are not used in cool weather, they should be sealed to prevent dusty inside air from exhausting through them.

High-pressure fogging with water pressure of 3.5 MPa is preferred to pad coolers for cooling air in broiler houses with built-up litter. The high pressure creates a fine aerosol, causing minimal litter wetting. Timers and/or thermostats control the cooling. Evaporative efficiency and installation cost are about one-half those of a well-designed evaporative pad. Foggers can also be used with naturally ventilated, open-sided housing. Low-pressure systems are not recommended for poultry, but may be used during emergencies.

Nozzles that produce water mist or spray droplets to wet animals directly are used extensively during hot weather in swine confinement facilities with solid concrete or slatted floors. Currently, misting or sprinkling systems with larger droplets that directly wet the skin surface of the animals (not merely the outer portion of the hair coat) are preferred. Timers that operate periodically, (e.g., 2 to 3 min on a 15 to 20 min cycle) help to conserve water.

Mechanical Refrigeration

Mechanical refrigeration can be designed for effective animal cooling, but it is considered uneconomical for most production animals. Air-conditioning loads for dairy housing may require 2.5 kW or more per cow. Recirculation of refrigeration air is usually not feasible because of high contaminant loads in the air in the animal housing. Sometimes, zone cooling of individual animals is used instead of whole-room cooling, particularly in swine farrowing houses, where a lower air temperature is needed for sows than for unweaned piglets. It is also beneficial for swine boars and gestating sows. Refrigerated air, 10 to 20 K below ambient temperature, is supplied through insulated ducts directly to the head and face of the animal. Air delivery rates are typically 10 to 20 L/s per animal for snout cooling, and 30 to 40 L/s per sow for zone cooling.

Earth Tubes

Some livestock facilities obtain cooling in summer and heating in winter by drawing ventilation air through tubing buried 2 to 4 m below grade. These systems are most practical in the north central United States for animals that benefit from both cooling in summer and heating in winter.

MWPS (1990b) details design procedures for this method. A typical design uses 15 to 50 m of 200 mm diameter pipe to provide 150 L/s of tempered air. Soil type and moisture, pipe depth, airflow, climate, and other factors affect the efficiency of buried pipe heat exchangers. The pipes must slope to drain condensation, and must not have dips that could plug with condensation.

Heat Exchangers

Ventilation accounts for 70 to 90% of the heat losses in typical livestock facilities during winter. Heat exchangers can reclaim some of the heat lost with the exhaust ventilating air. However, predicting fuel savings based on savings obtained during the coldest periods overestimates yearly savings from a heat exchanger. Estimates of energy savings based on air enthalpy can improve the accuracy of the predictions.

Heat exchanger design must address the problems of condensate freezing and/or dust accumulation on the heat-exchanging surfaces. If unresolved, these problems result in either reduced efficiency and/or the inconvenience of frequent cleaning.

Supplemental Heating

For poultry with a mass of 1.5 kg or more, for pigs heavier than 23 kg, and for other large animals such as dairy cows, body heat of animals at recommended space allocations is usually sufficient to maintain moderate temperatures (i.e., above 10°C) in a well-insulated structure. Combustion-type heaters are used to supplement heat for baby chicks and pigs. Supplemental heating also increases the moisture-holding capacity of the air, which reduces the quantity of air required for moisture removal. Various types of heating equipment may be included in ventilation, but they need to perform well in dusty and corrosive atmospheres.

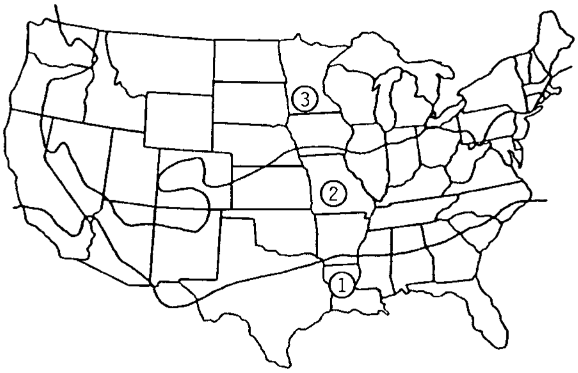

Fig. 4 Climatic Zones
(Reprinted with permission from ASAE *Standard* S401.2)

Table 1 Minimum Recommended Overall Coefficients of Heat Transmission *U* for Insulated Assemblies[a,b]

Climatic Zone[d]	Recommended Minimum *U*, W/(m²·K)[c] Cold Walls	Cold Ceiling	Modified Environment Walls	Modified Environment Ceiling	Supplementally Heated Walls	Supplementally Heated Ceiling
1	—	0.91[e]	0.91[e]	0.40	0.40	0.26
2	—	0.91	0.91	0.33	0.40	0.23
3	—	0.91	0.48	0.23	0.29	0.17

[a]Use assembly U-factors that include framing effects, air spaces, air films, linings, and sidings. Determine assembly U-factors by testing the full assembly in accordance with ASTM *Standard* C236 or C976 or calculate by the procedures presented in the 2017 *ASHRAE Handbook—Fundamentals.*
[b]Values shown do not represent the values necessary to provide a heat balance between heat produced by products or animals and heat transferred through the building.
[c]Current practice for poultry grow-out buildings uses a *U* of 0.63 to 0.81 W/(m²·K) in the roof and walls.
[d]Refer to Figure 4.
[e]Where ambient temperature and radiant heat load are severe, use *U* = 0.48 W/(m²·K).

Insulation Requirements

The amount of building insulation required depends on climate, animal space allocations, and animal heat and moisture production. Refer to Figure 4 and Table 1 for selecting insulation levels. In warm weather, ventilation between the roof and insulation helps reduce the radiant heat load from the ceiling. Insulation in warm climates can be more important for reducing radiant heat loads in summer than reducing building heat loss in winter.

Cold buildings have indoor conditions about the same as outdoor conditions. Examples are free-stall barns and open-front livestock buildings. Minimum insulation is frequently recommended in the roofs of these buildings to reduce solar heat gain in summer and to reduce condensation in winter.

Modified environment buildings rely on insulation, natural ventilation, and animal heat to remove moisture and to maintain the inside within a specified temperature range. Examples are warm free-stall barns, poultry production buildings, and swine finishing units.

Supplementary heated buildings require insulation, ventilation, and extra heat to maintain the desired inside temperature and humidity. Examples are swine farrowing and nursery buildings.

1.2 VENTILATION

Mechanical Ventilation

Mechanical ventilation uses fans to create a static pressure difference between the inside and outside of a building. Farm buildings use either positive pressure, with fans forcing air into a building, or negative pressure, with exhaust fans. Some ventilation systems use a combination of positive pressure to introduce air into a building and separate fans to remove air. These zero-pressure systems are particularly appropriate for heat exchangers.

Positive-Pressure Ventilation. Fans blow outdoor air into the ventilated space, forcing humid air out through any planned outlets and through leaks in walls and ceilings. If vapor barriers are not complete, moisture can condense within the walls and ceiling during cold weather. Condensation causes deterioration of building materials and reduces insulation effectiveness. The energy used by fan motors and rejected as heat is added to the building (an advantage in winter, but a disadvantage in summer).

Negative-Pressure Ventilation. Fans exhaust air from the ventilated space while drawing outdoor air in through planned inlets and leaks in walls, in ceilings, and around doors and windows. Air distribution in negative-pressure ventilation is often less complex and costly than positive- or neutral-pressure systems. Simple openings and baffled slots in walls control and distribute air in the building. However, at low airflow rates, negative pressure ventilation may not distribute air uniformly because of air leaks and wind pressure effects. Supplemental air mixing may be necessary.

Allowances should be made for reduced fan performance caused by dust, guards, and corrosion of louver joints (Person et al. 1979). Totally enclosed fan motors are protected from exhaust air contaminants and humidity. Periodic cleaning helps prevent overheating. Negative-pressure ventilation is more commonly used than positive-pressure ventilation.

Ventilation should always be designed so that manure gases are not drawn into the building from manure storages connected to the building by underground pipes or channels.

Neutral-Pressure Ventilation. Neutral-pressure (push/pull) ventilation typically uses supply fans to distribute air down a distribution duct to room inlets, and exhaust fans to remove air from the room. Supply and exhaust fan capacities should be matched.

Neutral-pressure systems are often more expensive, but they achieve better control of the air. They are less susceptible to wind effects and to building leakage than positive- or negative-pressure systems. Neutral-pressure systems are most frequently used for young stock and for animals most sensitive to environmental conditions, primarily where cold weather is a concern.

Natural Ventilation

Either natural or mechanical ventilation is used to modify environments in livestock shelters. Natural ventilation is most common for mature animal housing, such as free-stall dairy, poultry growing, and swine finishing houses. Natural ventilation depends on pressure differences caused by wind and temperature differences. Well-designed natural ventilation keeps temperatures reasonably stable, if automatic controls regulate ventilation openings. Usually, a design includes an open ridge (with or without a rain cover) and openable sidewalls, which should cover at least 50% of the wall for summer operation. Ridge openings are about 17 mm wide for each metre of house width, with a minimum ridge width of 150 mm to avoid freezing problems in cold climates. Upstand baffles on each side of the ridge opening greatly increase airflow (Riskowski et al. 1998). Small screens and square edges around sidewall openings can significantly reduce airflow through vents.

Openings can be adjusted automatically, with control based on air temperature. Some designs, referred to as flex housing, include a combination of mechanical and natural ventilation usually dictated by outdoor air temperature and/or the amount of ventilation required.

1.3 VENTILATION MANAGEMENT

Air Distribution

Pressure differences across walls and inlet or fan openings are usually maintained between 10 and 15 Pa. (The exhaust fans are usually sized to provide proper ventilation at pressures up to 30 Pa to compensate for wind effects.) This pressure difference creates inlet velocities of 3 to 5 m/s, sufficient for effective air mixing, but low enough to cause only a small reduction in fan capacity. A properly planned inlet system distributes fresh air equally throughout the building. Negative pressure ventilation that relies on cracks around doors and windows does not distribute fresh air effectively. Inlets require adjustment, since winter airflow rates are typically less than 10% of summer rates. Automatic controllers and inlets are available to regulate inlet areas.

Positive pressure ventilation, with fans connected directly to perforated air distribution tubes, may combine heating, circulation, and ventilation in one system. Air distribution tubes or ducts connected to circulating fans are sometimes used to mix the air in negative pressure ventilation. Zhang (1994) describes detailed design procedures for perforated ventilation tubes. However, dust in the ducts is of concern when air is recirculated, particularly when cold incoming air condenses moisture in the tubes.

Inlet Design. Inlet location and size most critically affect air distribution within a building. Continuous or intermittent inlets can be placed along the entire length of one or both outer walls. Building widths narrower than 6 m may need only a single inlet along one wall. The total inlet area may be calculated by the system characteristic technique, which follows. Because the distribution of the inlet area is based on the geometry and size of the building, specific recommendations are difficult.

System Characteristic Technique. This technique determines the operating points for the ventilation rate and pressure difference across inlets. Fan airflow rate as a function of pressure difference across the fan should be available from the manufacturer. Allowances must be made for additional pressure losses from fan shutters or other devices such as light restriction systems or cooling pads.

Inlet flow characteristics are available for hinged baffle and center-ceiling flat baffle slotted inlets (Figure 5). Airflow rates can be calculated for the baffles in Figure 5 by the following:

For Case A:

$$Q = 1.1 W p^{0.5} \quad (1)$$

For Case B:

$$Q = 0.71 W p^{0.5} \quad (2)$$

For Case C (total airflow from sum of both sides):

$$Q = 1.3 W p^{0.5} (D/T)^{0.08} e^{(-0.867\ W/T)} \quad (3)$$

where

- Q = airflow rate, L/s per metre length of slot opening
- W = slot width, mm
- p = pressure difference across the inlet, Pa
- D = baffle width, mm
- T = width of slot in ceiling, mm

Zhang and Barber (1995) measured infiltration rates of five rooms in a newly built swine building at 0.6 L/s per square metre of surface area at 20 Pa. Surface area included the area of walls and ceiling enclosing the room. It is important to include this infiltration rate into the ventilation design and management. For example, at 0.6 L/s per square metre of surface area, the infiltration represents 1.4 ach. In the heating season, the minimum ventilation is usually about 3 ach. Thus, large infiltration rates greatly reduce the airflow from the controlled inlet and adversely affect the air distribution.

Room Air Velocity. The average air velocity inside a slot-ventilated structure relates to the inlet air velocity, inlet slot width

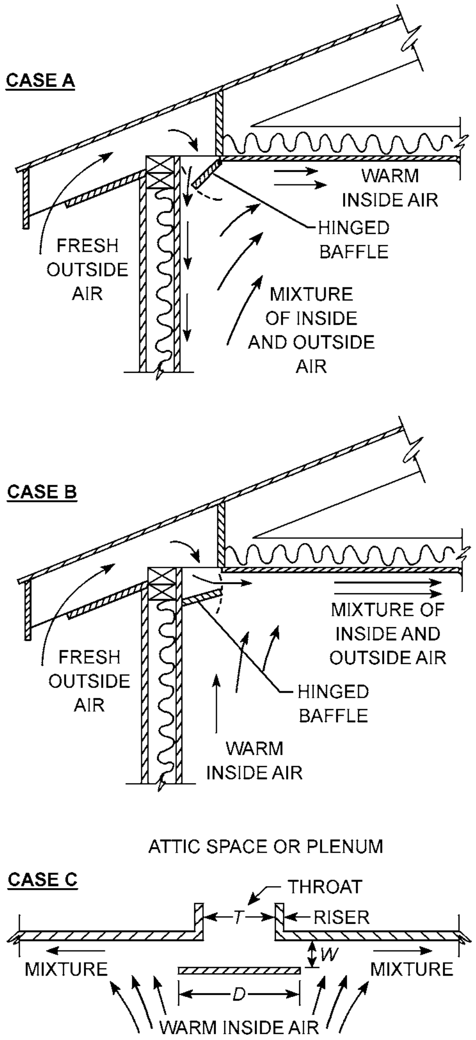

Fig. 5 Typical Livestock Building Inlet Configurations

(or equivalent continuous length for boxed inlets), building width, and ceiling height. Estimates of air velocity within a barn, based on air exchange rates, may be very low because of the effects of jet velocity and recirculation. Conditions are usually partially turbulent, and there is no reliable way to predict room air velocity at animal level. General design guidelines keep the throw distance less than 6 m from slots and less than 3 m from perforated tubes.

Fans

Fans should not exhaust against prevailing winds, especially for cold-weather ventilation. If structural or other factors require installing fans on the windward side, fans rated to deliver the required capacity against at least 30 Pa static pressure and with a relatively flat power curve should be selected. The fan motor should withstand a wind velocity of 50 km/h, equivalent to a static pressure of 100 Pa, without overloading beyond its service factor. Wind hoods on the fans or windbreak fences reduce the effects of wind.

Third-party test data should be used to obtain fan performance and energy efficiencies for fan selection (BESS Lab 1997). Fans should be tested with all accessories (e.g., louvers, guards, hoods) in place, just as they will be installed in the building. The accessories have a major effect on fan performance.

Flow Control. Because the numbers and size of livestock and climatic conditions vary, means to modulate ventilation rates are often required beyond the conventional off/on thermostat switch. The minimum ventilation rate to remove moisture, reduce air contaminant concentrations, and keep water from freezing should always be provided. Methods of modulating ventilation rates include (1) intermittent fan operation (fans operate for a percentage of the time controlled by a percentage timer with a 10 min cycle); (2) staging of fans using multiple units or fans with high/low-exhaust capability; (3) using multispeed fans [larger fans (400 W and up) with two flow rates, the lower being about 60% of the maximum rate]; and (4) using variable-speed fans [split-capacitor motors designed to modulate fan speed smoothly from maximum down to 10 to 20% of the maximum rate (the controller is usually thermostatically adjusted)].

Generally, fans are spaced uniformly along the winter leeward side of a building. Maximum distance between fans is 35 to 40 m. Fans may be grouped in a bank if this range is not exceeded. In housing with side curtains, exhaust fans that can be reversed or removed and placed inside the building in the summer are sometimes installed to increase air movement in combination with doors, walls, or windows being opened for natural ventilation.

Thermostats

Thermostats should be placed where they respond to a representative temperature as sensed by the animals. Thermostats need protection and should be placed to prevent potential physical or moisture damage (i.e., away from animals, ventilation inlets, water pipes, lights, heater exhausts, outer walls, or any other objects that will unduly affect performance). Thermostats also require periodic adjustment based on accurate thermometer readings taken in the immediate proximity of the animal.

Emergency Warning

Animals housed in a high-density, mechanically controlled environment are subject to considerable risk of heat prostration if a failure of power or ventilation equipment occurs. To reduce this danger, an alarm and an automatic standby electric generator are highly recommended. Many alarms detect failure of the ventilation. These alarms range from inexpensive power-off alarms to ones that sense temperature extremes and certain gases. Automatic telephone-dialing systems are effective as alarms and are relatively inexpensive. Building designs that allow some side wall panels (e.g., 25% of wall area) to be removed for emergency situations are also recommended.

1.4 RECOMMENDED PRACTICES BY SPECIES

Mature animals readily adapt to a broad range of temperatures, but efficiency of production varies. Younger animals are more temperature sensitive. Figure 6 illustrates animal production response to temperature.

Relative humidity has not been shown to influence animal performance, except when accompanied by thermal stress. Relative humidity consistently below 40% may contribute to excessive dustiness; above 80%, it may increase building and equipment deterioration. Disease pathogens also appear to be more viable at either low or high humidity. Relative humidity has a major influence on the effectiveness of skin-wetting cooling methods.

Dairy Cattle

Dairy cattle shelters include confinement stall barns, free stalls, and loose housing. In a stall barn, cattle are usually confined to stalls approximately 1.2 m wide, where all chores, including milking and feeding, are conducted. Such a structure requires environmental modification, primarily through ventilation. Total space requirements are 5 to 7 m^2 per cow. In free-stall housing, cattle are not confined to stalls but can move freely. Space requirements per cow are 7 to 9 m^2. In loose housing, cattle are free to move within a fenced lot containing resting and feeding areas. Space required in sheltered loose housing is similar to that in free-stall housing. Shelters for resting and feeding areas are generally open-sided and require no air conditioning or mechanical ventilation, but supplemental air mixing is often beneficial during warm weather. The milking area is in a separate area or facility and may be fully or partially enclosed, thus requiring some ventilation.

For dairy cattle, climate requirements for minimal economic loss are broad, and range from 2 to 24°C with 40 to 80% rh. Below 2°C, production efficiency declines and management problems increase. However, the effect of low temperature on milk production is not as extreme as are high temperatures, where evaporative coolers or other cooling methods may be warranted.

Ventilation Rates for Each 500 kg Cow

Winter	Spring/Fall	Summer
17 to 22 L/s	67 to 90 L/s	110 to 220 L/s

Required ventilation rates depend on specific thermal characteristics of individual buildings and internal heating load. The relative humidity should be maintained between 50 and 80%.

Both loose housing and stall barns require an additional milk room to cool and hold the milk. Sanitation codes for milk production contain minimum ventilation requirements. The market being supplied should be consulted for all applicable codes. Some state codes require positive-pressure ventilation of milk rooms. Milk rooms are usually ventilated with fans at rates of 4 to 10 ach to satisfy requirements of local milk codes and to remove heat from milk coolers. Most milk codes require ventilation in the passageway (if any) between the milking area and the milk room.

Beef Cattle

Beef cattle ventilation requirements are similar to those of dairy cattle on a unit mass basis. Beef production facilities often provide only shade and wind breaks.

Swine

Swine housing can be grouped into four general classifications:

1. Farrowing pigs, from birth to 14 kg, and sows
2. Nursery pigs, from 14 to 34 kg
3. Growing/finishing pigs, from 34 kg to market size
4. Breeding and gestation

In farrowing barns, two environments must be provided: one for sows and one for piglets. Because each requires a different temperature, zone heating and/or cooling is used. The environment within the nursery is similar to that within the farrowing barn for piglets. The requirements for growing barns and breeding stock housing are similar.

Currently recommended practices for **farrowing houses**:

- Temperature: 10 to 20°C, with small areas for piglets warmed to 28 to 32°C by brooders, heat lamps, or floor heat. Avoid cold drafts and extreme temperatures. Hovers are sometimes used. Provide supplemental cooling for sows (usually drippers or zone cooling) in extreme heat.
- Relative humidity: Up to 70% maximum
- Ventilation rate: 10 to 240 L/s per sow and litter (about 180 kg total mass). The low rate is for winter; the high rate is for summer temperature control.
- Space: 3.25 m^2 per sow and litter (stall); 6.0 m^2 per sow and litter (pens)

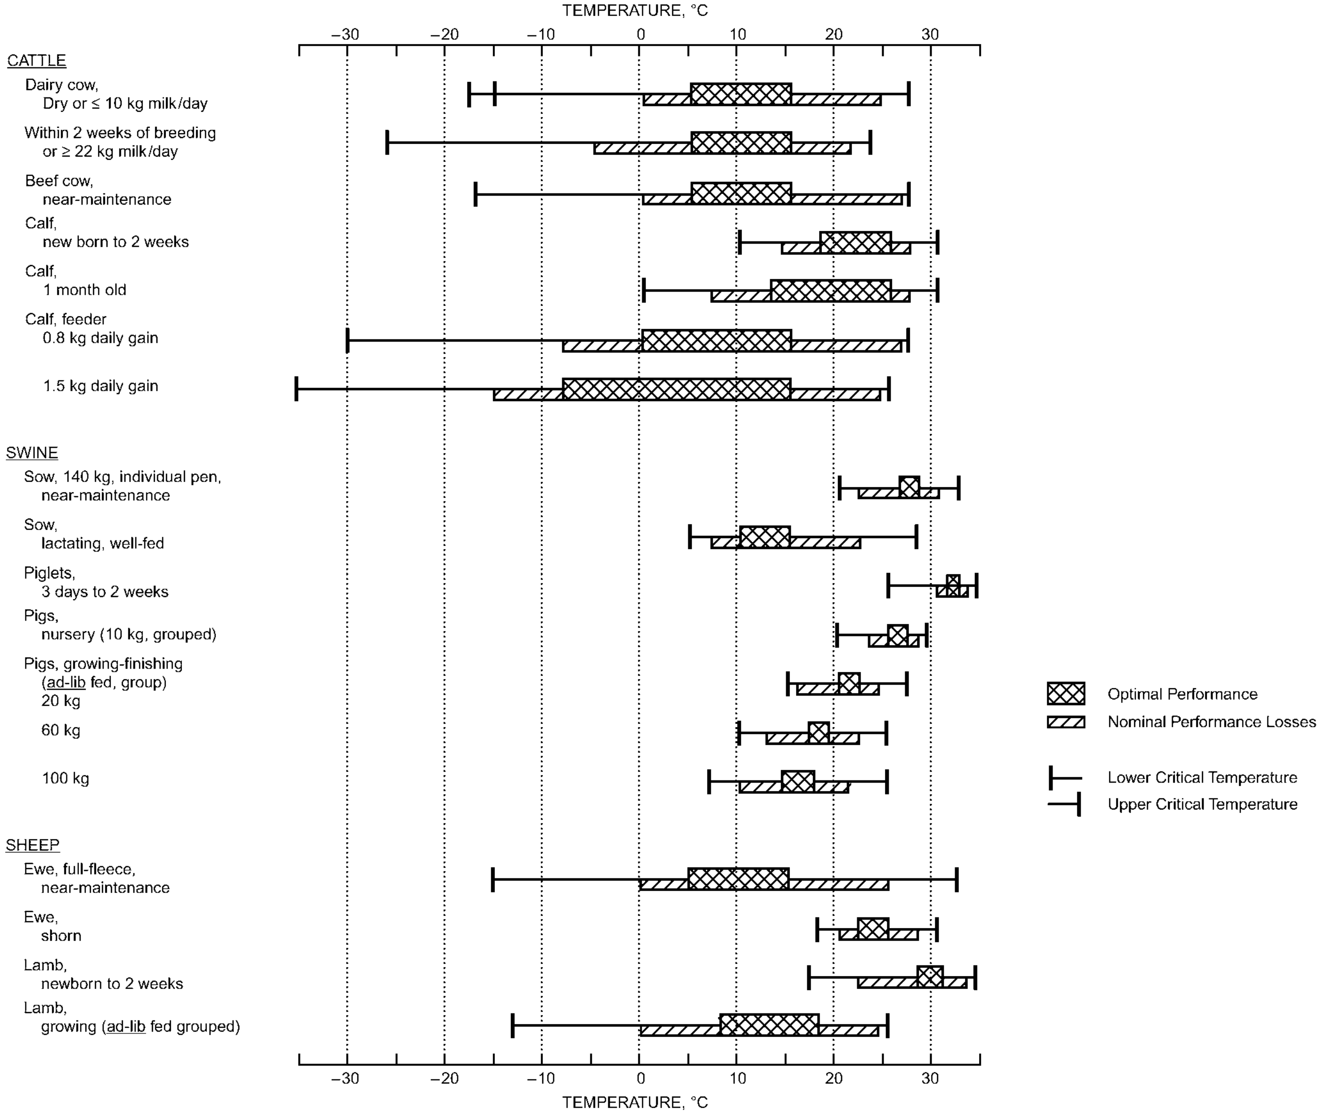

Fig. 6 Critical Ambient Temperatures and Temperature Zone for Optimum Performance and Nominal Performance Loss in Farm Animals
(Adapted from Hahn 1985, in *Stress Physiology in Livestock*, Vol. II, CRC Press)

Recommendations for **nursery barns**:

- Temperature:
  27°C for first week after weaning. Lower room temperature 1.5 K per week to 21°C. Provide warm, draft-free floors. Provide supplemental cooling for extreme heat (temperatures 30°C and above).
- Ventilation rate:
  1 to 12 L/s per pig, 5.5 to 14 kg each
  1.5 to 18 L/s per pig, 6 to 36 kg each
- Space:
  0.19 to 0.23 m^2 per pig, 5.5 to 14 kg each
  0.28 to 0.37 m^2 per pig, 6 to 14 kg each

Recommendations for **growing** and **gestation barns**:

- Temperature:
  13 to 22°C preferred. Provide supplemental cooling (sprinklers or evaporative coolers) for extreme heat.
- Relative humidity:
  75% maximum in winter; no established limit in summer
- Ventilation rate:
  Growing pig (34 to 68 kg), 3 to 35 L/s
  Finishing pig (68 to 100 kg), 5 to 60 L/s
  Gestating sow (150 kg), 6 to 70 L/s
  Boar/breeding sow (180 kg), 7 to 140 L/s
- Space:
  0.55 m^2 per pig, 34 to 68 kg each
  0.75 m^2 per pig, 68 to 100 kg each
  1.3 to 2.2 m^2 per pig, 110 to 130 kg each

Poultry

In broiler and brooder houses, growing chicks require changing environmental conditions, and heat and moisture dissipation rates increase as the chicks grow older. Supplemental heat, usually from brooders, is used until sensible heat produced by the birds is adequate to maintain an acceptable air temperature. At early stages of growth, moisture dissipation per bird is low. Consequently, low ventilation rates are recommended to prevent excessive heat loss.

Litter is allowed to accumulate over 3 to 5 flock placements. Lack of low-cost litter material may justify the use of concrete floors. After each flock, caked litter is removed and fresh litter is added.

Housing for poultry may be open, curtain-sided or totally enclosed. Mechanical ventilation depends on the type of housing used. For open-sided housing, ventilation is generally natural airflow in warm weather, supplemented with stirring fans, and by fans with closed curtains in cold weather or during the brooding period. Mechanical ventilation is used in totally enclosed housing. Newer houses have smaller curtains and well-insulated construction to accommodate both natural and mechanical ventilation operation.

Recommendations for **broiler houses**:

- Room temperature: 15 to 27°C
- Temperature under brooder hover: 30 to 33°C, reducing 3 K per week until room temperature is reached
- Relative humidity: 50 to 80%
- Ventilation rate: Sufficient to maintain house within 1 to 2 K of outdoor air conditions during summer. Generally, rates are about 0.1 L/s per kilogram live mass during winter and 1 to 2 L/s per kilogram for summer conditions.
- Space: 0.06 to 0.1 m^2 per bird (for the first 21 days of brooding, only 50% of floor space is used)
- Light: Minimum of 10 lx to 28 days of age; 1 to 20 lx for growout (in enclosed housing).

Recommendations for **breeder houses** with birds on litter and slatted floors:

- Temperature: 10 to 30°C maximum; consider evaporative cooling if higher temperatures are expected.
- Relative humidity: 50 to 75%
- Ventilation rate: Same as for broilers on live mass basis.
- Space: 0.2 to 0.3 m^2 per bird

Recommendations for **laying houses** with birds in cages:

- Temperature, relative humidity, and ventilation rate: Same as for breeders.
- Space: 0.032 to 0.042 m^2 per hen minimum
- Light: Controlled day length using light-controlled housing is generally practiced (January through June).

Laboratory Animals

The well-being and experimental response of laboratory animals depend greatly on the design of the facilities. Cage type, noise levels, light levels, air quality, and thermal environment can affect animal well-being and, in many cases, affect how the animal responds to experimental treatments (Clough 1982; Lindsey et al. 1978; McPherson 1975; Moreland 1975). If any of these factors vary across treatments or even within treatments, it can affect the validity of experimental results, or at least increase experimental error. Consequently, laboratory animal facilities must be designed and maintained to expose the animals to appropriate levels of these environmental conditions and to ensure that all animals in an experiment are in a uniform environment. See Chapter 16 for additional information on laboratory animal facilities.

In the United States, recommended environmental conditions within laboratory animal facilities are usually dictated by Institute for Laboratory Animal Research (ILAR 1996). Temperature recommendations vary from 16 to 29°C, depending on the species being housed. The acceptable range for relative humidity is 30 to 70%. For animals in confined spaces, daily temperature fluctuations should be minimized. Relative humidity must also be controlled, but not as precisely as temperature.

Ventilation recommendations are based on room air changes; however, cage ventilation rates may be inadequate in some cages and excessive in other cages, depending on cage and facility design. ILAR (1996) recommendations for room ventilation rates of 10 to 15 ach are an attempt to provide adequate ventilation for the room and cages. This recommendation is based on the assumption that adequate ventilation in the macroenvironment (room) provides sufficient ventilation to the microenvironment (cage). This may be a reasonable assumption when cages have a top of wire rods or mesh. However, several studies have shown that covering cages with filter tops, which provide a protective barrier for rodents and reduce airborne infections and diseases, especially neonatal diarrhea, can create significant differences in microenvironmental conditions.

Maghirang et al. (1995) and Riskowski et al. (1996) surveyed room and cage environmental conditions in several laboratory animal facilities and found that the animal's environmental needs may not be met even though the facilities were designed and operated according to ILAR (1996). The microenvironments were often considerably poorer than the room conditions, especially in microisolator cages. For example, ammonia levels in cages were up to 45 mg/m^3 even though no ammonia was detected in a room. Cage temperatures were up to 4 K higher than room temperature and relative humidities up to 41% higher.

Furthermore, cage microenvironments in the same room were found to have significant variation (Riskowski et al. 1996): ammonia levels varied from 0 to 45 mg/m^3, air temperature varied from 0.5 to 4 K higher than room temperature, relative humidity varied from 1 to 30% higher than room humidity, and average light levels varied from 2 to 337 lx. This survey found three identical rooms that had room ventilation rates from 4.4 to 12.5 ach but had no differences in room or cage environmental parameters.

A survey of laboratory animal environmental conditions in seven laboratory rat rooms was conducted by Zhang et al. (1992). They found that room air ammonia levels were under 0.37 mg/m^3 for all rooms, even though room airflow varied from 11 to 24 ach. Air exchange rates in the cages varied from less than 0.05 L/s to 1.2 L/s per rat, and ammonia levels ranged from negligible to 45 mg/m^3. Riskowski et al. (1996) measured several environmental parameters in rat shoebox cages in full-scale room mockups with various room and ventilation configurations. Significant variations in cage temperature and ventilation rates within a room were also found. Varying room ventilation rate from 5 to 15 ach did not have large effects on cage environmental conditions. These studies verify that designs based only on room air changes do not guarantee desired conditions in the animal cages.

In order to analyze the ventilation performance of different laboratory animal research facilities, Memarzadeh (1998) used **computational fluid dynamics** (CFD) to undertake computer simulation of over 100 different room configurations. CFD is a three-dimensional mathematical technique used to compute the motion of air, water, or any other gas or liquid. However, all conditions must be correctly specified in the simulation to produce accurate results. Empirical work defined inputs for such parameters as heat dissipation and surface temperature as well as the moisture, CO_2, and NH_3 mass generation rates for mice.

This approach compared favorably with experimentally measured temperatures and gas concentrations in a typical animal research facility. To investigate the relationships between room configuration parameters and the room and cage environments in laboratory animal research facilities, the following parameters were varied:

- Supply air diffuser type and orientation, air temperature, and air moisture content
- Room ventilation rate
- Exhaust location and number
- Room pressurization
- Rack layout and cage density
- Change station location, design, and status

- Leakage between the cage lower and upper moldings
- Room width

Room pressurization, change station design, and room width had little effect on ventilation performance. However, other factors found to affect the macroenvironment, microenvironment, or both led to the following observations:

- Ammonia production depends on relative humidity. Ten days after the last change of bedding, a high-humidity environment produced ammonia at about three times the rate of cages in a low-humidity environment.
- Acceptable room and cage ammonia concentrations after 5 days without changing cage bedding are produced by room supply airflow rates of around 4 L/s per kilogram of body mass of mice. This is equivalent to 5 ach for the room with single-density racks considered in this study, and 10 ach for the room with double-density racks. The temperature of the supply air must be set appropriately for the heat load in the room. The room with single-density racks contained 1050 mice with a total mass of 21 kg and the room with double-density racks contained 2100 mice with a total mass of 42 kg.
- Increasing the room ventilation rate does not have a large effect on the cage ventilation. Increasing the supply airflow from 5 to 20 ach around single-density racks parallel to the walls reduces the CO_2 concentration from 3175 to 3000 mg/m^3, a reduction of only 6%. For the double-density racks perpendicular to the walls, the reduction is larger, but still only from about 4140 to 3240 mg/m^3 (around 20%)
- Both the cage and the room ammonia concentrations can be reduced by increasing the supply air temperatures. This reduces the relative humidity for a given constant moisture content in the air, and the lower relative humidity leads to lower ammonia generation. Raising the supply discharge temperature from 19 to 22°C at 15 ach raises the room temperature by 3 K to around 23°C and the cages by 2 K to around 25°C. This can reduce ammonia concentrations by up to 50%.
- Using 22°C as the supply discharge temperature at 5 ach (the lowest flow rate considered) for double-density racks produces a room temperature around 26°C, with cage temperatures only slightly higher. Although this higher temperature provides a more comfortable environment for the mice (Gordon et al. 1997), the high room temperature may be unacceptable to the scientists working in the room.
- Ceiling or high-level exhausts tend to produce lower room temperatures (for a given supply air temperature, all CFD models were designed to have 22°C at the room exhaust) when compared to low-level exhausts. This indicates that low-level exhausts are less efficient at cooling the room.
- Low-level exhausts appear to ventilate the cages slightly better (up to 27% for the radial diffuser; much less for the slot diffuser) than ceiling or high-level exhausts when the cages are placed parallel to the walls, near the exhausts. Ammonia concentration in the cages decreased even further, although this is because of the higher temperatures in the low-level exhaust cases when compared to the ceiling and high-level exhausts. The room concentrations of CO_2 and ammonia do not show that any type of supply or exhaust is significantly better or worse than the other type.

2. DESIGN FOR PLANT FACILITIES

Greenhouses, plant growth chambers, and other facilities for indoor crop production overcome adverse outdoor environments and provide conditions conducive to economical crop production. The basic requirements of indoor crop production are (1) adequate light; (2) favorable temperatures; (3) favorable air or gas content; (4) protection from insects and disease; and (5) suitable growing media, substrate, and moisture. Because of their lower cost per unit of usable space, greenhouses are preferred over plant growth chambers for protected crop production. This section covers greenhouses and plant growth facilities.

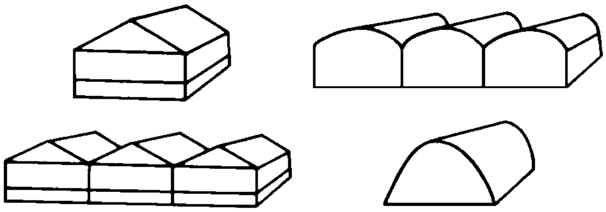

Fig. 7 Structural Shapes of Commercial Greenhouses

2.1 GREENHOUSES

Figure 7 shows the structural shapes of typical commercial greenhouses. Other greenhouses may have Gothic arches, curved glazing, or simple lean-to shapes. Glazing, in addition to traditional glass, now includes both film and rigid plastics. High light transmission by the glazing is usually important; good location and orientation of the house are also important in providing desired light conditions. Location affects heating and labor costs, exposure to plant disease and air pollution, and material handling requirements. As a general rule in the northern hemisphere, a greenhouse should be placed at a distance of at least 2.5 times the height of the object closest to it in the eastern, western, and southern directions.

Site Selection

Sunlight. Sunlight provides energy for plant growth and is often the limiting growth factor in greenhouses of the central and northern areas of North America during the winter. When planning greenhouses that are to be operated year-round, a designer should design for the greatest sunlight exposure during the short days of midwinter. The building site should have an open southern exposure, and if the land slopes, it should slope to the south.

Soil and Drainage. When plants are to be grown in the soil covered by the greenhouse, a growing site with deep, well-drained, fertile soil, preferably sandy loam or silt loam, should be chosen. Even though organic soil amendments can be added to poor soil, fewer problems occur with good natural soil. However, when good soil is not available, growing in artificial media should be considered. The greenhouse should be level, but the site can and often should be sloped and well-drained to reduce salt build-up and insufficient soil aeration. A high water table or a hardpan may produce water-saturated soil, increase greenhouse humidity, promote diseases, and prevent effective use of the greenhouse. If present, these problems can be alleviated by tile drains under and around the greenhouse. Ground beds should be level to prevent water from concentrating in low areas. Slopes within greenhouses also increase temperature and humidity stratification and create additional environmental problems.

Sheltered Areas. Provided they do not shade the greenhouse, surrounding trees act as wind barriers and help prevent winter heat loss. Deciduous trees are less effective than coniferous trees in midwinter, when the heat loss potential is greatest. In areas where snowdrifts occur, windbreaks and snowbreaks should be 30 m or more from the greenhouse to prevent damage.

Orientation. Generally, in the northern hemisphere, for single-span greenhouses located north of 35° latitude, maximum transmission during winter is attained by an east-west orientation. South of 35° latitude, orientation is not important, provided headhouse structures do not shade the greenhouse. North-south orientation provides more light on an annual basis.

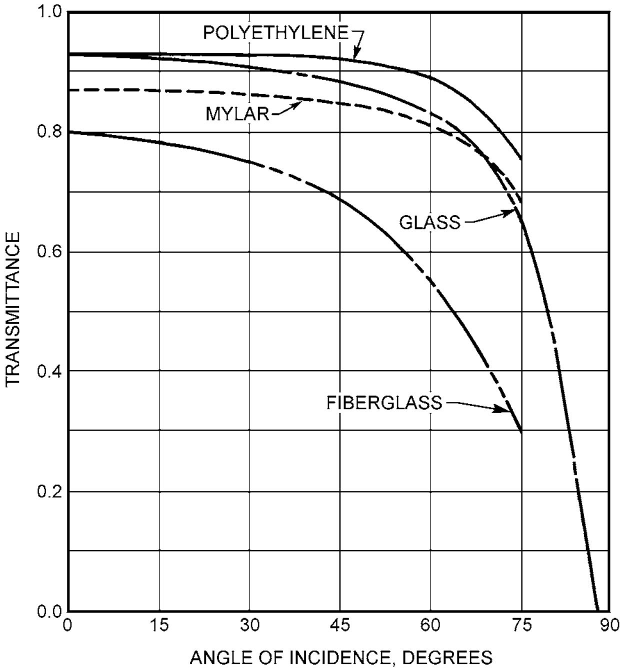

Fig. 8 Transmittance of Solar Radiation Through Glazing Materials for Various Angles of Incidence

Gutter-connected or ridge-and-furrow greenhouses are oriented preferably with the ridge line north-south regardless of latitude. This orientation allows the shadow pattern caused by the gutter superstructure to move from the west to the east side of the gutter during the day. With an east-west orientation, the shadow pattern would remain north of the gutter, and the shadow would be widest and create the most shade during winter when light levels are already low. Also, the north-south orientation allows rows of tall crops, such as roses and staked tomatoes, to align with the long dimension of the house (an alignment that is generally more suitable to long rows and the plant support methods preferred by many growers).

The slope of the greenhouse roof is a critical part of greenhouse design. If the slope is too flat, a greater percentage of sunlight is reflected from the roof surface (Figure 8). A slope with a 1:2 rise-to-run ratio is the usual inclination for a gable roof.

Heating

Structural Heat Loss. Estimates for heating and cooling a greenhouse consider conduction, infiltration, and ventilation energy exchange. In addition, the calculations must consider solar energy load and electrical input, such as light sources, which are usually much greater for greenhouses than for conventional buildings. Generally, conduction q_c plus infiltration q_i are used to determine the peak requirements q_t for heating.

$$q_t = q_c + q_i \quad (4)$$

$$q_c = UA(t_i - t_o) \quad (5)$$

$$q_i = 0.5VN(t_i - t_o) \quad (6)$$

where

U = overall heat loss coefficient, W/(m²·K) (Tables 2 and 3)
A = exposed surface area, m²
t_i = inside temperature, °C
t_o = outdoor temperature, °C
V = greenhouse internal volume, m³
N = number of air exchanges per hour (Table 4)

Table 2 Suggested Heat Transmission Coefficients

	U, W/(m²·K)
Glass	
Single-glazing	6.4
Double-glazing	4.0
Insulating	Manufacturers' data
Plastic film	
Single film[a]	6.8
Double film, inflated	4.0
Single film over glass	4.8
Double film over glass	3.4
Corrugated glass fiber	
Reinforced panels	6.8
Plastic structured sheet[b]	
16 mm thick	3.3
8 mm thick	3.7
6 mm thick	4.1

[a]Infrared barrier polyethylene films reduce heat loss; however, use this coefficient when designing heating systems because the structure could occasionally be covered with non-IR materials.
[b]Plastic structured sheets are double-walled, rigid plastic panels.

Table 3 Construction U-Factor Multipliers

Metal frame and glazing system, 400 to 600 mm spacing	1.08
Metal frame and glazing system, 1200 mm spacing	1.05
Fiberglass on metal frame	1.03
Film plastic on metal frame	1.02
Film or fiberglass on wood	1.00

Table 4 Suggested Design Air Changes (N)

New Construction	
Single glass lapped (unsealed)	1.25
Single glass lapped (laps sealed)	1.0
Plastic film covered	0.6 to 1.0
Structured sheet	1.0
Film plastic over glass	0.9
Old Construction	
Good maintenance	1.5
Poor maintenance	2 to 4

Type of Framing. The type of framing should be considered in determining overall heat loss. Aluminum framing and glazing systems may have the metal exposed to the exterior to a greater or lesser degree, and the heat transmission of this metal is higher than that of the glazing material. To allow for such a condition, the U-factor of the glazing material should be multiplied by the factors shown in Table 3.

Infiltration. Equation (6) may be used to calculate heat loss by infiltration. Table 4 suggests values for air changes N.

Radiation Energy Exchange. Solar gain can be estimated using the procedures outlined in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*. As a guide, when a greenhouse is filled with a mature crop of plants, one-half the incoming solar energy is converted to latent heat, and one-quarter to one-third, to sensible heat. The rest is either reflected out of the greenhouse or absorbed by the plants and used in photosynthesis.

Radiation from a greenhouse to a cold sky is more complex. Glass admits a large portion of solar radiation but does not transmit long-wave thermal radiation in excess of approximately 5000 nm. Plastic films transmit more of the thermal radiation but, in general, the total heat gains and losses are similar to those of glass. Newer plastic films containing infrared (IR) inhibitors reduce the thermal radiation loss. Plastic films and glass with improved radiation reflection are available at a somewhat higher cost. Some research greenhouses use a retractable horizontal heat curtain to reduce the

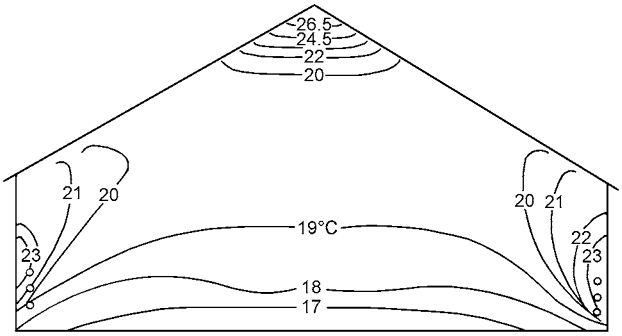

Fig. 9 Temperature Profiles in a Greenhouse Heated with Radiation Piping along the Sidewalls

effect of night sky losses. Normally, radiation energy exchange is not considered in calculating the design heat load.

Heating Systems. Greenhouses may have a variety of heaters. One is a convection heater that circulates hot water or steam through plain or finned pipe. The pipe is most commonly placed along walls and occasionally beneath plant benches to create desirable convection currents. A typical temperature distribution pattern created by perimeter heating is shown in Figure 9. More uniform temperatures can be achieved when about one-third the total heat comes from pipes spaced uniformly across the house. These pipes can be placed above or below the crop, but temperature stratification and shading are avoided when they are placed below. Outdoor weather conditions affect temperature distribution, especially on windy days in loosely constructed greenhouses. Manual or automatic overhead pipes are also used for supplemental heating to prevent snow buildup on the roof. In a gutter-connected greenhouse in a cold climate, a heat pipe should be placed under each gutter to prevent snow accumulation.

An overhead tube heater consists of a unit heater that discharges into 300 to 750 mm diameter plastic film tubing perforated to provide uniform air distribution. The tube is suspended at 2 to 3 m intervals and extends the length of the greenhouse. Variations include a tube and fan receiving the discharge of several unit heaters. The fan and tube system is used without heat to recirculate the air and, during cold weather, to introduce ventilation air. However, tubes sized for heat distribution may not be large enough for effective ventilation during warm weather.

Perforated tubing, 150 to 250 mm in diameter, placed at ground-level (underbench) heaters can also improve heat distribution. Ideally, the ground-level tubing should draw air from the top of the greenhouse for recirculation or heating. Tubes on or near the floor have the disadvantage of being obstacles to workers and reducing usable floor space.

Underfloor heating can supply up to 25% or more of the peak heating requirements in cold climates. A typical underfloor system uses 100 mm plastic pipe spaced 300 to 400 mm on center, and covered with 20 mm of gravel or porous concrete. Hot water, not exceeding 40°C, circulates at a rate of 0.5 to 1.0 L/s per loop. Pipe loops should generally not exceed 130 m in length. This can provide 50 to 65 W/m^2 from a bare floor, and about 75% as much when potted plants or seedling flats cover most of the floor.

Similar systems can heat soil directly, but root temperature must not exceed 25°C. When used with water from solar collectors or other heat sources, the underfloor area can store heat. This storage consists of a vinyl swimming pool liner placed on top of insulation and a moisture barrier at a depth of 200 to 300 mm below grade, and filled with 50% void gravel. Hot water from solar collectors or other clean sources enters and is pumped out on demand. Some heat sources, such as cooling water from power plants, cannot be used directly but require closed-loop heat transfer to avoid fouling the storage and the power plant cooling water.

Greenhouses can also be bottom-heated with 6 mm diameter EPDM tubing (or variations of that method) in a closed loop. The tubes can be placed directly in the growing medium of ground beds or under plant containers on raised benches. The best temperature uniformity is obtained by flow in alternate tubes in opposite directions. This method can supply all the greenhouse heat needed in mild climates.

Bottom heat, underfloor heating, and underbench heating are, because of the location of the heat source, more effective than overhead or peripheral heating, and can reduce energy loss by 20 to 30%.

Unless properly located and aimed, overhead unit heaters, whether hydronic or direct fired, do not give uniform temperature at the plant level and throughout the greenhouse. Horizontal blow heaters positioned so that they establish a horizontal airflow around the outside of the greenhouse offer the best distribution. The airflow pattern can be supplemented with the use of horizontal blow fans or circulators.

When direct combustion heaters are used in the greenhouse, combustion gases must be adequately vented to the outdoors to minimize danger to plants and humans from products of combustion. One manufacturer recommends that combustion air must have access to the space through a minimum of two permanent openings in the enclosure, one near the bottom. A minimum of 2200 mm^2 of free area per kilowatt input rating of the unit, with a minimum of 0.65 m^2 for each opening, whichever is greater, is recommended. Unvented direct-combustion units should not be used inside the greenhouse.

Many greenhouses combine overhead and perimeter heating. Regardless of the type of heating, it is common practice to calculate overall heat loss first, and then to calculate the individual elements such as the roof, sidewalls, and gables. It is then simple to allocate the overhead portion to the roof loss and the perimeter portions to the sides and gables, respectively.

The annual heat loss can be approximated by calculating the design heat loss and then, in combination with the annual degree-day tables using the 18.3°C base, estimating an annual heat loss and computing fuel usage on the basis of the rating of the particular fuel used. If a 10°C base is used, it can be prorated.

Heat curtains for energy conservation are becoming more important in greenhouse construction. Although this energy savings may be considered in the annual energy use, it should not be used when calculating design heat load; the practice is to open the heat curtains during snowstorms to facilitate snow melting, thereby nullifying its contribution to the design heat loss value.

Air-to-air and water-to-air heat pumps have been used experimentally on small-scale installations. Their usefulness is especially sensitive to the availability of a low-cost heat source.

Radiant (Infrared) Heating. Radiant heating is used in some limited applications for greenhouse heating. Steel pipes spaced at intervals and heated to a relatively high temperature by special gas heaters serve as the source of radiation. Because the energy is transmitted by radiation from a source of limited size, proper spacing is important to completely cover the heated area. Further, heavy-foliage crops can shade the lower parts of the plants and the soil, thus restricting the radiation from warming the root zone, which is important to plant growth.

Cogenerated Sources of Heat. Greenhouses have been built near or adjacent to power plants to use the heat and electricity generated by the facility. Although this energy may cost very little, an adequate standby energy source must be provided, unless the power supplier can assure that it will supply a reliable, continuous source of energy.

Cooling

Solar radiation is a considerable source of sensible heat gain; even though some of this energy is reflected from the greenhouse, some of it is converted into latent heat as the plants transpire moisture, and some is converted to plant material by photosynthesis. Natural ventilation, mechanical ventilation, shading, and evaporative cooling are common methods used to remove this heat. Mechanical refrigeration is seldom used to air-condition greenhouses because the cooling load and resulting cost is so high.

Natural Ventilation. Most older greenhouses and many new ones rely on natural ventilation with continuous roof sashes on each side of the ridge and continuous sashes in the sidewalls. The roof sashes are hinged at the ridge, and the wall sashes are hinged at the top of the sash. During much of the year, vents admit enough ventilating air for cooling without the added cost of running fans.

The principles of natural ventilation are explained in Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals*. Ventilation air is driven by wind and thermal buoyancy forces. Proper vent openings take advantage of pressure differences created by wind. Thermal buoyancy caused by the temperature difference between the inside and the outside of the greenhouse is enhanced by the area of the vent opening and the stack height (vertical distance between the center of the lower and upper opening). Within the limits of typical construction, the larger the vents, the greater the ventilating air exchanged. For a single greenhouse, the combined area of the sidewall vents should equal that of the roof vents. In ranges of several gutter-connected greenhouses, the sidewall area cannot equal the roof vent area.

Mechanical (Forced) Ventilation. Exhaust fans provide positive ventilation without depending on wind or thermal buoyancy forces. The fans are installed in the side or end walls of the greenhouse and draw air through vents on the opposite side or end walls. Air velocity through the inlets should not exceed 2 m/s.

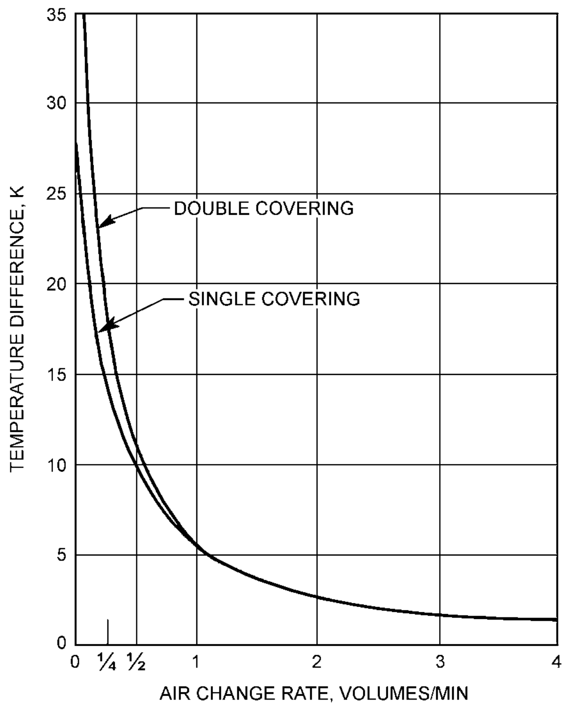

Fig. 10 Influence of Air Exchange Rate on Temperature Rise in Single- and Double-Covered Greenhouses

Air exchange rates between 0.75 and 1 change per minute effectively control the temperature rise in a greenhouse. As shown in Figure 10, the temperature inside the greenhouse rises rapidly at lower airflow rates. At higher airflow rates, the reduction of the temperature rise is small, fan power requirements are increased, and plants may be damaged by the high air speed.

Shading. Shading compounds can be applied in varying amounts to the exterior of the roof of the greenhouse to achieve up to 50% shading. Durability of these compounds varies; ideally, the compound wears away during the summer and leaves the glazing clean in the fall, when shading is no longer needed. In practice, some physical cleaning is needed. Compounds used formerly usually contained lime, which corrodes aluminum and attacks some caulking. Most compounds used currently are formulated to avoid this problem.

Mechanically orated shade cloth systems with a wide range of shade levels are also available. They are mounted inside the greenhouse to protect them from the weather. Not all shading compounds or shade cloths are compatible with all plastic glazings, so the manufacturers' instructions and precautions should be followed.

Evaporative Cooling.

Fan-and-Pad Systems. Fans for fan-and-pad evaporative cooling are installed in the same manner as fans used for mechanical ventilation. Pads of cellulose material in a honeycomb form are installed on the inlet side. The pads are kept wet continuously when evaporative cooling is needed. As air is drawn through the pads, the water evaporates and cools the air. New pads cool the air by about 80% of the difference between the outdoor dry- and wet-bulb temperatures, or to 1.5 to 2 K above the wet-bulb temperature. The principles of applying evaporative cooling are explained in Chapter 41 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and in Chapter 52 of this volume.

The empirical base rate of airflow is 40 L/s per square metre of floor area. This flow rate is modified by multiplying it by factors for elevation (F_e), maximum interior light intensity (F_l), and allowable temperature rise between the pad and fans (F_t). These factors are listed in Table 5. The overall factor for the house is given by the following equation:

$$F_h = F_e F_l F_t \tag{7}$$

The maximum fan-to-pad distance should be kept to 53 m, although some greenhouses with distances of 68 m have shown no serious reduction in effectiveness. With short distances, the air velocity becomes so low that the air feels clammy and stuffy, even though the airflow is sufficient for cooling. Therefore, a velocity factor F_v listed in Table 6 is used for distances less than 30 m. For distance less than 30 m, F_v is compared to F_h. The factor that gives the greatest airflow is used to modify the empirical base rate. For fan-to-pad distances greater than 30 m, F_v can be ignored.

For best performance, pads should be installed on the windward side, and fans spaced within 7.5 m of each other. Fans should not blow toward pads of an adjacent house unless it is at least 15 m away. Fans in adjacent houses should be offset if they blow toward each other and are within 4.5 m of each other.

Recommended air velocities through commonly used pads are listed in Table 7. Water flow and sump capacities are shown in Table 8. The system should also include a small, continuous bleed-off of water to reduce the build-up of dirt and other impurities.

Unit Evaporative Coolers. This equipment contains the pads, water pump, sump, and fan in one unit. Unit coolers are primarily used for small compartments. They are mounted 4.5 to 6 m apart on the sidewall and blow directly into the greenhouse. They cool a distance of up to 15 m from the unit. A side sash on the outside opposite wall is the best outlet, but roof vents may also work. The roof vent on the same side as the unit should be slightly open for better air distribution. If the roof vent on the opposite side is opened instead, air

Corrugated cellulose, 150 mm thick	0.16	40

may flow directly out the vent and not cool the opposite side of the greenhouse.

Fog. In a direct-pressure atomizer, a high-pressure pump forces water at 5.5 to 7 MPa through a special fog nozzle. Fog is considered to be a water droplet smaller than 40 µm in diameter. The direct-pressure atomizer generates droplets of 35 µm or less. This requires a superior filter to minimize clogging of the very small nozzle orifices.

A line of nozzles placed along the top of the vent opening can cool the entering air nearly to its wet-bulb temperature. Additional lines in the greenhouse continue to cool the air as it absorbs heat in the space.

Fogging cools satisfactorily with less airflow than fan-and-pad systems, but the fan capacity must still be based on one air change per minute to ventilate the greenhouse when the cooler will be used without fog.

Other Environmental Controls

Humidity Control. At various times during the year, humidity may need to be controlled in the greenhouse. When the humidity is too high at night, it can be reduced by adding heat and ventilating simultaneously. When the humidity is too low during the day, it can be increased by turning on a fog or mist nozzle.

Winter Ventilation. During the winter, houses are normally closed tightly to conserve heat, but photosynthesis by the plants may lower the carbon dioxide level to such a point that it slows plant growth. Some ventilation helps maintain inside carbon dioxide levels. A normal rate of airflow for winter ventilation is 10 to 15 L/s per square metre of floor area.

Air Circulation. Continuous air circulation within the greenhouse reduces still-air conditions that favor plant diseases. Recirculating fans, heaters that blow air horizontally, and fans attached to polyethylene tubes are used to circulate air. The amount of recirculation has not been well defined, except that some studies have shown high air velocities (greater than 1.0 m/s) can harm plants or reduce growth.

Insect Screening. Insect screening is used to cover vent inlets and outlets. These fine-mesh screens increase resistance to airflow, which must be considered when selecting ventilation fans. The screen manufacturer should provide static pressure data for its screens. The pressure drop through the screen can be reduced by framing out from the vent opening to increase the area of the screen.

Carbon Dioxide Enrichment. Carbon dioxide is added in some greenhouse operations to increase growth and enhance yields. However, CO_2 enrichment is practical only when little or no ventilation is required for temperature control. Carbon dioxide can be generated from solid CO_2 (dry ice), bottled CO_2, and misting carbonated water. Bulk or bottled CO_2 gas is usually distributed through perforated tubing placed near the plant canopy. Carbon dioxide from dry ice is distributed by passing greenhouse air through an enclosure containing dry ice. Air movement around the plant leaf increases the efficiency with which the plant absorbs available CO_2. One study found an air speed of 0.5 m/s to be equivalent to a 50% enrichment in CO_2 without forced air movement.

Radiant Energy. Light is normally the limiting factor in greenhouse crop production during the winter. North of the 35th parallel (in the northern hemisphere), light levels are especially inadequate or marginal in fall, winter, and early spring. Artificial light sources, usually high-intensity discharge (HID) lamps, may be added to greenhouses to supplement low natural light levels. High-pressure sodium (HPS), metal halide (MH), low-pressure sodium (LPS), and, occasionally, mercury lamps coated with a color-improving phosphor are currently used. Because differing irradiance or illuminance ratios are emitted by the various lamp types, the incident radiation is best described as radiant flux density (W/m²) between 400 and 850 nm, or as photon flux density between 400 and 700 nm, rather than in photometric terms of lux.

To assist in relating irradiance to more familiar illuminance values, Table 9 shows constants for converting illuminance (lux) and photon flux density [µmol/(s·m²)] of HPS, MH, LPS, and other lamps to the irradiance (W/m²).

Table 10 gives suggested values for irradiance at the top of the plant canopy, duration, and time of day for supplementing natural light levels for specific plants.

HID lamps in luminaires developed specifically for greenhouse use are often placed in a horizontal position, which may decrease both the light output and the life of the lamp. These drawbacks may be balanced by improved horizontal and vertical uniformity as compared to industrial parabolic reflectors.

Photoperiod Control. Artificial light sources are also used to lengthen the photoperiod during the short days of winter. Photoperiod control requires much lower light levels than those needed for

Table 9 Constants to Convert to W/m²

Light Source	klx	μmol/(s·m²)
400 to 700 nm		
Incandescent (INC)	3.99	0.20
Fluorescent cool white (FCW)	2.93	0.22
Fluorescent warm white (FWW)	2.81	0.21
Discharge clear mercury (HG)	2.62	0.22
Metal halide (MH)	3.05	0.22
High-pressure sodium (HPS)	2.45	0.20
Low-pressure sodium (LPS)	1.92	0.20
Daylight	4.02	0.22

photosynthesis and growth. Photoperiod illuminance needs to be only 6 to 12 W/m². The incandescent lamp is the most effective light source for this purpose because of its higher far-red component. Lamps such as 150 W (PS-30) silverneck lamps spaced 3 to 4 m on centers and 4 m above the plants provide a cost-effective system. Where a 4 m height is not practical, 60 W extended service lamps on 2 m centers are satisfactory. One method of photoperiod control is to interrupt the dark period by turning the lamps on at 2200 and off at 0200. The 4 h interruption, initially based on chrysanthemum response, induces a satisfactory long-day response in all photoperiodically sensitive species. Many species, however, respond to interruptions of 1 h or less. Demand charges can be reduced in large installations by operating some sections from 2000 to 2400 and others from 2400 to 0400. The biological response to these schedules, however, is much weaker than with the 2200 to 0200 schedule, so some varieties may flower prematurely. If the 4 h interruption period is used, it is not necessary to keep the light on throughout the interruption period. Photoperiod control of most plants can be accomplished by operating the lamps on light and dark cycles with 20% *on* times; for example, 12 s/min. The length of the dark period in the cycle is critical, and the system may fail if the dark period exceeds about 30 min. Demand charges can be reduced by alternate scheduling of the *on* times between houses or benches without reducing the biological effectiveness of the interruption.

Plant displays in places such as showrooms or shopping malls require enough light for plant maintenance and a spectral distribution that best shows the plants. Metal halide lamps, with or without incandescent highlighting, are often used for this purpose. Fluorescent lamps, frequently of the special phosphor plant-growth type, enhance color rendition, but are more difficult to install in aesthetically pleasing designs.

Design Conditions

Plant requirements vary from season to season and during different stages of growth. Even different varieties of the same species of plant may vary in their requirements. State and local cooperative extension offices are a good source of specific information on design conditions affecting plants. These offices also provide current, area-specific information on greenhouse operations.

Alternative Energy Sources and Energy Conservation

Limited progress has been achieved in heating commercial greenhouses with solar energy. Collecting and storing the heat requires a volume at least one-half the volume of the entire greenhouse. Passive solar units work at certain times of the year and, in a few localities, year-round.

If available, reject heat is a possible source of winter heat. Winter energy and solar (photovoltaic) sources are possible future energy sources for greenhouses, but the development of such systems is still in the research stage.

Energy Conservation. A number of energy-saving measures (e.g., thermal curtains, double glazing, and perimeter insulation)

Table 10 Suggested Radiant Energy, Duration, and Time of Day for Supplemental Lighting in Greenhouses

		Duration	
Plant and Stage of Growth	W/m²	Hours	Time
African violets	12 to 24	12 to 16	0600-1800

vegetative growth			
Zinnia	12 to 48	24	
early-flowering			

have been retrofitted to existing greenhouses and incorporated into new construction. Sound maintenance is necessary to keep heating system efficiency at a maximum level.

Automatic controls, such as thermostats, should be calibrated and cleaned at regular intervals, and heating-ventilation controls should interlock to avoid simultaneous operation. Boilers that can burn more than one type of fuel allow use of the most inexpensive fuel available.

Modifications to Reduce Heat Loss

Film covers that reduce heat loss are used widely in commercial greenhouses, particularly for growing foliage plants and other species that grow under low light levels. Irradiance (intensity) is reduced 10 to 15% per layer of plastic film.

One or two layers of transparent 0.10 or 0.15 mm continuous-sheet plastic is stretched over the entire greenhouse (leaving some vents uncovered), or from the ridge to the sidewall ventilation opening. When two layers are used, (outdoor) air at a pressure of 50 to 60 Pa is introduced continuously between the layers of film to maintain the air space between them. When a single layer is used, an air space can be established by stretching the plastic over the glazing bars and fastening it around the edges, or a length of polyethylene tubing can be placed between the glass and the plastic and inflated (using outdoor air) to stretch the plastic sheet.

Double-Glazing Rigid Plastic. Double-wall panels are manufactured from acrylic and polycarbonate plastics, with walls separated by about 10 mm. Panels are usually 1.2 m wide and 2.4 m or longer. Nearly all types of plastic panels have a high thermal expansion coefficient and require about 1% expansion space (10 mm/m). When a panel is new, light reduction is roughly 10 to 20%. Moisture accumulation between the walls of the panels must be avoided.

Double-Glazing Glass. The framing of most older greenhouses must be modified or replaced to accept double glazing with glass.

Light reduction is 10% more than with single glazing. Moisture and dust accumulation between glazings increases light loss. As with all types of double glazing, snow on the roof melts slowly and increases light loss. Snow may even accumulate enough to cause structural damage, especially in gutter-connected greenhouses.

Silicone Sealants. Transparent silicone sealant in the glass overlaps of conventional greenhouses reduces infiltration and may produce heat savings of 5 to 10% in older structures. There is little change in light transmission.

Precautions. The preceding methods reduce heat loss by reducing conduction and infiltration. They may also cause more condensation, higher relative humidity, lower carbon dioxide concentration, and an increase in ethylene and other pollutants. Combined with the reduced light levels, these factors may cause delayed crop production, elongated plants, soft plants, and various deformities and diseases, all of which reduce the marketable crop.

Thermal Blankets. Thermal blankets are any flexible material that is pulled from gutter to gutter and end to end in a greenhouse, or around and over each bench, at night. Materials ranging from plastic film to heavy cloth, or laminated combinations, have successfully reduced heat losses by 25 to 35% overall. Tightness of fit around edges and other obstruction are more important than the kind of material used. Some films are vaportight and retain moisture and gases. Others are porous and allow some gas exchange between the plants and the air outside the blanket. Opaque materials can control crop day length when short days are part of the requirement for that crop. Condensation may drip onto and collect on the upper sides of some blanket materials to such an extent that they collapse.

Multiple-layer blankets, with two or more layers separated by air spaces, have been developed. One such design combines a porous-material blanket and a transparent film blanket; this design is used for summer shading. Another design has four layers of porous, aluminum foil-covered cloths, with the layers separated by air.

Thermal blankets may be opened and closed manually as well as automatically. The decision to open or close should be based on irradiance level and whether it is snowing, rather than on time of day. Two difficulties with thermal blankets are the physical problems of installation and use in greenhouses with interior supporting columns, and the loss of space from shading by the blanket when it is not in use during the day.

Other Recommendations. Although the foundation can be insulated, the insulating materials must be protected from moisture, and the foundation wall should be protected from freezing. All or most of the north wall can be insulated with opaque or reflective-surface materials. The insulation reduces the amount of diffuse light entering the greenhouse and, in cloudy climates, causes reduced crop growth near the north wall.

Ventilation fan cabinets should be insulated, and fans not needed in winter should be sealed against air leaks. Efficient management and operation of existing facilities are the most cost-effective ways to reduce energy use.

2.2 PLANT GROWTH ENVIRONMENTAL FACILITIES

Controlled-environment rooms (CERs), also called plant growth chambers, include all controlled or partially controlled environmental facilities for growing plants, except greenhouses. CERs are indoor facilities. Units with floor areas less than 5 m^2 may be moveable with self-contained or attached refrigeration units. CERs usually have artificial light sources, provide control of temperature and, in some cases, control relative humidity and CO_2 level.

CERs are used to study all aspects of botany. Some growers use growing rooms to increase seedling growth rate, produce more uniform seedlings, and grow specialized, high-value crops. The main components of the CER are (1) an insulated room or an insulated box with an access door; (2) a heating and cooling mechanism with associated air-moving devices and controls; and (3) a lamp module at the top of the insulated box or room. CERs are similar to walk-in cold storage rooms, except for the lighting and larger refrigeration system needed to handle heat produced by the lighting.

Location

The location for a CER must have space for the outer dimensions of the chamber, refrigeration equipment, ballast rack, and control panels. Additional space around the unit is necessary for servicing the various components of the system and, in some cases, for substrate, pots, nutrient solutions, and other paraphernalia associated with plant research. The location requires electricity, water, compressed air, and ventilation and exhaust air systems. For planning purposes, electrical densities of up to 1500 W/m^2 of controlled environment space) are possible, or 1000 W/m^2 of total space housing CERs.

Construction and Materials

Wall insulation should have a thermal conductance of less than 0.15 W/(m^2·K). Materials should resist corrosion and moisture. The interior wall covering should be metal, with a high-reflectance white paint, or specular aluminum with a reflectivity of at least 80%. Reflective films or similar materials can be used, but require periodic replacement.

Floors and Drains

Floors that are part of the CER should be corrosion-resistant. Tar or asphalt waterproofing materials and volatile caulking compounds should not be used because they are likely to release phytotoxic gases into the chamber atmosphere. The floor must have a drain to remove spilled water and nutrient solutions. The drains should be trapped and equipped with screens to catch plant and substrate debris.

Plant Benches

Three bench styles for supporting the pots and other plant containers are normally encountered in plant growth chambers: (1) stationary benches; (2) benches or shelves built in sections that are adjustable in height; and (3) plant trucks, carts, or dollies on casters, which are used to move plants between chambers, greenhouses, and darkrooms. The bench supports containers filled with moist sand, soil, or other substrate, and is usually rated for loads of at least 240 kg/m^2. The bench or truck top should be constructed of nonferrous, perforated metal, wire, or metal mesh to allow free passage of air around the plants and to let excess water drain from the containers to the floor and subsequently to the floor drain.

Normally, benches, shelves, or truck tops are adjustable in height so that small plants can be placed close to the lamps and thus receive a greater amount of light. As the plants grow, the shelf or bench is lowered so that the tops of the plants continue to receive the original radiant flux density.

Control

Environmental chambers require complex controls to provide the following:

- Automatic transfer from heating to cooling with 1 K or less dead zone and adjustable time delay.
- Automatic daily switching of the temperature set point for different day and night temperatures (setback may be as much as 5 K).
- Protection of sensors from radiation. Ideally, the sensors are located in a shielded, aspirated housing, but satisfactory performance can be attained by placing them in the return air duct.
- Control of the daily duration of light and dark periods. Ideally, this control should be programmable to change the light period each day to simulate the natural progression of day length. Photoperiod control, however, is normally accomplished with mechanical time clocks, which must have a control interval of 5 min or less for satisfactory timing.
- Protective control to prevent the chamber temperature from going more than a few degrees above or below the set point. Control should also prevent short-cycling of the refrigeration system, especially when condensers are remotely located.
- Control of the CO_2 level in enriched environment chambers.
- Audible and visual alarms to alert personnel of malfunctions.
- Maintenance of relative humidity to prescribed limits.

Data loggers, recorders, or recording controllers are recommended for monitoring daily operation. Solid-state, microprocessor-based controls are widely used for programming, controlling, and monitoring the CER conditions. Host systems are also used to program and monitor larger numbers of units in a common facility, and most offer remote access functions. Host systems tend to be vendor-specific in their use and application.

Heating, Air Conditioning, and Airflow

When the lights are on, cooling will normally be required, and the heater will rarely be called on to operate. When the lights are off, however, both heating and cooling may be needed. Conventional refrigeration is generally used with some modification. Direct-expansion units usually operate with a hot-gas bypass to prevent numerous on/off cycles, and secondary coolant may use aqueous ethylene glycol rather than chilled water. Heat is usually provided by electric heaters, but other energy sources can be used, including hot gas from the refrigeration.

The plant compartment is the heart of the growth chamber. The primary design objective, therefore, is to provide the most uniform, consistent, and regulated environmental conditions possible. Thus, airflow must be adequate to meet specified psychrometric conditions, but it is limited by the effects of high air speed on plant growth. As a rule, the average air speed in CERs is restricted to about 0.5 m/s.

To meet the uniform conditions required by a CER, conditioned air is normally moved through the space from bottom to top, although some CERs use top-to-bottom airflow. There is no apparent difference in plant growth between horizontal, upward, or downward airflow when the speed is less than 0.9 m/s. Regardless of the method, a temperature gradient is certain to exist, and should be kept as small as possible. Uniform airflow is more important than the direction of flow; thus, selection of properly designed diffusers or plenums with perforations is essential for achieving it.

The ducts or false sidewalls that direct air from the evaporator to the growing area should be small, but not so small that the noise increases appreciably more than acceptable building air duct noise. CER design should include some provision for cleaning the interior of the air ducts.

Air-conditioning equipment for relatively standard chambers provides temperatures that range from 7 to 35°C. Specialized CERs that require temperatures as low as –20°C need low-temperature refrigeration equipment and devices to defrost the evaporator without increasing the growing area temperature. Other chambers that require temperatures as high as 45°C need high-temperature components. The air temperature in the growing area must be controlled with the least possible variation about the set point. Temperature variation about the set point can be held to 0.3 K using solid-state controls, but in older facilities, the variation is 0.5 to 1 K.

The relative humidity in many CERs is simply an indicator of the existing psychrometric conditions and is usually between 50 and 80%, depending on the temperature. Relative humidity in the chamber can be increased by steam injection, misting, hot-water evaporators, and other conventional humidification methods. Steam injection causes the least temperature disturbance, and sprays or misting cause the greatest disturbance. Complete control of relative humidity requires dehumidification as well as humidification.

A typical humidity control includes a cold evaporator or steam injection to adjust the chamber air dew point. The air is then conditioned to the desired dry-bulb temperature by electric heaters, a hot-gas bypass evaporator, or a temperature-controlled evaporator. A dew point lower than about 5°C cannot be obtained with a cold-plate dehumidifier because of icing. Dew points lower than 5°C usually require a chemical dehumidifier in addition to the cold evaporator.

Lighting Environmental Chambers

The type of light source and number of lamps used in CERs are determined by the desired plant response. Traditionally, cool-white fluorescent plus incandescent lamps that produce 10% of the fluorescent illuminance are used. Nearly all illumination data are based on either cool-white or warm-white fluorescent, plus incandescent lamps. A number of fluorescent lamps have special phosphors hypothesized to be the spectral requirements of the plant. Some of these lamps are used in CERs, but there is little data to suggest that they are superior to cool-white and warm-white lamps. In recent years, high-intensity discharge lamps have been installed in CERs, either to obtain very high radiant flux densities, or to reduce the electrical load while maintaining a light level equal to that produced by the less efficient fluorescent-incandescent systems.

One method to design lighting for biological environments is to base light source output recommendations on photon flux density μmol/(s·m^2) between 400 and 700 nm, or, less frequently, as radiant flux density between 400 and 700 nm, or 400 and 850 nm. Rather than basing illuminance measurements on human vision, this allows comparisons between light sources as a function of plant

Table 11 Input Power Conversion of Light Sources

Lamp Identification		Total Input Power, W	Radiation (400-700 nm), %	Radiation (400-850 nm), %	Other Radiation, %	Conduction and Convection, %	Ballast Loss, %
Incandescent	INC, 100A	100	7	15	75	10	0

	Height and Spacing, m			
HPS (400 W)	3.0	2.3	1.6	1.0
LPS (180 W)	2.4	1.7	1.2	0.8
MH (400 W)	2.7	2.0	1.4	0.9

photosynthetic potential. Table 9 shows constants for converting various measurement units to W/m^2. However, instruments that measure the 400 to 850 nm spectral range are generally not available, and some controversy exists about the effectiveness of 400 to 850 nm as compared to the 400 to 700 nm range in photosynthesis. The power conversion of various light sources is listed in Table 11.

The design requirements for plant growth lighting differ greatly from those for vision lighting. Plant growth lighting requires a greater degree of horizontal uniformity and, usually, higher light levels than vision lighting. In addition, plant growth lighting should have as much vertical uniformity as possible (a factor rarely important in vision lighting). Horizontal and vertical uniformity are much easier to attain with linear or broad sources, such as fluorescent lamps, than with point sources, such as HID lamps. Tables 12 and 13 show the type and number of lamps, mounting height, and spacing required to obtain several levels of incident energy. Because the data were taken directly under lamps with no reflecting wall surfaces nearby, the incident energy is perhaps one-half of what the plants would receive if the lamps had been placed in a small chamber with highly reflective walls.

Extended-life incandescents lower lamp replacement requirements. These lamps have lower lumen output, but are nearly equivalent in the red portion of the spectrum. For safety, porcelain lamp holders and heat-resistant lamp wiring should be used. Lamps used for CER lighting include fluorescent lamps (usually 1500 mA), 250, 400, and occasionally 1000 W HPS and MH lamps, 180 W LPS lamps, and various sizes of incandescent lamps. In many installations, the abnormally short life of incandescent lamps is caused by vibration from the lamp loft ventilation or from cooling fans. Increased incandescent lamp life under these conditions can be attained by using lamps constructed with a C9 filament.

Energy-saving lamps have approximately equal or slightly lower irradiance per input watt. Because the irradiance per lamp is lower, there is no advantage to using these lamps, except in tasks that can be accomplished with low light levels. Light output of all lamps declines with use, except perhaps for low-pressure sodium (LPS) lamps, which appear to maintain approximately constant output but require an increase in input power during use.

Fluorescent and metal halide designs should be based on 80% of the initial light level. Most CER lighting systems have difficulty maintaining a relatively constant light level over considerable periods of time. Combinations of MH and HPS lamps compound the problem, because the lumen depreciation of the two light sources is significantly different. Thus, over time, the spectral energy distribution at plant level shifts toward the HPS. Lumen output can be maintained in two ways: (1) individual lamps, or a combination of lamps, can be switched off initially and activated as the lumen output decreases; and (2) the oldest 25 to 33% of the lamps can be replaced periodically. Solid-state dimmer systems are commercially available only for low-wattage fluorescent lamps and for mercury lamps.

To maintain a constant distance from plant to light source, light fixtures in many CERs are mounted on movable, counterbalanced light banks. This design requirement precludes separation of the lamps from the plant chamber.

Large rooms, especially those constructed as an integral part of the building and retrofitted as CERs, rarely separate the lamps from the growing area with a transparent barrier. Rooms designed as CERs (at the time a building is constructed) and freestanding rooms or chambers usually separate the lamp from the growing area with a barrier of glass or rigid plastic. Light output from fluorescent lamps is a function of the temperature of the lamp. Thus, the barrier serves a twofold purpose: (1) to maintain optimum lamp temperature when the growing area temperature is higher or lower than optimum, and (2) to reduce the thermal radiation entering the growing area. Fluorescent lamps should operate in an ambient temperature and airflow environment that maintains the tube wall temperature at 40°C. Under most conditions, the light output of HID lamps is not affected by ambient temperature. The heat must be removed, however, to prevent high thermal radiation from causing adverse biological effects (Figure 11).

Transparent glass barriers remove nearly all radiation from about 350 to 2500 nm. Rigid plastic is less effective than glass; however, the lower mass and lower breakage risk of plastic makes it a popular barrier material. Ultraviolet is also screened by both glass and plastic (more by plastic). Special UV-transmitting plastic (which degrades rapidly) can be obtained if the biological process requires UV light. When irradiance is very high, especially from HID lamps or large numbers of incandescent lamps or both, rigid plastic can soften from the heat and fall from the supports. Furthermore, very high irradiance and the resulting high temperatures can darken plastic, which can increase the absorptivity and temperature enough to

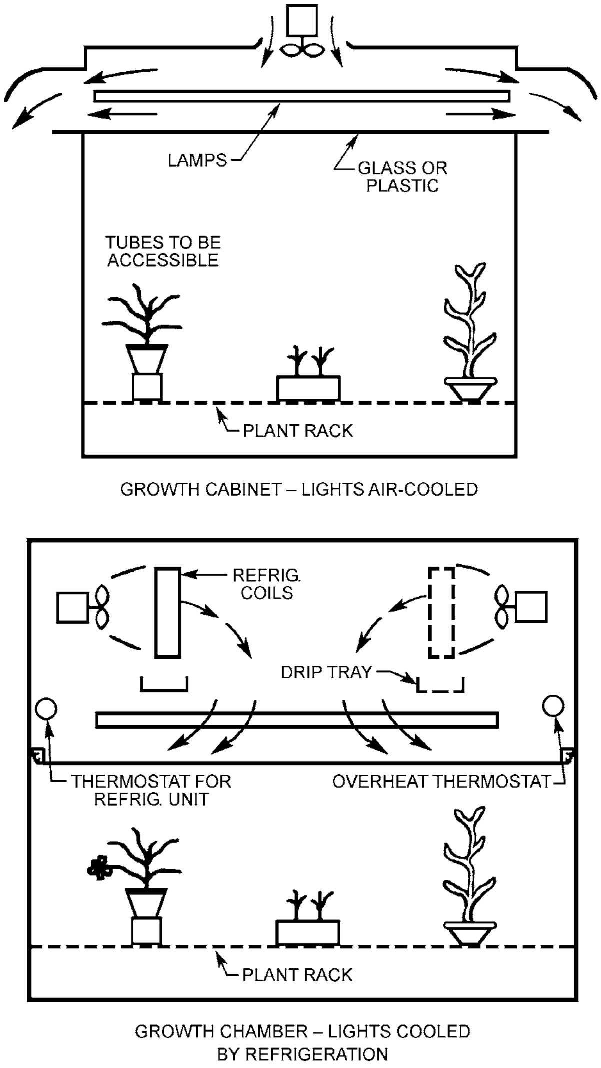

Fig. 11 Cooling Lamps in Growth Chambers

destroy it. Under these conditions, heat-resistant glass may be necessary. The lamp compartment and barrier absolutely require positive ventilation regardless of the light source, and the lamp loft should have limit switches to shut down the lamps if the temperature rises to a critical level.

Phytotrons

A phytotron is a botanical laboratory comprising a series of chambers reproducing any condition of temperature, humidity, illumination, or other plant growth factor. They are typically found in plant-based research buildings. These facilities require substantial electrical and mechanical systems to generate light required for plant growth as well as to remove heat generated by lights and CER cooling systems.

Electrical Requirements. If the exact number and size of units is unknown, an electrical consumption of 2 kW/m^2 may be assumed for lighting input to the CERs. If the CERs have a built-in refrigeration system, the compressor input is typically 80% of lighting input, because the units are designed to maintain the chamber at 10°C with lights on, creating a high latent load on the compressor at an inefficient operating point. Remote condensing units and remote air-cooled condensers require a separate electrical feed and interconnecting control wiring.

Heat Rejection. Most of the electrical input to the CERs is converted to heat. The heat rejection system must be able to remove that heat from the phytotron; this can be done in a number of ways.

If the CERs are primarily self-contained air-cooled units, the room can be ventilated at a rate that maintains acceptable working conditions in the space (see Chapter 14). Because of the high ventilation rates needed, ensure that air returned to the space is properly filtered to limit the introduction of dust, pollen, insects, and bacteria from the outdoors.

Self-contained CERs with water-cooled condensing units typically use a condenser water loop connected to a cooling tower or fluid cooler to reject heat. Chapter 13 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* describes selection and design of these systems. Because phytotron facilities operate all year, operation of fluid coolers and cooling towers at ambient temperatures below freezing in cold climates must be considered. Sediment must also be removed from the condenser water, because the condenser on the CER is a relatively low-velocity point in the loop and will plug up with these solids.

Locations of remote condensing units or remote air-cooled condensers should be easily accessible, because they require servicing at all times of the year. Ensure good airflow around all air-cooled condensers so that discharge air from one unit is not reentrained into adjacent units. Locate equipment away from laboratory exhaust systems that could accelerate corrosion of metal on the units. Refrigerant piping must be carefully designed, sized, and installed to ensure proper oil return and long-term operation of the compressors. Chapter 1 of the 2018 *ASHRAE Handbook—Refrigeration* details these requirements.

Central chilled water can be used for the CERs. The primary consideration is the chilled-water temperature to be provided to each unit. In practice, most CERs operate at internal temperatures between 20 and 25°C when lights are on. As a result, standard chilled-water supply temperatures of 7°C can be used successfully. When lights are off, temperatures of 10°C can be achieved using the same chilled-water temperature. Chambers that require cooler daytime temperatures can use water-cooled condensing units and reject their heat to the chilled-water loop. Some phytotrons use chilled-water supply temperatures of –10°C, but with a high failure rate on the compressors because of low suction temperatures and poor oil return.

Energy Conservation. Because of CERs' very high energy consumption and the predictable day/night cycle of the lighting load, consider balancing the units' schedule to limit electrical demand. Most plants require a 12 to 16 h daily photoperiod. By adjusting the day/night schedule, it is possible to reduce the phytotron's electrical demand by up to 25%.

Chilled-water CERs can have the lowest total energy consumption because of the economy of scale available by using large-capacity chillers versus small compressors. Large laboratory facilities can reject heat from the phytotron to preheat laboratory makeup air. In cold climates, chilled water can be produced without mechanical cooling at ambient temperatures below –2°C. If exposing chilled water to ambient air that could be below freezing, use an appropriate concentration of suitable antifreeze.

Condenser water can also be used to preheat fresh air or, because of its higher temperature, other process loads, such as domestic hot water.

Operating Considerations. CERs with self-contained compressors generate noise. When a large number of units are placed in a room, consideration should be given to attenuating this sound. Chilled-water and remote-condensing-unit CERs provide the quietest environment for workers, because the compressors are remotely located. The total installed cost of these systems may be higher because of the extra cost to remotely locate and energize the cooling systems.

Plants require CO_2 to grow. Many CERs in phytotrons have a central exhaust system to exhaust any chemicals used inside the chambers and to pull in a constant supply of air. Because the units are under a slight negative pressure, makeup air entering the unit must be filtered to limit uncontrolled spread of pollen, insect pests, and bacteria. The flow rate from units depends on the type of crop being grown. A normal rate of ventilation is 10 to 15 L/s per square metre of plant growth area.

Water is required for humidification, plant watering, and cleaning. This often means that three totally separate systems are used. High-purity water is often available in laboratory buildings, and can be used to directly humidify the chambers without introducing waterborne minerals into the chamber. Water for plants should be tempered to avoid root shock. A tempered-water loop with provision for introducing chemical fertilizer, supplied to designated hose stations in the phytotron, is common in larger installations, but normal municipal water supplies are all that is required. Cleaning of these areas is important.

CERs require drainage of cooling coil condensate and plant overwatering. It is important to provide good drainage near the units without excess use of drain lines running exposed across the floor. Similarly, any piping or ducts that operate below the room design dew-point temperature should be insulated to prevent condensation on those lines. These puddles of water are prime breeding grounds for plant pests, and could cause slip hazards for staff.

Keeping the phytotron clean is important for plants' health. Phytotrons typically have separate potting areas and harvest rooms, both of which generate a lot of dust and dirt. Potting areas must remain sanitary to minimize contamination of seedlings and plantlets. In harvest rooms, mature plants may host insects that can damage young plants. Ventilation systems should keep harvest rooms at negative pressure relative to the cleaner potting areas and phytotron.

Genetically modified plants must be autoclaved once the plant is harvested. Provision should be made for an autoclave next to the harvest room, with a supply of steam or electricity. Odors and steam from the autoclave should be exhausted out of the building.

2.3 OTHER PLANT ENVIRONMENTAL FACILITIES

Plants may be held or processed in warehouse-type structures prior to sale or use in interior landscaping. Required temperatures range from slightly above freezing for cold storage of root stock and cut flowers, to 20 to 25°C for maintaining growing plants, usually in pots or containers. Provision must be made for venting fresh air to avoid CO_2 depletion.

Light duration must be controlled by a time clock. When they are in use, lamps and ballasts produce almost all the heat required in an insulated building. Ventilation and cooling may be required. Illumination levels depend on plant requirements. Table 14 shows approximate mounting heights for two levels of illumination. Luminaires mounted on chains permit lamp height to be adjusted to compensate for varying plant height.

The main concerns for interior landscape lighting are how it renders the color of plants, people, and furnishings, as well as how it meets the minimum irradiation requirements of plants. The temperature required for human occupancy is normally acceptable for plants. Light level and duration determine the types of plants that can be grown or maintained. Plants grow when exposed to higher levels, but do not survive below the suggested minimum. Plants may be grouped into three levels based on the following of irradiances:

Low (survival): A minimum light level of 0.75 W/m² and a preferred level of 3 W/m² irradiance for 8 to 12 h daily.

Table 14 Mounting Height for Luminaires in Storage Areas

	Survival = 3 W/m²		Maintenance = 9 W/m²	
	Distance, m	lux	Distance, m	lux
Fluorescent (F)				
FCW two 40 W	0.9	1000	0.75	3000
FWW	0.9	1000	0.75	3000
FCW two 215 W	2.8	1000	1.6	3000
Discharge (HID)				
MH 400 W	3.3	800	2.0	2400
HPS 400 W	4.5	800	2.5	2400
LPS 180 W	3.4	1300	1.2	4000
Incandescent (INC)				
INC 160 W	1.3	350	0.3	1000
INC-HG 160 W	1.2	500	1.6	1500
DL	—	500	—	1500

Medium (maintenance): A minimum of 3 W/m² and a preferred level of 9 W/m² irradiance for 8 to 12 h daily.

High (propagation): A minimum of 9 W/m² and a preferred level of 24 W/m² irradiance for 8 to 12 h daily.

Fluorescent (warm-white), metal halide, or incandescent lighting is usually chosen for public places. Table 13 lists the irradiance of various light sources.

CHAPTER 26

DRYING AND STORING SELECTED FARM CROPS

DRYING 26.2
Drying Equipment and Practices 26.2
Shallow-Layer Drying 26.3
Deep-Bed Drying 26.4
DRYING SPECIFIC CROPS 26.7
Soybeans 26.7
Hay 26.8
Cotton 26.8
Peanuts 26.9
Rice 26.9
STORAGE PROBLEMS AND PRACTICES 26.9
Moisture Migration 26.9
Grain Aeration 26.9
SEED STORAGE 26.12

CONTROL of moisture content and temperature during storage is critical to preserving the nutritional and economic value of farm crops as they move from the field to the market. Fungi (mold) and insects feed on poorly stored crops and reduce crop quality. Relative humidity and temperature affect mold and insect growth, which is reduced to a minimum if the crop is kept cooler than 10°C and if the relative humidity of the air in equilibrium with the stored crop is less than 60%.

Mold growth and spoilage are a function of elapsed storage time, temperature, and moisture content above critical values. Approximate allowable storage life for cereal grains is shown in Table 1. For example, corn at 16°C and 20% wet basis (w.b.) moisture has a storage life of about 25 days. If it is dried to 18% w.b. after 12 days, half of its storage life has elapsed. Thus, the remaining storage life at 16°C and 18% w.b. moisture content is 25 days, not 50 days.

Insects thrive in stored grain if the moisture content and temperature are not properly controlled. At low moisture contents and temperatures below 10°C, insects remain dormant or die.

Most farm crops must be dried to, and maintained at, a suitable moisture content. For most grains, a suitable moisture content is in the range of 12 to 15% w.b., depending on the specific crop, storage temperature, and length of storage. Oilseeds such as peanuts, sunflower seeds, and flaxseeds must be dried to a moisture content of 8 to 9% w.b. Grain stored for more than a year, grain that is damaged, and seed stock should be dried to a lower moisture content. Moisture levels above these critical values lead to the growth of fungi, which may produce toxic compounds such as aflatoxin.

Based on composite of 0.5% maximum dry matter loss calculated on the basis of USDA research; *Transactions of ASAE* 333-337, 1972; and "Unheated Air Drying," Manitoba Agriculture Agdex 732-1, rev. 1986.

[a]Grain moisture content calculated as percent wet basis: (mass of water in a given amount of wet grain ÷ mass of the wet grain) × 100.

*Approximate allowable storage time exceeds 300 days.

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

The maximum yield of dry matter can be obtained by harvesting when the corn has dried in the field to an average moisture content of 26% w.b. However, for quality-conscious markets, the minimum damage occurs when corn is harvested at 21 to 22% w.b. Wheat can be harvested when it has dried to 20% w.b., but harvesting at these moisture contents requires expensive mechanical drying. Although field drying requires less expense than operating drying equipment, total cost may be greater because field losses generally increase as the moisture content decreases.

The price of grain to be sold through commercial market channels is based on a specified moisture content, with price discounts for moisture levels above the specified amount. These discounts compensate for the mass of excess water, cover the cost of water removal, and control the supply of wet grain delivered to market. Grain dried to below the base moisture content set by the market (15.0% w.b. for corn, 13.0% w.b. for soybeans, and 13.5% w.b. for wheat) is not generally sold at a premium; thus, the seller loses the opportunity to sell water for the price of grain.

Grain Quantity

The **bushel** is a volume measure (0.03524 m^3) that is the common measure used for marketing grain in the United States, while the tonne (Mg) is the more common international measure. The legal mass for the bushel in the United States is set at 25.40 kg for corn and 27.22 kg for wheat. The densities of some crops are listed in Table 2.

The percent of mass lost due to water removed may be calculated by the following equation:

$$\text{Moisture shrink, \%} = \frac{M_o - M_f}{100 - M_f} \times 100$$

where

M_o = original or initial moisture content, wet basis
M_f = final moisture content, wet basis

Applying the formula to drying a crop from 25% to 15%,

$$\text{Moisture shrink} = \frac{25 - 15}{100 - 15} \times 100 = 11.76\%$$

In this case, the moisture shrink is 11.76%, or an average 1.176% mass reduction for each percentage point of moisture reduction. The moisture shrink varies depending on the final moisture content. For example, the average shrink per point of moisture when drying from 20% to 10% is 1.111.

Economics

Producers generally have the choice of drying their grain on the farm before delivering it to market, or delivering wet grain with a price discount for excess moisture. The expense of drying on the farm

Note: Includes all energy requirements for fans and heat.

includes both fixed and variable costs. Once a dryer is purchased, the costs of depreciation, interest, taxes, and repairs are fixed and minimally affected by volume of crops dried. The costs of labor, fuel, and electricity vary directly with the volume dried. Total drying costs vary widely, depending on the volume dried, the drying equipment, and fuel and equipment prices. Energy consumption depends primarily on dryer type. Generally, the faster the drying speed, the greater the energy consumption (Table 3).

1. DRYING

1.1 DRYING EQUIPMENT AND PRACTICES

Contemporary crop-drying equipment depends on mass and energy transfer between the drying air and the product to be dried. The drying rate is a function of the initial temperature and moisture content of the crop, the air-circulation rate, the entering condition of the circulated air, the length of flow path through the products, and the time elapsed since the beginning of the drying operation. Outdoor air is frequently heated before it is circulated through the product. Heating increases the rate of heat transfer to the product, increases its temperature, and increases the vapor pressure of the product moisture. For more information on crop responses to drying, see Chapter 11 of the 2005 *ASHRAE Handbook—Fundamentals*.

Most crop-drying equipment consists of (1) a fan to move the air through the product, (2) a controlled heater to increase the ambient air temperature to the desired level, and (3) a container to distribute the drying air uniformly through the product. The exhaust air is vented to the atmosphere. Where climate and other factors are favorable, unheated air is used for drying, and the heater is omitted.

Fans

The fan selected for a given drying application should meet the same requirements important in any air-moving application. It must deliver the desired amount of air against the static resistance of the product in the bin or column, the resistance of the delivery system, and the resistance of the air inlet and outlet.

Foreign material in the grain can significantly change the required air pressure in the following ways:

- Foreign particles larger than the grain (straw, plant parts, and larger seeds) reduce airflow resistance. The airflow rate may be increased by 60% or more.
- Foreign particles smaller than the grain (broken grain, dust, and small seeds) increase the airflow resistance. The effect may be dramatic, decreasing the airflow rate by 50% or more.
- The method used to fill the dryer or the agitation or stirring of the grain after it is placed in the dryer can increase pressure requirements by up to 100%. In some grain, high moisture causes less pressure drop than does low moisture.

Vaneaxial fans are normally recommended when static pressures are less than 0.75 kPa. Backward-curved centrifugal fans are commonly recommended when static pressures are higher than 1.0 kPa. Low-speed centrifugal fans operating at 1750 rpm perform well up to about 1.75 kPa, and high-speed centrifugal fans operating at about 3500 rpm have the ability to develop static pressure up to about 2.5 kPa. The in-line centrifugal fan consists of a centrifugal fan impeller mounted in the housing of an axial flow fan. A bell-shaped inlet funnels the air into the impeller. The in-line centrifugal fan operates at about 3450 rpm and has the ability to develop pressures up to 2.5 kPa on 6 kW or larger fans.

After functional considerations are made, the initial cost of the dryer fan should be taken into account. Drying equipment has a low percentage of annual use in many applications, so the cost of dryer ownership per unit of material dried is sometimes greater than the energy cost of operation. The same considerations apply to other components of the dryer.

Heaters

Most crop dryer heaters are fueled by either natural gas, liquefied petroleum gas, or fuel oil, though some electric heaters are used. Dryers using coal, biomass (e.g., corn cobs, stubble, or wood), and solar energy have also been built.

Fuel combustion in crop dryers is similar to combustion in domestic and industrial furnaces. Heat is transferred to the drying air either indirectly, by means of a heat exchanger, or directly, by combining the combustion gases with the drying air. Direct combustion heating is generally limited to natural gas or liquefied petroleum (LP) gas heaters. Most grain dryers use direct combustion. Indirect heating is sometimes used in drying products such as hay because of its greater fire hazard.

Controls

In addition to the usual temperature controls for drying air, all heated air units must have safety controls similar to those found on space-heating equipment. These safety controls shut off the fuel in case of flame failure and stop the burner in case of overheating or excessive drying air temperatures. All controls should be set up to operate the machinery safely in the event of power failure.

1.2 SHALLOW-LAYER DRYING

Batch Dryers

The batch dryer cycles through the loading, drying, cooling, and unloading of the grain. Fans force hot air through columns (typically 300 mm wide) or layers (600 to 1500 mm thick) of grain. Drying time depends on the type of grain and the amount of moisture to be removed. Some dryers circulate and mix the grain to prevent significant moisture content gradients from forming across the column. A circulation rate that is too fast or a poor selection of handling equipment may cause undue damage and loss of market quality. Batch dryers are suitable for farm operations and are often portable.

Continuous-Flow Dryers

This type of self-contained dryer passes a continuous stream of grain through the drying chamber. Some dryers use a second chamber to cool the hot, dry grain before storage. Handling and storage equipment must be available at all times to move grain to and from the dryers. These dryers have cross-flow, concurrent flow, or counterflow designs.

Cross-Flow Dryers. A cross-flow dryer is a column dryer that moves air perpendicular to the grain movement. These dryers commonly consist of two or more vertical columns surrounding the drying and cooling air plenums. The columns range in thickness from 200 to 400 mm. Airflow rates range from 0.7 to 2.7 m^3/s per cubic metre of grain. The thermal efficiency of the drying process increases as column width increases and decreases as airflow rate increases. However, moisture uniformity and drying capacity increase as airflow rate increases and as column width decreases. Dryers are designed to obtain a desirable balance of airflow rate and column width for the expected moisture content levels and drying air temperatures. Performance is evaluated in terms of drying capacity, thermal efficiency, and dried product moisture uniformity.

As with the batch dryer, a moisture gradient forms across the column because the grain nearest the inside of the column is exposed to the driest air during the complete cycle. Several methods minimize the problem of uneven drying.

One method uses turnflow devices that split the grain stream and move the inside half of the column to the outside and the outside half to the inside. Although effective, turnflow devices tend to plug if the grain is trashy. Under these conditions, a scalper/cleaner should be used to clean the grain before it enters the dryer.

Another method is to divide the drying chamber into sections and duct the hot air so that its direction through the grain is reversed in alternate sections. This method produces about the same effect as the turnflow method.

A third method is to divide the drying chamber into sections and reduce the drying air temperature in each section consecutively. This method is the least effective.

Rack-Type Dryers. In this special type of cross-flow dryer, grain flows over alternating rows of heated air supply ducts and air exhaust ducts (Figure 1). This action mixes the grain and alternates exposure to relatively hot drying air and air cooled by previous contact with the grain, promoting moisture uniformity and equal exposure of the product to the drying air.

Concurrent-Flow Dryers. In the concurrent-flow dryer, grain and drying air move in the same direction in the drying chamber. The drying chamber is coupled to a counterflow cooling section. Thus, the hottest air is in contact with the wettest grain, allowing the use of higher drying air temperatures (up to 230°C). Rapid evaporative cooling in the wettest grain prevents the grain temperature from reaching excessive levels. Because higher drying air temperatures are used, the energy efficiency is better than that obtained with a conventional cross-flow dryer. In the cooling section, the coolest air initially contacts the coolest grain. The combination of drying and cooling chambers results in lower thermal stresses in the grain kernels during drying and cooling and, thus, a higher-quality product.

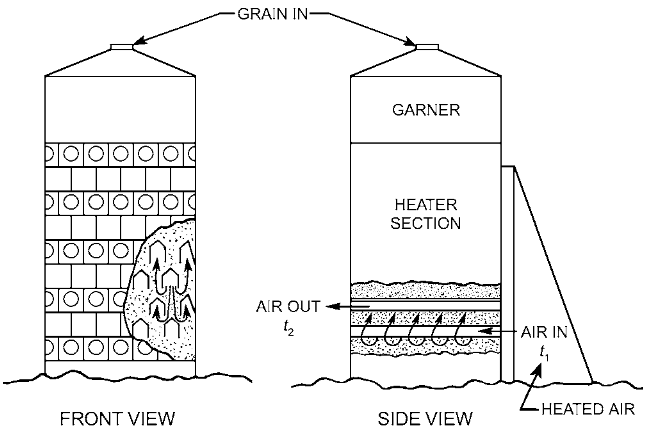

Fig. 1 Rack-Type Continuous-Flow Grain Dryer with Alternate Rows of Air Inlet and Outlet Ducts

Counterflow Dryers. The grain and drying air move in opposite directions in the drying chamber of this dryer. Counterflow is common for in-bin dryers. Drying air enters from the bottom of the bin and exits from the top. The wet grain is loaded from overhead, and floor sweep augers can be used to bring the hot, dry grain to a center sump, where it is removed by another auger. The travel of the sweep is normally controlled by moisture- or temperature-sensing elements.

A drying zone exists only in the lower layers of the grain mass and is truncated at its lower edge so that the grain being removed is not overdried. As a part of the counterflow process, the warm, saturated or near-saturated air leaving the drying zone passes through the cool incoming grain. Some energy is used to heat the cool grain, but some moisture may condense on the cool grain if the bed is deep and the initial grain temperature is low.

Reducing Energy Costs

Recirculation. In most commercially available continuous-flow dryers, optional ducting systems recycle some of the exhaust air from the drying and cooling chambers back to the inlet of the drying chamber (Figure 2). Systems vary, but most make it possible to recirculate all of the air from the cooling chamber and from the lower two-thirds of the drying chamber. The relative humidity of this recirculated air for most cross-flow dryers is less than 50%. Energy savings of up to 30% can be obtained from a well-designed system.

Dryeration. This is another means of reducing energy consumption and improving grain quality. In this process, hot grain with a moisture content one or two percentage points above that desired for storage is removed from the dryer (Figure 3). The hot grain is placed in a dryeration bin, where it tempers without airflow for at least 4 to 6 h. After the first grain delivered to the bin has tempered, the cooling fan is turned on as additional hot grain is delivered to the bin. The air cools the grain and removes 1 to 2% of its moisture before the grain is moved to final storage. If the cooling rate equals the filling rate, cooling is normally completed about 6 h after the last hot grain is added. The crop cooling rate should equal the filling rate of the dryeration bin. A faster cooling rate cools the grain before it has tempered. A slower rate may result in spoilage, since the allowable storage time for hot, damp grain may be only a few days. The required airflow rate is based on dryer capacity and crop density. An airflow rate of 0.2 m^3/s for each cubic metre per hour of grain capacity provides cooling capacity to keep up with the dryer when

drying corn that has a density of 900 kg/m^3. Recommended airflow rates for some crops are listed in Table 4.

Combination Drying. This method was developed to improve drying thermal efficiency and corn quality. First, a high-temperature dryer dries the corn to 18 to 20% moisture content. Then it is transferred to a bin, where the full-bin drying system brings the moisture down to a safe storage level.

Dryer Temperature. For energy savings, operating temperatures of batch and continuous-flow dryers are usually set at the highest level that will not damage the product for its end use.

1.3 DEEP-BED DRYING

A deep-bed drying system can be installed in any structure that holds grain. Most grain storage structures can be designed or adapted for drying if a means of distributing the drying air uniformly through the grain is provided. A perforated floor (Figure 4) and duct systems placed on the floor of the bin (Figure 5) are the two most common means.

Perforations in the floor should have a total area of at least 10% of the floor area. A perforated floor distributes air more uniformly and offers less resistance to airflow than do ducts, but a duct system is less expensive for larger floor area systems. Ducts can be removed after the grain is removed, and the structure can be cleaned and used for other purposes. Ducts should not be spaced farther apart than one-half times the depth of the grain. The amount of perforated area or the duct length will affect airflow distribution uniformity.

Air ducts and tunnels that disperse air into the grain should be large enough to prevent the air velocity from exceeding 10 m/s; slower speeds are desirable. Sharp turns, obstructions, or abrupt changes in duct size should be eliminated, as they cause pressure loss. Operating methods for drying grain in storage bins are (1) full-bin drying, (2) layer drying, (3) batch-in-bin drying, and (4) recirculating/continuous-flow bin drying.

Full-Bin Drying

Full-bin drying is generally performed with unheated air or air heated up to 11°C above ambient. A humidistat is frequently used to sense the humidity of the drying air and turn off the heater if the weather conditions are such that heated air would cause overdrying. A humidistat setting of 55% stops drying at approximately the 12% moisture level for most farm grains, assuming that the ambient relative humidity does not go below this point.

Airflow rate requirements for full-bin drying are generally calculated on the basis of cubic metre per second of air required per cubic metre of grain. The airflow rate recommendations depend on

the weather conditions and on the type of grain and its moisture content. Airflow rate is important for successful drying. Because faster drying results from higher airflow rates, the highest economical airflow rate should be used. However, the cost of full-bin drying at high airflow rates may exceed the cost of using column dryers, or the electric power requirement may exceed the available capacity.

Recommendations for full-bin drying with unheated air are shown in Tables 5, 6, and 7. These recommendations apply to the principal production areas of the continental United States and are based on experience under average conditions; they may not be applicable under unusual weather conditions or even usual weather conditions in the case of late-maturing crops. Full-bin drying may not be feasible in some geographical areas.

The maximum practical depth of grain to be dried (distance of air travel) is limited by the cost of the fan, motor, air distribution system, and power required. This depth seems to be 6 m for corn and soybeans, and about 4.5 m for wheat.

To ensure satisfactory drying, heated air may be used during periods of prolonged fog or rain. Burners should be sized to raise

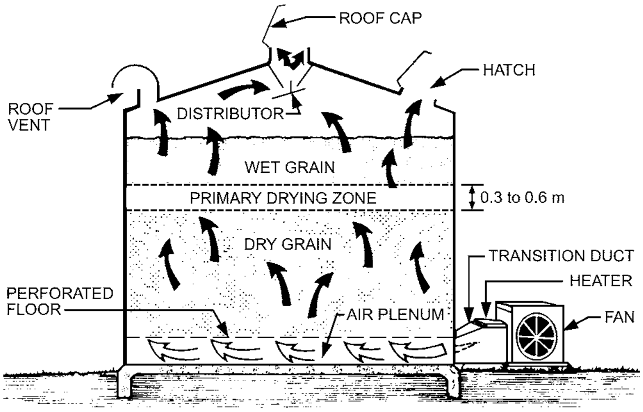

Fig. 6 Three Zones Within Grain During Full-Bin Drying

the temperature of the drying air by no more than 6 K above ambient. The temperature should not exceed about 27°C after heating. Overheating the drying air causes the grain to overdry and dry nonuniformly; heat is recommended only to counteract adverse weather conditions. Electric controllers can be applied to fan and heater operation to achieve the final desired grain moisture content.

Drying takes place in a drying zone, which advances upward through the grain (Figure 6). Grain above this drying zone remains at or slightly above the initial moisture content, while grain below the drying zone is at a moisture content in equilibrium with the drying air.

As the direction of air movement does not affect the rate of drying, other factors must be considered in choosing the direction. A pressure system moves the moisture-laden air up through the grain, and it is discharged under the roof. If there are insufficient roof outlets, moisture may condense on the underside of metal roofs. During pressure system ventilation, the wettest grain is near the top

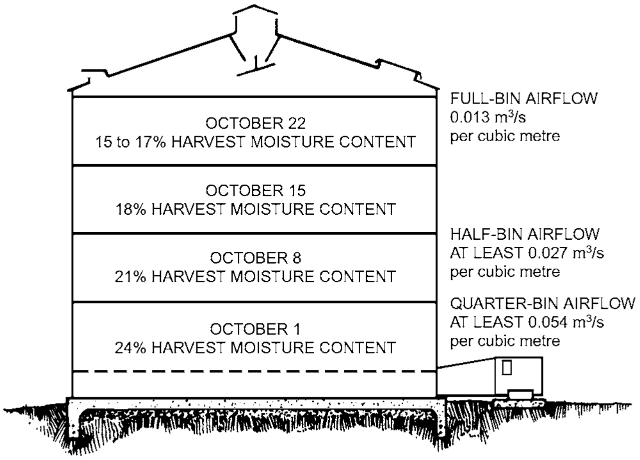

Fig. 7 Example of Layer Filling of Corn

surface and is easy to monitor. Fan and motor waste heat enter into the airstream and contribute to drying.

A negative-pressure system moves air down through the grain. Moisture-laden air discharges from the fan to the outdoors; thus, roof condensation is not a problem. Also, the air picks up some solar heat from the roof. However, the wettest grain is near the bottom of the mass and is difficult to sample. Of the two systems, the pressure system is recommended because it is easier to manage.

The following management practices must be observed to ensure the best performance of the dryer:

1. Minimize foreign material. A scalper-cleaner is recommended for cleaning the grain to reduce air pressure and energy requirements and to help provide uniform airflow for elimination of wet spots.
2. Distribute the remaining foreign material uniformly by installing a grain distributor.
3. Place the grain in layers and keep it leveled.
4. Start the fan as soon as the floor or ducts are covered with grain.
5. Operate the fan continuously with unheated air unless it is raining heavily or there is a dense ground fog. Once all the grain is within 1% of desired storage moisture content, run the fans only when the relative humidity is below 70%.

Layer Drying

In layer drying, successive layers of wet grain are placed on top of dry grain. When the top 150 mm has dried to within 1% of the desired moisture content, another layer is added (Figure 7). Compared to full-bin drying, layering reduces the time that the top layers of grain remain wet. Because the effective airflow rate is greater for lower layers, allowable harvest moisture content of grain in these levels can be greater than that in the upper layers. Either unheated air or air heated 6 to 11°C above ambient may be used, but using heated air controlled with a humidistat to prevent overdrying is most common. The first layer may be about 2 m deep, with successive layers of about 1 m.

Batch-in-Bin Drying

A storage bin adapted for drying may be used to dry several batches of grain during a harvest season, if the grain is kept to a shallow layer so that higher airflow rates and temperatures can be used. After the batch is dry, the bin is emptied, and the cycle is repeated. The drying capacity of the batch system is greater than that of other in-storage drying systems. In a typical operation, batches of corn in 1 m depths are dried from an initial moisture content of 25% with 54°C air at the rate of about 0.33 m^3/s per cubic metre. Considerable nonuniformity of moisture content may be present in the batch after drying is stopped; therefore, the grain should be well mixed as it is

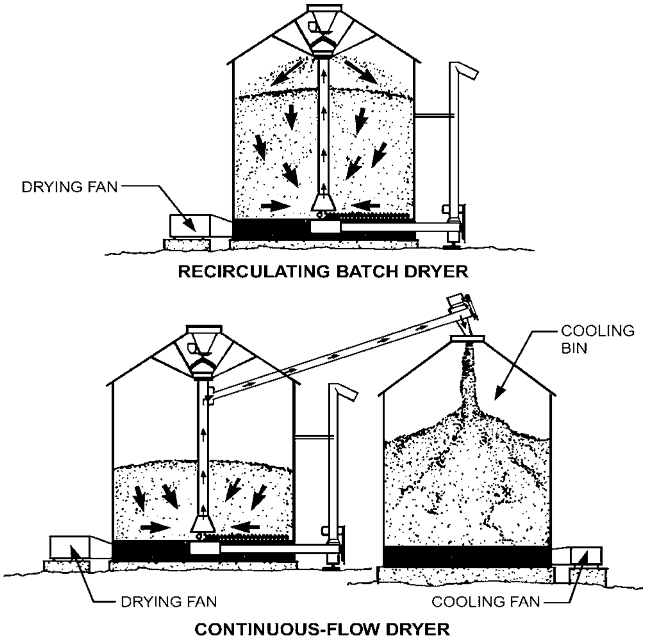

Fig. 8 Grain Recirculators Convert Bin Dryer to High-Speed Continuous-Flow Dryer

placed into storage. If the mixing is done well, grain that is too wet equalizes in moisture with grain that is too dry before spoilage can occur. Aeration of the grain in storage will facilitate the equalization of moisture.

Grain may be cooled in the dryer to ambient temperature before it is stored. Cooling is accomplished by operating the fan without the heater for about 1 h. Some additional drying occurs during the cooling process, particularly in the wetter portions of the batch.

Grain stirring devices are used with both full-bin and batch-in-bin drying systems. Typically, these devices consist of one or more open, 50 mm diameter, standard pitch augers suspended from the bin roof and extending to near the bin floor. The augers rotate and simultaneously travel horizontally around the bin, mixing the drying grain to reduce moisture gradients and prevent overdrying of the bottom grain. The augers also loosen the grain, allowing a higher airflow rate for a given fan. Stirring equipment reduces bin capacity by about 10%. Furthermore, commercial stirring devices are available only for round storage enclosures.

Recirculating/Continuous-Flow Bin Drying

This type of drying incorporates a tapered sweep auger that removes uniform layers of grain from the bottom of the bin as it dries (Figure 8). The dry grain is then redistributed on top of the pile of grain or moved to a second bin for cooling. The sweep auger may be controlled by temperature or moisture sensors. When the desired condition is reached, the sensor starts the sweep auger, which removes a layer of grain. After a complete circuit of the bin, the sweep auger stops until the sensor determines that another layer is dry. Some drying takes place in the cooling bin. Up to two percentage points of moisture may be removed, depending on the management of the cooling bin.

2. DRYING SPECIFIC CROPS

2.1 SOYBEANS

Soybeans usually need drying only when there is inclement weather during the harvest season. Mature soybeans left exposed to rain or damp weather develop a dark brown color and a mealy or chalky texture. Seed quality deteriorates rapidly. Oil from weather-damaged beans costs more to refine and is often not of edible grade. In addition to preventing deterioration, the artificial drying of soybeans offers the advantage of early harvest, which reduces the chance of loss from bad weather and reduces natural and combine shatter loss. Soybeans harvested with a wet basis moisture content greater than 13.5% exhibit less damage.

Drying Soybeans for Commercial Use

Conventional corn-drying equipment can be used for soybeans, with some limitations on heat input. Soybeans for commercial use can be dried at 55 to 60°C; drying temperatures of 90°C reduce the oil yield. If the relative humidity of the drying air is below 40%, excessive seedcoat cracking occurs, causing many split beans in subsequent handling. Physical damage can cause fungal growth on the beans, storage problems, and a slight reduction in oil yield and quality. Flow-retarding devices should be used during handling, and beans should not be dropped more than 6 m onto concrete floors.

Drying Soybeans for Seed and Food

The relative humidity of the drying air should be kept above 40%, regardless of the amount of heat used. The maximum drying temperature to avoid germination loss is 43°C. Natural air drying at a flow rate of 0.0267 m^3/s per cubic metre is adequate for drying seed with an initial moisture content of up to 16% w.b.

If adding heat, raise the drying air temperature no more than 3 K above ambient. This drying method is slow, but it results in excellent quality and avoids overdrying. However, drying must be completed before spoilage occurs. At higher moisture contents, good results have been obtained using an airflow rate of 0.0534 m^3/s per cubic metre with humidity control. Data on allowable drying time for soybeans are unavailable. Without better information, an estimate of storage life for oil crops can be made based on the values for corn, using an adjusted moisture content calculated by the following equation:

$$\text{Comparable moisture content} = \frac{\text{Oilseed moisture content}}{100 - \text{Seed oil content}} \times 100$$

A corn moisture content 2% greater than that of the soybeans should generally be used to estimate allowable drying time (e.g., 12% soybeans are comparable to 14% corn). Soybeans are dried from a lower initial moisture content than corn.

Dry high-moisture soybeans in a bin with the air temperature controlled to keep the relative humidity at 40% or higher. Airflow rates of 0.130 m^3/s per cubic metre are recommended, with the depth of the beans not to exceed 1.2 m.

2.2 HAY

Hay normally contains 65 to 80% wet basis moisture at cutting. Field drying to 20% may result in a large loss of leaves. Alfalfa hay leaves average about 50% of the crop by mass, but they contain 70% of the protein and 90% of the carotene. The quality of hay can be increased and the risk of loss due to bad weather reduced if the hay is put under shelter when partially field dried (35% moisture content) and then artificially dried to a safe storage moisture content. In good drying weather, hay conditioned by mechanical means can be dried sufficiently in one day and placed in the dryer. Hay may be long, chopped, or baled for this operation; unheated or heated air can be used.

In-Storage Drying

Unheated air is normally used for in-storage or mow drying. Hay is dried in the field to 30 to 40% moisture content before being placed in the dryer. For unheated air drying, airflow should be at least 0.10 m^3/s per megagram. The fan should be able to deliver required airflow against static pressure of 250 to 500 Pa.

Slotted floors, with at least 50% of the area open, are generally used for drying baled hay. For long or chopped hay in mows narrower than 11 m wide, the center duct system is the most popular. A slotted floor should be placed on each side of the duct to within 1.5 m of its ends and the outer walls (Figure 9). If the mow is wider than 11 m, it should be divided crosswise into units of 8.5 m or narrower. These should then be treated as individual dryers. If the storage depth exceeds about 4 m, vertical flues and/or additional levels of ducts may be used. If tiered ducts are used, a vertical air chamber, about 75% of the probable hay depth, should be used. The supply ducts are then connected at 2 to 3 m vertical intervals as the mow is filled. With either of these methods, hay in total depths up to 9 m can be dried. The duct size should be such that the air velocity is less than 5 m/s.

The maximum depth of wet hay that should be placed on a hay-drying system at any time depends on hay moisture content, weather conditions, the physical form of the hay, and the airflow rate. The maximum drying depth is about 5 m for long hay, 4 m for chopped hay, and 7 small rectangular bales deep for baled hay. Baled hay should have a density of about 130 kg/m^3. For best results, bales should be stacked tightly together on edge (parallel to the stems) to ensure that no openings exist between them.

For mow drying, the fan should run continuously during the first few days. Afterward, it should be operated only during low relative humidity weather. During prolonged wet periods, the fan should be operated only enough to keep the hay cool.

Batch Wagon Drying

Batch drying can be done on a slotted floor platform; however, because this method is labor-intensive, wagon dryers are more commonly used. With a wagon dryer system, hay is baled at about 45% moisture content to a density of about 180 kg/m^3. The hay is then stacked onto a wagon with tight, high sides and a slotted or expanded metal floor. Drying is accomplished most efficiently by forcing the heated air (up to 70°C) down the canvas duct of a plenum chamber secured to the top of the wagon. After 4 or 5 h of drying, the exhaust air is no longer saturated with moisture, and about 75% of it may be recirculated or passed through a second wagon of wet hay for greater drying efficiency.

In this method, the amount of hay harvested each day is limited by the capacity of the drying wagons. In this 24 h process, the hay cut one day is stored the following day; only enough hay to load the drying wagons should be harvested each day.

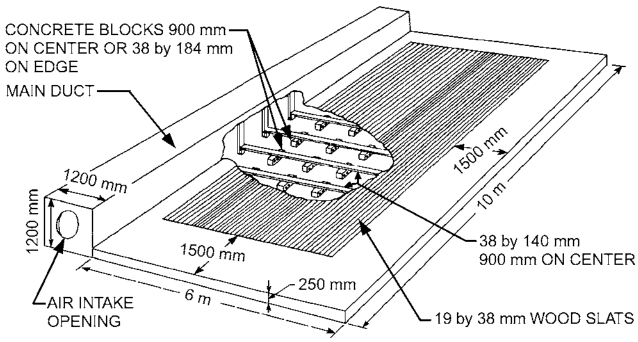

Fig. 9 Central Duct Hay-Drying System with Lateral Slatted Floor for Wide Mows

The airflow rate in this method is normally much higher than when unheated air is used. About 0.2 m^3/s per square metre of wagon floor space is required. As with mow drying, the duct size should be such that the air velocity is less than 5 m/s.

2.3 COTTON

Producers normally allow cotton to dry naturally in the field to 12% moisture content or less before harvest. Cotton harvested in this manner can be stored in trailers, baskets, or compacted stacks for extended periods with little loss in fiber or seed quality. Thus, cotton is not normally aerated or artificially dried before ginning. Cotton harvested during inclement weather and stored cotton exposed to precipitation must be dried at the cotton gin within a few days to prevent self heating and deterioration of the fiber and seed.

Though cotton may be safely stored at moisture contents as high as 12%, moisture levels near the upper limit are too high for efficient ginning and for obtaining optimum fiber grade. The cleaning efficiency of cotton is inversely proportional to its moisture content, with the most efficient level being 5% fiber moisture content. However, fiber quality is best preserved when the fiber is separated from the seed at moisture contents between 6.5 and 8%. Therefore, if cotton comes into the system below this level, it can be cleaned, but moisture should be added before separating the fiber from the seed to improve the ginning quality. Dryers in the cotton gins are capable of drying the cotton to the desired moisture level.

The tower dryer is the most commonly used among several types of commercially available dryers. This device operates on a parallel flow principle: 0.015 to 0.025 m^3/s of drying air per kilogram of cotton also serves as the conveying medium. As it moves through the dryer's serpentine passages, cotton impacts on the walls. This action agitates the cotton for improved drying and lengthens its exposure time. Drying time depends on many variables, but total exposure seldom exceeds 15 s. For extremely wet cotton, two stages of drying are needed for adequate moisture control.

Wide variations in initial moisture content dictate different drying amounts for each load of cotton. Rapid changes in drying requirements are accommodated by automatically controlling drying air temperature in response to moisture measurements taken before or after drying. These control systems prevent overdrying and reduce energy requirements. For safety and to preserve fiber quality, drying air temperature should not exceed 177°C in any portion of the drying system.

If the internal cottonseed temperature does not exceed 60° C, germination is unimpaired by drying. This temperature is not exceeded in a tower dryer; however, the moisture content of the seed after drying may be above the 12% level recommended for safe long-term storage. Wet cottonseed is normally processed immediately at a cottonseed oil mill. Cottonseed under the 12% level is frequently stored for several months before milling or delinting and treatment at a seed processing plant. The aeration that cools deep beds of stored cottonseed effectively maintains viability and prevents an increase in free fatty acid content. For aeration, ambient air is normally drawn downward through the bed at a rate of at least 0.0004 m^3/s per cubic metre of oil mill seed and 0.0021 m^3/s per cubic metre of planting seed.

2.4 PEANUTS

Peanuts normally have a moisture content of about 50% at the time of digging. Allowing the peanuts to dry on the vines in the windrow for a few days removes much of this water. However, peanuts usually contain 20 to 30% moisture when removed from the vines, and some artificial drying is necessary. Drying should begin within 6 h after harvesting to keep the peanuts from self heating.

Both the maximum temperature and the rate of drying must be carefully controlled to maintain quality.

High temperatures result in an off flavor or bitterness. Drying too rapidly without high temperatures results in blandness or nuts that do not develop flavor during roasting. High temperatures, rapid drying, or excessive drying cause the skin to slip easily and the kernels to become brittle. These conditions result in high damage rates in the shelling operation but can be avoided if the moisture removal rate does not exceed 0.5% per hour. Because of these limitations, continuous-flow drying is not usually recommended for peanuts.

Peanuts can be dried in bulk bins using unheated air or air with supplemental heat. Under poor drying conditions, unheated air may cause spoilage, so supplemental heat is preferred. Air should be heated no more than 7 to 8°C to a maximum temperature of 35°C. An airflow rate of 0.050 to 0.130 m^3/s per cubic metre of peanuts should be used, depending on the initial moisture content.

The most common method of drying peanuts is bulk wagon drying. Peanuts are dried in depths of 1.5 to 1.8 m, using airflow rates of 0.05 to 0.08 m^3/s per cubic metre of peanuts and air heated 6 to 8 K above ambient. This method retains quality and usually dries the peanuts in three to four days. Wagon drying reduces handling labor but may require additional investment in equipment.

2.5 RICE

Of all grains, rice is probably the most difficult to process without quality loss. Rice containing more than 13.5% moisture cannot be safely stored for long periods, yet the recommended harvest moisture content for best milling and germination ranges from 20 to 26%. When rice is harvested at this moisture content, drying must be started promptly to prevent souring. Normally, heated air is used in continuous-flow dryers, where large volumes of air are forced through 100 to 250 mm layers of rice. Temperatures as high as 55°C may be used, if (1) the temperature drop across the rice does not exceed 11 to 17 K, (2) the moisture reduction does not exceed two percentage points in a 0.5 h exposure, and (3) the rice temperature does not exceed 38°C. During the tempering period following drying, the rice should be aerated to ambient temperature before the next pass through the dryer. This removes additional moisture and eliminates one to two dryer passes. It is estimated that full use of aeration following dryer passes could increase the maximum daily drying capacity by about 14%.

Unheated air or air with a small amount of added heat (7 K above ambient, but not exceeding 35°C) should be used for deep-bed rice drying. Too much heat overdries the bottom, resulting in checking (cracking), reduced milling qualities, and possible spoilage in the top. Because unheated air drying requires less investment and attention than supplemental heat drying, it is preferred when conditions permit. In the more humid rice-growing areas, supplemental heat is desirable to ensure that the rice dries. The time required for drying varies with weather conditions, moisture content, and airflow rate. In California, the recommended airflow rate is 0.001 to 0.012 m^3/s per cubic metre. Because of less favorable drying conditions in Arkansas, Louisiana, and Texas, greater airflow rates are recommended (e.g., a minimum of 0.01 m^3/s per cubic metre is recommended in Texas). Whether unheated air or supplemental heat is used, the fan should be turned on as soon as rice uniformly covers the air distribution system. The fan should then run continuously until the moisture content in the top 300 mm of rice is reduced to about 15%. At this point, the supplemental heat should be turned off. The rice can then be dried to a safe storage level by operating the fan only when the relative humidity is below 75%.

3. STORAGE PROBLEMS AND PRACTICES

3.1 MOISTURE MIGRATION

Redistribution of moisture generally occurs in stored grain when grain temperature is not controlled (Figure 10). Localized spoilage can occur even when the grain is stored at a safe moisture level. Grain placed in storage in the fall at relatively high temperatures cools nonuniformly through contact with the outer surfaces of the storage bin as winter approaches. Thus, the grain near the outer walls and roof may be at cool outdoor temperatures while the grain nearer the center is still nearly the same temperature it was at harvest. These temperature differentials induce air convection currents that flow downward along the outer boundaries of the porous grain mass and upward through the center. When the cool air from the outer regions contacts the warm grain in the interior, the air is heated and its relative humidity is lowered, increasing its capacity to absorb moisture from the grain. When the warm, humid air reaches the cool grain near the top of the bin, it cools again and transfers vapor to the grain. Under extreme conditions, water condenses on the grain. The moisture concentration near the center of the grain surface causes significant spoilage if moisture migration is uncontrolled. During spring and summer, the temperature gradients are reversed. The grain moisture content increases most at depths of 600 to 1200 mm below the surface. Daily variations in temperature do not cause significant moisture migration. Aside from seasonal temperature variations, the size of the grain mass is the most important factor in fall and winter moisture migration. In storages containing less than 35 m^3, there is less trouble with moisture migration. The problem becomes critical in large storages and is aggravated by incomplete cooling of artificially dried grain. Artificially dried grain should be cooled to near ambient temperature soon after drying. 10°C

3.2 GRAIN AERATION

Aeration by mechanically moving ambient air through the grain mass is the best way to control moisture migration. Aeration systems are also used to cool grain after harvest, particularly in warmer climates where grain may be placed in storage at temperatures exceeding 38°C. After the harvest heat is removed, aeration may be continued in cooler weather to bring the grain to a temperature within 11 K of the coldest average monthly temperature. The temperature must be maintained below 10°C.

Aeration systems are not a means of drying because airflow rates are too low. However, in areas where the climate is favorable, carefully controlled aeration may be used to remove small amounts of moisture. Commercial storages may have pockets of higher-moisture grain if, for example, some batches of grain are delivered after a rain shower or early in the morning. Aeration can control heating damage in the higher-moisture pockets.

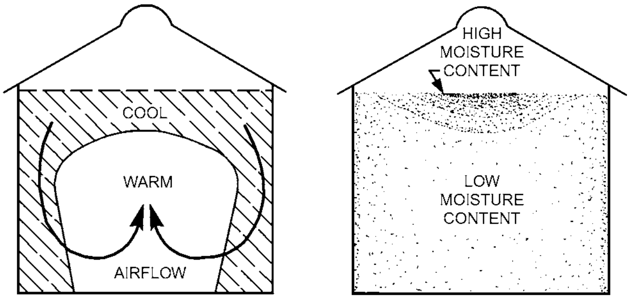

Fig. 10 Grain Storage Conditions Associated with Moisture Migration During Fall and Early Winter

Aeration Systems Design

Aeration systems include fans capable of delivering the required amount of air at the required static pressure, suitable ducts or floors to distribute the air into the grain, and controls to regulate the operation of the fan. The airflow rate determines how many hours are required to cool the crop (Table 8). Most aeration systems are designed with airflow rates between 0.0007 to 0.0027 m^3/s per cubic metre of grain.

Stored grain is aerated by forcing air up or down through the grain. Upward airflow is more common because it is easier to observe when the cooling front has moved through the entire grain mass. In large, flat storages with long ducts, upward airflow results in more uniform air distribution than downdraft systems.

During aeration, a warming or cooling front moves through the crop (Figure 11); it is important to run the fan long enough to move the front completely through the crop.

Static pressure for an aeration system can be determined using the airflow resistance information in Chapter 11 of the 2005 *ASHRAE Handbook—Fundamentals*. All common types of fans are used in aeration systems. Attention should be given to noise levels with fans that are operated near residential areas or where people work for extended periods. The supply ducts connecting the fan to the distribution ducts in the grain should be designed and constructed according to the standards of good practice for any air-moving application. A maximum air velocity of 13 m/s may be used, but 8 to 10 m/s is preferred. In large systems, one large fan may be attached to a manifold duct leading to several distribution ducts in one or more storages, or smaller individual fans may serve individual distribution ducts. Where a manifold is used, valves or dampers should be installed at each takeoff to allow adjustment or closure of airflow when part of the aerator is not needed.

Table 8 Airflow Rates Corresponding to Approximate Grain Cooling Time

Airflow Rate, m^3/s per cubic metre of grain	Cooling Time, h
0.0007	240
0.0013	120
0.0027	60
0.0040	40
0.0054	30
0.0067	24
0.0080	20
0.0107	15
0.0134	12

Distribution ducts are usually perforated sheet metal with a circular or inverted U-shaped cross section, although many functional arrangements are possible. The area of the perforations should be at least 10% of the total duct surface. The holes should be uniformly spaced and small enough to prevent the passage of the grain into the duct (e.g., 2.5 mm holes or 2 mm wide slots do not pass wheat).

Since most problems develop in the center of the storage, and the crop cools naturally near the wall, the aeration system must provide good airflow in the center. Flush floor systems work well in storages with sweep augers and unloading equipment. Ducts should be easily removable for cleaning. Duct spacing should not exceed the depth of the crop; the distance between the duct and storage structure wall should not exceed one-half the depth of the crop for bins and flat storages. Common duct patterns for round bins are shown in Figure 12. Duct spacing for flat storages is shown in Figure 13.

When designing the distribution duct system for any type of storage, the following should be considered: (1) the cross-sectional area and length of the duct, which influences both the air velocity within the duct and the uniformity of air distribution; (2) the duct surface area, which affects the static pressure losses in the grain surrounding the duct; and (3) the distance between ducts, which influences the uniformity of airflow.

For upright storages where distribution ducts are relatively short, duct velocities up to 10 m/s are permissible. Maximum recommended air velocities in ducts for flat storages are shown in Table 9. Furthermore, these velocities should not be exceeded in the air outlets from the storage; therefore, an air outlet area at least equal to the duct cross-sectional area should be provided.

The duct surface area that is perforated or otherwise open for air distribution must be great enough that the air velocity through the

Table 9 Maximum Recommended Air Velocities Within Ducts for Flat Storages

Grain	Airflow Rate, m^3/s per cubic metre (grain)	Air Velocity (m/s) within Ducts for Grain Depths of: 3 m	6 m	9 m	12 m	15 m
Corn, soybeans, and other large grains	0.0007	—	3.8	5.0	6.3	6.3
	0.0013	3.8	5.0	6.3	7.6	8.8
	0.0027	5.0	6.3	—	—	—

	0.0027	5.0	10.0	—	—	—

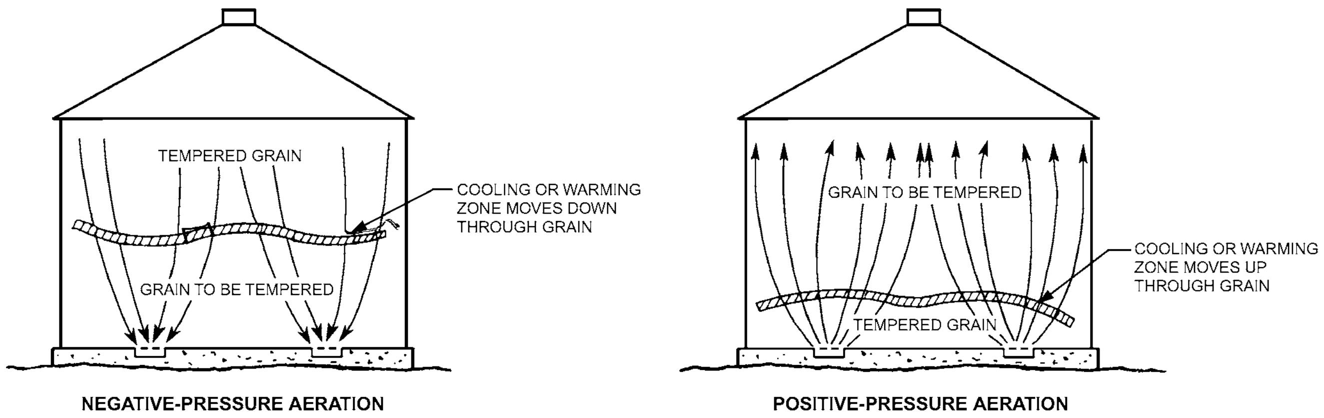

Fig. 11 Aerating to Change Grain Temperature

grain surrounding the duct is low enough to avoid excessive pressure loss. When a semicircular perforated duct is used, the entire surface area is effective; only 80% of the area of a circular duct resting on the floor is effective. For upright storages, the air velocity through the grain near the duct (duct face velocity) should be limited to 0.15 m/s or less; in flat storages, to 0.10 m/s or less.

Duct strength and anchoring are important. If ducts placed directly on the floor are to be held in place by the crop, the crop flow should be directly on top of the ducts to prevent movement and damage. Distribution ducts buried in the grain must be strong enough to withstand the pressure the grain exerts on them. In tall, upright storages, static grain pressures may reach 70 kPa. When ducts are located in the path of the grain flow, as in a hopper, they may be subjected to many times this pressure during grain unloading.

Operating Aeration Systems

The operation of aeration systems depends largely on the objectives to be attained and the locality. In general, cooling should be carried out any time the outdoor air temperature is about 8 K cooler than the grain. Stored grain should not be aerated when the air humidity is much above the equilibrium humidity of the grain because moisture will be added. The fan should be operated long enough to cool the crop completely, but it should then be shut off and covered, thus limiting the amount of grain that is rewetted.

Aeration to cool the grain should be started as soon as the storage is filled, and cooling air temperatures are available. Aeration to prevent moisture migration should be started whenever the average air temperature is 6 to 8 K below the highest grain temperature. Aeration is usually continued as weather permits until the grain is uniformly cooled to within 11 K of the average temperature of the coldest month, or to 0 to 5°C.

Grain temperatures of about 0 to 10°C are desirable. In the northern corn belt, aeration may be resumed in the spring to equalize the grain temperature and raise it to between 5 to 10°C This reduces the risk of localized heating from moisture migration. Storage problems are the only reason to aerate when air temperatures are above 15°C. Aeration fans and ducts should be covered when not in use.

In storages where fans are operated daily in fall and winter months, automatic controls work well when air is not too warm or humid. One thermostat usually prevents fan operation when the air temperature is too high, and another prevents operation when the air is too cold. A humidistat allows operation when the air is not too humid. Fan controllers that determine the equilibrium moisture content of the crop based on existing air conditions can regulate the fan based on entered information.

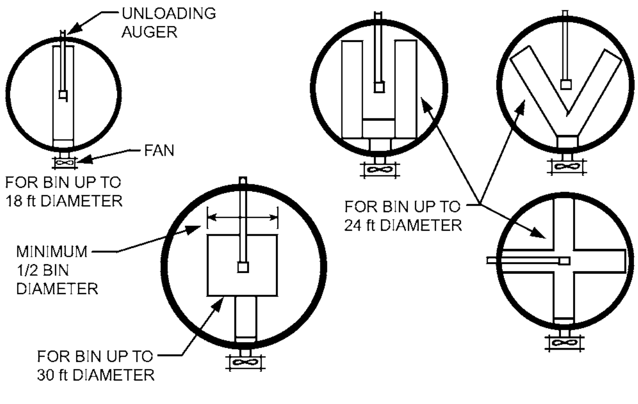

Fig. 12 Common Duct Patterns for Round Grain Bins

4. SEED STORAGE

Seed must be stored in a cool, dry environment to maintain viability. Most seed storages have refrigeration equipment to maintain a storage environment of 7 to 12°C. Seed storage conditions must be achieved before mold and insect damage occur.

CHAPTER 27

AIR CONDITIONING OF WOOD AND PAPER PRODUCT FACILITIES

General Wood Product Operations 27.1
Pulp and Paper Operations 27.2

THIS chapter covers some of the standard requirements for air conditioning of facilities that manufacture finished wood products as well as for pulp and paper product process operations.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. GENERAL WOOD PRODUCT OPERATIONS

In wood product manufacturing facilities, ventilation can be considered a part of the process. Metal ductwork should be used and grounded to prevent a buildup of static electricity. Hoods should be made of spark-free, noncombustible material. A pneumatic conveying system should be furnished to reduce the accumulation of wood dust in the collecting duct system. The airflow rate and velocity should be able to maintain the air-dust mixture below the minimum explosive concentration level. If dampers are unavoidable in the system, they should be firmly fastened after balancing work. Dust collectors should be located outside the building. Fans or blowers should be placed downstream of the dust collector and air-cleaning equipment, and should be interlocked with the wood-processing equipment. When the fan or blower stops, the wood process should stop immediately and forward a signal to the alarm system.

Deflagration venting and suppression should be furnished for wood-processing workshops and wood-processing equipment such as vessels, reactors, mixers, blenders, mills, dryers, ovens, filters, dust collectors, storage equipment, material-handling equipment, and aerosol areas. The deflagration suppression system must be disarmed before performing any maintenance work to avoid possible injury from discharging the suppressant. Warning signs should be displayed prominently at all maintenance access points.

Finished lumber products to be used in heated buildings should be stored in areas that are heated 6 to 11 K above ambient. This provides sufficient protection for furniture stock, interior trim, cabinet material, and stock for products such as ax handles and glue-laminated beams. Air should be circulated within the storage areas. Lumber that is kiln-dried to a moisture content of 12% or less can be kept within a given moisture content range through storage in a heated shed. The moisture content can be regulated either manually or automatically by altering the dry-bulb temperature (Figure 1).

Some special materials require close control of moisture content. For example, musical instrument stock must be dried to a given moisture level and maintained there because the moisture content of

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

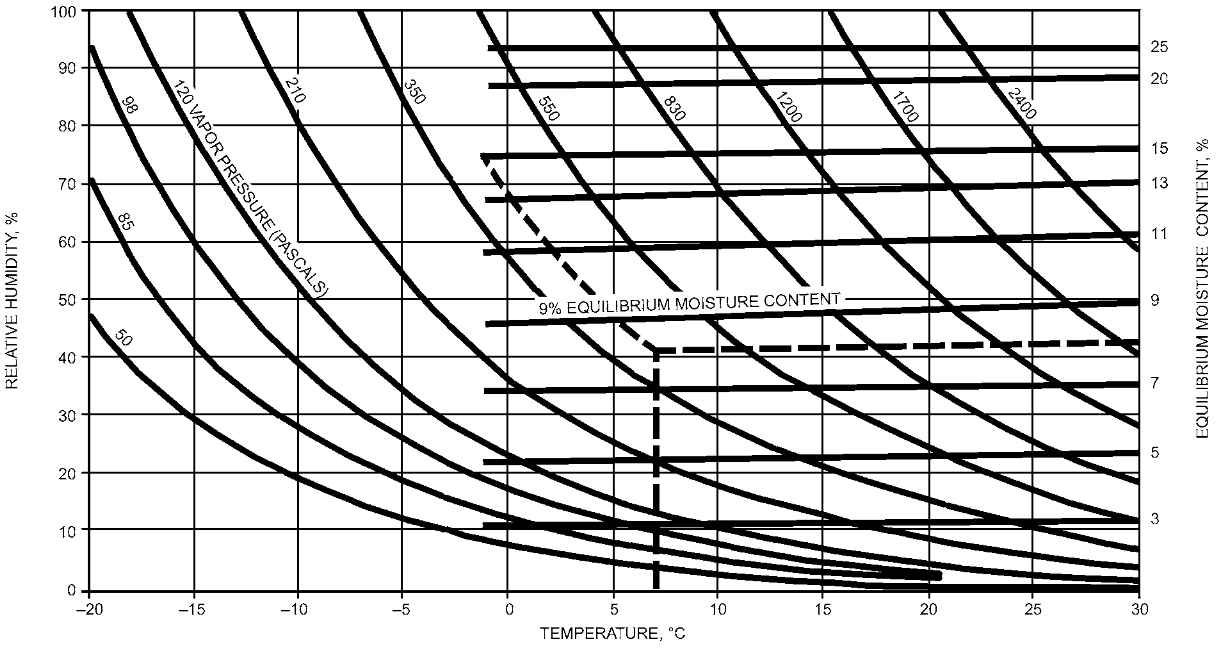

Fig. 1 Relationship of Temperature, Relative Humidity, and Vapor Pressure of Air and Equilibrium Moisture Content of Wood

the wood affects the harmonics of most stringed wooden instruments. This control may require air conditioning, heating, and/or humidification, with or without reheating.

Process Area Air Conditioning

Temperature and humidity requirements in wood product process areas vary according to product, manufacturer, and governing code. For example, in match manufacturing, the match head must be cured (i.e., dried) after dipping. This requires careful control of humidity and temperature to avoid a temperature near the ignition point. Any process involving application of flammable substances should follow the ventilation recommendations of the National Fire Protection Association, the National Fire Code, and the U.S. Occupational Safety and Health Act.

Finished Product Storage

Finished lumber to be made into furniture, equipment parts, musical instruments, architectural woodwork, or other wood products of value is stored and/or manufactured under controlled temperature and humidity to maintain proper wood dryness. Improper drying can cause laminated or glued joints to fail. Finished wood that has changed dimension because of excess moisture gain or loss can cause fitting problems. Cracking, splitting, checking, warping, and discoloration can also occur in improperly dried and/or stored wood.

Green, rough, cut lumber is stacked end to end in layers, each layer being separated by wood strips to allow air circulation. Lumber can be stacked and left to dry naturally in open-sided sheds. Enclosed, heated kilns with steam coils and/or direct steam injection, forced air circulation, makeup air, and exhaust air vents could be used where faster, controlled drying is preferred. Drying (or addition of moisture) can be accomplished by HVAC systems using dehumidifying coils and/or desiccants, heating/reheat coils, humidifiers, makeup and exhaust air, distribution air ducts, and automatic controls. An insulated dehumidifying/humidifying room could be constructed and finished to minimize moisture migration from higher-humidity areas. Lumber can also be dried by solar kilns, microwaves, dielectric heating, superheated steam, and vacuum.

Wood is composed of natural fibers and moisture content varies according to the environment. Samples from the wood being dried must be tested for moisture content at predetermined time intervals to prevent overdrying and defects. Drying rates are determined by the wood species. Final moisture content depends upon the wood's ultimate use.

The formula for determining moisture content is

$$\frac{\left[\begin{pmatrix}\text{Mass of sample}\\ \text{when cut}\end{pmatrix} - \begin{pmatrix}\text{Mass of oven-}\\ \text{dried sample}\end{pmatrix}\right] \times 100}{\text{Mass of oven-dried sample}} = \begin{matrix}\text{Moisture}\\ \text{content, \%}\end{matrix}$$

Lumber/wood drying using HVAC systems can be accomplished with factory- or field-assembled systems. The quantity of lumber/wood to be dried, wood species, rate of drying, total moisture removal, drying room construction, economics (cost and rate of return on investment), fire and safety codes, maintenance, and ease of use influence the type of HVAC system to be installed.

2. PULP AND PAPER OPERATIONS

The papermaking process comprises two basic steps: (1) wood is reduced to pulp (i.e., wood fibers), and (2) the pulp is converted to paper. Wood can be pulped by either mechanical action (e.g., grinding in a groundwood mill), chemical action (e.g., kraft pulping), or a combination of both.

Many different types of paper can be produced from pulp, ranging from the finest glossy finish to newsprint to bleached board to fluff pulp for disposable diapers. To make newsprint, a mixture of mechanical and chemical pulps is fed into the paper machine. To make kraft paper (e.g., grocery bags, corrugated containers), however, only unbleached chemical pulp is used. Disposable diaper material and photographic paper require bleached chemical pulp with a very low moisture content of 6 to 9%.

Paper Machine Area

In papermaking, extensive air systems are required to support and enhance the process (e.g., by preventing condensation) and to provide reasonable comfort for operating personnel. Radiant heat from steam and hot-water sources and mechanical energy dissipated as heat can result in summer temperatures as high as 50°Cin the machine room. In addition, high paper machine operating speeds of 10 to 23 m/s and a stock temperature near 50°C produce warm vapor in the machine room.

Outdoor air makeup units and process exhausts absorb and remove room heat and water vapor released from the paper as it is dried (Figure 2). Makeup air is distributed to working areas above and below the operating floor. Part of the air delivered to the basement migrates to the operating floor through hatches and stairwells. Motor-cooling equipment distributes cooler basement air to the paper machine drive motors.

Wet and basement exhaust should be installed inside the room. Outdoor air intakes with insulated adjustable louvers should be installed on the outside wall to supplement the mechanical air supply. In facilities with no basement exterior wall, sufficient mechanical air intake should be provided. The exhaust, adjustable louver, or mechanical air intake should be furnished with modulating control. When the ambient temperature drops to near freezing, outdoor airflow must be reduced to a minimum and the appropriate heater started to prevent freezing.

The most severe ventilation demand occurs in the area between the wet-end forming and press sections and the dryer section. In the forming section, the pulp slurry, which contains about 90% water, is deposited on a traveling screen. Gravity, rolls, foils, vacuum, steam boxes, and three or more press roll nips are sequentially used to remove up to 50% of the water in the forming and press sections. The wet end is very humid because of evaporation of moisture and mechanical generation of vapor by turning rolls and cleaning showers. Baffles and a custom-designed exhaust in the forming section help control the vapor. A drive-side exhaust in the wet end removes heat from the motor vent air and removes the process generated vapor.

To prevent condensation or accumulated fiber from falling on the traveling web, a false ceiling is used with ducts connected to roof

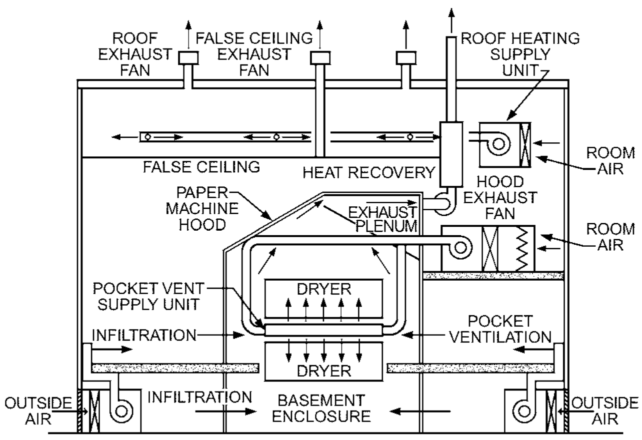

Fig. 2 Paper Machine Area

exhausters that remove humid air not captured at a lower point. At the wet end, heated inside air is usually circulated to scrub the underside of the roof to prevent condensation in cold weather. Additional roof exhaust may also remove accumulated heat from the dryer section and the dry end during warmer periods. Ventilation in the wet end should be predominantly accomplished by roof exhaust.

The large volume of moisture and vapor generated from the wet-end process rises and accumulates under the roof. To keep condensation from forming in winter, the roof is normally exhausted and hot air is distributed under the roof. Sufficient roof insulation should be installed to keep the inside surface temperature above the dew point. Heat transfer from the room to the interior surface is

$$\frac{t_r - t_{is}}{R_{r-is}} = \frac{t_{is} - t_o}{R_{is-o}} \quad (1)$$

where

t_r = room air temperature, °C
t_{is} = roof interior surface temperature, °C
t_o = outdoor air temperature, °C
R_{r-is} = heat transfer resistance from room air to roof interior surface. In winter, R_{r-is} = 0.11 (m²·K)/W
R_{is-o} = required total R-value from roof interior surface to outdoor air, (m²·K)/W

For a given project, t_o and t_r have been determined and only t_{is} needs to be selected. For wet-end roof insulation and assuming 96% relative humidity, t_{is} can be shown on a psychrometric chart to be

$$t_{is} = t_r - 0.7°C \quad (2)$$

Then Equation (1) can be simplified to find the required roof R-value as

$$R_{is-o} = \frac{0.11}{0.7}(t_r - t_o - 0.7) \quad (3)$$

In the dryer section, the paper web is dried as it travels in a serpentine path around rotating steam-heated drums. Exhaust hoods remove heat from the dryers and moisture evaporated from the paper web. Most modern machines have enclosed hoods, which reduce the airflow required to less than 50% of that required for an open-hood exhaust. The temperature inside an enclosed hood ranges from 50 to 60°C at the operating floor to 80 to 95°C in the hood exhaust plenum at 70 to 90% rh, with an exhaust rate generally ranging from 140 to 190 m³/s per machine.

Where possible, pocket ventilation air (see Figure 3) and hood supply air are drawn from the upper level of the machine room to take advantage of the preheating of makeup air by process heat as it rises. The basement of the dryer section is also enclosed to control infiltration of machine room air to the enclosed hood. The hood supply and the pocket ventilation air typically operate at 95°C; however, some systems run as high as 120°C. Enclosed hood exhaust is typically 0.16 m³/s per megagram of machine capacity. The pocket ventilation and hood supply are designed for 75 to 80% of the exhaust, with the balance infiltrated from the basement and machine room. Large volumes of air (240 to 380 m³/s) are required to balance the paper machine's exhaust with the building air balance.

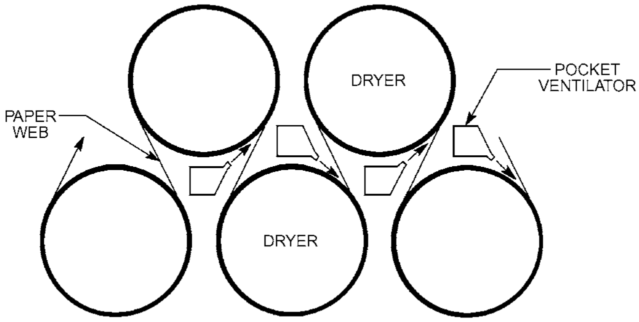

Fig. 3 Pocket Ventilation

The potential for heat recovery from hood exhaust air should be evaluated. Most of the energy in steam supplied to the paper dryers is converted to latent heat in the hood exhaust as water evaporates from the paper web. Air-to-air heat exchangers are used where the air supply is located close to the exhaust. Air-to-liquid heat exchangers that recirculate water/glycol to heat remote makeup air units can also be used. Air-to-liquid systems provide more latent heat recovery, resulting in three to four times more total heat recovery than air-to-air units. Some machines use heat recovered from the exhaust air to heat process water. Ventilation in paper machine buildings in the United States ranges from 10 to 25 air changes per hour in northern mills to 20 to 50 in southern mills. In some plants, computers monitor the production rate and outdoor air temperature to optimize operation and conserve energy.

After fine, bond, and cut papers have been bundled and/or packaged, they should be wrapped in a nonpermeable material. Most papers are produced with less than 10% moisture by mass, the average being 7%. Dry paper and pulp are hygroscopic and begin to swell noticeably and deform permanently when the relative humidity exceeds 38%. Therefore, finished products should be stored under controlled conditions to maintain their uniform moisture content.

Finishing Area

To produce a precisely cut paper that stabilizes at a desirable equilibrium moisture content, the finishing areas require temperature and humidity control. Further converting operations such as printing and die cutting require optimum sheet moisture content for efficient processing. Finishing room conditions range from 21 to 24°C db and from 40 to 45% rh. Rooms should be maintained within reasonably close limits of the selected conditions. Without precise environmental control, the paper equilibrium moisture content varies, influencing dimensional stability, the tendency to curl, and further processing.

Process and Motor Control Rooms

In most pulp and paper applications, process control, motor control, and switchgear rooms are separate from the process environment. Air conditioning removes heat generated by equipment, lights, etc., and reduces the air-cleaning requirement. (See Chapter 20 for air conditioning in control rooms that include a computer, a computer terminal, or data processing equipment.) Ceiling grilles or diffusers should be located above access aisles to avoid the risk of condensation on control consoles or electrical equipment during start-up and recovery after an air-conditioning shutdown. Electrical rooms are usually maintained in the range of 24 to 27°C, with control rooms at 23°C; the humidity is maintained in the range of 45 to 55% in process control rooms and is not normally controlled in electrical equipment rooms.

Motor and electrical control rooms for process and electrical distribution control contain electronic equipment that is susceptible to corrosion. The typical pulp and paper mill environment contains both particulate and vapor-phase contaminants with sulfur- and chloride-based compounds. To protect equipment, multistage particulate and adsorbent filters should be used. They should have treated activated charcoal and potassium permanganate-impregnated alumina sections for vapor-phase contaminants, as well as fiberglass and cloth media for particulates.

To ensure normal operation of air-conditioning systems, redundancy of supply fans, fan motors, and fan power supply in air-handling units that serve process control rooms and motor control centers is strongly recommended in new-construction plants.

Switchgear and motor control centers are not as heat-sensitive as control rooms, but the moisture-laden air carries chemical residues onto the contact surfaces. Arcing, corrosion, and general deterioration can result. A minimum amount of filtered, outdoor air and air conditioning is used to protect these areas.

In most projects, the electric distribution control system (DCS) is energized before the room air conditioning is installed and started. If a temporary air conditioner is used in the DCS room, a condensate drain pan and temporary drain pipe should be installed to keep condensate from the cable channel beneath the DCS panels.

Paper Testing Laboratories

Design conditions in paper mill laboratories must be followed rigidly. The most recognized standard for testing environments for paper and paper products (paperboard, fiberboard, and containers) is TAPPI (the Technical Association of the Pulp and Paper Industry) *Standard* T402. ASTM E171 is also relevant.

Standard pulp and paper testing laboratories have three environments: preconditioning, conditioning, and testing. The physical properties of a sample are different if it is brought to the testing humidity from a high humidity than if it is brought from a lower humidity. Preconditioning at lower relative humidity tends to eliminate hysteresis. For a preconditioning atmosphere, TAPPI *Standard* T402 recommends 10 to 35% rh and 22 to 40°C db. Samples are usually conditioned in a controlled, conditioned cabinet.

Conditioning and testing atmospheres should be maintained at 50 ± 2.0% rh and 23°C ± 1 K db. However, a change of 1 K db at 23°C without starting a humidifier causes the relative humidity to fluctuate as much as 3%. A dry-bulb temperature tolerance of ±0.5 K must be held to maintain a ±2% rh. A well-designed temperature and humidity control system should be provided.

Miscellaneous Areas

The pulp digester area contains many components that release heat and contribute to dusty conditions. For batch digesters, the chip feeders are a source of dust and need hooded exhaust and makeup air. The wash and screen areas have numerous components with hooded exhausts that require considerable makeup air. Good ventilation controls fumes and humidity. The lime kiln feed-end releases extremely large amounts of heat and requires high ventilation rates or air conditioning.

Recovery-boiler and power-boiler buildings have conditions similar to those of power plants; the ventilation rates are also similar. The control rooms are generally air conditioned. The grinding motor room, in which groundwood is made, contains many large motors that require ventilation to keep the humidity low.

System Selection

The system and equipment selected for air conditioning a pulp and paper mill depends on many factors, including the plant layout and atmosphere, geographic location, roof and ceiling heights (which can exceed 30 m), and degree of control desired. Chilled-water systems are economical and practical for most pulp and paper operations, because they have both the large cooling capacity needed by mills and the precision of control to maintain the proper temperature and humidity in laboratories and finishing areas. In the bleach plant, the manufacture of chlorine dioxide is enhanced by using water with a temperature of 7°C or lower; this water is often supplied by the chilled-water system. If clean plant or process water is available, water-cooled chillers are satisfactory and may be supplemented by water-cooled direct-expansion package units for small, remote areas. However, if plant water is not clean enough, a separate cooling tower and condenser water system should be installed for the air conditioning.

Most manufacturers prefer water-cooled over air-cooled systems because of the gases and particulates present in most paper mills. The most prevalent contaminants are chlorine gas, caustic soda, borax, phosphates, and sulfur compounds. With efficient air cleaning, the air quality in and about most mills is adequate for properly placed air-cooled chillers or condensing units that have properly applied coil and housing coatings. Phosphor-free brazed coil joints are recommended in areas where sulfur compounds are present.

Heat is readily available from processing operations and should be recovered whenever possible. Most plants have good-quality hot water and steam, which can be used for unit heater, central station, or reheat quite easily. Evaporative cooling should be considered. Newer plant air-conditioning methods, using energy conservation techniques such as temperature destratification and stratified air conditioning, have application in large structures. Absorption systems should be considered for pulp and paper mills because they provide some degree of energy recovery from the high-temperature steam processes.

Safety Considerations 28.12

THIS chapter discusses HVAC systems for industrial facilities that produce process heat and power and for electrical generating stations and transmission facilities. Not every type of power plant is specifically covered, but the process areas addressed normally correspond to similar process areas in any given plant. For example, wood-fired boilers are not specifically discussed, but the requirements for coal-fired boilers generally apply. Aspects of HVAC system design unique to nuclear power plants are covered in Chapter 29.

Caution: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are fire- and life-safety issues that may be beyond the scope of this chapter and not completely addressed. Recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), the American National Standards Institute (ANSI), the facility's insurance carriers, and authorities having jurisdiction (AHJs) can be consulted for advice regarding specific situations. In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety or seek advice from the AHJ and insurance carrier.

1. GENERAL DESIGN CRITERIA

Space-conditioning systems in power plant buildings are designed to maintain an environment conducive to reliable operation of power generation systems and equipment and the convenience and safety of plant personnel. A balance should be achieved between the cost of the process systems designed to operate in a specified environment and the cost of providing HVAC to modify or condition the environment.

Environmental criteria for personnel safety and comfort are governed by several sources. The U.S. Occupational Safety and Health Administration (OSHA) defines noise, thermal environment, and air contaminant exposure limits. Chapters 15 and 32 of this volume and *Industrial Ventilation* by the American Conference of Governmental Industrial Hygienists (ACGIH 2016) also provide guidance for safety in work spaces, primarily in the areas of industrial ventilation and worker-related heat stress. Worker comfort is somewhat subjective and more difficult to quantify. The plant owner or operator ordinarily establishes the balance between cost and worker comfort.

Exhaust vents are subject to regulation of the plant's air quality permit and local air pollution control board's requirements. For this reason, all exhaust vent locations should be properly identified and classified, and coordinated with the plant's environmental compliance permits. Treatment of exhaust streams is discussed in Chapter 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Criteria should be clearly defined at the start of design, because they document an understanding between the process designer and the HVAC system engineer that is fundamental to achieving the environment required for the various process areas. Typical criteria for a coal-fired power plant are outlined in Table 1. Review criteria for compliance with local codes, the plant operator's experience and preferences, and the facility's overall financial objectives. Additional discussion of criteria may be found in the sections on specific areas.

Temperature and Humidity

Due to the heavy mass of buildings and structures at fuel-fired power plants, brief variations in outdoor air temperature have little or no short-term effect on indoor temperatures, even when those areas are ventilated with 100% outdoor air. (It takes a couple of months to achieve equilibrium on some of these structures.) Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* shows outdoor design in the 0.4% (Cooling)/99.6% (Heating) columns that suggests that the outdoor temperatures for cooling load design can exceed those in the tables about 0.4% of the time annually. Because temperature excursions above the ASHRAE design outdoor air temperatures are brief (1 to 4 h), the effect on indoor room temperature is considered to be negligible. Hence, using outdoor temperatures as shown in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* for the design of HVAC systems is acceptable.

Certain areas such as electrostatic precipitator transformer/rectifier (TR) set and control enclosures are sometimes cooled with 100% outdoor air. These and other similar enclosures are typically insulated prefabricated structures with little or no thermal mass. Although the ASHRAE 99.6%/0.4% conditions may be adequate, extreme weather conditions or other cooling methodologies need to be considered.

Indoor temperatures should match the specified operating temperatures of the equipment. Electrical equipment (such as switchgear, motor control centers, and motors) typically determines the design temperature limits in the plant; common temperature ratings are 40 or 50°C. Other areas such as elevator machine rooms may include electronic equipment with temperature restrictions.

In plant areas where compressed-gas containers are stored, the design temperature is dictated by the gas supplier. Typically, the minimum temperature should be high enough that the gas volume can be effectively released from the containers. If the gas is hazardous (e.g., chlorine), the minimum temperature does not apply during personnel occupancy periods, when high dilution ventilation rates are needed.

Practical ventilation rates for fuel-fired power plants provide indoor conditions 6 to 11 K above the outdoor ambient. Therefore,

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

[h]Lower criteria should be considered for occupied substations.

ventilation design criteria establish a temperature rise above the design outdoor temperature to produce an expected indoor temperature that matches the electrical equipment ratings. For example, an outdoor extreme design temperature of 44°C with a ventilation system designed for a 6 K rise would meet the requirements of 50°C-rated plant equipment. Because excursions above selected design outdoor air temperature are often brief (e.g., 2 to 3 h), the effect on room temperature is minimal. In addition, the electrical equipment temperature ratings are associated with design life, not sudden failures. In hot climates where outdoor temperatures may cause indoor temperatures to exceed electrical equipment ratings for extended periods, evaporative cooling or air conditioning of electrical equipment areas may be required to hold temperatures below the equipment design values. When high area temperatures are possible, the quality of environment for plant maintenance workers should also be considered. Velocity (spot) cooling may be necessary in some areas to support work activities.

Low temperatures may affect plant reliability because of the potential for freezing. Selection of the low design temperature should be balanced by selection of the heating design margin. The indoor design temperatures of 2 to 4°C may be used for providing for freeze protection. In the heating system design, credit is generally not taken for heat generated from operating equipment.

The selection of outdoor design humidity levels affects the selection of cooling towers and evaporative cooling processes and the sizing of air-conditioning coils for outdoor air loads. When values from Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* are used for design, the mean coincident wet bulb is appropriate. If extreme dry-bulb temperatures are selected for the design basis, the use of extreme wet bulbs is too restrictive because the extremes are not coincident. It is prudent to use the wet bulb associated with the 1% dry bulb when extreme dry-bulb temperatures are used for design.

Indoor design humidity is not a factor in ventilated areas unless the plant is in a harsh, corrosive environment. In this case, lower humidity reduces the potential for corrosion. In air-conditioned areas for personnel or electronic equipment, ASHRAE *Standard* 62.1, Instrumentation, Systems, and Automation Society (ISA) *Standard* 71.04, and manufacturers' recommendations dictate the humidity criteria.

Equipment Selection

Equipment should be selected to successfully operate in the localized environment in which it is installed. This may require additional insulation (as opposed to that required for a typical commercial space) on equipment such as air handlers and piping located in hot areas (i.e., 43 to 49°C). Direct-expansion condensing units may need to be selected for ambient environments greater than 35°C if located on building roof decks or where higher than ambient temperatures can be expected.

In urban industrial areas, HVAC items such as copper coils and piping may need to be either coated with a polyurethane, polyester, or epoxy coating or special ordered using suitable materials to protect the equipment from corrosion caused by hydrogen sulfide, ammonia, and similar substances.

Equipment located inside powerhouses that may be subjected to the effect of flue gas, fly ash, coal dust, etc., should be specified to operate within that environment.

Ventilation Rates

Ventilation within plant structures provides heat removal and dilution of potentially hazardous gases. Ventilation rates for heat removal are calculated during HVAC system design to meet summer indoor design temperatures.

The numbers in Table 1 for air change rates are for estimating approximate ventilation needs. Actual heat emission rates should be obtained from equipment manufacturers (White and Piesciorovsky 2010; White et al. 2004). American Boiler Manufacturer's Association (ABMA) heat loss curves (Stultz and Kitto 2005) can be used to approximate heat loads from boiler casings if better information is not available.

The ventilation rate for room heat removal is

$$Q = \frac{q}{(t_r - t_o)(\rho c_p)} \tag{1}$$

where

Q = ventilation rate, m^3/s
q = room heat, kW
t_r = suggested room temperature from Table 1, °C
t_o = outdoor air temperature, °C
ρ = air density, kg/m^3
c_p = specific heat of air = 1.0 kJ/(kg·K)

Hazardous gases are mostly handled by the process system design functions. Natural gas and other combustible fuel gases are controlled by ignition safeties and may contain odorants for detection. Hydrogen and other gases used for generator and bus cooling are monitored for leakage by pressure loss or makeup rates. Escaped gases are diluted by outdoor air infiltration. For a building with very tight construction (i.e., very little natural infiltration), perform an analysis to verify that dilution rates are acceptable.

Flue gas is confined to the boiler and flue gas ductwork and generally poses no hazard. In some types of boilers and associated gas ducts, however, flue gas is at a higher pressure than the surroundings and can leak into occupied areas. Also, special-treatment gases such as ammonia or sulfur compounds encountered in flue gas conditioning systems can leak into the boiler building, depending on the location of the treatment device in the flue gas stream. In these cases, gas detection monitors should be used.

Some areas containing combustible liquids may require a minimum ventilation rate of 5 L/(s·m^2) as required by NFPA *Standard* 30, with compressed gas storage areas falling under NFPA *Standard* 55.

Chlorine Room Ventilation

Chlorine gas is often used in power generation facilities for treatment of raw water coolant, cooling tower/condenser water, potable water, and sanitary sewage treatment. Based on an **immediately dangerous to life or health (IDLH)** concentration of 10 mg/kg, chlorine is classified as corrosive and a highly toxic chemical, and the ventilation system designer should review the latest safety data sheets and recommended/required exposure/control limits before undertaking a ventilation design (NIOSH 1994).

The chlorine storage room is required to have a dedicated exhaust designed to operate anytime the room or facility is occupied and to operate in the event a leak is detected. The ventilation system should consist of supply and exhaust fans. The ventilation system should not be operated continuously unless required to maintain the storage room at a slight negative pressure with respect to an adjoining space. Any chlorine leak in the room should be contained and exhausted to the environment in a controlled manner. Exhaust intakes should be located within about 305 mm of the floor because chlorine is heavier than air. The supply air source should be located high and designed to provide a clean sweep of the room, ensuring good air distribution.

A minimum ventilation rate of 5 L/(s·m^2) or 30 air changes per hour (whichever is higher) for the chlorine room is recommended. The fan switches with indicating lights, along with the light switch, should be located just outside the chlorine room entry door, which should have a small transparent glass window. Because chlorine gas is corrosive, the exhaust fan should be designed with a totally enclosed corrosion-protected motor. Heating should be provided in the room to maintain temperatures at about 10 to 16°C to ensure freeze protection is provided to the valve train and associated gas piping. The heating source should not be any local combustion device (e.g., a gas fired unit heater); electric is preferable. The hot airflow should be directed away from chlorine storage containers. The maximum room temperature should be maintained at less than 52°C.

Chlorine detection should be provided where possible, with local and possibly remote alarming to enable activation of the ventilation system and discharge any leaked chlorine in a controlled manner.

Ventilation system and chlorine room designers should obtain additional information on ventilation system design requirements from NFPA *Standards* 55 and 400, Centers for Disease Control (NIOSH), OSHA, and information from chlorine manufacturers and suppliers.

Infiltration and Exfiltration

Infiltration of outdoor air into boiler and power-generation structures and exfiltration of room air from these buildings are driven by thermal buoyancy of heated air. Both infiltration and exfiltration are beneficial; infiltration air dilutes fugitive fumes, whereas exfiltration air carries out excess heat during hot weather. However, infiltration adds to the cold-weather load on the heating system.

Filtration and Space Cleanliness

Filtration of ventilation air for process areas is usually not needed because some process areas are dirtier than the outdoor surroundings, and the process equipment is designed to operate in a dusty environment. However, the plant may be located in an area with sources of outdoor particulate contaminants that need to be managed to protect the process equipment. Power plants in dusty or sandy areas, or where there are seasonal nuisances such as airborne plant matter, may require filtration of ventilation air. Plants at industrial sites such as refineries and paper mills may need to address gaseous contaminants and corrosive gases, as well.

Indoor air cleanliness is a concern in control room HVAC system design. Even if the control center is in an independent building, remote from the boiler-turbine building, other operations such as coal transportation, coal crushing, fuel/air distribution and combustion, ash handling, fume heat recovery, fume/smoke exhaust diffusion, and so forth may contaminate the entire plant and its surroundings.

When potential outdoor contaminants are a factor, the quality of outdoor air may need to be evaluated. This may include collection of typical particulates and the use of corrosion coupons to quantify gaseous contaminants. The U.S. Environmental Protection Agency (EPA) is a good data source. Filtration requirements may include 30% dust-spot test efficiency prefilters, 65 to 90% efficiency final filters, and gas-phase filtration units.

Air-conditioned areas for people should satisfy ASHRAE *Standard* 62.1 requirements. Air-conditioned areas for control and electrical equipment should meet the requirements of the equipment manufacturer(s). Guidelines for reliability of electrical equipment are found in ISA *Standard* 71.04.

Redundancy

Maintaining design operating temperatures in the power plant is essential for reliable operation. Operating electrical equipment above its rated temperature reduces equipment life. Sensitive electronic equipment, such as in the main control center, may not function reliably at high temperatures. Low temperatures also affect plant availability; for example, low temperatures in batteries or freezing of pipes, instrument lines, or tanks could prevent normal operation.

The HVAC systems or components essential for plant operation should be designed with redundancy to ensure plant availability. Automatic switchover to the back-up system may be required in normally unoccupied areas. Where back-up systems are impractical, consider using temperature monitoring and alarming systems to initiate temporary corrective measures.

HVAC systems that include multiple units (indicated as "multiplicity" in Table 1) also improve power plant reliability. A space ventilated by multiple fans, such as four at 1/4 capacity, may retain sufficient ventilation even if one fan is out of service.

Noise

Pay attention to noise levels produced by HVAC system equipment both inside and outside plant spaces, and establish indoor noise guidelines for air-conditioned areas and ventilated areas with continuous occupancies. Outdoor noise levels are established by the environmental noise pollution concerns of adjacent areas.

Air-conditioned indoor spaces should meet the normal sound level guidelines for occupancies (e.g., offices) listed in Chapter 49. Special occupancies such as control rooms should follow the guidelines in Table 1.

Ventilated areas of the plant should be treated as other industrial areas following OSHA regulations. Sound levels in Table 1 are suggested guidelines that may be appropriate in the absence of a specific engineered solution to meet the OSHA requirements. Where "background" is indicated in Table 1, noise generated by HVAC equipment is usually not a major noise source in comparison to the noise from processes or equipment such as turbine generators, motors, pumps, and relieving of process steam. In these areas, overall noise level criteria are established by the process equipment requirements.

HVAC system components contribute to the overall noise level outside the plant buildings either by generating noise or by having ventilation openings. HVAC designs for power plants in urban areas can be significantly influenced by outdoor noise level requirements. Equipment may have to include sound-absorbing materials or be located indoors in sound attenuation enclosures. Openings may require acoustical louvers.

Ductwork and Equipment Location

All outdoor HVAC equipment should be secured to foundations or structures to prevent being blown into transmission and other equipment in the event of high winds. In addition, ductwork and equipment in the room should be adequately supported and restrained to prevent collateral damage to the switching equipment by failed HVAC equipment/ductwork in the event of an earthquake or similar event, following local codes and plant design criteria. Preventing damage from dripping/overflowing condensate or other water sources should also be considered. Also, where possible, equipment and system components must meet CAN/CSA *Standard* C2.1 and NFPA *Standard* 70 guidance for minimum distance from energized transmission equipment to ensure adequate separation from energized equipment and power lines.

2. VENTILATION APPROACH

Summer ventilation can be achieved by natural draft, forced mechanical supply and exhaust, or natural and mechanical combined systems. **Natural-draft systems** use a combination of adjustable inlet louvers and open doors or windows and relieve warmed air through roof or high side-wall openings. **Mechanical systems** use fans, power roof ventilators (PRVs), or air-handling units to move air. A **combined system** typically uses lower and upper wall and roof openings for natural ventilation while using mechanical ventilation as a supplement. With any ventilation arrangement, maintain physical separation of inlet and outlet openings to minimize recirculation, as discussed in Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*.

3. APPLICATIONS

Large plants or units with layouts containing large ducts and equipment in the ventilation airflow path, possibly with limited separation between pieces of major equipment and/or exterior walls, imposing a pressure drop exceeding the capability of gravity ventilation systems, require mechanical assistance. The plant design may have cavities, such as the area under the boiler arch and between the casing and flue gas duct (see Figures 1 and 2), which require mechanical ventilation. Areas of the plant such as the conveyor gallery usually require mechanical assistance in the makeup air system to ensure pressurization control and proper functioning of dust collectors and associated equipment.

Natural or gravity systems are appropriate for facilities without basements and with relatively open airflow paths. The pressure drop of intake louvers, control dampers, powerhouse airflow path, and exhaust louvers/gravity vents should not exceed the minimum expected buoyancy forces. Be sure to configure the system so as not to interfere with mechanical dust collection equipment.

In any system configuration, the engineer should ensure all areas of the plant are provided airflow. Air intakes and supply ducts/fans should be located to prevent short-circuiting with relief openings. Ventilation air should be supplied to electrical boards and other equipment located in upper elevations of the plant, because these areas are usually significantly hotter than the lower elevations.

Driving Forces

Natural ventilation systems use the thermal buoyancy of the air as the motive force for air movement through a building. Equations for determining differential pressures for natural ventilation are found in Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals*. With natural ventilation, air enters the enclosed space and is heated by the plant equipment. The difference in density between the inside air and the outdoor air causes air to be drawn into the building at low elevations and relieved at high elevations.

Mechanical ventilation depends on fans (or fans and buoyancy forces) to provide required ventilation regardless of the building configuration or the temperature difference.

Air Distribution

With natural ventilation, small differential pressures drive air movement. Accordingly, air is drawn into the building at low velocities; it penetrates a short distance into the building and then disperses.

Mechanical ventilation supplied from the walls or roof can distribute air more effectively throughout the structure.

A combined system uses both natural and mechanical ventilation to achieve effective air distribution and prevent air stagnation. A typical combined system uses lower-level sidewall openings as the primary natural air intake and roof or upper-level sidewall openings for hot-air relief. The location and size of openings can prevent hot-air accumulation under the roof naturally. Provide mechanical ventilation where sufficient airflow cannot otherwise be established.

Inlet and Exhaust Areas

Because of the low differential pressure driving the air, natural ventilation requires numerous large inlet louver and exhaust relief areas. Mechanical ventilation requires fewer openings.

Noise

Openings required for natural ventilation allow noise generated by indoor plant equipment to pass more easily to the outdoors.

Mechanical equipment such as fans and PRVs generate noise directly, but the noise level can be managed by fan selection and acoustical treatment.

Plant Cleanliness

Natural ventilation creates negative pressure in the lower portions of the building, which may draw dust and fumes into the building through openings near ground level.

Mechanical ventilation can pressurize the building and can draw air from relatively clean sources at higher elevations.

Economics

The primary advantage to natural ventilation is that there are no operating costs for fan power. Because natural ventilation is passive, it is more reliable and has lower maintenance costs than a mechanical system. However, natural ventilation may not always be the most economical selection. The cost of louvers and inlet openings, architectural features, and gravity relief openings to achieve an acceptable ventilation rate may be higher than the first cost for mechanical ventilation.

Another consideration is the average building temperature. Because internal heat is the driving force, the naturally ventilated building is normally warmer than the power-ventilated building. This warmer average temperature may shorten the life of plant equipment such as expansion joints, seals, motors, electrical switchgear, and instrumentation. Warmer temperatures may also affect operator performance.

The large louver areas associated with natural ventilation may allow greater infiltration, thereby increasing the winter heating load. This additional heating cost may offset some of the summer energy savings of natural ventilation.

A combined system takes on the s5trengths of both natural and mechanical ventilation and can offer the advantages of reduced capital and operating costs.

4. STEAM GENERATOR BUILDINGS: INDUSTRIAL AND POWER FACILITIES

A steam generator uses heat energy to convert water to steam. The two basic subsystems of a steam generator are the heat energy system and the steam process system.

The heat energy system for a fueled (oil, gas, coal, etc.) steam generator includes fuel distribution piping or conveyors, preparation subsystems, and supply rate and ignition controls. Provision to supply and regulate combustion air is required at the combustion chamber; flue gas is handled downstream of the combustion area. With ash-producing fuels, bottom ash below the steam generator and fly ash entrained in the flue gas must be processed. Figure 1 shows a steam generator building with typical components.

Steam process components typically found in the steam generator building include an enclosure for the fire and heat transfer surfaces and feedwater equipment such as pumps, piping, and controls. Steam lines for primary and reheat steam are typically routed from the steam drum and reheat sections of the steam generator to the steam turbine or process systems.

The heat energy and steam process systems impose requirements on the HVAC systems for specific areas of the steam generator building.

Burner Areas

Fuel (gas, oil, coal, etc.) is transferred to the furnace, mixed with combustion air, and ignited in the burner area of the steam generator. Instrumentation must modulate the fuel in response to combustion needs. Viewports typically allow operators to monitor combustion. In many cases, these viewports are equipped with aspirating air systems to limit the amount of flue gas and heat escaping the boiler and entering the boiler room.

The burner area requires special attention for the steam generator building ventilation system. This area is often occupied by plant operators who monitor and inspect the controls and the

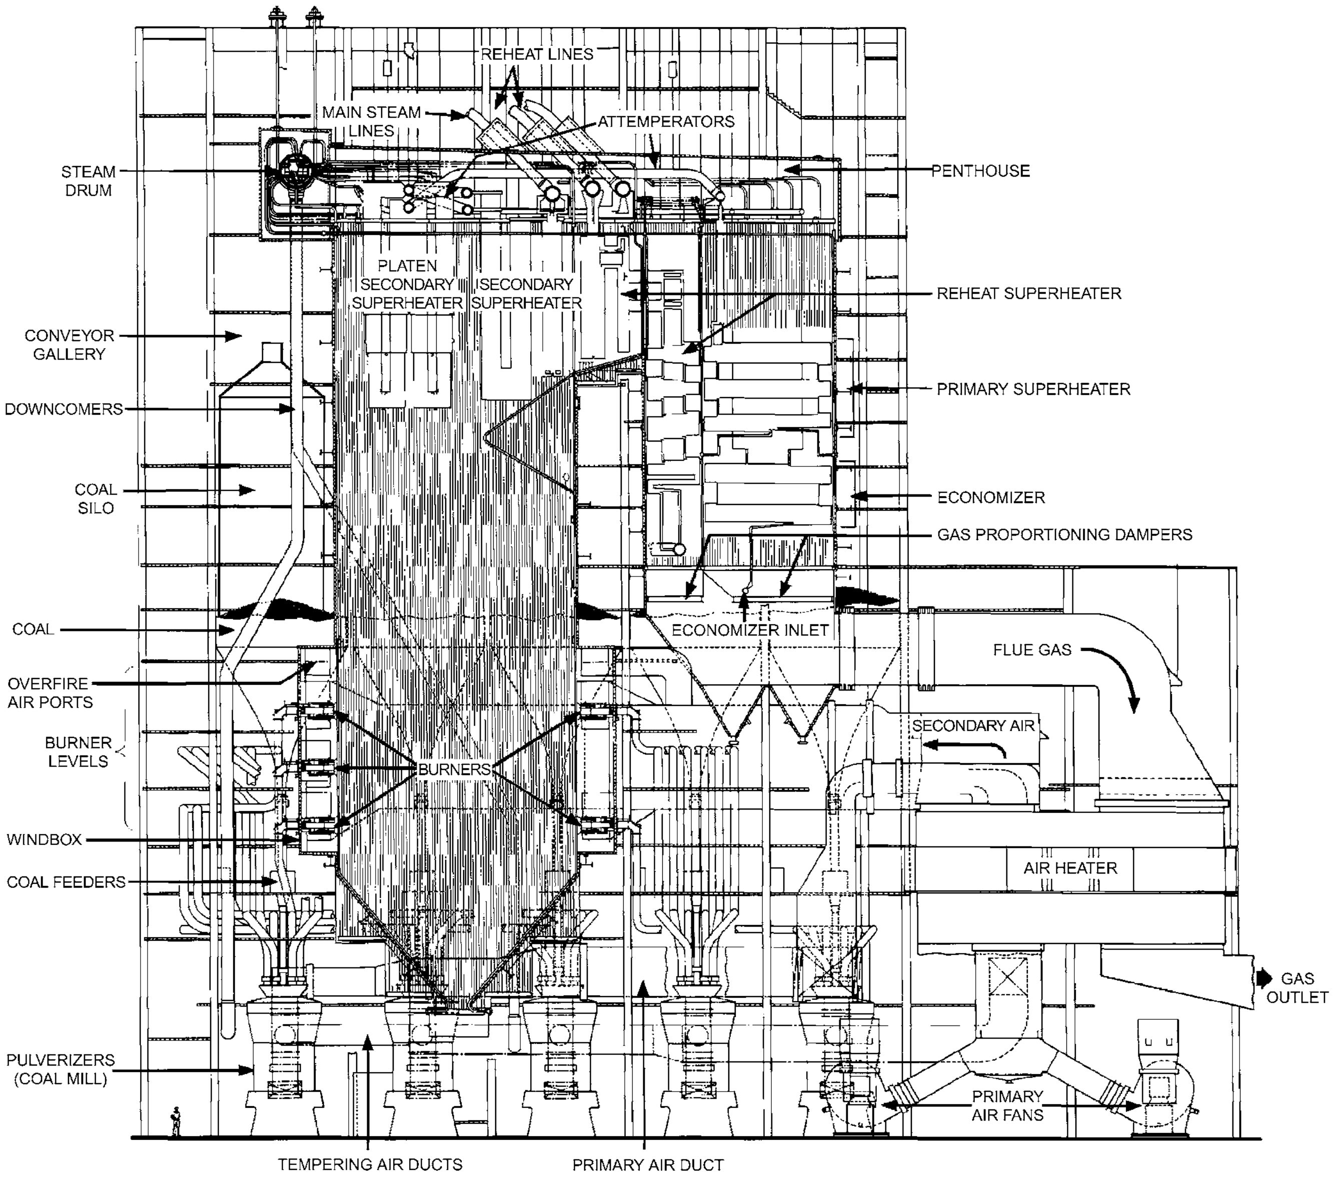

Fig. 1 Steam Generator Building
(Courtesy The Babcock & Wilcox Company)

combustion process. Heat is radiated and conducted to adjacent spaces from inspection ports, penetrations, and the steam generator. Fumes and combustion gases also can leak.

Both the burner area operator and the controls require ventilation with outdoor air. Outdoor air also provides dilution for fugitive fumes. Outdoor air can be ducted to burner areas and discharged by supply registers or blown directly into the area with wall-mounted fans, depending on the building arrangement. The flow rate is difficult to quantify; generally, 60 air changes per hour (ach) supplied to an area 4 to 6 m around the steam generator provide adequate ventilation. Consider providing spot or localized velocity cooling of personnel workstations. In cold climates, outdoor air may need to be tempered with indoor air or with heating coils.

Steam Drum Instrumentation Area

A typical steam generator has a steam drum at the top of the boiler that provides the water-to-steam interface. The water level in the drum is monitored to regulate the flow of steam and feedwater. This is a critical steam generator control function, so accurate and reliable process flow measurement is important.

The steam drum instrumentation area may include sections of uninsulated furnace surface, which conducts and radiates heat to the surrounding area. The ventilation system should remove this heat to ensure that area temperatures are within instrumentation temperature limits. Instrumentation may need to be shielded from hot surfaces. Velocity cooling may be needed at operator workstations.

Wall-mounted panel fans in the outer walls are an option for providing ventilation air during warm weather. Heating is generally not a concern unless the steam generator is expected to be out of service during cold weather.

Once-through steam generators do not have drums, but have instrumentation in similar high-temperature, dusty areas.

Local Control and Instrumentation Areas

In addition to the drum and burners, the steam generator building may house local control areas for functions such as fuel supply, draft fans, or ash handling. Because areas around a steam generator may be hot and dirty, the location and selection of the control equipment should be coordinated between the electrical system engineer and the HVAC system engineer.

The alternatives are to (1) locate the control equipment remotely from the steam generator, (2) use electrical components that can withstand the environment, or (3) provide a local environmentally controlled enclosure. The first alternative requires additional cable and raceway and perhaps additional signal boosters and conditioners. The second alternative requires more robust electrical equipment that can tolerate extremely hot or dirty areas.

When the electrical and control system design dictates that the equipment be located near the steam generator, a dedicated enclosure with a supporting environmental control system may be necessary. A typical environmental control system may control an air-handling unit capable of providing adequate filtration, pressurization, and temperature control. The temperature control may be obtained with a chilled-water or direct-expansion (DX) coil with a remote condensing unit. An air-cooled condensing unit may be used if it is rated to match the surroundings.

Coal- and Ash-Handling Areas

Coal is typically stored on site, either in piles or in storage structures, including semienclosed, fully enclosed, and underground storage facilities. Material-handling equipment moves the coal to conveyors for transportation to preconditioning equipment (e.g., a crusher). Processed coal is conveyed to steam generator building storage silos. Coal feed equipment regulates the supply of coal from the silos either to the burner or to final processing equipment such as pulverizing mills.

Many new power plants are designed to burn low-cost coals from Wyoming's Powder River Basin and other similar coal seams. Many of these coals are extremely friable when dry, creating significant amounts of dust during handling. In new plants, the material handling and ventilation systems should be designed to control dusting, preferably by using modern chutework and coal-handling machinery design to reduce or control dust emissions during fuel handling. This can reduce the effects of mechanical dust collectors and associated makeup air on plant HVAC systems.

Some coals spontaneously begin to burn during normal outdoor ambient weather and normal powerhouse interior conditions. Under some conditions, accumulated coal dust spontaneously smolders, then suddenly flashes if the surface crust of the pile is broken, exposing the smoldering coal to oxygen. It is important that equipment in areas subject to dust accumulation be designed to reduce dust accumulation with sloped or curved surfaces, and designed to facilitate manual cleaning and washdown. Spontaneous combustion must be addressed in ventilation and dust collector design and installation to facilitate emptying dust out of the collector without exposing plant personnel to fire and explosion hazards.

Coal-handling areas in the steam generator building that require special ventilation system consideration are the conveyor, silo, feeder, mill, and their transition areas, and ash-handling areas.

Conveyor Areas. Primary concerns are dust control, outgassing from the coal, freezing of the coal and personnel access areas, and fire protection. Dust can be a concern because of the potential for environmental emission and also as a personnel and/or explosive hazard. Dust may be controlled by water-based spray systems or by air induction pickups at the point of generation.

Control of fugitive dust at conveyor transfer points involves specific concerns. Outdoor transfer points fall under the facility's air permit requirements for fugitive dust emissions and thus could require controls. For indoor transfer points and conveyors, the fugitive dust quantity could drive the electrical hazardous location from NFPA *Standard* 70 (NEC) Class II, Division II to Class II, Division I, requiring different hazardous location rating for electrical components in the area. Since 2008, OSHA has been providing enhanced enforcement of existing industry combustible dust standards through the directive CPL-03-00-08. Additional information is available in NFPA *Standards* 652 and 654, which sometimes are more stringent than the classification criteria for hazardous locations provided in NFPA *Standard* 499.

Some types of coal may outgas small quantities of methane, which could accumulate in the conveyor and storage structures. See the section on Coal Crusher and Coal Transportation System Buildings for a discussion of ventilation of methane fumes.

Natural or forced ventilation must remove heat from conveyor motors, other equipment, and building envelope loads. Ventilation air can also remove outgassed fumes. Generally, ventilation requirements can be as low as 2 to 5 ach. If air entrainment dust collection equipment is used, include provisions for makeup in the design. If natural openings are not sufficient for makeup air, supply ventilation fans may need to be electrically interlocked to operate with the dust suppression/collection equipment. Makeup air may have to be heated if freeze protection is a design criterion. Unit heaters are generally used for spot heating. The unit heater should be specified to the hazard classification for the area it serves. Because coal dust can produce acids when wet, consider specifying noncorrosive materials and coatings.

NFPA *Standard* 120 and the U.S. Bureau of Mines (1978) provide other safety considerations for coal handling and preparation areas.

Silo and Feeder Areas. Coal is generally fully contained by feeders and silos, so no special ventilation is needed. Occasionally, coal systems include an inert gas purge system for fire prevention. Ventilation may be needed for life safety dilution ventilation of purge gases.

Coal Mill Areas. Coal mills require large power motors for the grinding process. These motors may have their own ventilation system, or the motor heat may be rejected directly to the surrounding space.

The challenge for the ventilation system is to provide enough ventilation to remove heat without creating high air velocities that disturb accumulated dust. Blowing dust can pose health risks to operators and create a dust ignition hazard. Although occurrence of dust ignition air-to-dust ratios is possible, this area is generally not classified as hazardous. The dust ignition risk is managed by housekeeping, maintenance of seals on the mill equipment, and other dust-control measures.

Forced supply ventilation is generally required for equipment cooling. Sidewall propeller fans work well if the mills are arranged near outer walls. Mills located in the interior of the building may require ducted supply air. Supply air velocities at the coal-handling equipment must be lower than the particulate entrainment velocity for the expected dust size. The maximum air velocity is established using the particle size distribution spectrum and the associated air settling velocities indicated in Figure 3 and Table 1 of Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals*.

Many utilities use carbon monoxide (CO) monitoring/trending to detect fires in coal bunkers, silos, and other areas. These systems are sometimes integrated with dust collector and other exhaust streams in these areas. Specification and design of the CO monitoring should be the responsibility of a special hazards fire protection engineer and coordinated with the industrial ventilation and HVAC design.

The National Fire Protection Association (NFPA) does not differentiate between coal types/seams in the codes and standards. The utility industry, however, has accumulated experience and established best practices in handling these fuels. This information is shared between member utilities through groups such as Edison Electric Institute and Electric Power Research Institute. Other

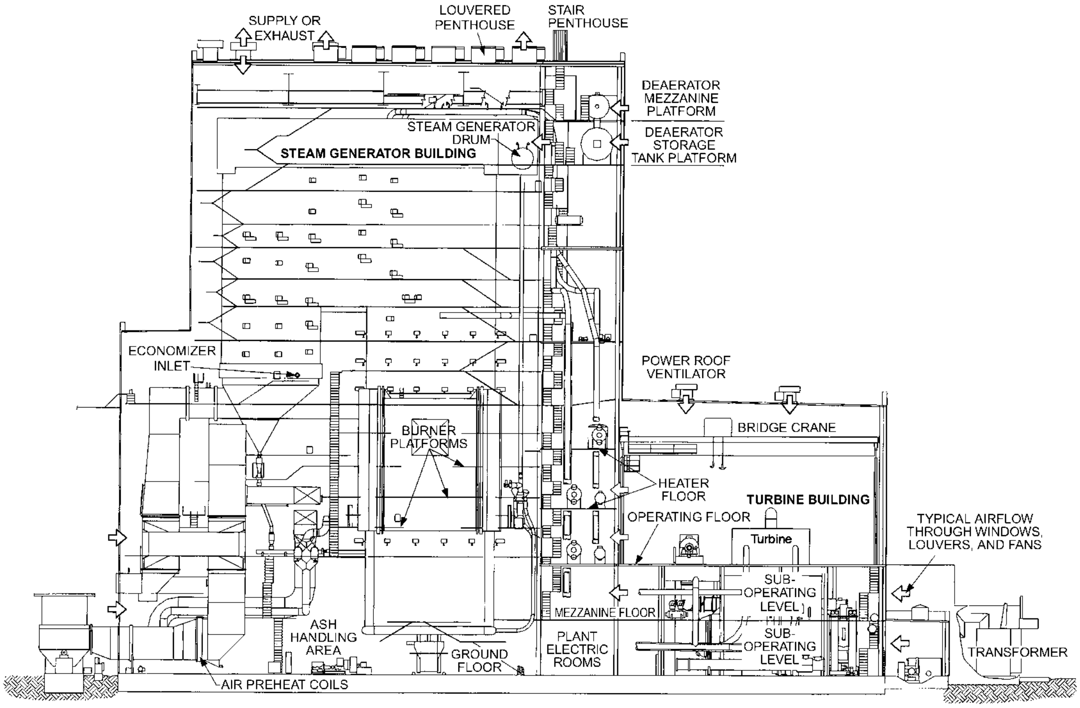

Fig. 2 Generation Building Arrangement
(Courtesy Black & Veatch Corporation)

sources of specific requirements include local fire code authorities and the plant's insurance carrier.

Ash-Handling Areas. Ash is generated when coal or heavy fuel oil is burned. Fine ash particles carried by the flue gas from the top of the steam generator are called **fly ash**. Ash that accumulates as slag in the bottom of the steam generator is called **bottom ash**.

Ash-handling equipment generally demands no special HVAC system consideration. Although fly ash is captured in the flue gas stream by a baghouse or electrostatic precipitator, uncaptured (fugitive) fly ash can create problems in equipment mechanisms because of its abrasiveness. If fugitive fly ash is expected to be in the air, HVAC equipment in the ash-handling areas should include filters to capture the ash before it enters building areas.

Stack Effect

One consideration in HVAC system design for a steam generator building is the stack effect caused by buoyancy of heated air. A 90 m tall steam generator building with –18°C outdoor air temperature and 38°C indoor air temperature may have 125 Pa (gage) negative internal pressure at ground level. This high level of negative pressure causes abnormally large forces on doors, creating a hazard for operators.

Sources of Combustion Air

Large-draft fans supply combustion air for the steam generator. A positive-pressure steam generator is supplied by forced-draft fans, and a negative-pressure steam generator uses induced-draft fans. A balanced-draft steam generator, typical for a larger unit, uses both forced- and induced-draft fans. Because the air is heated to furnace temperatures in the combustion process, part of the fuel energy is used to heat the air. Forced-draft fans on a large steam generator can supply 50 m^3/s or more to the combustion process. A significant amount of energy is needed to preheat the combustion air.

Two prevailing methods of preheating combustion air are used. One method is to draw air in from outdoors and heat it using steam or hot-water coils using energy directly from the power cycle. Another method uses heat rejected from steam generator surfaces to the building space to heat combustion air. This approach provides energy savings over heating outdoor air. Temperatures in higher levels of the generator building can be 38°C or higher. Heat recovery is accomplished by locating the draft fan intake high in the building. Although the potential for savings is large in a cold climate, the total effect on building heating and ventilation systems should be evaluated. One effect is that drawing the air from the building makes the building pressure more negative; this increases infiltration and adds to the building heating system load, possibly offsetting the potential power cycle thermal efficiency advantage. Increased negative pressure can also contribute to stack effect problems associated with negative pressure low in the building. The draft fan can also be used to supplement ventilation during warm outdoor conditions.

5. TURBINE GENERATOR BUILDING

As shown in Figure 2, a turbine generator building usually includes a high-bay operating level, a deaerator mezzanine, and one or more suboperating levels. Typically, the turbines and electric generators are located along the centerline of the building between the operating level and the first suboperating level and are the major heat sources in the building. Deaerators are another significant heat contributor; the deaerator mezzanine is commonly open to the turbine operating level. Other room heat sources are steam, steam condensate and hot-water piping, heat exchangers, steam valve stations and traps, motors, electric transformers, and other electrical equipment.

Local Control and Instrumentation Areas

Some power plants include a local turbine-generator control panel on the operating floor. The local control panel area of the turbine generator may be either enclosed or open; for the enclosed arrangement, the environmental requirements are the same as those given in the Main Control Center section.

For an open arrangement, velocity cooling with conditioned air improves the operator's working environment. Because the area may be directly exposed to high-temperature surroundings, the recommended velocity of the conditioned air discharge is 1.5 to 3 m/s, depending on its service distance and workers' preference. The air distribution system should have manually adjustable air deflectors for operator comfort. In addition, the control panel may need a separate cooling source.

Deaerator Mezzanine

The deaerator and associated storage tank reject significant heat at the deaerator mezzanine level. This plant area also typically includes instrumentation and control equipment enclosures; accordingly, the area should have local ventilation to provide the necessary cooling.

Bridge Crane Operating Rooms

Outdoor air entering the building is heated by process heat, rises toward higher elevation, and is relieved through openings. The bridge crane operating room is as high as the roof beam and within the building exhaust airstream. If the outdoor air temperature is 35°C, the crane operating room may be surrounded by 40°C or hotter air. Hence, the bridge crane operating room is normally air conditioned.

Because the bridge crane operating room moves within the building during its operation, through-the-wall mounted air conditioners are commonly used; to simplify the electrical work, an additional power plug in the crane for the air conditioner should be provided by the crane supplier. Include provisions for the cooling-coil condensate drain in the design.

Suboperating Level

The turbine generator is located on the operating floor, a large deck surface open to the turbine building roof. The deck may be 70% or more of the turbine building area. Below the operating level are one or more suboperating levels. Ventilation supply air should be provided to the suboperating levels and at the lower elevations of the operating floor. Air rising through the operating levels brings room heat to the roof area, where it is relieved through high-elevation openings (gravity vents) or exhausted by roof-mounted exhaust fans or PRVs.

The major heat sources in the suboperating levels are high-temperature mechanical and piping systems. Other contributors are electric transformer room exhaust, switchgear room exhaust, electric reactor room exhaust, electric motor heat, etc. Electrical equipment exhaust heat in the turbine generator building is small compared to heat emitted from mechanical and piping systems. Accordingly, ventilation air from the plant distribution electric room can generally be exhausted directly into the turbine building without ducting to the outdoors. Conditioned air may be supplied to local instrumentation panel areas.

For plants in cold climates (temperatures below 0°C), consider spot heating and/or exterior door heated-air curtains. Also consider providing freeze protection for piping close to building walls; stack effect and wind-driven infiltration can increase local heating requirements at the building perimeter. This problem can be addressed by adding capacity to installed heating systems or by providing mobile, temporary heating.

Electric Transformer Rooms

Transformer rooms are typically located at a suboperating level between the turbine building and steam generator buildings. To isolate dust, the transformer rooms should not have inlet openings to the steam generator building.

The transformer room exhaust air temperature should not exceed the design limit of the transformers. Typically, air intake is from a turbine building suboperating level or from outdoors, and exhaust air discharges at the higher level of the transformer room toward the turbine building.

Plant Electrical Distribution Equipment and Switchgear/MCC Rooms

Air for the main station switchgear and motor control center (MCC) rooms should be relatively clean. Supply air from outdoors should be filtered with MERV 6 (30% efficiency) air filters. Air can be relieved through louvers into the plant or to the outdoors.

A similar approach is used for the ventilation system for an electric reactor room. If the reactors have ducted connections for the exhausts, a removable section may be required so that the ducts can be disassembled when the reactor is lifted during maintenance.

Isophase Bus Duct Cooling

Power from the generator is conveyed by isophase bus ducts to the main transformer. This generates heat, which must be dissipated to a heat sink unless the bus duct is rated for natural cooling. A specialized forced-air system cools the isophase bus duct and consists of cooling coils, fans, dampers, and filters. For a low-velocity system, air is supplied to the cooler along two phases of the bus duct and returned in the third phase. For a higher-velocity system, air is supplied and returned midway between the transformer and generator, or is supplied at the generator end along bus ducts of all three phases and returned at the transformer end. Isophase bus cooling is essential for power production and delivery, so it is important to specify sufficient redundancy (in the form of dual fans, dual cooling coils and a bypass duct to provide cooling with outdoor air, or another source) in the system design.

6. COMBUSTION TURBINE AREAS

Combustion turbines are adaptable for outdoor or indoor installation. The outdoor type is usually a skid-mounted structure, with support systems typically designed and furnished by the combustion turbine vendor. The indoor type is typically enclosed in a weatherproof and acoustically treated enclosure and may have indoor support systems, designed and installed separately.

Combustion turbine installations have some or all of the following support facilities: fuel oil handling facility, natural gas pressure-reducing facility, office or administration areas, maintenance shops, battery rooms, control rooms, distributed control system (DCS) control room, communication or computer room, and a water treatment facility. Heating and ventilation design issues associated with combustion turbines include airflow, combustion air source, hot duct and equipment surfaces, fuel supply, turbine inlet cooling, noise, etc.

The turbine manufacturer typically establishes HVAC requirements and, if required by the purchaser, provides HVAC equipment for the various compartments on the turbine skid. Turbine ventilation and equipment requirements should be coordinated with the building ventilation design.

Turbine and generator casings and the surface of the exhaust duct are large contributors to the heat removal requirements. Insulate hot surfaces with appropriate materials as much as is practical and with approval of the turbine manufacturer, with appropriate airflow established to eliminate hot spots.

When heat recovery equipment is installed in the turbine exhaust, allow for the additional heat rejected into the building because of increased back pressure on the hot exhaust.

Airflow through the combustion turbine building should consider combustion air requirements, combustible gas dilution requirements based on design leakage rates, heat removal requirements, exhaust gas dilution, and electrical component cooling requirements. Combustion turbines draw combustion air through ducts from outside the building. The system design should ensure control of the building pressurization to keep the building under positive pressure, and building outdoor air should be filtered. This also offsets infiltration of dust, rain, snow, insects, and other contaminants into the building. System design should address freeze protection for vulnerable components. For cold-climate applications during normal operation, mixing outdoor and building air to keep the outdoor supply air temperature above freezing is recommended. In electrically classified installations, the ventilation system must switch to 100% outdoor air during upset conditions.

Noise from combustion turbines is managed by a combination of site location considerations, acoustic enclosures; sound attenuation devices and engineered sound controls include those that are part of HVAC systems.

HVAC design requirements for various areas of the building or turbine skid are in Table 1. The design should use NFPA standards such as 37, 70, and 90A; insurance carrier requirements; and applicable local codes and standards. Coordinate HVAC system design and operation with fire protection systems to ensure adequate concentration of fire suppressant and to prevent fire and smoke spread. HVAC systems also must shut down when fire or extremely high concentrations of gases are detected.

7. MAIN CONTROL CENTER

The main control center usually includes a control room, electronic and electric control panel and instrumentation rack room, computational equipment server room, automation process control system room, telecommunications equipment room, battery room, UPS room, engineer and operator training simulation room, and associated administration areas.

Because the control center usually contains temperature-sensitive electronic equipment critical to plant operation, it is generally provided with redundant air-handling units and refrigeration equipment. A back-up power supply may also be required. Passive components such as distribution ductwork and piping do not have to be duplicated. Design controls so that failure of a component common to both the primary and back-up systems does not cause failure of both systems; manual changeover is a simple solution. If the main control building is located in a fly-ash-contaminated area, room pressurization is highly recommended.

Control Rooms

The control room houses the microprocessor, printer, electronic and emergency response controls, fire protection controls, communication and security systems, regional system networks, accessories, and relevant wiring and tubing systems. An air-conditioning system typical for office occupancy, with features to meet overall design requirements for reliability and the specific environmental needs of the control equipment, is generally appropriate.

Battery Rooms

Battery rooms should be maintained between approximately 21 and 27°C for optimum battery capacity and service life. Temperature variations are acceptable as long as they are accounted for in battery sizing calculations, but the minimum room design temperature should be considered in determining battery capacity. Batteries typically used in power generation facilities produce hydrogen gas, so the HVAC system must be designed to limit the hydrogen concentration in the room. See IEEE *Standard* 1635/ASHRAE *Guideline* 21-2012 for methods of estimating hydrogen generation by various battery types and operating modes and optimizing the design of the ventilation system. That guideline recommends a maximum average concentration in the room of <2% by volume; however, the designer may consider a lower value based on project requirements.

Chemical Analysis Facilities

Many generation facilities have water chemistry laboratories equipped with various analytical devices for monitoring and controlling boiler feed water and cooling tower water chemistry. If the laboratories contain fume hoods, the hood exhaust and room makeup air supply should be designed in accordance with ACGIH (2016), NFPA *Standard* 45, and applicable chapters of the ASHRAE Handbooks.

8. SUBSTATION AND SWITCHYARD CONTROL STRUCTURES

Substations and switchyards increase electricity voltage from the power plant generator output voltage to transmission-level voltage, and regulate power for distribution levels. These facilities are generally located remotely, so their HVAC design should be simple, reliable, and easy to maintain.

Design Considerations

The design of the HVAC, filtration, and pressurization system should be based on the type of equipment in the room and its sensitivity to dust, smoke, temperatures, and humidity. Considerations include reliability, simplicity, and low installation and maintenance costs. ANSI/IEEE *Standard* C2 addresses HVAC requirements. If the substation control building is occupied, typical human comfort conditions for office areas (see Table 1) are adequate; otherwise, temperature limitations and humidity control protect equipment in the room. Filtration with MERV 7 or 8 efficiency filters protects equipment from dust and prolongs its life. If the substation control building is located in a heavy industrial area or near a chemical or a wastewater plant, provide gas-phase filtration to remove airborne contaminants and protect the electrical equipment from corrosion. When designing outdoor air economizers for cooling the area, use MERV 12 efficiency filters. In addition, if electrical panels or enclosures are susceptible to dust, it may be necessary to pressurize the room to control infiltration and prevent entry of dust in the building. For critical applications or remote locations, design fans and other HVAC equipment with 100% redundancy, and ensure the standby unit autostarts after a failure of the primary unit. Substations have batteries and chargers that provide back-up power for operation during blackouts or other power disruptions. Batteries and chargers should preferably be in a separate room, in accordance with Table 1 and the section on Battery Rooms.

Typical cooling systems in substations and switchyards control structures include packaged, split-type, or wall-mounted DX air-conditioning units. The design should be simple, so that equipment repair or replacement can be performed as quickly as possible and the system returned to service.

HVAC systems in dispatch and load control centers should be designed like those for process computer rooms and data centers, with similar temperature, relative humidity, cleanliness, reliability, and redundancy considerations. These facilities are continuously occupied, and the HVAC system should be designed as for a control room.

9. TURBINE LUBRICATING OIL STORAGE

A typical power plant has a turbine lubricating oil storage tank and associated filtration equipment. If this storage area is inside the building, the tank should be vented to the outdoors or ventilation rates should provide for dilution of oil fumes. The ventilation systems should be coordinated with fire protection systems to ensure adequate fire suppressant concentration and to prevent spread of fire.

10. OIL STORAGE AND PUMP BUILDINGS

At a power plant, fuel oil may be the main source of energy for the steam generator, combustion turbine, or diesel generator. It may also be a back-up or supplemental fuel. Coal-fueled plants usually use oil or gas as the initial light-off fuel or for operation of an auxiliary steam generator. Auxiliary steam generators provide initial plant warm-up and building heating.

Oil for combustion is generally light oil such as No. 2 fuel oil, or heavy oil such as No. 6. Light oils can be pumped at normal temperatures, but heavy oils are highly viscous and may need to be heated for pumping. Oils are usually received by rail or truck, transported by pipeline, and stored in tanks.

Enclosures for pumps, valves, heat exchangers, and associated equipment should be heated and ventilated to remove excess heat and to dilute hydrocarbon fumes. Tank ventilation is an integral part of the tank and piping system design, which is separate from the enclosure ventilation design. Fuel oils are classified in NFPA *Standard* 30 as either combustible or flammable, depending on their vapor pressure at the indoor design temperature. Flammable liquids are hazardous; combustible liquids are not.

HVAC systems for areas containing combustible fuels must follow ventilation principles for heat removal and for good air mixing. Ventilation rates should dilute fumes expected from evaporation of spilled or leaking fuel, following ACGIH (2016) guidelines and safety data sheets (SDSs) provided by the material manufacturer. For fuel handling confined to piping systems, the expected leakage is nearly zero, so very low fresh air rates are required for ventilation (generally less than 1 ach). If fuel is handled in open containers or hoses, higher rates are prudent.

If the fuel is flammable at temperatures expected in the room, follow NFPA *Standard* 30 and other safety and building codes. Electrical systems may need to be classified for operation in a hazardous location.

11. COAL CRUSHER AND COAL TRANSPORTATION SYSTEM BUILDINGS

Coal-handling facilities at a power plant receive and prepare coal and then transport it to the burners. Intermediate steps in the process may include long- or short-term storage, cleaning, and crushing. Receipt may include barge, rail car, or truck unloading. Storage may be in piles on the ground, underground, or in barns or silos. At the site, the coal is handled by mobile equipment or conveyor systems.

The following general HVAC considerations apply for the types of structures involved.

Potential for Dust Ignition Explosion

Most types of coal readily break down into dust particles when handled or conveyed. The dust can become fine enough and occur in the right particle size distribution and concentration to create a dust explosion. The design engineer should review and apply the referenced NFPA standards and guidelines to determine the dust ignition potential for each ventilation system application.

Ventilation of Conveyor and Crusher Motors in Coal Dust Environment

Heat from motors and process equipment should be removed through ventilation, either by using ducted, ventilated motors or by ventilating the building enclosures. Ventilation in enclosures containing coal should keep the velocity below the entrainment velocities of the expected particle sizes. Table 1 in Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals* has information on settling velocity. Generally, air should be mechanically exhausted to allow ventilation air to enter the building through louvers at low velocities.

Cooling or Ventilation of Electrical and Control Equipment

Electrical and control equipment may be located near coal piles or other coal-handling facilities. Air-conditioned control rooms should be pressurized with filtered outdoor air. Ventilated motor control or switchgear areas should also be pressurized with filtered air. Because of high dust concentrations in coal yards, ordinary filter media have a short life; a solution is to use inertial filters. For air-conditioned areas, inertial filters can be followed by higher-efficiency media filters.

For electrical equipment rooms adjacent to an area with the potential for a dust ignition explosion, follow NFPA *Standard* 496, which recommends the flow of clean air away from electrical equipment into the dusty area.

Ventilation of Methane Fumes

Methane and other hydrocarbons are present in coal both as free gas in cracks and voids and as adsorbents within the coal. Although most of the methane is released from the interstitial coal structure during mining and handling, some methane or other potentially flammable gases may remain in the coal. Thus, flammable concentrations of methane can accumulate when large amounts of coal are stored. The design engineer should identify the potential for methane accumulation when designing for structures associated with silos or coal storage buildings. At the mine or mine mouth, methane gas emission rates as high as 150 L/Mg·day are possible; at other locations, the rate is usually less than 30 L/Mg·day. Dust collection air exhaust or natural ventilation is often sufficient to prevent the methane level from reaching the 1% explosion limit. The design engineer should apply guidelines from NFPA *Standards* 85, 120, and 850.

Underground Tunnels and Conveyors

Enclosed conveyors are generally of loose construction and require no ventilation. Smoke or gases in underground conveyor tunnels, hoppers, or conveyor transfer points could cause a personnel safety hazard. Ventilation systems should be coordinated with escape route passages to move fresh air from the direction of the egress. Ventilation rates in the range of 2 to 5 ach are generally appropriate for normal system operation.

Dust Collectors

Dust collectors are used primarily in coal- and limestone-handling operations to reduce the spread of fugitive dust. Collector effects on plant air supply, disposal of collected dust, and associated fire safety and air quality permit issues must be considered. Consult Chapter 15 in this volume, Chapters 29 and 30 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, and applicable ACGIH publications for detailed design and specification guidance. Provide adequate make-up air to ensure proper dust collector operation.

Successful coal dust control depends on proper conveyor transfer chute design (including transfer hoods, settling boxes, and skirt board seals) and on proper selection of air intake velocities and airflow quantities at transfer points or chutes. Most conveyor manufacturers either have proprietary transfer chute designs meeting these objectives or follow guidance from ACGIH (2016) and other authoritative sources.

Airflow associated with these pickup points may be sufficient to meet the ventilation requirements. Air inlets must be provided. If additional ventilation is needed, the ventilation fan must coordinate with the dust collection system. For heated structures, makeup air may need to be heated.

Dust collectors should be located in an area where the exhaust can be easily vented to a safe outdoor location because this exhaust stream may contain combustible gas. Dust collectors and associated ductwork may be required to either contain the detonation pressure of an explosion or relieve the pressure through relief panels or blast doors to the outdoors. Fire or explosion suppression systems may be required by the AHJ. Dust collection systems in this application are typically required to conform to NFPA *Standards* 67, 68, and 120 in addition to other referenced NFPA and other applicable standards.

12. HEATING/COOLING SYSTEMS

Selection of the heating and cooling systems in a power plant depends on several variables, including the geographical location and orientation of the plant and the type of fuel used. Most plants are ventilated with outdoor air, but it is customary in hot climates to air-condition many plant areas. Evaluate heating alternatives (e.g., steam, hot water, gas, electricity) to identify the most economical choice. Electricity is the primary energy source for general-purpose cooling of various areas of the plant. Areas such as the main control room, office areas, and electrical switchgear/MCC rooms are air-conditioned for continuous human occupancy or for maintaining the operability of the electrical equipment and controls. Spot cooling may also be needed at local control panel areas in the power generation (turbine-electrical generator building) and steam generator (boiler) buildings.

Cooling

The cooling source may be either a centrally located system providing chilled water to various area coolers or individual DX area coolers with either air- or water-cooled condensing units. Selection depends on the layout of the areas to be cooled and the comparative costs of the two options. The condensing system of the water chiller may be cooled with either air or available water from the plant service water system. Air-cooled chillers are used when air near the proposed chiller location is moderately clean and no fly ash or coal dust problem is anticipated. For a water-cooled system, a closed-loop cooling tower is sometimes used if service water is poor or unavailable (e.g., during start-up or plant outages). To protect chillers from fouling and corrosion by the service water, a heat exchanger is sometimes used between the chiller condenser and the service water source. In a power plant with several operating units and individual self-supporting chilled-water systems, the chilled-water systems of each unit are sometimes interconnected to provide back-up and redundancy.

Heating

Heating in various areas of the power plant is usually provided by electric, steam, or hot-water unit heaters or heating coils in air-handling units. In a hot-water distribution system, glycol is usually added into the system for protection against freezing. Because the building's stack effect induces large quantities of infiltration air, heating requirements in the lower levels of the steam generator building may increase when the steam generator is operating. Pressurization fans directing cooler, outdoor air into the warmer upper elevations of the plant can offset this infiltration. Also, the design engineer may evaluate redistribution of hotter air from higher to lower elevations.

An alternative to heating the open areas of the plant is to use pipeline heat tracing and spot heating at personnel workstations. For this approach, the design engineer should consider all components that may require heat tracing, such as instrument lines, small and large pipes, traps, pumps, tanks, and other surfaces that may be subject to freezing temperatures. Often the large number of components and surfaces to be heat traced and insulated makes this impractical.

Hydroelectric Power Plants

Hydroelectric power plants consist of a dam structure, draft tubes with gates, and turbine generators. The facility may be arranged with the generation components within the dam structure or within structures attached to the dam. HVAC systems should be provided for reliable operation of the mechanical, electrical, and control equipment and office areas.

The system design should consider the geographical location, humidity, degree of automation needed, and potential for flooding. Dams are typically built in remote locations, so the design and arrangement of the equipment, air intakes, and exhaust ports should consider the potential for vandalism. Accordingly, intakes should include security grating or bars, should not provide a line of sight into the structure, and should be constructed of heavy-gage steel to thwart bullets. HVAC equipment should be indoors if practical, or made otherwise inaccessible.

Humidity is a major design consideration. The lake surface and outfall structure create humid outdoor conditions. Outdoor air used for ventilation may introduce humidity into indoor spaces that may cause corrosion of electrical and control equipment. In addition, dam structure and turbine components below the lake water level are usually at temperatures colder than the dew point of the outdoor air. Introducing unconditioned outdoor air can create a significant amount of condensation on structure and equipment surfaces.

Another consideration of the remote location of hydroelectric plants is that the HVAC systems need to be reliable and able to operate with minimum attention by operating and maintenance personnel. Thus, these systems may require seasonal changeover features and fully automatic functions. System controls should be integrated with the generation plant controls, such as communication of status and alarm of critical functions to an off-site monitoring facility.

HVAC design should consider the maximum and minimum lake water level. Intakes and exhausts should be above the maximum design flooding level. Suction points for cooling water sources should be below the minimum water level.

Because of the potential for introducing outdoor humidity, cooling of mechanical equipment areas (e.g., turbine generator hall, turbine and wicker gate) should use a minimum amount of ventilation air. When practical, dehumidify air mechanically or with coils using cold lake water. Areas with heat-producing equipment such as for stop-log storage generally do not need ventilation air, which may introduce unwanted humidity. To minimize the effect of outdoor air humidity on electrical and control equipment areas, consider using water-cooled equipment and radiant cooling to cool structural surfaces. Design battery rooms and oil storage areas for the specific hazards to minimize excessive ventilation rates.

13. ENERGY RECOVERY

Energy recovery should be considered in any new system design or system upgrade. Considerations in the power plant should include the following:

- **Interfaces with existing plant process systems.** Using waste steam or steam bled from a process stream must consider process system behavior during generating unit start-up, part load, full load, shutdown, and cold standby/shutdown conditions. Any water returned to the boiler steam cycle must consider effects on the generating unit boiler water chemistry/water treatment.
- **Operating environment,** including cross contamination of clean airstreams from dirty airstreams, dusty environments, and corrosive conditions from substances such as flue gas. For details, see Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

- **Safety,** including issues resulting from the presence of coal dust, flammable gases, etc. Consult fire codes and insurance underwriters for guidance.
- **Control strategies.**
- **Constructability.**
- **Codes, standards, and local rules and regulations.**

Energy recovery systems should be evaluated by economic analysis of life-cycle costs, including

- Initial cost, including equipment and installation cost
- Fuel and station service power cost
- Operating cost savings
- Maintenance cost

Utility economic evaluations should follow the accounting guidelines and requirements as established by the Federal Energy Regulatory Commission (FERC). See Chapter 38 for further information on owning and operating costs.

14. SAFETY CONSIDERATIONS

Power plant HVAC systems should be engineered and designed to operate safely and reliably. HVAC systems often interface with other plant systems; specific requirements for these interfaces and for plant safety are defined by applicable codes and standards, regulatory authorities, owners' requirements, and insurance carriers. These requirements vary regionally, and appropriate authorities must be consulted during the design and modification of HVAC systems.

Mixed-Oxide Fuel Fabrication Facilities 29.12

The HVAC requirements for facilities using radioactive materials are discussed in this chapter. Such facilities include nuclear power plants, fuel fabrication and processing plants, plutonium processing plants, hospitals, corporate and academic research facilities, and other facilities housing nuclear operations or materials. The information presented here should serve as a guide; however, careful and individual analysis of each facility is required for proper application.

1. GENERAL DESIGN ISSUES

Criticality, radiation fields, and regulation are three issues that are more important in the design of nuclear-related HVAC systems than in that of other special HVAC systems.

Criticality. Criticality considerations are unique to nuclear facilities. Criticality is the condition reached when the chain reaction of fissionable material, which produces extreme radiation and heat, becomes self-sustaining. Unexpected or uncontrolled conditions of criticality must be prevented at all cost. In the United States, only a limited number of facilities, including fuel-processing facilities, weapons facilities, naval shipboard reactors, and some national laboratories, handle special nuclear material subject to criticality concerns.

Radiation Fields. All facilities using nuclear materials contain radiation fields. They pose problems of material degradation and personnel exposure. Although material degradation is usually addressed by regulation, it must be considered in all designs. The personnel exposure hazard is more difficult to measure than the amount of material degradation because a radiation field cannot be detected without special instruments. It is the responsibility of the designer and of the end user to monitor radiation fields and limit personnel exposure.

Regulation. In the United States, the Department of Energy (DOE) regulates weapons-related facilities and national laboratories, and the Nuclear Regulatory Commission (NRC) regulates commercial nuclear plants. Other local, state, and federal regulations may also be applicable. For example, meeting an NRC requirement does not relieve the designer or operator of the responsibility of meeting Occupational Safety and Health Administration (OSHA) requirements. The design of an HVAC system to be used near radioactive materials must follow all guidelines set by these agencies and by the local, state, and federal governments.

For facilities outside the United States, a combination of national, local, and possibly some U.S. regulations apply. In Canada, the Canadian National Safety Commission (CNSC), formerly the Atomic Energy Control Board (AECB), is responsible for nuclear regulation, whereas in the United Kingdom, the Nuclear Installations Inspectorate (NII) and the Environment Agency (EA), are involved in issuing operation licenses.

1.1 AS LOW AS REASONABLY ACHIEVABLE (ALARA)

ALARA means that all aspects of a nuclear facility are designed to limit worker exposure and discharges to the environment to the minimum amount of radiation that is reasonably achievable. This refers not to simply meeting legal requirements, but rather to attaining the lowest cost-effective levels within those requirements.

1.2 DESIGN

HVAC requirements for a facility using or associated with radioactive materials depend on the type of facility and the specific service required. The following are design considerations:

- Physical layout of the HVAC system that minimizes the accumulation of material within piping and ductwork
- Control of the system so that portions can be safely shut down for maintenance and testing or in the case of any event, accident, or natural catastrophe that causes radioactivity to be released
- Modular design for facilities that change operations regularly
- Preservation of confinement integrity to limit the spread of radioactive contamination in the physical plant and surrounding areas

The design basis in existing nuclear facilities requires that safety-class systems and their components have active control for safe shutdown of the reactor, for mitigating a design basis accident (DBA) and for controlling radiation release to the environment as the result of an accident.

Advanced nuclear steam supply systems (NSSS) are being designed that incorporate more passive control to minimize dependence on mechanical equipment to mitigate the consequences of a DBA.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

1.3 NORMAL OR POWER DESIGN BASIS

The normal or power design basis for nuclear power plants covers normal plant operation, including normal operation mode and normal shutdown mode. This design basis imposes no requirements more stringent than those specified for standard indoor conditions.

1.4 SAFETY DESIGN BASIS

The safety design basis establishes special requirements necessary for a safe work environment and public protection from exposure to radiation. Any system designated essential or safety related must mitigate the effect of a design basis accident, or natural catastrophe that may result in the release of radioactivity into the surroundings or the plant atmosphere. These safety systems must be operable at all times unless allowed by a limited condition of operation (LCO). The degree to which an HVAC system contributes to safety determines which components must function during and after a DBA or specific combinations of such events as a safe shutdown earthquake (SSE), a tornado, a loss of coolant accident (LOCA), fuel-handling accident (FHA), control rod drop accident (CRDA), main steam line break (MSLB), and loss of off-site electrical power (LOSP). Non-safety-related systems are not credited in any design basis accident and are designed not to adversely affect safety-related systems.

Most U.S. nuclear facilities (both NRC and DOE regulated) were built and licensed under the deterministic approach for safety classification of structures, systems, and components (SSC). This approach is changing to a probabilistic risk assessment (PRA) classification system. NRC classifies SSCs as safety-significant (SS) or low safety-significant (LSS), and categorizes them in four groups per 10 CFR 50.69 (RISC-1, safety related and safety significant; RISC-2, non-safety-related and safety significant; RISC-3, safety related and low safety significant; RISC-4, non-safety-related and low safety significant). NRC *Regulatory Guide* 1.201 provides information on safety classification of systems, structures, and components. The U.S. DOE classifies SSCs based on DOE *Order* 420.1 and DOE *Standards* 1020 and 1189.

System Redundancy. Systems important to safety must be redundant and single-failure-proofed. Such a failure should not cause a failure in the back-up system. For additional redundancy requirements, refer to the section on Commercial Facilities.

Seismic Qualification. All safety-class components, including equipment, pipe, duct, and conduit, must be seismically qualified by testing or calculation to withstand and perform under the shock and vibration caused by an SSE or an operating-basis earthquake (OBE) (the largest earthquake postulated for the region). This qualification also covers any amplification by the building structure. In addition, any HVAC component that could, if it failed, jeopardize the essential function of a safety-related component, must be seismically qualified or restrained to prevent such failure.

Environmental Qualification. Safety-class components must be environmentally qualified; that is, the useful life of the component in the environment in which it operates must be determined through a program of accelerated aging. Environmental factors such as temperature, humidity, pressure, and cumulative radiation dose must be considered.

Quality Assurance. All designs and components of safety-class systems must comply with the requirements of a quality assurance (QA) program for design control, inspection, documentation, and traceability of material. For U.S. plant designs, refer to Appendix B of Title 10 of the U.S. *Code of Federal Regulations*, Part 50 (10 CFR 50) or ASME *Standard* NQA-1 for quality assurance program requirements.

Canadian plant designs use two related series of quality assurance standards: CAN3-286.0 and its six daughter standards, plus four standards in the N299 series. Quality programs in the United Kingdom are based on ISO 9000. For other countries, refer to the applicable national regulations.

Emergency Power. All safety-class systems must have a backup power source such as an emergency diesel generator.

1.5 OUTDOOR CONDITIONS

Chapters 14 and 15 of the 2017 *ASHRAE Handbook—Fundamentals*, the U.S. National Oceanic and Atmospheric Administration, national weather service of the site country, or site meteorology can provide information on outdoor conditions, temperature, humidity, solar load, altitude, and wind.

Nuclear facilities generally consist of heavy structures with high thermal inertia. Time and temperature lag should be considered in determining heat loads. For some applications, such as diesel generator buildings or safety-related pumphouses in nuclear power plants, the 24 h average temperature may be used as a steady-state value. For critical ventilation system design, site meteorological data should be evaluated.

1.6 INDOOR CONDITIONS

Indoor temperatures are dictated by occupancy, equipment or process requirements, and comfort requirements based on personnel activities. HVAC system temperatures are dictated by the environmental qualification of the safety-class equipment located in the space and by ambient conditions during the different operating modes of the equipment.

1.7 INDOOR PRESSURES

Where control of airflow pattern is required, a specific building or area pressure relative to the outdoor atmosphere or to adjacent areas must be maintained. The effect of prevailing wind speed and direction, based on site meteorological information, should be considered. For process facilities with pressure zones, the pressure relationships are specified in the section on Confinement Systems.

In facilities where zoning is different from that in process facilities, and in cases where any airborne radioactivity must not spread to rooms within the same zone, this airborne radioactivity must be controlled by airflow.

1.8 AIRBORNE RADIOACTIVITY

The level of airborne radioactivity within a facility and the amount released to the surroundings must be controlled to meet the requirements of 10 CFR 20, 10 CFR 50, 10 CFR 61, 10 CFR 100, 10 CFR 835, and U.S. DOE *Policy* P 450.4A, or equivalent national regulations of the site country.

1.9 TORNADO/MISSILE PROTECTION

Protection of buildings, housings, and essential equipment from effects of tornados and missiles launched by wind or other design basis events is required to allow controlled shutdown of the plant. A tornado passing over a facility causes a sharp drop in ambient pressure. If exposed to this transient pressure, ducts and filter housings could collapse because the pressure inside the structure would still be that of the environment prior to the pressure drop. Protection is usually provided by tornado dampers and missile barriers in all appropriate openings to the outdoors. Tornado dampers are heavy-duty, low-leakage dampers designed for pressure differences in excess of 20 kPa. They are normally considered safety-class and are environmentally and seismically qualified.

1.10 FIRE PROTECTION

Fire protection for HVAC and filtration systems must comply with applicable requirements of RG 1.189, Appendix R of 10 CFR

50, and NFPA, UL, and ANSI or equivalent standards of the site country. Design criteria should be developed for all building fire protection systems, including secondary sources, filter plenum protection, fire dampers, and systems for detection/suppression and smoke management. Fire protection systems may consist of a combination of building sprays, hoses and standpipes, and gaseous or foam suppression. The type of fire postulated in the Fire Hazard Analysis (FHA) or equivalent determines which kind of system is used.

A requirement specific to U.S. nuclear commercial facilities is protection of carbon filter plenums and ventilation ductwork. Manually activated water sprays (window nozzles, fog nozzles, or standard dry pipe/wet pipe system spray heads) are usually used for fire suppression in carbon filter plenums.

Heat detectors and fire suppression systems should be considered for special equipment such as glove boxes. Application of the two systems in combination allows the shutdown of one system at a time for repairs, modifications, or maintenance.

In a DOE facility, the exhaust system duct penetrating a fire-rated boundary does not need a fire damper for maintaining the integrity of the boundary if the duct is fire rated. The exhaust duct may be rated at up to two hours by either wrapping, spraying, or enclosing the duct in an approved material and qualifying it by an engineering analysis. Additional design guidance can be obtained from the *Nuclear Air Cleaning Handbook* (DOE-HDBK-1169-2003) and *Fire Protection* (DOE-STD-1066-2016).

Fire protection and smoke control criteria can be found in NFPA *Standards* 801, 803, 804, 805, and 901, or equivalent standards of the site country.

1.11 SMOKE MANAGEMENT

The design objective for smoke management in a nuclear facility is to protect the plant operators and equipment from internally and externally generated smoke. Smoke management involves (1) use of materials with low smoke-producing characteristics, (2) prevention of smoke movement to areas where operators may be overcome, (3) use of differential pressures to contain smoke to fire areas, (4) smoke venting to permit access to selected areas, and (5) purging to permit access to areas after a fire.

Smoke control may be static, by prevention of smoke movement (NFPA 90A), or it may be dynamic, by controlling building pressure or air velocities (NFPA 92A). Ventilation systems in the affected areas should be shut down to prevent smoke from migrating and overcoming occupants in other areas. Smoke management for an *internal* fire source should allow the plant operator to shut down the reactor in a controlled manner and maintain shutdown condition. Smoke from an *external* fire should be isolated and appropriate measures provided to prevent smoke from entering the main control room envelope. This envelope includes the main control room and other necessary areas such as restrooms, kitchens, and offices. The location of the safe shutdown panels and the pathway to the safe shutdown panel must be such that, in case of abandonment of the main control room because of fire and smoke, safe egress is ensured.

Capabilities should be provided for purging smoke from fire areas to permit reentry into the areas after the fire is isolated and extinguished. Venting may be used to remove heat and smoke at the point of the fire to permit firefighting and to control pressures generated by fires.

NFPA 90A, 204, and 92A and NUREG 800 SRP Branch Technical Position CMEB 9.5.1.1 provide guidance for smoke management and discuss the discharge of smoke and corrosive gases.

Control Room Habitability Zone

The HVAC system in a control room is a safety-related system that must fulfill the following requirements during all normal and postulated accident conditions:

- Maintain conditions comfortable to personnel, and ensure that control room equipment functions continuously and complies with its qualification limit
- Protect personnel from exposure to radiation or toxic chemicals, in the event of a design basis accident
- Protect personnel from combustion products (smoke) emitted from on-site and off-site fires
- Limit unfiltered in-leakage to that credited in the design basis dose calculation.

Additional information may be obtained from the NRC Standard Review Plans (NUREG 800), Sections 6.4 and 9.4.1, and TSTF *Standard* 448, Revs. 0 and 3.

Air Filtration

HVAC filtration systems can be designed to remove either radioactive particles or radioactive gaseous iodine from the airstream. They filter potentially contaminated exhaust air prior to discharge to the environment and may also filter potentially contaminated makeup air for power plant control rooms and technical support centers.

The composition of the filter train is dictated by the type and concentration of the contaminant, the process air conditions, and the filtration levels required by the applicable regulations (e.g., NRC *Regulatory Guides* RG 1.52, RG 1.140; ASME AG-1, N509, and 510 [for equipment designed to N509], and N511 [for equipment designed to AG-1]; 10 CFR 20, 10 CFR 100). Filter trains may consist of one or more of the following components: prefilters, high-efficiency particulate air (HEPA) filters, carbon filters (adsorbers), heaters, demisters and associated ductwork, housings, fans, dampers, and instrumentation. For nuclear-safety-related versions of this equipment, the latest edition of ASME AG-1 codifies rules for materials; design; inspection and testing; fabrication; packaging, shipping, receiving, storage, and handling; and quality assurance. Information common to all equipment is compiled in AG-1, Section AA: General Requirements. The AG-1 code discusses specific rules for each of the major components in separate sections

For DOE facilities, the *Nuclear Air Cleaning Handbook* (DOE-HDBK-1169-2003) recommends the design of systems and use of major components for nuclear process facilities and laboratories.

Demisters (Mist Eliminators). Demisters are required to protect HEPA and carbon filters if entrained moisture droplets are expected in the airstream. They should be fire resistant. For details, see AG-1, Section FA.

Heaters. Electric heating coils may be used to limit the relative humidity to 70% for carbon filters based on credited laboratory test condition. For safety-class systems, electric heating coils should be connected to the emergency power supply. Interlocks should be provided to prevent heater operation when the exhaust fan is de-energized. For details, see AG-1, Section CA.

Prefilters/Postfilters. Extended-surface filters are selected for the efficiency required by the particular application. AG-1, Table FB-4200-1, lists the average atmospheric dust spot efficiency ranges. AHRI 850 provides efficiency tolerances for the various classes. These types of filters are often used as prefilters for HEPA filters to prevent them from being loaded with atmospheric dust and to minimize replacement costs. High-efficiency (90 to 95%) filters are also often used as postfilters downstream of the carbon filter in lieu of downstream HEPAs. For details, see AG-1, Section FB.

European filter standards use efficiency tolerances from ISO 16890 in place of ARI 850.

HEPA Filters. HEPA filters are used where there is a risk of particulate airborne radioactivity. For details, see AG-1, Sections FC and FK. For DOE sites, the construction and quality assurance testing of HEPA filters are per DOE *Standards* 3020 and 3025.

Carbon Filters. Activated carbon adsorbers are used mainly to remove radioactive iodine in gaseous state. Bed depths are typically

50 or 100 mm. Carbon filters have an efficiency 95 to 99% for organic iodine, although they lose efficiency as relative humidity increases. For this reason, they are often preceded by a heating element to keep the relative humidity of the entering air below 70%, and are tested at that condition. If the heater operation is not credited for maintaining relative humidity of the air stream, the carbon is tested at relative humidity of 95%. Nuclear carbon filters can be either tray type (Type II), rechargeable (Type III), or modular (Type IV). For details on each type, see AG-1, Sections FD, FE, and FH. Carbon efficiency is tested in accordance with Generic Letter 99-02 and ASTM D3803-89 (2014) or its latest edition.

Both carbon and HEPA filters may be affected by exposure to paint solvent, chemicals, and fire, and thus should be evaluated on exposure.

Design information for ventilation and air-conditioning system design, ductwork, housings, fans, dampers, and instrumentation are contained in AG-1, Sections CA, RA, SA, HA, BA, DA, and IA, respectively.

Sand Filters. Sand filtration is a passive air filtration system that consists of multiple layers of sand and gravel through which air is drawn and filtered. The air enters an inlet tunnel that runs the entire length of the filter. Smaller cross-sectional laterals running perpendicular to the inlet tunnel distribute air across the base of the sand. Air rises through several layers of various sizes of sand and gravel, typically at a facial velocity of 25 mm/s. It is then collected in the outlet tunnel for discharge to the atmosphere. Sand filters require no maintenance, and the sand is not changed or replaced during its active service life. A detailed discussion of sand filters is given in Chapter 9 of the DOE's (2003) *Nuclear Air Cleaning Handbook*. Additionally, AG-1, Section FL, issued by ASME's Code of Nuclear and Air Gas Treatment (CONAGT) Committee, addresses deep bed sand filters.

2. DEPARTMENT OF ENERGY FACILITIES

The following discussion applies to U.S. National Laboratory facilities. Nonreactor nuclear HVAC systems must be designed in accordance with DOE *Order* O 420.1 and the associated DOE standards, guides, and handbooks listed at the end of this chapter. Critical items and systems in plutonium processing facilities are designed to confine radioactive materials under both normal and DBA conditions.

2.1 CONFINEMENT SYSTEMS

Zoning

Typical process facility confinement systems are shown in Figure 1. Process facilities comprise several zones.

Primary Confinement Zone. This zone includes the interior of the hot cell, canyon, glove box, or other means of containing radioactive material. Containment must prevent the spread of radioactivity within or from the building under both normal conditions and upset conditions up to and including a facility DBA. Complete isolation from neighboring facilities is necessary. Multistage HEPA filtration of the exhaust is required.

Secondary Confinement Zone. This zone is bounded by the walls, floors, roofs, and associated ventilation exhaust systems of the operating and maintenance areas or rooms surrounding the primary confinement zone.

Tertiary Confinement Zone. This zone is bounded by the walls, floors, roofs, and associated ventilation exhaust systems of the facility. They provide a final barrier against the release of hazardous material to the environment. Radiation monitoring may be required at exit points.

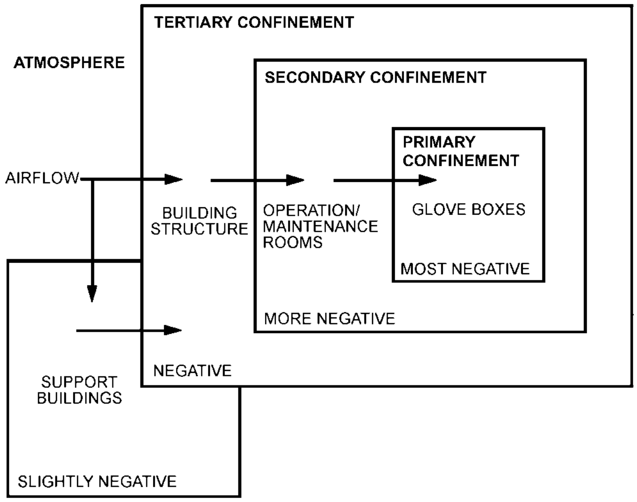

Fig. 1 Typical Process Facility Confinement Categories

Uncontaminated Zone. This zone includes offices and cold shop areas.

Air Locks

Air locks in nuclear facilities are used as safety devices to maintain a negative differential pressure when a confinement zone is accessed. They are used for placing items in primary confinement areas and for personnel entry into secondary and tertiary confinement areas. Administrative controls ensure proper operation of the air lock doors.

There are three methods of ventilating personnel air locks (ventilated vestibules):

- The **clean conditioned supply air** method, where the air lock is at positive pressure with respect to the adjacent zones. For this method to be effective, the air lock must remain uncontaminated at all times.
- The **flow-through ventilation air** method, where no conditioned air is supplied to the air lock and the air lock stays at negative pressure with respect to the less contaminated zone.
- The **combined ventilation air** method, which is a combination of the other two methods. This may be the most effective method, when properly designed.

Zone Pressure Control

Negative static pressure increases (becomes more negative) from the uncontaminated zone to the primary confinement zone, causing any air leakage to be inward, toward areas of higher potential contamination. All zones should be maintained negative with respect to atmospheric pressure. Zone pressure control cannot be achieved through the ventilation system alone; confinement barrier construction must meet all applicable specifications.

Cascade Ventilation

Confinement barriers are enhanced by the use of a cascaded ventilation system, in which pressure gradients cause air to flow from areas of lower contamination to areas of higher contamination through engineered routes. In a cascade ventilation system, air is routed through areas or zones from lower contamination to higher contamination and then to highest contamination, thus reducing the number of separate ventilation systems and the amount of air required for contamination control.

Properly designed air locks should be provided for access between noncontaminated and contaminated areas. If there is a potential for development of differential pressure reversal, HEPA filters should be used at the inlet air openings between areas of higher and lower contamination levels to control the spread of contamination into less contaminated or cleaner areas. Appropriate sealing mechanisms should be used for doors or hatches leading into highly contaminated areas.

Differential Pressures

Differential pressures help ensure that air flows in the proper direction in case of a breach in a confinement zone barrier. The design engineer must incorporate the desired magnitudes of the differential pressures into the design early to avoid later operational problems. These magnitudes are normally specified in the design basis document of the safety analysis report (SAR). The following are approximate values for differential pressures between the three confinement zones.

Primary Confinement. With respect to the secondary confinement area, air-ventilated glove boxes are typically maintained at pressures of –75 to –312 Pa, inert gas glove boxes at –75 to –375 Pa, and canyons and cells at a minimum of –250 Pa.

Secondary Confinement. Differential pressures of –25 to –37 Pa with respect to the tertiary confinement area are typical.

Tertiary Confinement. Differential pressures of –2.5 to –37 Pa with respect to the atmosphere are typical.

2.2 VENTILATION

Ventilation systems are designed to confine radioactive materials under normal and DBA conditions and to limit radioactive discharges to allowable levels. They ensure that airflows are, under all normal conditions, toward areas (zones) of progressively higher potential radioactive contamination. Air-handling equipment should be sized conservatively so that upsets in the airflow balance do not cause the airflow to reverse direction. Examples of upsets include improper use of an air lock, a credible breach in the confinement barrier, or excessive loading of HEPA filters.

HEPA filters at the ventilation inlets in all primary confinement zone barriers prevent movement of contamination toward zones of lower potential contamination in case of an airflow reversal. Ventilation system balancing helps ensure that the building air pressure is always negative with respect to the outdoor atmosphere.

Recirculating refers to the reuse of air in a particular zone or area. Room air recirculated from a space or zone may be returned to the primary air-handling unit for reconditioning and then, with the approval of health personnel, be returned to the same space (zone) or to a zone of greater potential contamination. All air recirculated from secondary and tertiary zones must be HEPA-filtered before reintroduction to the same space. Recirculating air is not permitted in primary confinement areas, except those with inert atmospheres.

A safety analysis is necessary to establish minimum acceptable response requirements for the ventilation system and its components, instruments, and controls under normal, abnormal, and accident conditions.

Analysis determines the number of exhaust filtration stages required in different areas of the facility to limit (in conformance with the applicable standards, policies, and guidelines) the amount of radioactive or toxic material released to the environment during normal and accident conditions. Consult DOE *Order* O 420.1, *Standard* 1189, and Handbook 1169 (DOE 2003) for air-cleaning system criteria.

Ventilation Requirements

A partial recirculating ventilation system may be considered for economic reasons. However, it must be designed to prevent contaminated exhaust from entering the room air-recirculating systems.

The exhaust system is designed to (1) clean radioactive contamination from the discharge air, (2) safely handle combustion products, and (3) maintain the building under negative pressure relative to the outdoors.

Provisions may be made for independent shutdown of ventilation systems or isolation of portions of the systems to facilitate operations, filter change, maintenance, or emergency procedures such as firefighting. All possible effects of partial shutdown on the airflows in interfacing ventilation systems should be considered. Positive means must be provided to control the backflow of air that might transport contamination. A HEPA filter installed at the interface between the enclosure and the ventilation system minimizes contamination in the ductwork; a prefilter reduces HEPA filter loading. These HEPA filters should not be considered the first stage of an airborne contamination cleaning system.

Ventilation Systems

The following is a partial list of elements that may be included in the overall air filtration and air-conditioning system:

- Air-sampling devices
- Pre- and/or postfilters (e.g., carbon adsorbers, deep bed sand, HEPA)
- Scrubbers
- Demisters
- Process vessel vent systems
- Condensers
- Distribution baffles
- Fire suppression systems
- Fire and smoke dampers
- Exhaust stacks
- Fans
- Coils
- Heat removal systems
- Pressure- and flow-measuring devices
- Duct test ports
- Radiation-measuring devices
- Criticality-safe drain systems
- Tornado dampers
- Smoke dampers

The ventilation system and associated fire suppression system are designed for fail-safe operation. The ventilation system is equipped with alarms and instruments that report and record its behavior through readouts in control areas and utility service areas.

Control Systems

Control systems for HVAC systems in nuclear facilities have some unique safety-related features. Because the exhaust system is to remain in operation during both normal and accident-related conditions, redundancy in the form of standby fans is often provided. These standby fans and their associated isolation dampers energize automatically upon a set reduction in either airflow rate or specific location pressure, as applicable. For DOE facilities, maintaining exhaust airflow is important, so fire dampers are excluded from all potentially contaminated exhaust ducts.

Pressure control in the facility interior maintains zones of increasing negative pressure in areas of increasing contamination potential. Care must be taken to prevent wind from unduly affecting the atmospheric control reference. Pulsations can cause the pressure control system to oscillate strongly, resulting in potential reversal of relative pressures. One alternative is to use a variety of balancing and barometric dampers to establish an air balance at the desired differential pressures, lock the dampers in place, and then control the exhaust air to a constant flow rate.

Air and Gaseous Effluents Containing Radioactivity

Air and all other gaseous effluents are exhausted through a ventilation system designed to remove radioactive particulates. Exhaust ducts or stacks located downstream of final filtration that may contain radioactive contaminants should have two monitors, one a continuous air monitor (CAM) and the other a fixed sampler. These monitors may be a combination unit. Exhaust stacks from nuclear facilities are usually equipped with an isokinetic sampling system that relies on a relatively constant airflow rate. The isokinetic sensing probe is a symmetrically arranged series of pickup tubes connected through sweeping bends to a stainless steel header that connects with capillary tubing to a sampling station (CAM). The air velocity through an isokinetic sampling system should be the same as the airstream being sampled. This ensures that particles captured by the isokinetic sampling probe and conveyed to the sampling station are the same size particles that are conveyed in the airstream being sampled. Typically, an exhaust system flow controller modulates the exhaust fan inlet dampers or motor speed to hold the exhaust airflow rate steady while the HEPA filters load.

CAMs can also be located in specific ducts where a potential for radiological contamination has been detected. These CAMs are generally placed beyond the final stage of HEPA filtration, as specified in HPS *Standard* N13.1. Each monitoring system is connected to an emergency power supply.

The following are design considerations for CAM systems:

- Maintain fully developed turbulent flow at the nonisokinetic sampling point.
- Maintain fully developed laminar flow at the isokinetic sampling point.
- Ensure fully developed turbulent flow is established between the final filtration and the isokinetic sampling point.
- For accurate CAM operation, heat tracing on the sampling air tubing may be required.
- Maintain the ratio of the sample airflow rate to total discharge airflow rate constant.

3. COMMERCIAL FACILITIES

3.1 OPERATING NUCLEAR POWER PLANTS

The two kinds of commercial light-water power reactors currently in operation in the United States, and in many other countries, are the pressurized water reactor (PWR) and the boiling water reactor (BWR). Heavy water (deuterium oxide) reactors are used in Canada and some other countries. Gas-cooled reactors constitute most of the installed base in Great Britain, but are in the process of being phased out. For all these types, the main objective of the HVAC systems, in addition to ensuring personnel comfort and reliable equipment operation, is protecting operating personnel and the general public from airborne radioactive contamination during normal and accident conditions. Radiation exposure limits are controlled by 10 CFR 20. The “as low as reasonably achievable” (ALARA) concept is the design objective of the HVAC system. The radiological dose is not allowed to exceed the limits as defined in 10 CFR 50 and 10 CFR 100. For other countries operating commercial nuclear plants, the specific national rules and regulations should be consulted.

NRC Regulatory Guides (RGs) delineate techniques of evaluating specific problems and provide guidance to applicants concerning the information the NRC needs for its review of the facility. The regulatory guides that relate directly to HVAC system design are RG 1.52, RG 1.78, RG 1.140, RG 1.194, RG 1.196, and RG 1.197. Deviations from RG criteria must be justified by the owner and approved by the NRC. Some countries also invoke NRC regulatory guides as part of the design requirements. Deviations from RG criteria must be requested through the applicable government agency in the country of construction.

The design of the HVAC systems for a U.S. nuclear power generating station must ultimately be approved by the NRC in accordance with Appendix A of 10 CFR 50. The NRC developed standard review plans (SRPs) as part of Regulatory Report NUREG-0800 to provide an orderly and thorough review. The SRP provides a good basis or checklist for the preparation of a safety analysis report (SAR). The SRP is the basis for information provided by an applicant in an SAR as required by Section 50.34 of 10 CFR 50. Technical specifications for nuclear power plant systems are developed by the owner and approved by the NRC as outlined in Section 50.36 of 10 CFR 50. Technical specifications define the safety limits, limiting conditions for operation (LCO), and surveillance requirements (SR) for all systems important to plant safety.

Minimum requirements for the performance, design, construction, acceptance testing, and quality assurance of equipment used in safety-related air and gas treatment systems in nuclear facilities are found in ASME N509, N510, N511, and AG-1.

Temperature and humidity conditions are dictated by the nuclear steam supply system (NSSS). For U.S. plants, the common modes of operation are normal, hot shutdown, cold shutdown, and refueling.

Normal Operation. NSSS temperature and humidity requirements are specified by the NSSS supplier. Some plants require recirculation filtration trains in the containment building to control the level of airborne contamination. In existing plants, containment cooling is necessary for maintaining the components in the containment and to ensure that design limits are not exceeded during accidents. Cooling is provided by a containment cooling system. Some next-generation plants are mostly of passive design and thus do not need active containment cooling systems.

Refueling Condition. The temperature in the refueling or fuel-handling area is determined by the need to perform refueling activities safely. Also, because personnel work in protective clothing, they can be vulnerable to heat stress. To prevent this, area cooling can be provided by a normal non-safety-related cooling system. Outdoor air should be provided for ventilation.

Accident Scenarios

Plants are analyzed for four types of accidents: (1) loss of coolant accident (LOCA), (2) fuel handling accident (FHA), (3) control rod drop accident (CRDA), and (4) a main steam line break (MSLB). For all plant types, it necessary to evaluate the limiting accident event and to conduct safety assessments, so measures can be taken to mitigate any accident’s any accident’s consequences.

Major NSSS Types

Pressurized-Water Reactors (PWRs). These reactors, widely used in the United States, use enriched uranium for fuel. The reactor, steam generators, and other components of the NSSS are housed in the containment structure. Other support systems are housed in the auxiliary building, control building, turbine building, and diesel building. In PWR design, the steam turbine is powered by nonradioactive steam for the generation of electricity. General design requirements of the PWR plant are contained in ANSI/ANS *Standard* 56.6-1986. Figure 2 shows a typical PWR.

Boiling-Water Reactor (BWRs). Also widely used in the United States, this type of design reactor uses enriched uranium for fuel. The reactor pressure vessel and related piping are housed within the primary containment, which is also referred to as the drywell (Figure 3). The drywell is a low-leakage, pressure-retaining structure designed to withstand the high temperature and pressure from a major break in the reactor coolant line. The drywell is housed within a concrete structure called the secondary containment or the reactor building. Other support systems are housed in the control building, turbine building, and diesel building. In BWR design, the steam turbine is powered by radioactive steam for the generation of

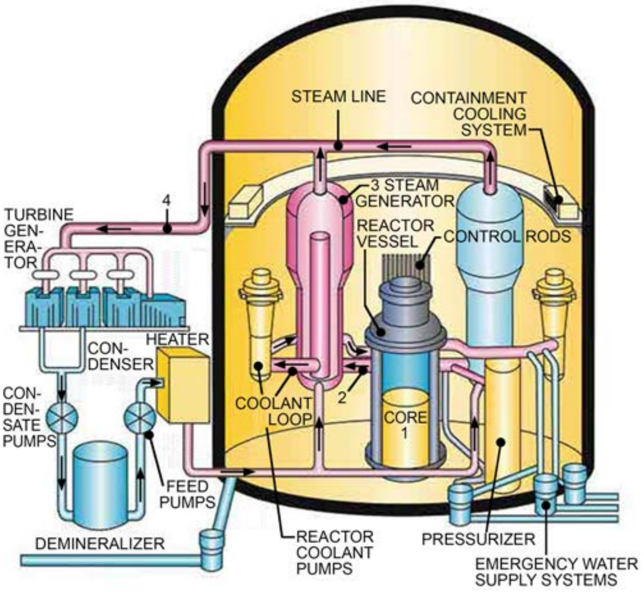

Fig. 2 Typical Pressurized-Water Reactor
(From NRC web site: www.nrc.gov)

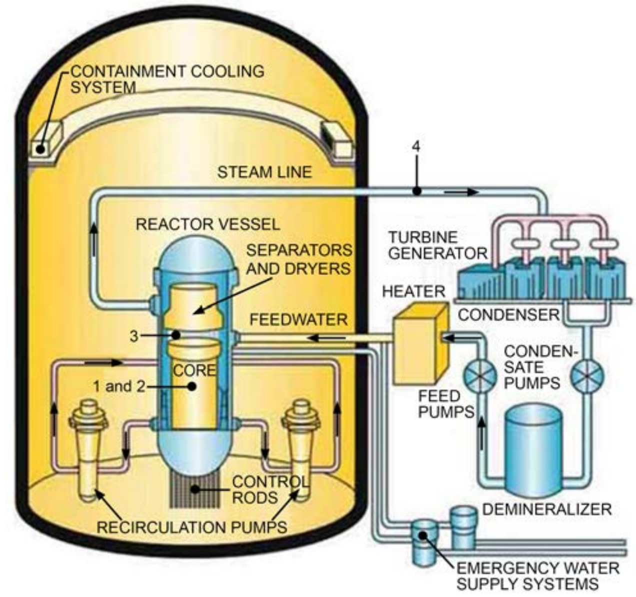

Fig. 3 Typical Boiling-Water Reactor
(From NRC web site: www.nrc.gov)

electricity. General design requirements of the BWR plant are contained in ANSI/ANS *Standard* 56.7-1987.

Heavy Water Reactors. Canadian power reactors use natural uranium fuel and heavy water (deuterium oxide), which acts as a moderator and a coolant source. The reactor core is mounted in a large, horizontal steel vessel called a calandria, which is enclosed in a concrete containment structure. This design enables the reactors to be refueled while the unit is operating at full power.

Commercial Plant License Renewal and Power Uprate

Nuclear power plants were originally licensed for a 40 year term and a defined power output capacity. Most nuclear plants currently operating in the United States have applied for or will be applying for license renewal to extend the plant operating license from 40 to 60 years. As part of the license renewal process, passive plant components, such as HVAC ductwork and piping, are reviewed, and renewal licenses are granted based on the commitment to perform aging management review (AMR) of long-lived components. Credit is taken for the maintenance rule to address upkeep and replacement of active components. Maintenance rule requirements are outlined in 10 CFR 50.65, Nuclear Energy Institute documents, Nuclear Management Resources Council (NUMARC) 93-0, and NRC Regulatory Guide RG 1.160.

In addition to license renewal, most plants are increasing their power output capacity by as much as 5 to 15% by conducting power uprate evaluations. Power uprates are often done in steps, and are often categorized as (1) measurement uncertainty recapture power uprates, (2) stretch power uprates, and (3) extended-power uprates. As part of the power uprate, the effects of power output on plant and HVAC systems are evaluated, and these systems are upgraded as needed.

3.2 NEW NUCLEAR POWER PLANTS

Many new nuclear power generation plants are being considered for construction in the United States, as well as in other parts of the world. The U.S. NRC has streamlined the application and licensing process for the new reactors, and the *Code of Federal Regulations* 10 CFR 52 governs the issuance of combined construction and operating license. The new plants are being designed and licensed to satisfy the demand for additional generation capacity in a competitive environment, while contributing to sustainable growth. Advantages of the newer plants include standardized designs with shortened construction times; up to 60-year service life; and the possibility of using flexible fuel (including mixed oxide [MOX] fuel). The status of design certification and combined construction and operating license (COL) applications for various new U.S. plants can be found at the NRC Web site (www.nrc.gov).

New reactors being considered in the United States are the advanced passive 1000 (AP1000), economic simplified boiling-water reactor (ESBWR), U.S. evolutionary power reactor (USEPR), advanced boiling-water reactor (ABWR) and U.S. advanced pressurized water reactor (USAPWR). The AP1000 and the ESBWR use passive cooling systems, and the need for safety-related HVAC systems is limited. The ABWR and the USAPWR are enhanced designs of the boiling water reactor and pressurized water reactor, respectively, and HVAC systems for these reactors are not expected to be very much different than those at currently operating BWR and PWR plants. The USEPR is a pressurized water reactor of European design. Brief overviews of HVAC for AP1000, ESBWR, and USEPR plants are as follows.

Advanced Passive AP1000

HVAC systems at AP1000 plants have several differences from those at pressurized-water reactor plants. The main control room (MCR) has both a normal and an emergency HVAC system. The normal system maintains temperature and relative humidity during normal plant operation, and the emergency system uses passive cooling heat sinks to maintain habitability in the main control room during accident conditions. The normal HVAC system has supplemental air filtration that can be used to filter outdoor air with HEPA and charcoal filters, and maintains the main control room at a slight positive pressure to prevent infiltration of unfiltered air into the main control room envelope. On detection of high radiation in the supply air or an extended loss of ac power, the normal system is isolated and the safety-related emergency habitability system is activated. During emergency-mode operation, air is supplied to the MCR from pressurized storage tanks that are sized to meet the ventilation and pressurization requirements for a 72 h accident event.

Passive heat sinks are used in the MCR, instrumentation and control (I&C), and dc equipment rooms to limit temperature rise in those rooms after loss of normal HVAC systems. The heat sinks primarily consist of the thermal mass of concrete in the ceilings and walls. Safety-related HVAC equipment is limited to containment isolation valves, control room isolation valves, and the emergency habitability system. Limiting active safety equipment and using passive safety features is part of the AP1000 design philosophy.

The AP1000 has a containment air filtration system, but it serves no safety-related function and is isolated during accident conditions. It is designed to provide intermittent venting of the containment to the atmosphere during normal plant operation. HVAC systems serving the AP1000 diesel generator, radioactive waste (radwaste), annex, and turbine buildings are similar to those in existing PWRs, with a few exceptions: (1) the containment HVAC recirculation system is non-safety-related; (2) the containment HVAC recirculation system uses chilled water to cool containment; and (3) the diesel generators (and thus the diesel generator building) are not safety related.

Economic Simplified Boiling-Water Reactor (ESBWR)

ESBWR HVAC systems have several differences from those at operating boiling-water reactor plants. The control building ventilation system has two subsystems: the control building general-area ventilation system (CBGAVS), which serves general areas in the control building, and the control room habitability-area (CRHA) ventilation system (CRHAVS), which serves the main control room. The CRHAVS provides cooling to MCR, which is served by two redundant recirculation air-handling units (AHUs). Recirculation air-handling units in the main control room draw air from the ceiling space plenum, condition it, and discharge it to an underfloor air distribution system. There is an outdoor air AHU for providing makeup to the MCR for normal habitability. During emergency mode, the CRHA is isolated at the boundary by isolation dampers. The recirculation AHU continues to cool while a battery-powered emergency filter unit (EFU) with HEPA and carbon filters provides filtered outdoor air. If power is lost, the EFU continues to operate for pressurization and to maintain the MCR at 30 Pa positive relative to the surroundings for the 72 h accident coping period. During this time, the walls and boundary areas act as passive heat sinks to limit the temperature rise in the main control room.

The reactor building (RB) ventilation system (RBVS) has three non-safety-related subsystems: the contaminated-area ventilation subsystem (CONAVS), refueling and pool-area ventilation subsystem (REPAVS), and the reactor building clean-area ventilation subsystem (CLAVS). These systems are separated from the each other with isolation dampers. The CLAVS and CONAVS subsystems are split into separate trains for serving the two halves of the RB. The RBVS has two non-safety-related filter trains (with HEPA and carbon filters), which are backed up with power supply from the diesel generators. Those systems operate on loss of power, but are not credited in the accident analysis. The fuel building ventilation system (FBVS) has two non-safety-related subsystems: the fuel building general-area ventilation subsystem (FBGAVS) and the fuel building fuel-pool-area ventilation subsystem (FBFPVS). The FBGAVS and the FBFPVS subsystems are once-through systems, and room coolers provide supplementary cooling for selected rooms in the fuel building.

The ESBWR uses a centralized non-safety-related chilled-water plant and provides chilled water to various buildings, including the drywell, based on the primary/secondary loop design concept.

U.S. Evolutionary Power Reactor (USEPR)

Unlike the AP1000 and the ESBWR, the USEPR is not of passive design and is similar to PWR plants, except that the emergency (safety) systems have a four-loop or four-train design: there are four electrical trains of safety systems, four emergency diesels and four loops of safety chilled water. The main control room HVAC system has an active and diverse cooling system consisting of two trains of safety-related water-cooled chillers and two trains of safety-related air-cooled chillers. The main control room air-conditioning system (CRACS) is designed to maintain habitability in the main control room and adjoining rooms during normal operation and during accident conditions involving radiation and toxic gas releases. The CRACS maintains the control room envelope at a 30 Pa positive pressure relative to surrounding areas during accident conditions. The CRACS filtration and air-conditioning equipment and associated ductwork are located inside the control room pressure boundary, thus eliminating the potential for in leakage of unfiltered air. Smoke detectors and toxic gas sensors in the outdoor air supply duct actuate an alarm in the main control room and automatically place the cooling system in recirculation mode.

The containment building ventilation system (CBVS) is composed of three separate subsystems: the (1) non-safety-related full- and low-flow containment purge system, (2) non-safety-related containment filtration system, and (3) safety-related containment cooling system. The containment low-flow purge subsystem operates during normal plant operation to facilitate containment entry and to support outages activities, whereas the full-flow purge system operates only during outages to control the containment environment. The containment filtration subsystem consists of a filter unit with HEPA and carbon filters and a heater, and is used for clean-up of the containment environment. The containment cooling subsystem contains fans, cooling coils, and associated ductwork for cooling various areas of the containment.

4. PLANT HVAC&R SYSTEMS

4.1 PRESSURIZED-WATER REACTORS

Containment Building

Containment Cooling. The following systems are typical for containment cooling:

Reactor containment coolers. These units remove most of the heat load. Distribution of the air supply depends on the containment layout and the location of the major heat sources.

Reactor cavity air-handling units or fans. These units are usually transfer fans without coils that provide cool air to the reactor cavity.

Control rod or control element drive mechanism (CRDM or CEDM) air-handling units. The CRDM and CEDM are usually cooled by an induced-draft system using exhaust fans. Because the flow rates, pressure drops, and heat loads are generally high, the air should be cooled before it is returned to the containment atmosphere.

Essential containment cooling units. The containment air-cooling system, or a part of it, is normally designed to provide cooling during normal plant operation and after a postulated accident. The system must be able to perform at high temperature, pressure, humidity, and levels of radioactivity. Cooling coils are provided with essential plant service water.

System design must accommodate both normal and accident conditions. The ductwork must be able to endure the rapid pressure build-up associated with accident conditions, and fan motors must be sized to handle the high-density air.

In addition, the system must be analyzed to identify measures to mitigate the effect of water hammer as addressed in NRC's Generic Letter 96-06.

Radioactivity Control. Airborne radioactivity is controlled by the following means:

Essential air filtration units. Redundant filter units powered by two Class 1E buses are used to reduce the amount of airborne radioactivity. The typical system consists of a demister, a heater, a HEPA filter bank, and a carbon adsorber, possibly followed by a second HEPA filter bank or by a high-efficiency (90 to 95%) filter bank. The electric heater is designed to reduce the relative humidity of the incoming air from 100% to less than 70%. All the components of the air filtration unit are environmentally qualified (EQ), and designed to meet the requirements of a LOCA.

In the case of an accident and the subsequent operation of the filter train, the carbon can become loaded with radioactive iodine such that the decay heat could cause the carbon to self-ignite if the airflow stops. Heat build-up in the carbon adsorber bed should be evaluated, and an appropriate redundant decay heat removal mechanism should be provided.

Containment power access purge or minipurge. Ventilation is sometimes necessary during normal operation, when the reactor is under pressure, to control containment pressure or the level of airborne radioactivity within the containment. The maximum opening size allowed in the containment boundary during normal operation is 200 mm.

The system consists of a supply fan, double containment isolation valves in each of the containment wall penetrations (supply and exhaust), and an exhaust filtration unit with a fan. The typical filtration unit contains a HEPA filter and a carbon adsorber, possibly followed by a second HEPA filter or by a medium-efficiency (90 to 95%) filter bank. The system is non-safety-related, and operates during personnel access into the containment with the reactor under pressure. During normal plant operation, the containment tends toward positive pressure because of air leaks and the exhaust fan is often operated as needed to control pressure inside the containment.

This **minipurge** system should not be connected to any duct system inside the containment. It should include a debris screen within the containment over the inlet and outlet ducts, so that the containment isolation valves can close even if blocked by debris or collapsed ducts.

Containment refueling purge. Ventilation is required to control the level of airborne radioactivity during refueling. Because the reactor is not under pressure during refueling, there are no restrictions on the size of the penetrations through the containment boundary. Large openings of 1000 to 1200 mm, each protected by double containment isolation valves, may be provided. The required ventilation rate is typically based on 1 air change per hour.

The system consists of a supply air-handling unit, double containment isolation valves at each supply and exhaust containment penetration, and an exhaust fan. Filters are recommended.

Containment combustible gas control. In the case of a LOCA, when a strong solution of sodium hydroxide or boric acid is sprayed into the containment, various metals react and produce hydrogen. Also, if some of the fuel rods are not covered with water, the fuel rod cladding can react with steam at elevated temperatures to release hydrogen into the containment. Therefore, redundant hydrogen recombiners are needed to remove hydrogen from the containment atmosphere, recombine the hydrogen with oxygen, and return the air to the containment. The recombiners may be backed up by special exhaust filtration trains.

4.2 BOILING-WATER REACTORS

Primary Containment

The primary containment HVAC system consists of recirculating cooling units. It normally recirculates and cools the primary containment air to maintain the environmental conditions specified by the NSSS supplier. During an accident, the system may perform a safety-related function of recirculating the air to prevent stratification of any hydrogen that may be generated if the system is credited in the accident analysis. Depending on the specific plant design, the cooling function may or may not be safety related. Primary containment cooling is necessary for maintaining the life of the components inside the containment and for ensuring that the safety temperature limit of the primary containment is maintained during an accident.

Resistance temperature detectors (RTDs) measure containment temperatures at various locations, and provide input into the volumetric average temperature, which is used as the measure of the containment temperature. The plant's technical specification operating limit is established based on the volumetric average temperature. Temperature problems have been experienced in many BWR primary containments because of temperature stratification and underestimation of heat loads. The cooling system should be designed to adequately mix the air to prevent stratification. Heat load calculations should include a safety factor sufficient to allow for deficiencies and degradation in insulation.

Reactor Building

The reactor building completely encloses the primary containment, auxiliary equipment, and refueling area. Under normal conditions, the reactor building HVAC system maintains the design space conditions and minimizes the release of radioactivity to the environment. The HVAC system consists of a 100% outdoor air cooling system. Outdoor air is filtered, heated, or cooled as required before being distributed throughout the various building areas. The exhaust air flows from areas with the least potential contamination to areas of most potential contamination. Before exhausting to the environment, potentially contaminated air is filtered with HEPA filters and carbon adsorbers; all exhaust air is monitored for radioactivity. To ensure that no unmonitored exfiltration occurs during normal operations, the ventilation systems maintain the reactor building at a negative pressure relative to the atmosphere.

During an event involving a LOCA, MSLB, FHA, or high radiation in the ventilation exhaust, the HVAC system's safety-related function is to isolate the secondary containment consisting of the reactor building and the refueling area. Once isolated by fast-closing valves, the secondary containment boundary functions to contain any leakage from the primary containment or refueling area.

Once the secondary containment is isolated, a safety-related standby gas treatment system (SGTS) is started to reduce the ground level releases by drawing down the secondary containment pressure to about –60 Pa within 120 s. The SGTS exhausts air from the secondary containment to the environment at an elevated release location referred to as the main stack. The SGTS consists of redundant filtration trains, which consist primarily of HEPA filters and carbon adsorbers. The capacity of the SGTS is based on the amount of exhaust air needed to reduce the pressure in the secondary containment and maintain it at the design level, given the containment leakage rates and required drawdown times.

In addition to the SGTS, some designs include safety-related recirculating air systems within the secondary containment to mix, cool, and/or treat the air during accidents. These recirculation systems sometimes use portions of the normal ventilation system ductwork; therefore, if the ductwork is used for that purpose, then it must be classified as safety related.

Other than the emergency core cooling system (ECCS) pump rooms, the isolated secondary containment area is not cooled during accident events. All safety-related components in the secondary containment must be environmentally qualified to operate at the maximum temperature and the temperature profile for the accident event. Safety-related room coolers served by the plant service water provide cooling to the emergency core cooling system (ECCS) pumps during accident conditions.

Turbine Building

Only a BWR supplies radioactive steam directly to the turbine, which could cause a release of airborne radioactivity to the surroundings. Therefore, areas of the BWR turbine building in which release of airborne radioactivity is possible should be enclosed. These areas must be ventilated and the exhaust filtered to ensure that no radioactivity is released to the atmosphere. Filtration trains are non-safety-related and they typically consist of a prefilter, a HEPA filter, and a carbon adsorber, possibly followed by a second HEPA filter bank or by a medium-efficiency (90 to 95%) filter bank. Filtration requirements and testing are based on the plant and site configuration and commitments for 10 CFR 50, Appendix I requirements. Depending on outdoor air conditions at the location, the turbine building is cooled either with outdoor air or by area coolers served by a dedicated chilled-water system.

4.3 HEAVY WATER REACTORS

Containment Inlet Air-Conditioning/Exhaust Ventilation System

The production of heavy water in sufficient quantities for the needs of a heavy water reactor is complex and expensive. Once produced, however, deuterium oxide (D_2O) may be reused indefinitely as long as it does not become contaminated. Because heavy water reactor containments are vented and require makeup air, ordinary water (H_2O) is one contaminant that must be contained. This is normally accomplished by means of a non-nuclear safety desiccant air-conditioning unit mounted on the roof of the service building. This unit typically contains a rotary desiccant dryer, hot-water heating coils and chilled-water cooling coils both upstream and downstream of the desiccant wheel, a desiccant regeneration duct containing an electric heater, and a flow control system. The resulting inlet makeup air contains very little moisture. To prevent any radioactive contaminants from escaping up the stack, the containment exhaust ventilation unit typically contains a prefilter bank, a HEPA filter bank, a Type III carbon filter, a second HEPA filter bank, and an exhaust fan.

4.4 AREAS OUTSIDE PRIMARY CONTAINMENT

All areas located outside the primary containment are designed to the general requirements contained in ANSI/ANS *Standard* 59.2. These areas are common to any type of plant.

Auxiliary Building

The auxiliary building contains a large amount of support equipment, much of which handles potentially radioactive material. The building may be air conditioned for equipment protection, and the exhaust is filtered to prevent the release of potential airborne radioactivity. The filtration trains typically consist of a prefilter, a HEPA filter, and a carbon adsorber, possibly followed by a second HEPA filter bank or by a high-efficiency (90 to 95%) filter bank.

The HVAC system is a once-through system, as needed for general cooling. Ventilation is augmented by area or room coolers in the individual equipment rooms requiring additional cooling. The building is maintained at negative pressure relative to the outdoors.

If the equipment in these rooms is not safety related, the area is cooled by normal air-conditioning units. If they are safety related, the area is cooled by safety-related or essential area or room coolers units powered from the same Class 1E (according to IEEE *Standard* 323) power supply as the equipment in the room.

The normal and essential functions may be performed by one cooling unit having both a normal and an essential cooling coil and a safety-related fan served from a Class 1E bus. The normal coil can be a direct-expansion or chilled-water cooling coil served by a normal chilled-water system. The essential coil operates with chilled water from a safety-related chilled-water system or the plant service water, or a safety-related cooling water source.

Control Room

The control room HVAC system serves the control room habitability zone (those spaces that must be habitable following a postulated accident to allow orderly shutdown of the reactor) and performs the following functions:

- Controls indoor environmental conditions
- Provides pressurization to prevent infiltration
- Minimizes unfiltered in-leakage to the level credited in control room operator dose assessments
- Protects the zone from hazardous chemical fume or particle intrusion
- Protects the zone from fire
- Removes noxious fumes, such as smoke

In defining the control room envelope or pressure boundary, it is necessary to ensure that, in the event of abandonment as a result of fire or smoke in the control room, access to the remote shutdown panel is safeguarded.

Design requirements for the control room HVAC system are outlined in 10 CFR 50, GDC 19 Appendix A, Standard Review Plan Sections 6.4 and 9.4.1, NCR *Regulatory Guides* RG 1.52, 1.78, 1.194, 1.196, and 1.197, and NUREG 0737. In 2003, NRC issued Generic Letter 2003-01 to address control room habitability findings at U.S. nuclear power plants, which suggested that licensees may not have been meeting the control room licensing and design basis, and applicable regulatory requirements, and that existing technical specification surveillance requirements may not have been adequate. As a result, all nuclear plants are required to conduct control room inleakage testing using the tracer gas (SF_6) to validate the integrity of the control room boundary and to ensure compliance with dose assessments per GDC 19, Appendix A. It is also necessary to develop and maintain a control room integrity program in accordance with the plant technical specification requirements to control and maintain boundary breaches. Plants are also required to conduct self-assessments of their control room habitability program every three years and inleakage testing every six years. Control room HVAC filter units are designed to filter radioactive contaminants and are fabricated, designed, and tested per ASME *Standards* N509, N510, N511, and AG-1.

Control Cable Spreading Rooms

These rooms are located directly above and below the control room. They are usually served by an independent ventilating or cooling system or by the air-handling units that serve the electric switchgear room or the control room.

Diesel Generator Building

Nuclear power plants have an auxiliary or back-up power source for all essential and safety-related equipment in case of loss of off-site electrical power. The auxiliary power source consists of at least redundant diesel generators, each sized to meet the emergency power load. Heat released by the diesel generator and associated auxiliary systems is normally removed by a safety-related ventilation.

Emergency Electrical Switchgear Rooms

These rooms house the electrical switchgear that controls essential or safety-related equipment. The switchgear located in these rooms must be protected from excessive temperatures (1) to ensure that its qualified life, as determined by environmental qualification, is maintained and (2) to preserve power circuits required for proper operation of the plant, especially its safety-related equipment.

Battery Rooms

Battery rooms should be maintained at approximately 20 to 25°C for optimum battery capacity and service life. Temperature variations are acceptable as long as they are accounted for in battery sizing calculations. The minimum room design temperature should be taken into account in determining battery capacity. Because batteries produce hydrogen gas during charging periods, the HVAC system must be designed to limit the hydrogen concentration to the lowest of the levels specified by IEEE *Standard* 484, ASHRAE guidelines, OSHA, and the lower explosive limit (LEL) (see Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals* for more information). The IEEE 1635/ASHRAE *Guideline* 21 recommends limiting hydrogen concentration (by volume) in the battery room to 2% or less. If battery design information is not available, it is recommended that the exhaust system be designed to provide a minimum of five air changes per hour.

Fuel-Handling Building

New and spent fuel is stored in the fuel-handling building. The building is air conditioned for equipment protection and ventilated with a once-through air system to control potential airborne radioactivity. Normally, the level of airborne radioactivity is so low that the exhaust need not be filtered, although it should be monitored. If significant airborne radioactivity is detected, as can happen during an FHA, the normal building ventilation is isolated and the safety-related system started automatically. The safety-related ventilation system should exhaust through filtration trains powered by Class 1E buses.

Personnel Facilities

For nuclear power plants, these areas usually include decontamination facilities, laboratories, and medical treatment rooms.

Pumphouses

Cooling water pumps are protected by houses that are often ventilated by fans to remove the heat from the pump motors. If the pumps are essential or safety related, the ventilation equipment must also be considered safety related.

Radioactive Waste Building

The building is normally air conditioned for equipment protection and ventilated to control potential airborne radioactivity. The air may require filtration through HEPA filters and/or carbon adsorbers prior to release to the atmosphere.

Technical Support Center

The technical support center (TSC) is an outside facility located close to the control room. Although normally unoccupied, it is used by plant management and technical support personnel during training exercises and accident events.

The TSC HVAC system is designed to provide the same level of comfort (temperature and humidity) and radiological habitability conditions as provided for the control room. The TSC HVAC system is a non-safety-related system, but is augmented to the same level of importance as the main control room HVAC system. An air filtration system (HEPA, carbon, postfilter) provides the facility protection from radiological releases during an accident. Additional components, such as moisture separators, heaters, and prefilters, are sometimes also used. Because the operation and availability of the TSC is credited in the plant's emergency operating procedures, the TSC HVAC system should be designed with some redundancy such that maintenance on the HVAC system does not require declaration of the TSC as unavailable. Consult NUREG-0696 for additional information.

4.5 NONPOWER MEDICAL AND RESEARCH REACTORS

The requirements for HVAC and filtration systems for nuclear nonpower medical and research reactors are set by the NRC. The criteria depend on the type of reactor (ranging from a nonpressurized swimming pool type to a 10 MW or more pressurized reactor), the type of fuel, the degree of fuel enrichment, and the type of facility and environment. Many of the requirements discussed in the sections on various nuclear power plants apply to a certain degree to these reactors. It is therefore imperative for the designer to be familiar with the NRC requirements for the reactor under design.

4.6 LABORATORIES

Requirements for HVAC and filtration systems for laboratories using radioactive materials are set by the DOE and/or the NRC. Laboratories located at DOE facilities are governed by DOE regulations. All other laboratories using radioactive materials are regulated by the NRC. Other agencies may be responsible for regulating other toxic and carcinogenic material present in the facility.

Laboratory containment equipment for nuclear processing facilities is treated as a primary, secondary, or tertiary containment zone, depending on the level of radioactivity anticipated for the area and on the materials to be handled. For additional information see Chapter 17.

Glove Boxes

Glove boxes are windowed enclosures equipped with one or more flexible gloves for handling material inside the enclosure from the outside. The gloves, attached to a porthole in the enclosure, seal the enclosure from the surrounding environment. Glove boxes permit hazardous materials to be manipulated without being released to the environment.

Because the glove box is usually used to handle hazardous materials, the exhaust is filtered with a HEPA filter before leaving the box and prior to entering the main exhaust duct. In nuclear processing facilities, a glove box is considered primary confinement (see Figure 1), and is therefore subject to the regulations governing those areas. For non-nuclear processing facilities, the designer should know the designated application of the glove box and design the system according to the regulations governing that particular application.

Additional information for glove boxes can be found in documentation published by the American Glovebox Society (AGS).

Laboratory Fume Hoods

Nuclear laboratory fume hoods are similar to those used in non-nuclear applications. Air velocity across the hood opening must be sufficient to capture and contain all contaminants in the hood. Excessive hood face velocities should be avoided because they cause contaminants to escape when an obstruction (e.g., an operator) is positioned at the hood face. For information on fume hood testing, refer to ASHRAE *Standard* 110.

Radiobenches

A radiobench has the same shape as a glove box except that in lieu of the panel for the gloves, there is an open area. Air velocity across the opening is generally the same as for laboratory hoods. The level of radioactive contamination handled in a radiobench is much lower than that handled in a glove box.

4.7 DECOMMISSIONING NUCLEAR FACILITIES

The exhaust air filtration system for decontamination and decommissioning (D&D) activities in nuclear facilities depends on the type and level of radioactive material expected to be found during the D&D operations. The exhaust system should be engineered to accommodate the increase in dust loading, with more radioactive contamination than is generally anticipated, because the D&D activities dislodge previously fixed materials, making them airborne. Good housekeeping measures include chemical fixing and vacuuming the D&D area as frequently as necessary.

The following are some design considerations for ventilation systems required to protect the health and safety of the public and the D&D personnel:

- Maintain a higher negative pressure in the areas where D&D activities are being performed than in any of the adjacent areas.
- Provide an adequate capture velocity and transport velocity in the exhaust system from each D&D operation to capture and transport fine dust particles and gases to the exhaust filtration system.
- Exhaust system inlets should be as close to the D&D activity as possible to enhance the capture of contaminated materials and to minimize the amount of ductwork that is contaminated. A movable inlet capability is desirable.
- With portable enclosures, filtration of the enclosure inlet and exhaust air must sustain the correct negative internal pressure.

Low-Level Radioactive Waste

Requirements for the HVAC and filtration systems of low-level radioactive waste facilities are governed by 10 CFR 61. Each facility must have a ventilation system to control airborne radioactivity. The exhaust air is drawn through a filtration system that typically includes a demister, heater, prefilter, HEPA filter, and carbon adsorber, maybe followed by a second filter. Ventilation systems and their CAMs should be designed for the specific characteristics of the facility.

4.8 WASTE-HANDLING FACILITIES

The handling of radioactive waste requires inventory control of the different radioactive wastes. See the section on Codes and Standards for pertinent publications.

4.9 REPROCESSING PLANTS

A reprocessing plant is a specific-purpose facility. Spent nuclear fuel is opened and the contents dissolved in nitric acid to enable the constituents to be chemically separated and recovered. The offgas contains hazardous chemical and radioactive contaminants. Special cleanup equipment, such as condensers, scrubbers, cyclones, mist eliminators, and special filtration, is required to capture the vapors.

4.10 MIXED-OXIDE FUEL FABRICATION FACILITIES

The mixed-oxide (MOX) fuel fabrication facility (MFFF) is designed to produce MOX fuel for use in commercial nuclear power plants. In the United States, this facility is DOE operated and NRC licensed. MOX fuel fabrication consists of blending polished plutonium dioxide with uranium dioxide to form mixed-oxide pellets and loading them into fuel rods that form fuel assemblies for use as nuclear fuel. The MFFF HVAC design includes several important design features, and it complies with the performance criteria of 10 CFR 70, ASME AG-1, IEC/IEEE 60780-323, IEEE 344, and other applicable codes and standards.

In addition to maintaining the design environmental conditions, the HVAC systems are designed to maintain a pressure differential between the building confinement zones and between the building and the outdoors to ensure that cascaded airflow is from zones of lesser contamination potential to zones of greater contamination. The supply air system provides air to all confinement zones. Each confinement zone has its own exhaust system, and the pressure boundaries are maintained by cascaded airflow from tertiary confinement (negative) to secondary confinement (more negative), and then to primary confinement (most negative) zones. Primary and secondary confinement ventilation exhaust systems include both the intermediate and the final filter units in series. Tertiary confinement exhaust systems include only the final filter units. Intermediate filter units contain roughing filter(s) (i.e., stainless steel mesh filter) and HEPA filter(s) in series. Final filter units contain roughing filter(s), prefilter(s) (i.e., stainless steel/glass fiber mesh filter), and two banks of HEPA filter(s) in series. Air locks between confinement zones are designed to minimize personnel contamination exposure by maintaining pressures between various zones. Primary and secondary confinement exhaust systems are provided with on-site emergency diesel power, and battery back-up is provided for the primary confinement exhaust system.

Glove boxes (GB) are provided with room ventilation air, dry air, or inert gas, as determined by the process requirements. GB exhaust piping is connected to common headers for intermediate and final filtration. The ventilation system is designed to maintain a normal operating pressure of –300 to –500 Pa. Pressure-relief valves and vacuum breakers are provided to keep GB pressures within their structural design limits under conditions such as loss of supply flow or failed open valves. Additionally, dump valves (high-volume relief valves connected to exhaust header) are provided to ensure that, in the event of a glove port or bag port breach, the capture velocity at the breach is at least 0.6 m/s.

Detailed analysis, using compressible-flow pipe network analysis software, is performed for the MFFF ventilation systems and GB ventilation system. and the results are used for airflow balancing and to confirm that confinement is maintained during normal and design-basis accident conditions.

Sprinkler systems for HEPA filtration units are eliminated by integrating ventilation exhaust system design with fire-safety design. To confirm this design approach, a prototype final filter unit is tested in a testing laboratory for higher soot loading and differential pressures than calculated design values. The test results should show no breach in any filter in the prototype unit.

Sheet metal thickness and reinforcement for galvanized steel and stainless steel duct systems, with pressures from +7.5 to –7.5 kPa, round duct diameter up to 1525 mm, rectangular duct width up to 3660 mm, and temperature exposure up to 204°C, are designed using SMACNA standards. Seismic supports for the duct systems and redundant tornado dampers at outer wall openings are designed to protect the duct systems during abnormal events.

Mine-Cooling Techniques ... 30.7
Selecting a Mine-Cooling Method ... 30.9
Mechanical Refrigeration Plants ... 30.9
Mine Air Heating ... 30.10
Mine Ventilation ... 30.11

IN underground mines, lower worker productivity, illness, and potentially death can result from poor working environment conditions. It is therefore extremely important to design, install, and manage underground ventilation systems with the necessary care and attention. Excess humidity, high temperatures, inadequate oxygen, and excessive concentrations of potentially dangerous gases can significantly affect the quality of the working environment if not properly controlled. Ventilation and air cooling are needed in underground mines to minimize heat stress and remove contaminants. As mines become deeper, heat removal and ventilation problems become more difficult and costly to solve.

Caution: This chapter presents only a very brief overview of the principles of mine ventilation planning. The person responsible for such planning should either be an experienced engineer, or work under the direct supervision of such an engineer. Several English-language texts have been written on mine ventilation since 1980 (Bossard 1982; Hall 1981; Hartman et al. 1997; Hemp 1982; Kennedy 1996; McPherson 1993; Mine Ventilation Society of South Africa 1982; Tien 1999). The ventilation engineer is strongly encouraged to study these references.

Certain industrial spaces may contain flammable, combustible, and/or toxic aerosol concentrations under either normal or abnormal conditions. In spaces such as these, there are fire- and life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the most stringent code or standard, or that which best addresses and safeguards life safety. The facility's insurance carriers and relevant authorities having jurisdiction (AHJs) can be consulted for advice regarding specific situations.

1. DEFINITIONS

Definitions specific to mine ventilation and air conditioning are as follows.

Heat stress is a qualitative assessment of the work environment based on temperature, humidity, air velocity, and radiant energy. Many heat stress indices have been proposed (see Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* for a thorough discussion); the most common in the mining industry are effective temperature (Hartman et al. 1997), air cooling power (Howes and Nixon 1997), and wet-bulb temperature. The following wet-bulb temperature ranges were derived from experience at several deep western U.S. metal mines:

$t_{wb} \le 27°C$	Worker efficiency 100%
$27 < t_{wb} \le 29°C$	Economic range for acclimatized workers
$29 < t_{wb} \le 33°C$	Safety factor range; corrective action required
$33°C < t_{wb}$	Only short-duration work with adequate breaks

Heat strain is the physiological response to heat stress. Effects include sweating, increased heart rate, fatigue, cramps, and progressively worsening illness up to heat stroke. Individuals have different tolerance levels for heat.

Reject temperature, based on the heat stress/strain relationship, is the wet-bulb temperature at which air should be either rejected to exhaust or recooled. Reject temperature ranges between 25.5 and 29°C wb, depending on governmental regulation, air velocity, and expected metabolic heat generation rate of workers. Specifying the reject temperature is one of the first steps in planning air-conditioning systems. The ventilation engineer must be able to justify the reject temperature to management, because economics are involved. If set too high, work productivity, health, safety, and morale suffer; if too low, capital and operating costs become excessive.

Critical ventilation depth is the depth at which the air temperature in the intake shaft rises to the reject temperature through autocompression and shaft heat loads. Work areas below the critical ventilation depth rely totally on air conditioning to remove heat. The critical ventilation depth is reached at about 2500 to 3000 m, depending on surface climate in the summer, geothermal gradient, and shaft heat loads such as pump systems.

Base heat load is calculated at an infinite airflow at the reject temperature passing through the work area. The temperature of an infinite airflow will not increase as air picks up heat. **Actual heat load** is measured or calculated at the average stope temperature. It is always greater than the base heat load because the average stope temperature is lower than the reject temperature. More heat is drawn from the wall rock. **Marginal heat load** is the difference between base and actual heat loads. It is the penalty paid for using less than an infinite airflow (i.e., the lower the airflow, the lower the inlet temperature required to maintain the reject temperature and the higher the heat load).

Temperature-dependent heat sources (TDHs) depend on the temperature difference between the source and air. Examples include wall rock, broken rock, and fissure water (in a ditch or pipe). **Temperature-independent heat sources (TIHs)** depend only on the energy input to a machine or device after the energy required to raise the potential energy of a substance, if any, is deducted. Examples include electric motors, lights, substation losses, and the calorific value of diesel fuel.

Passive thermal environmental control separates heat sources from ventilating airflows. Examples include insulating pipes and wall rock, and blocking off inactive areas. **Active thermal environmental control** removes heat via airflow and air conditioning quickly enough that air temperature does not rise above the reject.

Positional efficiency, an important design parameter for mine cooling systems, is the cooling effect reaching the work area divided by the machine evaporator duty. The greater the distance between the machine and work area, the more heat that the cooling medium (air or water) picks up en route.

Percent utilization is the ratio of the evaporator duty of the refrigeration plant over a year in energy units to the duty if the plant had

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

worked the entire year at 100% load. This consideration becomes important when evaluating surface versus underground plants.

Coefficient of performance (COP) is usually defined as the evaporator duty divided by the work of compression in similar units. In mines, the overall COP is used: the evaporator duty divided by all power-consuming devices needed to deliver cooling to the work sites. This includes pumps and fans as well as refrigeration machine compressors.

A **shaft** is a vertical opening or steep incline equipped with skips to hoist ore and the cages (elevators) that move personnel and supplies. Electric cables and pipes for fresh water, compressed air, cooling water, pump water, and other utilities are installed in shafts. **Drifts** and **tunnels** are both horizontal openings; a tunnel opens to daylight on both ends, whereas a drift does not. In metal mining, a **stope** is a production site where ore is actually mined. In coal mining, coal is usually produced by either **longwall** (one continuous production face many metres long) or **room-and-pillar** (multiple production faces in a grid of rooms with supporting pillars in between) methods.

2. SOURCES OF HEAT ENTERING MINE AIR

Adiabatic Compression

Air descending a shaft increases in pressure (because of the mass of air above it) and thus also increases in temperature, as if compressed in a compressor. This is because of conversion of potential energy to internal energy, even if there is no heat interchange with the shaft and no evaporation of moisture.

For dry air at standard conditions (15°C at 101.325 kPa), the specific heat at constant pressure c_p is 1.004 kJ/(kg·K). For most work, c_p can be assumed constant, but extreme conditions might warrant a more precise calculation: 1 kJ is added (for descending airflow) or subtracted (for ascending airflow) to each kilogram of air for every 102 m. The dry-bulb temperature change is $1/(1.004 \times 102 \times 1)$ = 0.00977 K per metre or 1 K per 102 m of elevation. The specific heat for water vapor is 1.884 kJ/(kg·K). So, for constant air/vapor mixtures, the change in dry-bulb temperature is $(1 + W)/(1.004 + 1.884W)$ per 102 m of elevation, where W is the humidity ratio in kilograms of water per kilogram of dry air.

The theoretical heat load imposed on intake air by adiabatic compression is given in Equation (1), which is a simplified form of the general energy equation:

$$q = Q\rho E\,\Delta d \tag{1}$$

where

q = theoretical heat of autocompression, W
Q = airflow in shaft, m³/s
ρ = air density, kg/m³
E = energy added per unit distance of elevation change, 1 kJ/(102 m·kg)
Δd = elevation change, m

Example 1. What is the equivalent heat load from adiabatic compression of 140 m³/s at 1.12 kg/m³ density flowing down a 1500 m shaft?

Solution:

$$q = (140)(1.12)(1/102)(1500) = 2306 \text{ kW}$$

The adiabatic compression process is seldom truly adiabatic: *autocompression* is a more appropriate term. Other heating or cooling sources, such as shaft wall rock, introduction of groundwater or water sprayed in the shaft to wet the guides, compressed-air and water pipes, or electrical facilities, often mask the effects of adiabatic compression. The actual temperature increase for air descending a shaft usually does not match the theoretical adiabatic temperature increase, for the following reasons:

- The effect of seasonal and daily surface temperature fluctuations, such as cool night air on the rock or shaft lining (rock exhibits thermal inertia, which absorbs and releases heat at different times of the day)
- The temperature gradient of rock related to depth
- Evaporation of moisture in the shaft, which suppresses the dry-bulb temperature rise while increasing the moisture content of the air

The wet-bulb temperature lapse rate varies, depending on the entering temperature and humidity ratio, and the pressure drop in the shaft. It averages about 1.4 K wet bulb per 300 m, and is much less sensitive to evaporation or condensation than the dry bulb.

Electromechanical Equipment

Electric motors and diesel engines transfer heat to the air. Loss components of substations, electric input to devices such as lights, and all energy used on a horizontal plane appear as heat added to the mine air. Energy expended in pumps, conveyors, and hoists to increase the potential energy of a material does not appear as heat, after losses are deducted.

Vehicles with electric drives, such as scoop-trams, trucks, and electric-hydraulic drill jumbos, release heat into the mine at a rate equivalent to the nameplate and a utilization factor. For example, a 100 kW electric loader operated at 80% of nameplate for 12 h a day liberates (100 kJ/s)(12 h)(3600 s/h)(0.80) = 3 456 000 kJ/day. Dividing by 24 h/day gives an average heat load over the day of 144 000 kJ/h. During the 12 h the loader is operating, the heat load is doubled to 288 000 kJ/h. The dilemma for the ventilation engineer is that, if heat loads are projected at the 144 000 rate, the stope temperature will exceed the reject temperature for half the day, and the stope will be overventilated for the other half; if projected at 288 000 kJ/h, the stope will be greatly overventilated when the loader is not present. Current practice is to accept the additional heat load while the loader is present. Operators get some relief when they leave the heading to dump rock, at which time the ventilation system can partially purge the heading.

Diesel equipment dissipates about 90% of the heat value of the fuel consumed, or 35 000 kJ/L, to the air as heat (Bossard 1982). The heat flow rate is about three times higher for a diesel engine than for an equivalent electric motor. If the same 100 kW loader discussed previously were diesel powered, the heat would average about 475 000 kJ/h over the day, and 950 000 kJ/h during actual loader operation. Both sensible and latent heat components of the air are increased because combustion produces water vapor. If a wet scrubber is used, exhaust gases are cooled by adiabatic saturation and the latent heat component increases even further.

Fans raise the air temperature about 0.25 K per kPa static pressure. Pressures up to 2.5 kPa are common in mine ventilation. This is detrimental only when fans are located on the intake side of work areas or circuits.

Groundwater

Transport of heat by groundwater has the largest variance in mine heat loads, ranging from essentially zero to overwhelming values. Groundwater usually has the same temperature as the virgin rock. Ventilating airflows can pick up more heat from hot drain water in an uncovered ditch than from wall rock. Thus, hot drain water should be stopped at its source or contained in pipelines or in covered ditches. Pipelines can be insulated, but the main goal is isolating the hot water so that evaporation cannot occur.

Heat release from open ditches increases in significance as airways age and heat flow from surrounding rock decreases. In one Montana mine, water in an open ditch was 22 K cooler than when it flowed out of the wall rock; the heat was transferred to the air.

Table 1 Maximum Virgin Rock Temperatures

Mining District	Depth, m	Temperature, °C

Evaporation of water from wall rock surfaces lowers the surface temperature of the rock, which increases the temperature gradient of the rock, depresses the dry-bulb temperature of the air, and allows more heat to flow from the rock. Most of this extra heat is expended in evaporation.

Example 2. Water leaks from a rock fissure at 1.26 L/s and 52°C. If the water enters the shaft sump at 29°C, what is the rate of heat transfer to the air?

Solution:

$$\text{Heat rate} = (1.26\text{ L/s})(1\text{ kg/L})[4.1868\text{ kJ/(kg·K)}](52 - 29°\text{C}) = 121.33\text{ kW}$$

Wall Rock Heat Flow

Wall rock is the main heat source in most deep mines. Temperature at the earth's core has been estimated to be about 5700°C. Heat flows from the core to the surface at an average of 0.07 W/m². The implication for mine engineers is that a geothermal gradient exists: rock gets warmer as the mine deepens. The actual gradient varies from approximately 1 to over 7 K per 100 m of depth, depending on the thermal conductivity of local rock. Table 1 gives depths and maximum **virgin rock temperatures (VRTs)** for various mining districts. Table 2 gives thermal conductivities and diffusivities for rock types commonly found in mining. These two variables are required for wall rock heat flow analysis.

Wall rock heat flow is unsteady-state: it decays with time because of the insulating effect of cooled rock near the rock/air boundary. Equations exist for both cylindrical and planar openings, but this section discusses cylindrical equations (Goch and Patterson 1940). The method can solve for either instantaneous or average heat flux rate. The instantaneous rate is recommended because it is better used for older tunnels or drifts. For newer drifts, a series of instantaneous rates over short time periods is equivalent to the average rate. The Goch and Patterson calculations are easily performed on a computer using the following variables and equations:

$$\text{Fo} = \frac{\alpha\theta}{r^2} \tag{2}$$

$$\varepsilon = \{1.017 + 0.7288\log_{10}(\text{Fo}) + 0.1459[\log_{10}(\text{Fo})]^2 - 0.01572[\log_{10}(\text{Fo})]^3 - 0.004525[\log_{10}(\text{Fo})]^4 + 0.001073[\log_{10}(\text{Fo})]^5\}^{-1} \tag{3}$$

$$\text{Heat flux, W/m}^2 = \frac{k(t_{vr} - t_a)(\varepsilon)}{r} \tag{4}$$

$$\text{Total heat flow (W)} = (\text{Heat flux})(L)(P) \tag{5}$$

where

Fo = Fourier number, dimensionless
k = thermal conductivity of rock, W/(m·K)
L = length of section, m
P = perimeter of section, m
r = radius of circular section, m, or equivalent radius of rectangular section; $r = (A/\pi)^{1/2}$, where
  A = cross-sectional area of section, m²
t_a = air dry-bulb temperature, °C
t_{vr} = virgin rock temperature, °C
α = thermal diffusivity of rock (equals $k/\rho c$), m²/h, where
  ρ = rock density, kg/m³
  c = heat capacity, kJ/(kg·K)
ε = function of Fourier number for instantaneous rate, dimensionless (Whillier and Thorpe 1982)
θ = average age of section, h

Example 3. A 150 m long section of drift, 3.7 m high by 4.5 m wide, was driven in quartzite with a VRT of 43°C. The drift was started 20 days before the face was reached, and the face is 1 day old. One design criterion is keeping the average dry-bulb temperature of the air in the drift at 27°C. How much heat will flow into the section?

Solution: From Table 2, the thermal conductivity of quartzite is 5.50 W/(m·K) and the diffusivity is 0.008 m²/h. The average age of the section is (20 + 1 days)/2 = 10.5 days, or 252 h. The cross-sectional area of the drift is 3.7 × 4.5 = 16.65 m² and the perimeter is (3.7 + 4.5) × 2 = 16.4 m. The equivalent radius of the drift is $(16.65/\pi)^{1/2}$ = 2.30 m. The following equations are then applied:

Using Equation (2), $\text{Fo} = \frac{\alpha\theta}{r^2} = \frac{(0.008)(252)}{2.30^2} = 0.381$

Using Equation (3), $\varepsilon = 1.336$

Using Equation (4),

$$\text{Heat flux} = \frac{k(t_{vr} - t_a)(\varepsilon)}{r} = \frac{(5.50)(43 - 27)(1.336)}{2.30} = 51.12\text{ W/m}^2$$

Using Equation (5),

$$\text{Total heat flow} = (\text{Heat flux})(L)(P) = (51.12)(150)(16.4) = 125\,755\text{ W}$$

Thus, to keep the average temperature of the drift section at 27°C db, 126 kW of refrigeration are needed in that section.

The Goch and Patterson method lacks a convective heat transfer coefficient at the rock/air boundary, and overestimates heat transfer in a dry drift by 8 to 15%. It also does not have a wetness factor. Because a drift with water on the perimeter draws more heat from wall rock, the method underestimates heat flow. Almost all drifts have some wetness on the floor, back, and side walls, though it may not be visible. Comparisons of the Goch and Patterson method with field measurements and results from commercial software under typical conditions (a drift with 20 to 60% of the perimeter wetted) indicate that the overestimate is nearly equal to the underestimate. When using Goch and Patterson for drift heat loads, keep drift section lengths under 60 m and do not apply any contingency factor to the calculated heat load.

Heat load calculations for stoping require a large number of variables. Irregular shapes, sporadic advance rates, intermittent TIH sources, fissure water, and non-homogeneous or anisotropic (with directionally differing heat conducting properties) rock are difficult to model (Duckworth and Mousset-Jones 1993; Marks and Shaffner 1993). For cut-and-fill stoping with a sand floor, measured heat loads are about 70% of the heat loads predicted by Goch and Patterson. Other stoping methods such as room-and-pillar or tabular reef mining are more amenable to planar heat load equations. Patterson (1992) gives empirical graphs relating heat load to productivity and depth.

Ventilation engineers needing to project heat loads for new mines or extensive tunnel projects can write their own computer program using the Goch and Patterson equations, or use a commercial software package. These programs account for convective heat transfer, wetness, elevation changes, and TIH sources that can make hand calculations tedious. However, program input must be carefully derived or the output will be misleading.

Heat from Broken Rock

Freshly blasted broken rock can liberate significant amounts of heat in a confined area. The broken rock's initial and final temperatures, and cooling of the rock en route from the face to the hoisting facility, must be estimated.

$$\text{Heat, kJ} = (\text{mass})(\text{specific heat})(\text{VRT} - \text{final temperature}) \quad (6)$$

$$\text{Heat load, W} = \frac{\text{Heat}}{(\text{time, s})} \quad (7)$$

Example 4. A 3.7 m high by 4.5 m wide by 3 m long drift round is blasted in quartzite where the VRT is 49°C. Quartzite has a 2700 kg/m^3 density and a 0.8 kJ/(kg·K) specific heat. By the time the rock is hoisted to the surface 4 h later, it has cooled to 32°C. What is the heat load imposed on the drift and shaft?

Solution:

$$\text{Heat} = (3.7\text{ m} \times 4.5\text{ m} \times 3\text{ m} \times 2700\text{ kg/m}^3)[0.8\text{ kJ/(kg·K)}] \times (49 - 32°\text{C}) = 1.8342 \times 10^6\text{ kJ}$$

$$\text{Heat load} = \frac{1.8342 \times 10^6\text{ kJ}}{14\,400\text{ s}} = 127\text{ kW}$$

Heat from Other Sources

Heat produced by oxidation of timber and sulfide minerals can be locally significant and even cause mine fires. Fortunately, timber is seldom used for ground support in modern mines. Heat from blasting can also be appreciable. The typical heat potential in various explosives is similar to that of 60% dynamite, about 4200 kJ/kg. This heat is usually swept out of the mine between shifts and thus is not tallied in heat load projections. Body metabolism is only a concern in refuge chambers and is rarely (if ever) included in heat load projections. Although these heat sources are usually neglected, the ventilation engineer must remain vigilant for cases where local effects might be significant.

Summation of Mine Heat Loads

Mine cooling requirements should be estimated after mining methods, work sites, production rates, and equipment are specified, and heat sources identified. The time frame, during which the ventilation and cooling systems must provide an acceptable work environment, is normally 10 years, but can vary.

Total heat for a mine or mine section is the summation of all TIH and TDH sources. It helps to plot heat sources on a schematic. The heat load from the surface to the entrance of the stope is assessed first, starting with TIH sources because they influence TDH sources. Shaft heat loads, autocompression, and drift heat loads are added to the air en route to stopes. The process should take only one iteration to find a stope entering temperature. Stope heat load is calculated by assuming that the wet bulb leaving the stope equals the design reject temperature. The air temperature entering the stope is estimated, and heat load equations are used to calculate the exit temperature. If this exit temperature exceeds the reject temperature, a lower stope entering temperature is assumed and a new exit temperature is calculated. The process is repeated with new stope entering temperatures until the calculated stope exit temperature equals the design reject temperature.

If the entering stope temperature calculated from the surface is greater than the entering stope temperature calculated from the reject temperature, higher airflow or air conditioning will be needed. Psychrometrics can determine the size of the airflow increase or cooling required.

3. HEAT EXCHANGERS

Underground heat exchangers can be water-to-refrigerant, air-to-refrigerant, water-to-water, air-to-water, or air-to-air. Brine can be used instead of water where freezing might occur. Heat exchangers can be direct (e.g., spray chambers) or indirect (e.g., conductive heat transfer through tubes or plates).

See Chapters 19 to 24, 26 to 30, 37 to 40, and 42 to 48 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for general guidelines when designing large cooling plants for mine duty.

Shell-and-Tube and Plate Heat Exchangers

Shell-and-tube heat exchangers are the mainstay of refrigeration machines used in mines. Machines in the 700 to 1400 kW range may use either direct expansion (DX) or flooded evaporators. In both cases, the working fluid (refrigerant or water) is circulated through the tubes.

South African mines often use plate-and-frame evaporators in large surface chilled-water plants (van der Walt and van Rensburg 1988). These machines can cool water to within a degree of freezing without danger of rupture. In contrast, shell-and-tube evaporators should not be expected to chill water below 3°C. Manufacturers must be consulted.

Shell-and-tube water-to-water heat exchangers have been used in mine cooling systems to avoid pumping return water against high heads (the U-tube effect). Chilled water from the surface is sent down to the high-pressure (tube) side of the exchanger. Water on the low-pressure side operates district chiller systems or spot coolers. The shell-and-tube water-to-water heat method is not very popular, perhaps because it requires high-pressure supply and return piping. The second law of thermodynamics limits the approach temperature of the outlet high-pressure water to the inlet low-pressure water temperature. This tends to limit heat removal in deep mines that would require at least three heat exchanger stations, in series, in the shaft.

Cooling Coils

Cooling coils can be DX or chilled-water coils. DX coils are used with spot coolers and typically range from 50 to 200 kW. Some modern spot coolers use dual coils in parallel for compactness. Chilled-water coils, used in district chiller systems, are also used in a wide range of sizes.

Air-side fouling is the main operational problem with cooling coils in mines. Coils with fin spacing tighter than 4.2 mm are not recommended. Water-side fouling is minimal if the water is of fair quality, the circuit is closed, and a corrosion inhibitor is added to the circuit.

Small Spray Chambers

Small spray chambers can be used as an alternative to cooling coils. Heat transfer is direct, air-to-water. Spray chamber maintenance is minimal, and the amount of water sprayed is typically one-half to one-third that required for a cooling coil at the same duty. Some washing effect also occurs in the chamber.

Spray chambers are open systems that dump water into a ditch or collection pond after spraying. This water drains to the dewatering system or is pumped back to the chiller plant. Small spray chambers are still popular for small duties in mines that chill service water, but the pumping system must be able to handle the increased service water requirement.

Cooling Towers

When heat loads are large, the full capacity of a mine's heat removal system will probably be needed. A key component of the heat removal system is exhaust air. The ventilation engineer for a deep, hot mine must be proficient at designing underground cooling towers for condenser heat rejection, and spray chambers for cooling airflows.

Rather than using the standard HVAC&R method of assessing cooling tower performance, as described in Chapter 40 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, mining engineers use the South African factor-of-merit method, developed in the 1970s for designing direct-contact heat exchangers (Bluhm 1981; Burrows 1982; Whillier 1977). This method requires a psychrometric program and the following equations:

$$\Sigma = h - (c_{pw})(W)(t) \tag{8}$$

Note that t is either the wet-bulb temperature for air, or the water temperature, depending on whether Σ_{ai} or Σ_{wi} is calculated.

$$q = (M_w)(c_{pw})(t_{wi} - t_{wo}) \tag{9}$$

$$q = (M_a)(\Sigma_{ao} - \Sigma_{ai}) \tag{10}$$

$$n_w = \frac{t_{wi} - t_{wo}}{t_{wi} - t_{ai}} \tag{11}$$

$$R = \frac{(M_w)(c_{pw})(t_{wi} - t_{ai})}{(M_a)(\Sigma_{wi} - \Sigma_{ai})} \tag{12}$$

$$N = \frac{F}{(1 - F)(R^{0.4})} \tag{13}$$

$$n_w = \frac{(1 - e^{-N(1-R)})}{(1 - Re^{-N(1-R)})} \quad \text{(for counterflow towers)} \tag{14}$$

where

a = air
c_{pw} = specific heat of water at constant pressure, 4.1868 kJ/(kg·K)
F = factor of merit, roughly equivalent to *UA* factor in conductive heat transfer, dimensionless; ranges from 0 (no heat transfer) to 1 (as much as heat transfer as allowed by second law takes place)
h = enthalpy of moist air, kJ/kg
i = inlet
M = mass flow rate, water or air, kg/s
N = number of transfer units, an intermediate factor for calculating water efficiency
n_w = water efficiency, dimensionless
o = outlet
q = heat rate to be transferred in chamber, W
R = tower capacity factor, dimensionless; ratio of heat capacity of water to heat capacity of air under limits of second law
t = temperature, °C
W = humidity ratio of moist air, kg water per kg air
w = water
Σ = energy of air, kJ/kg; total enthalpy minus enthalpy of liquid water evaporated into air (approximated by $c_{pw}Wt$, where t is wet bulb); dependent only on wet bulb and barometric pressure

Designing an underground cooling tower requires the exhaust air mass flowrate M_a, the wet- and dry-bulb temperatures available at the tower, and the ambient barometric pressure. A psychrometric program is needed to calculate enthalpy, density, humidity ratio, and specific volume from the wet bulb, dry bulb, and barometric pressure. Tower airflow is taken from measurements or from the mine plan. The temperature, if not measurable (e.g., in a new mine), can be assumed to approach the reject temperature. Experience shows that air usually enters exhaust at about 27 to 28°C wb. Designing a cooling tower involves the following steps:

1. Calculate heat rejection rate in the tower (evaporator duty × condenser heat rejection factor, typically between 1.2 and 1.4). Discuss with the manufacturer.
2. Select condenser water flow and use Equation (9) to calculate Δt_w in the tower and machine condensers.
3. Specify cooling tower diameter and tower air velocity.
4. Calculate M_w/M_a.
5. Calculate heat rejection rate per m^3/s in tower.
6. Calculate air enthalpy h and use Equation (8) to calculate Σ_{ai}.
7. Select a factor of merit for tower using Table 3.
8. Estimate tower capacity factor R (e.g., $R = 0.5$). Using $R = 1$ in Equation (14) will result in division by zero. Skip to Step 10 if $R = 1$, and use the value of F for n_w.
9. Use Equation (13) to calculate N.
10. Use Equation (14) to calculate water efficiency n_w.
11. Use Equation (11) to calculate inlet water temperature t_{wi}.
12. Use Equation (8) to calculate Σ_{wi}, the energy of air at inlet water temperature t_{wi}.
13. Use Equation (12) to calculate a new tower capacity factor R.
14. Compare the R calculated in Step 13 with the R estimated in Step 8. If different by more than 1%, return to Step 8 and re-estimate R. Repeat Steps 9 to 14 until the calculated R is within 1% of the estimated R.
15. Calculate air and water temperatures leaving the tower and the evaporation rate.

Keep the following empirical design criteria in mind during Steps 1 to 5:

- Realistic Δt_w in tower is 6.6 to 8.8 K
- Realistic water loading in tower is 4 to 12 L/s per square metre
- Optimum water velocity in machine condenser tubes (0.015 to 0.066 m/s, per manufacturer's recommendations) is based on tubing material and water quality
- Realistic maximum air velocity in tower is 8 m/s
- Realistic ratios of the mass flows of water to air M_w/M_a range from 0.5 to 2.5
- A realistic heat rejection rate in tower is 20 to 40 kW per L/s

Table 3 Factors of Merit

	Factor of Merit Range	Source
Vertical counterflow, open, unpacked	0.50 to 0.70	Hemp 1982
Horizontal cross-flow		
Single-stage	0.40 to 0.55	Hemp 1982
Two-stage	0.57 to 0.72	Marks 1988
Three-stage	0.69 to 0.81	Marks 1988
Four-stage	0.76 to 0.87	Marks 1988
Commercial packed cooling		
Counterflow tower	0.68 to 0.78	Patterson 1992
Cross-flow tower	0.55 to 0.65	Patterson 1992

Values outside these design parameters are sometimes used (especially when plant duty is increased at a future date), but the penalty paid is a higher condensing temperature and lower COP. Once q, F, M_a, t_{ai}, and M_w are specified, only one t_{wi}, t_{wo}, and t_{ao} will balance all equations.

Example 5. Design a cooling tower for a 3500 kW refrigeration plant planned for a deep, hot mine. Exhaust airflow for heat rejection is 118 m^3/s at 28°C saturated. Barometric pressure is 104.983 kPa (300 m below sea level). What size cooling tower is needed, how much condenser cooling water is required, what are the inlet and outlet air and water temperatures, and how much makeup water is needed?

Solution:

Step 1. For a refrigeration plant to produce 3500 kW of cooling, it must reject about 3500 kW × 1.25 condenser heat rejection factor = 4375 kW.

Step 2. Select a condenser water flow. For this example, start with 0.018 L/s per kilowatt rejected. The condenser flow is thus 78.75 L/s, or 78.75 kg/s at 1 kg/L. The change in water temperature is calculated from Equation (9):

$$\Delta t_w = \frac{4375 \text{ kW}}{(78.75 \text{ kg/s})[4.1868 \text{ kJ/(kg·K)}]} = 13.3 \text{ K}$$

That exceeds the realistic 6.6 to 8.8 K Δt_w, so arbitrarily increase the water flow to 125 L/s and recalculate Δt_w. In practice, selecting the condenser water flow is anything but arbitrary. Generally, the higher the flow, the better, but higher flows require larger condensers to keep tube velocity within design limits, larger cooling towers with more nozzles, and significantly larger pumps. Actual condenser water flow is a compromise between machine and tower performance, capital cost, and overall plant COP (operating cost). At 125 L/s for this example, Δt_w = 8.4 K, which is acceptable.

Step 3. Specify cooling tower diameter by using a midrange value to 8 L/s per m^2.

$$(\pi/4)d^2 = \frac{125 \text{ L/s}}{8 \text{ L/(s·m}^2)} \qquad \therefore d = 4.46 \text{ m} \approx 4.5 \text{ m}$$

$$\text{Air velocity} = \frac{118 \text{ m}^3\text{/s}}{(\pi/4)(4.5^2)} = 7.42 \text{ m/s } (< 8 \text{ m/s; acceptable})$$

Step 4. Calculate M_w/M_a.

$$M_w = (125 \text{ L/s})(1 \text{ kg/L}) = 125 \text{ kg}_w\text{/s}$$

The specific volume for 28°C saturated inlet air at 104.983 kPa is 0.86 m^3/kg$_a$. M_a is therefore

$$M_a = \frac{118 \text{ m}^3\text{/s}}{0.86 \text{ m}^3\text{/kg}_a} = 137 \text{ kg}_a\text{/s}$$

$$M_w/M_a = \frac{125}{137} = 0.9142 \qquad (0.5 < M_w/M_a < 2.5\text{; acceptable})$$

Step 5. The heat rejection rate in the tower is

$$\frac{4375 \text{ kW}}{118 \text{ m}^3\text{/s}} = 37 \text{ kW per m}^3\text{/s}$$

This rate is approaching the upper acceptable limit. Consideration should be given to routing more air through the tower if possible. All design criteria have now been met.

Step 6. The enthalpy of air h_{ai} at 28°C saturated and 104.983 kPa is 109 kJ/kg. Σ_{ai} = 109 – (4.1868)(0.037)(28) = 104.66 kJ/kg.

Step 7. Select a factor of merit for the tower. From Table 3, an open, unpacked, vertical counterflow cooling tower can conservatively be expected to have a 0.55 factor of merit. If the tower is well designed and actually has a higher factor, the tower will return cooler water to the plant and COP will increase.

Step 8. Estimate R = 0.5 (first pass).

Step 9. Calculate N from Equation (13):

$$N = \frac{0.55}{(1 - 0.55)(0.5^{0.4})} = 1.613$$

Step 10. Calculate n_w from Equation (14):

$$n_w = \frac{1 - e^{-1.613(1 - 0.5)}}{1 - 0.5e^{-1.613(1 - 0.5)}} = 0.713$$

Step 11. Calculate t_{wi} from Equation (11) (after manipulation, and assuming that $t_{wi} - t_{wo} = \Delta t_w$):

$$t_{wi} = \frac{\Delta t_w}{n_w} + t_{ai} = \frac{8.3}{0.713} + 28 = 39.64°\text{C}$$

Step 12. Σ_{wi} at 39.64°C and 104.983 kPa = 180.75 – (4.1868)(0.047)(39.64) = 172.95 kJ/kg.

Step 13. Calculate the new R using Equation (12):

$$R = \frac{(125)(4.1868)(39.64 - 28)}{(137)(172.95 - 104.66)} = 0.651$$

Step 14. The new R is higher than the 0.5 R estimated in Step 8. Return to Step 8 and iterate until the R calculated in Step 13 equals the R projected in Step 8. This occurs at R = 0.662.

Step 15. All other values can now be calculated.

Per Step 11, t_{wi} = 39.64°C

$$t_{wo} = 39.64 - 8.3 = 31.34°\text{C}$$

$$\Sigma_{ao} = \Sigma_{ai} + \frac{4375 \text{ kW}}{(137 \text{ kg/s})} = 104.66 + 31.93$$
$$= 136.59 \text{ kJ/kg}$$

$$t_{ao} = 34.7°\text{C (via psychrometric iteration)}$$

The water evaporated in the tower is the difference in humidity ratios ΔW × the mass flow of dry air. From psychrometric equations, $W_{28°C}$ = 0.0237 kg$_w$/kg$_a$ and $W_{34.7°C}$ = 0.0347 kg$_w$/kg$_a$.

$$\text{Evaporation rate} = (137 \text{ kg}_a\text{/s})(0.0347 - 0.0237 \text{ kg}_w\text{/kg}_a) = 1.5 \text{ L/s}$$

Total makeup water depends on evaporation rate, water carryover (if any), and blowdown used to control dissolved solids in the condenser circuit. Leakages and carryover can be deducted from the blowdown. Makeup water is usually planned at 1 to 3% of the condenser water flow, depending on the quality of the makeup water, allowable cycles of concentration of dissolved solids, and water treatment plan.

Vertical unpacked cooling towers in mines often use clog-resistant full-cone nozzles circling the top of the tower, at least 12 m above the pond. South African mines tend to use ham-type sprayers.

Nozzle pressure of 200 kPa (gage) is typically specified: lower water pressures do not generate the fine water droplets preferred for heat transfer, and higher pressures increase pumping costs. Higher pressures can also impinge water drops into side walls, where the water runs in sheets down the sides. This drastically reduces the surface area of the water flow, which reduces heat transfer. Rings circling the tower are recommended to kick water running down the sides back into the airstream. Unpacked towers do not have as high a factor of merit as towers with film packing or splash bars, but they are virtually maintenance free and have low resistance to airflow. Figure 1 shows a typical underground vertical counterflow cooling tower.

After a cooling tower begins operation, the actual factor of merit should be determined. This is accomplished by measuring air and water flow rates and temperatures at the tower inlet and outlet, and then working the cooling tower equations in reverse. The actual factor of merit can be used to determine performance at other inlet conditions. This applies to mine, industrial, and commercial cooling towers.

Large Spray Chambers (Bulk Air Coolers)

The procedure for designing spray coolers is the same as for cooling towers, with the following minor changes:

$$q = M_w c_{pw}(t_{wo} - t_{wi}) \tag{15}$$

$$q = M_a(\Sigma_{ai} - \Sigma_{ao}) \tag{16}$$

$$n_w = \frac{1 - e^{-R(1 - X)}}{R} \tag{17}$$

where $X = e^N$ for horizontal cross-flow chambers.

A perfect counterflow tower has a factor of merit of 1.0, but the factor of merit for a single cross-flow chamber (see Chapter 40 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*) cannot exceed 0.63 (Bluhm 1981). Two-stage cross-flow chambers are most often specified. Counterflow performance is approximated, and the counterflow equation for water efficiency can be used. Three-stage chambers can be designed when water flow must be limited to control pumping costs. Four-stage chambers are rarely cost effective in mining applications.

Spray chambers often use vee-jet nozzles at 200 kPa (gage), placed uniformly along the chamber length and designed to cover the cross section evenly. Sprays should just reach the back of the chamber. Mist eliminators are usually installed at the chamber exit. Whereas cooling towers need makeup water to replace evaporated water, bulk air coolers gain water through condensation. This water can be sent to the condenser side as makeup. Figure 2 shows a typical two-stage horizontal cross-flow spray chamber.

4. MINE-COOLING TECHNIQUES

A mine-cooling system typically sends air, water, or ice into the mine at a low enthalpy state and removes it at a higher one. In hot mines, heat is typically rejected to water being pumped to the surface, and to exhaust air being drawn from the mine. There are many combinations and variations on how this is accomplished. Economics and site-specific conditions determine the optimum methods.

Increasing Airflows

This alternative should be considered first: it is usually less expensive to moderately increase airflows than to install refrigeration if the mine is above the critical ventilation depth. Increasing airflows also helps remove diesel fumes, which is increasingly important for modern mining. However, in deep (usually older) mines with small cross-sectional airways, airflow increases may not be practical because of the cube relationship between fan power and airflow increase through a given resistance. Circuit resistance reduction via new airways or stripping existing airways is very expensive.

Chilling Service Water

When a mine requires additional heat removal, and airflow increases are not practical, consider chilling the service water. Most mining methods require that water be sprayed on rock immediately after blasting to control dust; chilled water can intercept rock heat before the heat escapes into the air. This is a very flexible method of heat removal because it is applied when and where it is needed the most. After blasted rock is removed, the water is turned off and routed elsewhere. Main water lines should be insulated when service water is chilled.

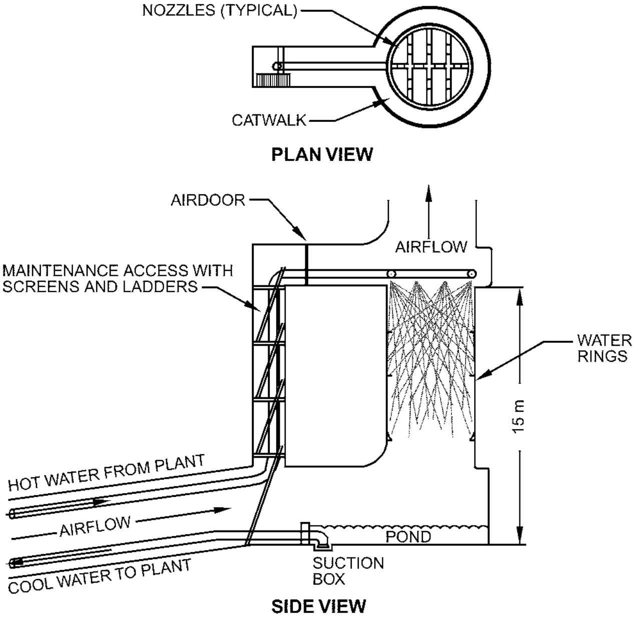

Fig. 1 Underground Open Counterflow Cooling Tower

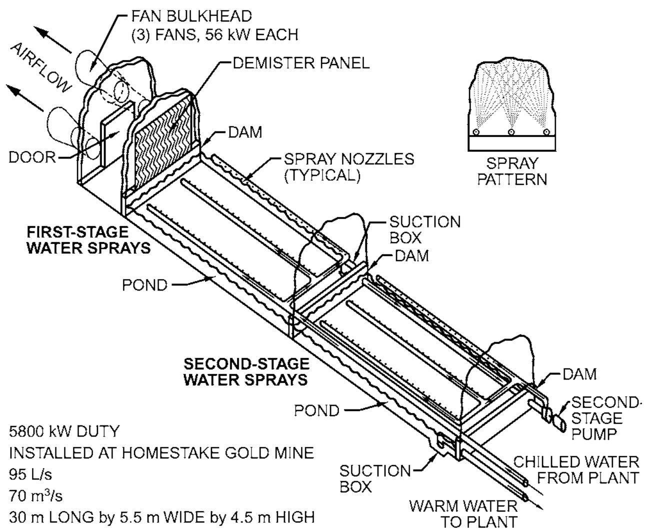

Fig. 2 Two-Stage Horizontal Spray Chamber

Water is usually chilled in surface plants. A single-pass system is used if regional water supplies are plentiful. If scarce, water is pumped to the surface, recooled, and returned underground. Recycling can ease discharge permit requirements and thus save on treatment costs. Some mines have zero discharge permits. Regions with low winter temperatures and low relative humidities during summer have a natural cooling capacity that is adaptable to water chilling on the surface. Warm mine water is precooled in an evaporative cooling tower before being sent to the refrigeration plant.

Reducing Water Pressure and Energy Recovery Systems

All mines send water underground for drilling, cleaning, suppressing dust, and wetting broken rock. Hot mines using extensive cooling systems often send large volumes of water underground solely for air conditioning. The pressure of descending water must be broken periodically. The most common methods are the open cascade system and pressure-reducing valves. Turbines can also break the pressure and recover a significant portion of the potential energy that would otherwise be lost. Two types of turbines are suitable for mine use: the Pelton wheel, which is most often used, and a centrifugal pump specially designed to run in reverse. The Pelton wheel rotor is shaped like the spokes of a wheel, with cups attached to the ends of the spokes. One or two nozzles shoot high-pressure water onto the cups, spinning the wheel. It is at least 80% efficient over a range of flows, simply constructed, and readily controlled. A wide operating range is important because water demand fluctuates. A turbine can turn either a generator or pump. Turning a generator is preferred because it separates service and cooling water from the mine dewatering system so that downtime in one system is less likely to disrupt the other.

Besides providing power to help return service water to the surface, turbines have another advantage: unrecovered potential energy is converted to heat at a rate of 1 kJ/kg per 102 m of depth. If, for example, a 1830 m deep mine uses 63 L/s for air conditioning without energy recovery, the water will heat by 4.28 K. If 80% efficient turbines are used, the water temperature rise is about $0.2 \times 4.28 = 0.856$ K. The refrigerating effect lost is only 225 instead of 1129 kW.

Other energy recovery devices include hydrotransformers (large pistons transfer force from the high-pressure side to the lower-pressure side), and three-pipe feeder systems that deliver chilled water on one side while pumping out crushed ore on the other. These concepts have been tested in Europe and South Africa.

Bulk Cooling Versus Spot Cooling

Engineers must balance bulk cooling and spot cooling. **Bulk cooling** using a centrally located plant cools the entire mine, or a large section of it. Benefits are lower cost per kilowatt installed, generally better maintenance, and lower temperatures in non-stoping areas such as haul drifts. Bulk cooling intake air is often done at warm-climate mines to provide winter-like or better conditions year round. Air is cooled in large direct-contact spray chambers adjacent to the shaft and then injected into the shaft below the main landing.

Cooling the entire mine draws more heat from surrounding wall rock, so a larger system must be designed to ensure proper stope cooling (i.e., positional efficiency suffers). When a multilevel mine is bulk cooled, cooling may be wasted on upper levels where heat load is low.

Spot cooling provides adequate temperature control in exploration and development headings, and in stopes on the fringes of mining activity. Total heat load is lower, but cost per kilowatt is higher, and temperatures in some areas might exceed design limits.

Combination (Integrated) Surface Systems

Combination (or integrated) systems can cool both air and water. Surface plants devote a higher fraction of cooling capacity to bulk cool intake air in the summer. In winter, a higher fraction is used to chill service or air-conditioning water. Water is delivered underground via open or closed systems, with or without energy recovery. Figure 3 shows components of an integrated mine cooling system.

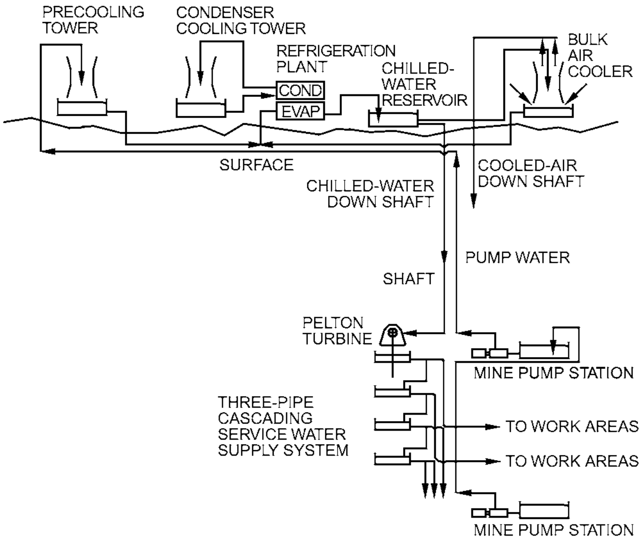

Fig. 3 Integrated Cooling System

Underground Refrigeration

Larger refrigeration machines also can be located underground. They usually produce chilled water for cooling air in spray chambers, and heat is rejected to exhaust air via cooling towers. Another method is to operate district cooling systems, using a chiller to produce water for a closed network of cooling coils installed in parallel. These coils can be used in auxiliary systems at individual work areas, or installed in a bank. As with spot coolers, coils should be installed upwind of blasting to limit air-side fouling. Condenser heat from district chiller systems is rejected either to service water or to the mine-dewatering system.

Ice Plants

For ultradeep mines (>3660 m), or those at the performance limits of existing water and airflow heat rejection systems, ice cooling should be considered. In going from 0 to 32°C before being pumped out of the mine, cooling water starting as ice can remove about 4.5 times the heat as the same mass flow of chilled water in going from 7 to 32°C:

$$\text{Heat removal (kJ/kg)} = \text{Sensible} + \text{Latent}$$

$$\text{Heat removal of chilled water} = [4.1868 \text{ kJ/(kg·K)}](32 - 7) = 105 \text{ kJ/kg}$$

$$\text{Heat removal of ice} = [4.1868 \text{ kJ/(kg·K)}](32 - 0) + 335 \text{ kJ/kg} = 469 \text{ kJ/kg}$$

$$\text{Heat removal factor increase of ice over water} = 469/105 = 4.5$$

South African mines have been at the forefront in this application (Sheer et al. 2001). Both chunk and slurry delivery methods send ice to underground chambers, where it mixes with warm water returning from the mining area. The cold mixed water is then sent back to the mining area.

Several successful systems have been installed. Cost has dropped as technology improves; the overall COP of ice systems for ultradeep mines is now competitive with traditional cooling methods.

Thermal Storage

This Canadian innovation uses near-surface ice stopes or rock rubble to effectively and inexpensively heat intake air in the winter and cool it in the summer (Stachulak 1989).

Controlled Recirculation

This technique, used in conjunction with bulk air cooling, can reduce ventilation and air-conditioning requirements in older, deep mines, especially heavily mechanized ones (Tien 1999). Besides increasing air velocities in work areas without drawing more surface air through a high-resistance circuit, controlled recirculation reduces the heat load caused by autocompression. Using Equation (1), for every 47 m^3/s at standard density brought from the surface, the lost cooling capacity per 300 m of descent is

$$\text{Heat Load} = (47\ \text{m}^3/\text{s})(1.2\ \text{kg/m}^3)\left(\frac{1\ \text{kJ/kg}}{102\ \text{m}}\right)(300\ \text{m})$$

$$= 166\ \text{kW lost per } 47\ \text{m}^3/\text{s, per } 300\ \text{m}$$

Controlled recirculation systems must be designed very carefully, with stringent monitoring and control safeguards.

Operator Cabs and Cooling Vests

Mechanization can add significant heat, especially in confined auxiliary-ventilated spaces. Most noncoal mines have converted to diesel equipment, although some use electric loaders and trucks. Coal mines are also mechanizing, but more slowly. The biggest problem with diesel engine heat is related to the greatest advantage of these vehicles: mobility. Heat and emissions from a diesel vehicle in a confined area can tax almost any ventilation system. Increasingly, cabs are being specified for large diesel vehicles. Cabs come equipped with window-type air conditioners and HEPA filters to capture diesel particulate and dust. After the diesel vehicle has left the heading, the mine ventilation and cooling system can provide an acceptable environment for other personnel. Cabs are expensive; however, because a loader often visits multiple headings in a week, the cost of a cab is much less than maintaining the design reject wet-bulb temperature in all headings at all times.

Cooling vests are not popular in mining. They are bulky, reduce mobility, and are time-consuming to prepare and use. Vests have limited application for mechanics, electricians, pipe-fitters, and others who must enter hot areas to set up ventilation and cooling. Vests using blue-ice packs or dry ice last two to three hours; those using compressed-air venturi-type coolers require an umbilical cord.

Other Methods

Other methods being developed include the air cycle (air, compressed on the surface and sent underground to a turbine, turns a generator and exits at –40°C), and the ammonia cycle (sending down liquid ammonia, evaporating it, and sending the vapor back to surface condensers). These methods may be best suited to ultradeep mines where other cooling methods are already fully developed.

Transferring heat from current stopes to wall rock or rock rubble in previously worked-out stopes (the only method that does not remove heat from the mine) has also been considered. Refrigeration equipment would have to operate at a high condensing temperature to produce water hot enough to transfer heat to worked-out stopes.

5. SELECTING A MINE-COOLING METHOD

After mine-cooling and ventilation requirements have been projected, the designer must analyze and select the best method(s) for meeting those requirements. Cost-benefit analysis is the most widely used, but hardware reliability, dependency on outside factors, flexibility, safety, and technological level are just as important. Some factors to consider include the following:

- **Seasonal ambient conditions.** Warm-climate mines tend to bulk-cool air on the surface in industrial direct-contact spray chambers located close to the intake shaft.
- **Orebody and mining methods.** The more massive the orebody, the more ideal bulk cooling becomes. When stopes are scattered and continuously advanced into new areas, district or spot cooling might be better.
- **Mining rate.** This is critical: heat removal is energy, but not necessarily power, related. A fast mining rate prompts a high instantaneous heat load (kilowatts), but less heat energy (kilojoules) per tonne of production. This is because wall rock is covered by fill or isolated before its total heat energy has escaped into the airstream. The kilojoules per tonne of production incurs the air-conditioning costs. Leave as much heat in the wall rock as possible.
- **Size and condition of major airways.** In older mines, small airways often limit airflow increases. This may prompt the need for air conditioning sooner than it normally would have been necessary.
- **Heat sources.** The contribution of TIH and TDH sources to the total can help determine the balance of passive to active thermal environmental controls, the ratio of airflow to air conditioning, and whether cabs should be specified.
- **Cost of power, water, labor, and supplies.** Knowing these costs is critical for assessing optimum capital expenditure to control operating costs. For example, if power cost is high, spending extra for a higher-COP system may be warranted.
- **Governmental regulations.** Heat stress standards can influence the size of the system. Other safety issues may constrain design, such as not using combustible pipe insulation or ammonia machines underground.

Basic cooling alternatives for specific cases are summarized in Table 4. Airflows are described as limited, medium, or large. One way to express airflow for a given mine is the ratio of tonnes of airflow per tonne of ore. Limited airflow is defined as less than 8 tonnes of air per tonne of ore, medium airflow is 8 to 16 tonnes per tonne, and large airflow is over 16 tonnes per tonne.

These ranges are based on an unpublished study of approximately 100 mines of all types, worldwide. The ranges discussed are for heat removal only. Additional airflow for methane or radon removal must be addressed separately.

6. MECHANICAL REFRIGERATION PLANTS

Surface Plants

Centrifugal or helical rotary screw machines are typically used in surface plants to chill water or bulk-cool air. Banks of machines are usually installed in parallel: plant design must accommodate one machine being down at any given time for maintenance while others operate. Shell-and-tube heat exchangers are standard, although plate-and-frame are used if water close to the freezing point is specified. The most common refrigerant for positive-displacement compression is HCFC-22. Ammonia is also commonly used in surface plants. Absorption machines can be considered if external waste heat is available.

Underground Plants

Large underground plants do the same work as surface plants, but are closer to work areas. Better positional efficiency and percent utilization are the advantages. Whereas surface plants use atmospheric air for heat rejection, underground plants use mine exhaust air, which raises natural ventilation pressure and aids circuit fans.

Table 4 Basic Cooling Alternatives

	Warm Climate	Cool/Cold Climate
Massive orebody (deep)	Large or medium airflow Chill service water Bulk-cool air on surface Bulk-cool air underground	Medium airflow Chill service water Bulk-cool air underground Thermal storage
Massive orebody (shallow)	Large airflow Bulk-cool air on surface Chill service water Shell and tube	Large or medium airflow Chill service water on surface Shell and tube
Scattered orebody (multilevel)	Large airflow if not too deep Chill service water Bulk-cool air on surface District chiller systems Spot coolers/spray chambers	Large or medium airflow Chill service water District chiller systems Thermal storage
Ultradeep orebody (massive and/or multilevel)	Limited airflow Chill service water District chiller systems Ice cooling Controlled recirculation	Limited airflow Chill service water District chiller systems Ice cooling Controlled recirculation
Small orebody	Bulk-cool air on surface Chill service water District chiller systems Spot coolers	District chiller systems Chill service water Spot coolers
Porous rock	District chiller systems Spot coolers	District chiller systems Spot coolers

Components for underground machines must be disassembled for transport down the shaft.

The main disadvantage of underground refrigeration is that heat rejection is limited by the amount of available exhaust air. Excavating underground refrigeration rooms and spray chambers is more costly than erecting prefabricated surface buildings. Maintenance is also more difficult because of shaft logistics. Power is more difficult to supply to an underground facility, and subject to more disruptions.

Spot Coolers

Spot coolers with 50 to 350 kW capacity allow driving long development headings, or cooling exploration sites before installing primary ventilation and cooling equipment. Development headings can be advanced more rapidly and under more comfortable conditions. Condenser heat is most often removed by service water, although some air-to-air condensers are used.

Spot coolers use reciprocating, scroll, or small screw compressors. Hermetic scroll compressors are becoming more popular because they handle liquid slugging better than reciprocating compressors and are less expensive. Spot coolers use direct exchange (DX) air-cooling coils. The packaged unit includes a fan, which draws air through the coil (or coils, in a dual-coil unit) and then blows it through duct to the heading. Spot coolers must be compact and portable because they are moved often. The service water required is typically 0.02 L/s per kilowatt, but can be less if the water temperature is under 13°C, or more if it is over 21°C. A return drain pipe is recommended to prevent contact between hot discharge water (often over 38°C) and ambient air. Coils sometimes receive dusty air immediately after blasting; if so, coils must be washed at least every other day.

Spot coolers are expensive, but often are the only choice for cooling exploration, development, and small-scale stoping on the fringes of mining activity.

Maintenance

Mines with extensive systems (e.g., a large chiller plant, or over 10 spot coolers) should employ a mechanic specializing in refrigeration. Mines with over 7000 kW probably need a second mechanic. These persons should be factory trained and must be certified to handle refrigerants. Refrigeration specialists can be assisted periodically or full time by apprentice mechanics. Another viable approach is a maintenance contract with the equipment manufacturer or supplier, or an independent HVAC&R shop. Some mines have a full-time person cleaning coils.

A fouling factor ($m^2 \cdot K/W$) should be calculated from lab analysis of the condenser water, especially for district chillers using sump water. Planning a tube-cleaning regimen, either manual, acid circulation, or automatic with brushes and a flow reversal valve, is critical. Underground condensers can become plugged within a couple of weeks without cleaning, depending on the fouling factor. Water treatment is needed to control scale, corrosion, and organisms in surface or underground plants with cooling towers.

7. MINE AIR HEATING

Cold-climate mines typically heat intake air in the winter. In Canada, heating intake air can cost more than all other ventilation costs combined (Hall et al. 1989). However, without heat, water in the shaft will freeze, disrupting hoisting operations and damaging shaft support members, cables, and pipes. Very cold air and icy floors are safety and health hazards; heavy gloves and other protective clothing required can make routine tasks difficult. Intake air is typically heated to just above the freezing point. Autocompression and shaft heat loads further temper the air as it downcasts into the mine.

Steam coils operated by boilers burning wood, coal, fuel oil, or natural gas often served as shaft heaters in the past. Electric resistance heaters have also been used, but they are expensive to operate. Waste heat from compressor stations has also been used.

When exhaust and intake shafts are located close together, a circulating glycol or heat pump system can be used to transfer heat from exhaust air to intake. For every kelvin of total heat (sensible plus latent) given up by warm saturated exhaust air, the same mass flow of cold intake air can be heated sensibly by 4 K. Either coils or a cooling tower extracts heat from exhaust air, and then coils transfer this heat to the intake air.

Controlled recirculation (up to 25% of total airflow) can also be applied to heat intake air (Hall et al. 1989). The system is temporarily shut down during blasting.

Some cold-climate mines isolate the primary production shaft from the ventilation circuit. A slight upcast flow of uncontaminated air maintains good conditions in the shaft for hoisting ore and moving personnel and supplies. The disadvantage of this method is that ventilation duties of the production shaft must be transferred to one or more expensive stand-alone intake airways.

Natural gas and/or propane heaters are typically used at modern mines. Natural gas is preferred because it is less expensive and it burns more cleanly. Where natural gas is not available, propane must be trucked to the mine site. The same heater can burn either natural gas or propane; thus, propane can be used for back-up in case natural gas is cut off (mechanical conversion is required from gas to propane). Direct-fired heaters are usually preferred because the entire heat value of the fuel enters the intake airstream. If indirect heaters are used, roughly 15 to 25% of the heat is lost up the flue pipe.

Two types of natural gas or propane heaters have been used to heat intake air: (1) a grid of burner bars installed in a housing at the intake shaft, sometimes with louvers to adjust the flow of intake air and to mix air from the heaters with outdoor air; and (2) a crop dryer type of burner. Temperature sensors installed downstream can modulate

Table 5 Heating Values for Fuels

Fuel	Value	Source
Natural gas	37 250 kJ/m^3	Kennedy 1996
Propane	25 000 kJ/L	Kennedy 1996
Bituminous coal	28 600 to 33 500 kJ/kg	Abbeon Cal 2001
Fuel oil	40 000 kJ/L	Abbeon Cal 2001
Wood	4 350 000 to 9 000 000 kJ/m^3	Abbeon Cal 2001

both heater types to ensure that no more heat is applied than necessary to bring the temperature of the mixed intake air to 1°C.

Carbon monoxide sensors should also be installed downstream of the heaters. Experience at two mines in the western United States shows that the CO content of intake air heated by direct-fired burners can reach 10 to 20 mg/kg.

Equation (18) is used to calculate the total heat required, assuming that the air has a low humidity ratio (which is the case for very cold air), and that no water is evaporated in the heater. Heating values for different fuels are given in Table 5.

$$\text{Heat, kW} = (\text{Airflow, m}^3\text{/s})(\text{density, kg/m}^3) \times [1\ \text{kJ/(kg·K)}](\Delta t, \text{K}) \qquad (18)$$

where Δt = 1°C minus the intake air temperature.

Example 6. A mine is located where the atmospheric air temperature can drop to –30°C for two or more weeks per year. Occasionally the temperature drops to –35°C. An intake shaft handles 190 m^3/s, and the density of air entering the shaft in winter is 1.12 kg/m^3. What heating should be installed at the shaft intake to keep the shaft free of ice?

Solution: Sizing heaters is usually based on average cold periods, not extreme cold snaps. Here, a direct-fired heater is sized to raise –30°C air to 1°C. When the temperature drops to –35°C for short periods, intake airflow should be temporarily reduced. Using Equation (18),

$$\text{Heat} = (190)(1.12)(1)[1 - (-30)] = 6600\ \text{kW}$$

If natural gas is used, the volume required is

$$\frac{6600\ \text{kW}}{37\ 250\ \text{kJ/m}^3} = 0.18\ \text{m}^3\text{/s} = 638\ \text{m}^3\text{/h}$$

If propane is used, the litres required are

$$\frac{6600\ \text{kW}}{25\ 000\ \text{kJ/L}} = 0.264\ \text{L/s} = 950\ \text{L/h}$$

8. MINE VENTILATION

Mine ventilation supplies air (oxygen) to underground facilities, and removes dangerous or harmful contaminants such as methane, radon, strata gases, dust, blasting fumes, and diesel emissions. Ventilation also removes heat and helps control humidity in hot mines. Planning a ventilation system consists of five basic steps: (1) determining airflows; (2) planning the primary circuit; (3) specifying circuit fans, ventilation controls, and their installation; (4) determining auxiliary system requirements; and (5) assessing health and safety aspects.

Determining Airflows

Mining operations generate differing types and amounts of contaminants, and airflows dilute and remove these contaminants. The ventilation engineer must work closely with mine planning staff to understand where and how much production will take place, and what contaminants will be generated. The federal Mine Safety and Health Administration (MSHA 2013) regulates contaminant concentrations to limits specified in the Federal Register, CFR 30. Controlling the most problematic contaminant normally keeps all others within their legal limits. For coal mines, contaminants of concern are typically methane and coal dust; for uranium mines, radioactive dust and radon progeny; for non-dieselized hard rock mines, usually silica dust and blasting fumes; for dieselized mines, typically diesel emissions. Design airflows for dieselized nonuranium metal mines range from 0.05 to 0.09 m^3/s per diesel kilowatt, depending on the reference cited. With the current emphasis on controlling diesel emissions, planning should start at 0.06 m^3/s per kilowatt.

Total airflow is a summation of airflows for individual work areas, plus a leakage factor. Leakage is defined as airflow that does not ventilate any active work area or permanent site such as a pump room. A "tight" system minimizes leakage through well-constructed doors and seals, by minimizing the number of possible leakage paths, and by careful fan placement. Leakage can range from 10% of total airflow at a tight metal mine to 80% at some coal mines.

The ratio of tonnes of air per tonnes of ore production is about 2 to 4 for block cave mines, 6 to 8 for nondieselized cut-and-fill metal mines, and 9 to 16 for dieselized metal mines. Gassy coal and uranium mines can have significantly higher ratios, depending on the methane or radon generation rate.

Example 7. A new mechanized cut-and-fill gold mine is planned. Ore production is expected to be 1 088 400 tonnes per year. Intake air density is 1.12 kg/m^3. What is the rough airflow required for ventilation?

Solution: The airflow range is 9 to 16 tonnes of air per tonne of ore for dieselized metal mines. For a first-pass guess, assume an average 12.5 tonnes per tonne. The total mass of the air through the mine in a year is

(1 088 400 tonnes ore per year) × (12.5 tonnes air per tonne ore)
= 13 605 000 tonnes air per year

$$\text{Airflow, m}^3\text{/s} = \frac{(13\ 605\ 000\ \text{tonnes/yr})(1000\ \text{tonnes/kg})}{(1.12\ \text{kg/m}^3)(31\ 536\ 000\ \text{s/yr})} = 385\ \text{m}^3\text{/s}$$

Ratios provide a good first guess. However, the ventilation engineer should derive the total airflow by listing all operations, estimating leakages, and adding the specific airflows required to ventilate each operation (zero-based planning). As with reject temperature, the total airflow selected should be economically justifiable to management.

Airflow specification may change with time because of production, equipment, or mining method changes.

Planning the Circuit

With airflow specified and work sites plotted, the ventilation engineer must lay out the primary circuit. The three basic types of airways are intake, work area, and exhaust. Sizing airways is normally based on keeping velocity within acceptable limits: if velocity is too low, the airway is oversized and thus costs more than necessary; if it is too high, pressure drop is too large and raises operating costs. Air velocity should not exceed 6 m/s in production shafts and haul drifts. Higher velocities can create dust problems and lead to employee discomfort. However, velocities in bare circular concrete exhaust shafts can approach 25 m/s if necessary. Air velocity in vertical upcast exhaust shafts should avoid the 7 to 12 m/s range because water droplets become entrained into the airstream and may form sheets, causing surging at the main fan.

Resistance to airflow is calculated using Atkinson's (1854) and McPherson's (1993) equations:

$$\Delta H = R_t \rho Q^2 \qquad (19)$$

where

ΔH = pressure drop, Pa

R = turbulent resistance, m^{-4}
ρ = air density, kg/m^3
Q = airflow, m^3/s

$$R = \frac{fLP}{2A^3} \quad (20)$$

where

f = coefficient of friction, dimensionless
L = length, m
P = perimeter of opening, m
A = area of opening, m^2

For rectangular drifts, the f factor ranges from 0.0067 for a smooth, concrete-lined straight drift to 0.027 for an unlined, irregular curved drift. For shafts, the f factor ranges from 0.004 for a smooth-sided borehole to over 0.15 for a heavily timbered rectangular shaft. See Hartman et al. (1997), McPherson (1993), and Tien (1999) for more precise airway resistance specification.

Example 8. Mine plans call for 30 m^3/s to be sent through 610 m of 3 m wide by 3 m high drift. The f factor from measurements of similar drifts is 0.020. The average temperature is 24°C wb and 27°C db. The barometric pressure is 95 kPa. What is the resistance of this drift, and what is the air pressure drop?

Solution: Using psychrometric equations in Chapter 1 of the 2017 *ASHRAE Handbook—Fundamentals*, the density is 1.09 kg/m^3.

$$R = \frac{fLP}{2A^3} = \frac{(0.020)(610)(12)}{2(9)^3} = 0.1004 \text{ m}^{-4}$$

$$\Delta H = R\rho Q^2 = (0.1004)(1.09)(30)^2 = 98.5 \text{ Pa, or } 0.0985 \text{ kPa}$$

A mine ventilation circuit contains airways in series and in parallel. The overall resistance (Hartman et al. 1997) is

For series: $$R_T = R_1 + R_2 + R_3 + \cdots + R_n \quad (21)$$

For parallel: $$\frac{1}{\sqrt{R_T}} = \frac{1}{\sqrt{R_1}} + \frac{1}{\sqrt{R_2}} + \frac{1}{\sqrt{R_3}} + \cdots + \frac{1}{\sqrt{R_n}} \quad (22)$$

Example 9. If Airway #1 has a resistance of 0.1, Airway #2 has a resistance of 0.2, and Airway #3 has a resistance of 0.3, what is the resistance of these three branches in series and in parallel?

Solution:

Series:

$$R = 0.1 + 0.2 + 0.3 = 0.6 \text{ m}^{-4}$$

Parallel:

$$\frac{1}{\sqrt{R}} = \frac{1}{\sqrt{(0.1)}} + \frac{1}{\sqrt{(0.2)}} + \frac{1}{\sqrt{(0.3)}}$$

$$R = 0.0192 \text{ m}^{-4}$$

$$\frac{1}{\sqrt{R}} = \frac{1}{\sqrt{(0.1)}} + \frac{1}{\sqrt{(0.2)}} + \frac{1}{\sqrt{(0.3)}}$$

$$R = 0.0192 \text{ (Pa·s}^2\text{)/m}^6$$

Modern ventilation network computer analysis uses Kirchhoff's laws to balance airflows: (1) the summation of airflows into a junction equals the summation out, and (2) the summation of pressure drops around any enclosed mesh equals zero.

Computer simulation allows quick analysis of a wide range of scenarios. Most programs use a balancing algorithm based on the work of Hardy Cross in the 1960s and 1970s. The program iterates as it converges on final balanced airflows. Fan curves or regulators can be inserted in almost any branch.

Regulators or section booster fans control airflow in branches. Without regulation, too little or too much airflow may occur; nevertheless, circuits should be designed with as many free-split branches (branches without a fan or regulator) as possible to minimize overall resistance. Free-split branches are often located in circuit extremities.

A mine should have more intakes than exhausts. This enhances safety, because miners have more escape paths, and because more paths bring in fresh air if a fire occurs in one of the intakes. Also, exhaust shafts can generally handle greater air velocities and hence larger quantities, so fewer exhaust shafts are needed.

Metal mines often contain circuit booster fans. Underground boosters can create neutral points in the system where air short circuits from intake to exhaust above the point, and recirculates from exhaust to intake below the point. Uncontrolled recirculation should be minimized.

Exhausting primary circuits are commonly used in both metal and coal mines (intakes do not have airlocks). Under normal operation, this produces a negative mine pressure gradient. If fans fail or are deactivated, barometric pressure in the mine rises, which temporarily helps keeps methane in coal mines from flowing away from gob (mining waste) areas (Kennedy 1996).

Specifying Circuit Fans

Primary fans are either centrifugal or axial. South African mines typically use large centrifugals, whereas most U.S. and Canadian mines use axials. Both types have advantages. Efficiency (up to 90%) is about the same with either type. Centrifugals are heavier duty, quieter, do not have a pronounced stall region, and can generate higher static pressures (over 7.5 kPa). Axials are more compact, and airflows can be easily adjusted by blade angle changes. Primary fans range from 75 to over 2600 kW each. Surface installations with multiple fans are common for large airflows and for back-up operation when one fan is turned off for maintenance. Circuit fans can also be installed underground, especially in metal mines.

The HVAC systems or components essential for plant operation should be designed with redundancy to ensure plant availability. Automatic switchover to the back-up system may be required in normally unoccupied areas. Where back-up systems are impractical, consider using temperature monitoring and alarming systems to initiate temporary corrective measures.

Primary fans are specified while the circuit is designed. Engineers must often balance airway considerations (sizes and numbers) and fan specifications. Select a fan that will operate on an efficient part of its curve. Fan speed, quantity, pressure, and power are related in the fan laws equations, described in Chapter 21 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. It is also important to anticipate future circuit changes as mining operations advance.

The fan installation must be designed after primary fans are selected. Consequences of fan downtime must be carefully considered, especially for coal mines, because methane concentrations can increase when circuit airflows decrease. Fans exhausting a mine are typically mounted horizontally near a vertical shaft or borehole. A 90° transition turns the air into the fan inlet. An isolation door is installed between the transition and fan. Coal mines require a blast door to dampen a shock wave caused by a possible methane or coal dust explosion. An evasé, or diffuser, is attached to the fan outlet to recover part of the velocity pressure exiting the mine.

Noise levels produced by HVAC system equipment both inside and outside plant spaces are an important consideration, as is the establishment of noise guidelines for air-conditioned areas and ventilated areas with continuous occupancies. Outdoor noise levels are established by the environmental noise pollution concerns of adjacent areas. A silencer can be added if surface noise reduction is desired. Noise level can be managed by fan selection and acoustical treatment.

Increasingly, variable-speed drives are used with electric motors to turn the fans. These drives provide soft start, and speeds from 50 to 100% of synchronous speed, and even to 110% for temporary emergency duty. The installation must be designed for accessibility and ease of maintenance.

Determining Auxiliary System Requirements

Auxiliary fan and duct systems deliver air into dead-end headings. These systems are generally not permitted in coal mines but are common in metal mines. A blowing system is most often used. A fan is set in a fresh air base at the start of a drift, and duct is installed as the drift advances. For drifts under 300 m, flexible brattice-cloth duct can be used. Longer drifts that require booster fans need rigid duct because duct gage pressure can drop below atmospheric. Rigid duct also offers less resistance than brattice-cloth duct, but it is about eight times as expensive.

The air quantity needed at the face is determined by the equipment used and the rate at which blasting and diesel fumes must be removed. Ducts are sized for the air quantity needed and for space limitations in the drift. Fans are selected to provide the specified airflow. In general, a single-stage axial fan can generate up to 2.5 kPa static pressure, which should deliver required airflow up to 760 m through properly sized duct. A larger duct or a two-stage axial fan is needed if distance is much longer. For very long drifts, booster fans are needed about every 760 m.

An exhausting system is often used for drifts requiring quick ingress after blasting. Air flows to the face through the drift, captures fumes, and is blown back to the circuit through duct. This keeps the drift clear of fumes. Disadvantages include the following: (1) the air picks up heat and humidity en route to the face, (2) rigid duct is required, and (3) the face is not swept by air as with a blowing system. A face overlap fan and duct can be installed.

Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals* provides a friction chart for round duct. However, it is better to acquire the friction chart of the specific duct being considered from the supplier. Shock losses through couplings and bends must be tallied. One important consideration is leakage through couplings. This can be minimized by careful installation, keeping duct pressure under 2.5 kPa static pressure, and installing longer pieces of duct (up to 30 m for brattice cloth, or 6 m for rigid).

Cassettes loaded with brattice-cloth duct are now used for drifts driven by rapidly advancing tunnel boring machines.

Duct damage is common in mines. Mobile equipment and fly rock from blasting can punch holes in the duct. These factors can drastically reduce airflow. Take care to minimize damage, and to quickly repair or replace damaged pieces.

Assessing Health and Safety

Few aspects of underground mining have as direct an impact on health, safety, and morale as ventilation. No component of ventilation design should be undertaken without a rigorous review of health and safety aspects, including the risk of

- Fire and explosion
- Dangerous and toxic substances
- Heat
- Ventilation equipment usage

For metal mines, fire is the most significant potential ventilation hazard. Fuel, heat, and oxygen are required for combustion; removing any of these components will prevent combustion. Fuel sources such as oil, diesel fuel, and blasting agents are kept in special areas designed to keep out ignition sources. Sprinkler or chemical suppression systems can be installed in these areas as well as in repair shops. Mobile equipment fires are a special concern for modern mining: vehicles should be fitted with a dry chemical fire suppression system, triggered either automatically or by the operator. Electric substation and conveyor fires can be very dangerous.

Engineers should anticipate various scenarios in ventilation circuits. What are the fire risks in any given area? If a fire broke out in any location, how would circuits respond? Would fire-induced natural drafts change airflow quantities and directions? How would fire be detected, how would miners be notified, how would they escape, and how would the fire be fought? MSHA requires that refuge chambers be constructed if miners cannot be hoisted to the surface within 1 h of notification. The ventilation staff must work closely with the safety department and mine management in preplanning how to respond to different emergencies.

Spontaneous combustion is a problem for both metal and coal mines. Fortunately, timber is now seldom used for ground support, although many older mines have worked-out areas that contain timber. Coal, being combustible, can be particularly troublesome. Circuits must be designed so that spontaneous combustion fires will not contaminate active workings.

For coal mines, methane and coal dust explosions pose the greatest risk. Equipment must be rated “permissible,” or non-sparking. Airways should be coated with rock dust to prevent a methane ignition from propagating. Methane is explosive in air from 5 to 15% concentration. Whenever methane reaches 0.25%, MSHA requires that changes be made to improve ventilation. At 0.5%, further steps must be taken, and no other work is permitted until the concentration drops. At 1%, all personnel except those working on ventilation must be evacuated from the affected area.

Ventilation is the first line of defense against toxic or asphyxiating gases. These can be generated by blasting (CO, CO_2, NH_3, and NO_x) and by diesel engines (CO, NO_x, SO_2, various hydrocarbon compounds, and soot). The rock itself can release CO_2 and H_2S.

The relationship between heat stress and accident frequency has been clearly established in South African mines (Stewart 1982). Work area temperatures should be kept under 29.5°C wb, especially where heavy physical work is performed.

Ventilation and air-conditioning equipment may also pose health and safety risks. All fan inlets require screens. Fans should be equipped with vibration sensors that can deactivate the fan if necessary. Silencers may be needed if personnel work nearby. Refrigeration rooms must be well ventilated in case of a sudden refrigerant release. Duct, pipe insulation, and other substances such as foam for seals should be approved by MSHA in accordance with 30 CFR Part 7. Electrical systems must meet rigorous MSHA codes.

CHAPTER 31

INDUSTRIAL DRYING SYSTEMS

Mechanism of Drying 31.1
Applying Hygrometry to Drying 31.1
Determining Drying Time 31.2
Drying System Selection 31.3
Types of Drying Systems 31.3

DRYING removes water and other liquids from gases, liquids, and solids. The term is most commonly used, however, to describe removing water or solvent from solids by thermal means. **Dehumidification** refers to the drying of a gas, usually by condensation or by absorption with a drying agent (see Chapter 32 of the 2017 *ASHRAE Handbook—Fundamentals*). **Distillation**, particularly **fractional distillation**, is used to dry liquids.

It is cost-effective to separate as much water as possible from a solid using mechanical methods *before* drying using thermal methods. Mechanical methods such as filtration, screening, pressing, centrifuging, or settling require less power and less capital outlay per unit mass of water removed.

This chapter describes industrial drying systems and their advantages, disadvantages, relative energy consumption, and applications.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. MECHANISM OF DRYING

When a solid dries, two processes occur simultaneously: (1) the transfer of heat to evaporate the liquid and (2) the transfer of mass as vapor and internal liquid. Factors governing the rate of each process determine the drying rate.

The principal objective in commercial drying is to supply the required heat efficiently. Heat transfer can occur by convection, conduction, radiation, or a combination of these. Industrial dryers differ in their methods of transferring heat to the solid. In general, heat must flow first to the outer surface of the solid and then into the interior. An exception is drying with high-frequency electrical currents, where heat is generated within the solid, producing a higher temperature at the interior than at the surface and causing heat to flow from inside the solid to the outer surfaces.

2. APPLYING HYGROMETRY TO DRYING

In many applications, recirculating the drying medium improves thermal efficiency. The optimum proportion of recycled air balances the lower heat loss associated with more recirculation against the higher drying rate associated with less recirculation.

Because the humidity of drying air is affected by the recycle ratio, the air humidity throughout the dryer must be analyzed to determine whether the predicted moisture pickup of the air is physically attainable. The maximum ability of air to absorb moisture corresponds to the difference between saturation moisture content at wet-bulb (or adiabatic cooling) temperature and moisture content at supply air dew point. The actual moisture pickup of air is determined by heat and mass transfer rates and is always less than the maximum attainable.

ASHRAE psychrometric charts for normal and high temperatures (No. 1 and No. 3) can be used for most drying calculations. The process does not exactly follow the adiabatic cooling lines because some heat is transferred to the material by direct radiation or by conduction from the metal tray or conveyor.

Example 1. A dryer has a capacity of 41 kg of bone-dry gelatin per hour. Initial moisture content is 228% bone-dry basis, and final moisture content is 32% bone-dry basis. For optimum drying, supply air is at 48.9°C db and 29.4°C wb in sufficient quantity that the exhaust air is 37.8°C db and 29.2°C wb. Makeup air is available at 26.7°C db and 18.3°C wb.

Find (1) the required amount of makeup and exhaust air and (2) the percentage of recirculated air.

Solution: In this example, the humidity in each of the three airstreams is fixed; hence, the recycle ratio is also determined. Refer to ASHRAE Psychrometric Chart No. 1 to obtain the humidity ratio of makeup air and exhaust air. To maintain a steady-state condition in the dryer, water evaporated from the material must be carried away by exhaust air. Therefore, the pickup (the difference in humidity ratio between exhaust air and makeup air) is equal to the rate at which water is evaporated from the material divided by the mass of dry air exhausted per hour.

Step 1. From ASHRAE Psychrometric Chart No. 1, the humidity ratios are as follows:

	Dry bulb, °C	Wet bulb, °C	Humidity ratio, g/kg dry air
Supply air	50	30	18.7
Exhaust air	40	29.5	22
Makeup air	27	18.6	10

Moisture pickup is 22 – 10 = 12 g/kg (dry air). The rate of evaporation in the dryer is

$$41[(228 - 32)/100] = 80.36 \text{ kg/h} = 22.3 \text{ g/s}$$

The dry air required to remove the evaporated water is 22.3/12 = 1.86 kg/s.

Step 2. Assume x = percentage of recirculated air and $(100 - x)$ = percentage of makeup air. Then

Humidity ratio of supply air =
(Humidity ratio of exhaust and recirculated air)(x/100)
+ (Humidity ratio of makeup air)(100 – x)/100

Hence,

$$18.7 = 22(x/100) + 10(100 - x)/100$$

$$x = 72.5\% \text{ recirculated air}$$
$$100 - x = 27.5\% \text{ makeup air}$$

3. DETERMINING DRYING TIME

The following three methods of finding drying time are listed in order of preference:

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

- Conduct tests in a laboratory dryer simulating conditions for the commercial machine, or obtain performance data using the commercial machine.
- If the specific material is not available, obtain drying data on similar material by either of the above methods. This is subject to the investigator's experience and judgment.
- Estimate drying time from theoretical equations (see the References). Care should be taken in using the approximate values obtained by this method.

When designing commercial equipment, tests are conducted in a laboratory dryer that simulates commercial operating conditions. Samples used in the laboratory tests should be identical to the material found in the commercial operation. Results from several tested samples should be compared for consistency. Otherwise, test results may not reflect the drying characteristics of the commercial material accurately.

When laboratory testing is impractical, commercial drying data can be based on the equipment manufacturer's experience.

Commercial Drying Time

When selecting a commercial dryer, the estimated drying time determines what size machine is needed for a given capacity. If the drying time has been derived from laboratory tests, the following should be considered:

- In a laboratory dryer, considerable drying may result from radiation and heat conduction. In a commercial dryer, these factors are usually negligible.
- In a commercial dryer, humidity may be higher than in a laboratory dryer. In drying operations with controlled humidity, this factor can be eliminated by duplicating the commercial humidity condition in the laboratory dryer.
- Operating conditions are not as uniform in a commercial dryer as in a laboratory dryer.
- Because of the small sample used, the test material may not be representative of the commercial material.

Thus, the designer must use experience and judgment to modify the test drying time to suit the commercial conditions.

Dryer Calculations

To estimate preliminary cost for a commercial dryer, the circulating airflow rate, makeup and exhaust airflow rate, and heat balance must be determined.

Circulating Air. The required circulating or supply airflow rate is established by the optimum air velocity relative to the material. This can be obtained from laboratory tests or previous experience, keeping in mind that the air also has an optimum moisture pickup. (See the section on Applying Hygrometry to Drying.)

Makeup and Exhaust Air. The makeup and exhaust airflow rate required for steady-state conditions within the dryer is also discussed in the section on Applying Hygrometry to Drying. In a **continuously operating dryer**, the relationship between moisture content of the material and quantity of makeup air is given by

$$G_T(W_2 - W_1) = M(w_1 - w_2) \tag{1}$$

where

G_T = dry air supplied as makeup air to the dryer, kg/s
M = stock dried in a continuous dryer, kg/s
W_1 = humidity ratio of entering air, kg water vapor per kg dry air
W_2 = humidity ratio of leaving air, kg water vapor per kg dry air (in a continuously operating dryer, W_2 is constant; in a batch dryer, W_2 varies during part of the cycle)
w_1 = dry basis moisture content of entering material, kg of water/kg
w_2 = dry basis moisture content of leaving material, kg of water/kg

In **batch dryers**, the drying operation is given as

$$G_T(W_2 - W_1) = (M_1)\frac{dw}{d\theta} \tag{2}$$

where

M_1 = mass of material charged in a discontinuous dryer, kg per batch
$dw/d\theta$ = instantaneous time rate of evaporation corresponding to w

The makeup air quantity is constant and is based on the average evaporation rate. Equation (2) then becomes identical to Equation (1), where $M = M_1/\theta$. Under this condition, humidity in the batch dryer decreases during the drying cycle, whereas in the continuous dryer, humidity is constant with constant load.

Heat Balance. To estimate the fuel requirements of a dryer, a heat balance consisting of the following is needed:

- Radiation and convection losses from the dryer
- Heating of the commercial dry material to the leaving temperature (usually estimated)
- Vaporization of the water being removed from the material (usually considered to take place at the wet-bulb temperature)
- Heating of the vapor from the wet-bulb temperature in the dryer to the exhaust temperature
- Heating of the total water in the material from the entering temperature to the wet-bulb temperature in the dryer
- Heating of the makeup air from its initial temperature to the exhaust temperature

The energy absorbed must be supplied by the fuel. The selection and design of the heating equipment is an essential part of the overall design of the dryer.

Example 2. Magnesium hydroxide is dried from 82% to 4% moisture content (wet basis) in a continuous conveyor dryer with a fin-drum feed (see Figure 7). The desired production rate is 0.38 kg/s. The optimum circulating air temperature for drying is 71.1°C, which is not limited by the existing steam pressure of the dryer.

Step 1. Laboratory tests indicate the following:

Specific heats
air (c_a) = 1.00 kJ/(kg·K)
material (c_m) = 1.25 kJ/(kg·K)
water (c_w) = 4.18 kJ/(kg·K)
water vapor (c_v) = 1.84 kJ/(kg·K)
Temperature of material entering dryer = 15°C
Temperature of makeup air
dry bulb = 21.1°C
wet bulb = 15.6°C
Temperature of circulating air
dry bulb = 71.1°C
wet bulb = 37.8°C
Air velocity through drying bed = 1.27 m/s
Dryer bed loading = 33.3 kg/m²
Test drying time = 25 min

Step 2. Previous experience indicates that the commercial drying time is 70% greater than the time obtained in the laboratory test. Thus, the commercial drying time is estimated to be 1.7 × 25 = 42.5 min.

Step 3. The holding capacity of the dryer bed is

$$0.38(42.5 \times 60) = 969 \text{ kg at 4\% (wet basis)}$$

The required conveyor area is 969/33.3 = 29.1 m². Assuming the conveyor is 2.4 m wide, the length of the drying zone is 29.1/2.4 = 12.125 m.

Step 4. The amount of water in the material entering the dryer is

$$0.38[82/(100 + 4)] = 0.30 \text{ kg/s}$$

The amount of water in the material leaving is

$$0.38[4/(100 + 4)] = 0.015 \text{ kg/s}$$

Thus, the moisture removal rate is 0.30 – 0.015 = 0.285 kg/s.

Step 5. The air circulates perpendicular to the perforated plate conveyor, so the air volume is the face velocity times the conveyor area:

$$\text{Air volume} = 1.27 \times 29.1 = 36.96 \text{ m}^3/\text{s}$$

ASHRAE Psychrometric Charts 1 and 3 show these air properties:

Supply air (71°C db, 38°C wb)

Humidity ratio	= 29.0 g/kg (dry air)
Specific volume	= 1.02 m^3/kg (dry air)

Makeup air (21°C db, 15.5°C wb)

Humidity ratio W_1	= 8.7 g/kg (dry air)

The mass flow rate of dry air is

$$36.96/1.02 = 36.24 \text{ kg/s}$$

Step 6. The amount of moisture pickup is

$$0.285/36.24 = 7.9 \text{ g/kg (dry air)}$$

The humidity ratio of the exhaust air is

$$W_2 = 29.0 + 7.9 = 36.9 \text{ g/kg (dry air)}$$

Substitute in Equation (1) and calculate G_T as follows:

$$G_T(36.9 - 8.7)(1 \text{ kg}/1000 \text{ g}) = (0.38/1.04)(82 - 4)/100$$

$$G_T = 10.11 \text{ kg (dry air)/s}$$

Therefore,

Makeup air	= 100 × 10.11/36.24 = 27.9%
Recirculated air	= 72.1%

Step 7. Heat Balance

Sensible heat of material	= $M(t_{m2} - t_{m1})c_m$
	= (0.38/1.04)(38 – 15)1.25
	= 10.5 kW
Sensible heat of water	= $M_{w1}(t_w - t_{m1})c_w$
	= 0.30(38 – 15)4.18
	= 28.8 kW
Latent heat of evaporation	= $M(w_1 - w_2)H$
	= 0.285 kg/s × 2411 kJ/(kg·K)
	= 687.1 kW
Sensible heat of vapor	= $M(t_2 - t_w)c_v$
	= 0.285(71 – 38)1.84
	= 17.3 kW
Required heat for material	= 741.1 kW

The temperature drop $(t_2 - t_3)$ through the bed is

$$\frac{\text{Required heat}}{\text{Supplied air, kg/s} \times c_a} = \frac{741.1}{36.24 \times 1.00} = 20 \text{ K}$$

Therefore, the exhaust air temperature is 71 − 20 = 51°C.

Required heat for makeup air	= $G_T(t_3 - t_1)c_a$
	= 10.1(51 – 21)1.00
	= 303 kW

The total heat required for material and makeup air is

$$741.1 + 303 = 1044.1 \text{ kW}$$

Additional heat that must be provided to compensate for radiation and convection losses can be calculated from the known construction of the dryer surfaces.

4. DRYING SYSTEM SELECTION

A general procedure for selecting a drying system is as follows:

1. Survey of suitable dryers.
2. Preliminary cost estimates of various types.
   (a) Initial investment
   (b) Operating cost
3. Drying tests conducted in prototype or laboratory units, preferably using the most promising equipment available. Sometimes a pilot plant is justified.
4. Summary of tests evaluating quality of samples of the dried products.

Factors that can overshadow the operating or investment cost include the following:

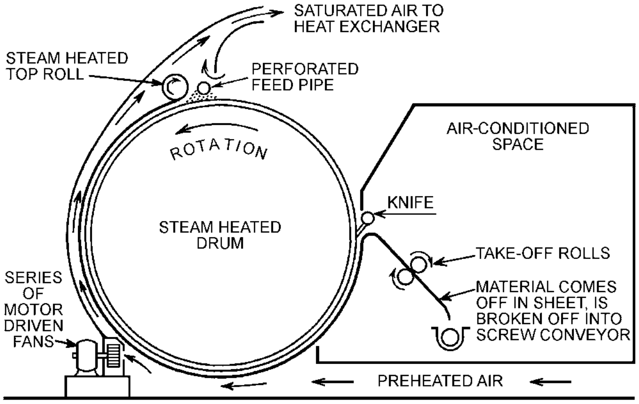

Fig. 1 Drum Dryer

- Product quality, which should not be sacrificed
- Dusting, solvent, or other product losses
- Space limitation
- Bulk density of the product, which can affect packaging cost

Friedman (1951) and Parker (1963) discuss additional aids to dryer selection.

5. TYPES OF DRYING SYSTEMS

Radiant Infrared Drying

Thermal radiation may be applied by infrared lamps, gas-heated incandescent refractories, steam-heated sources, and, most often, electrically heated surfaces. Infrared heats only near the surface of a material, so it is best used to dry thin sheets.

Using infrared heating to dry webs such as uncoated materials has been relatively unsuccessful because of process control problems. Thermal efficiency can be low; heat transfer depends on the emitter's characteristics and configuration, and on the properties of the material to be dried.

Radiant heating is used for drying ink and other coatings on paper, textile fabrics, paint films, and lacquers. Inks have been specifically formulated for curing with tuned or narrow wavelength infrared radiation.

Ultraviolet Radiation Drying

Ultraviolet (UV) drying uses electromagnetic radiation. Inks and other coatings based on monomers are cure-dried when exposed to UV radiation. This method has superior properties (Chatterjee and Ramaswamy 1975): the print resists scuff, scratch, acid, alkali, and some solvents. Printing can also be done at higher speeds without damage to the web.

Major barriers to wider acceptance of UV drying include the high capital installation cost and the increased cost of inks. The cost and frequency of replacing UV lamps are greater than for infrared ovens.

Overexposure to radiation and ozone, which is formed by UV radiation's effect on atmospheric oxygen, can cause severe sunburn and possibly blood and eye damage. Safety measures include fitting the lamp housings with screens, shutters, and exhausts.

Conduction Drying

Drying rolls or drums (Figure 1), flat surfaces, open kettles, and immersion heaters are examples of direct-contact drying. The heating surface must have close contact with the material, and agitation may increase uniform heating or prevent overheating.

Conduction drying is used to manufacture and dry paper products. It (1) does not provide a high drying rate, (2) does not furnish uniform

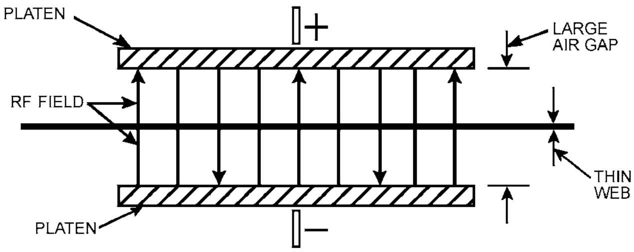

Fig. 2 Platen-Type Dielectric Dryer

heat and mass transfer conditions, (3) usually results in a poor moisture profile across the web, (4) lacks proper control, (5) is costly to operate and install, and (6) usually creates undesirable working conditions in areas surrounding the machine. Despite these disadvantages, replacing existing systems with other forms of drying is expensive. For example, Joas and Chance (1975) report that RF (dielectric) drying of paper requires approximately four times the capital cost, six times the operating (heat) cost, and five times the maintenance cost of steam cylinder conduction drying. However, augmenting conduction drying with dielectric drying sections offsets the high cost of RF drying and may produce savings and increased profits from greater production and higher final moisture content.

Further use of large conduction drying systems depends on reducing heat losses from the dryer, improving heat recovery, and incorporating other drying techniques to maintain quality.

Dielectric Drying

When wet material is placed in a strong, high-frequency (2 to 100 MHz) electrostatic field, heat is generated within the material. More heat is developed in the wetter areas than in the drier areas, resulting in automatic moisture profile correction. Water is evaporated without unduly heating the substrate. Therefore, in addition to its leveling properties, dielectric drying provides uniform heating throughout the web thickness.

Dielectric drying is controlled by varying field or frequency strength; varying field strength is easier and more effective. Response to this variation is quick, with neither time lag nor thermal lag in heating. The dielectric heater is a sensitive moisture meter.

Several electrode configurations are used. The platen type (Figure 2) is used for drying and baking foundry cores, heating plastic preforms, and drying glue lines in furniture. The rod or stray field types (Figure 3) are used for thin web materials such as paper and textile products. The double-rod types (over and under material) are used for thicker webs or flat stock, such as plywood.

Dielectric drying is popular in the textile industry. Because air is entrained between fibers, convection drying is slow and uneven. Because the yarn is usually transferred to large packages immediately after drying, however, even and correct moisture content can be obtained by dielectric drying. Knitting wool seems to benefit from internal steaming in hanks.

Warping caused by nonuniform drying is a serious problem for plywood and linerboard. Dielectric drying yields warp-free products.

Dielectric drying is not cost effective for overall paper drying but has advantages when used at the dry end of a conventional steam drum dryer. It corrects moisture profile problems in the web without overdrying. This combination of conventional and dielectric drying is synergistic: the drying effect of the combination is greater than the sum of the two types of drying. This is more pronounced in thicker web materials, accounting for as much as a 16% line speed increase and a corresponding 2% energy input increase.

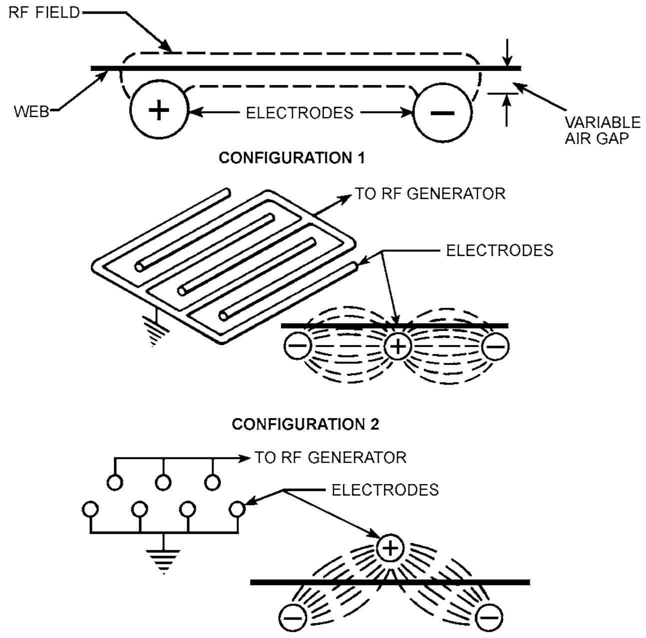

Fig. 3 Rod-Type Dielectric Dryers

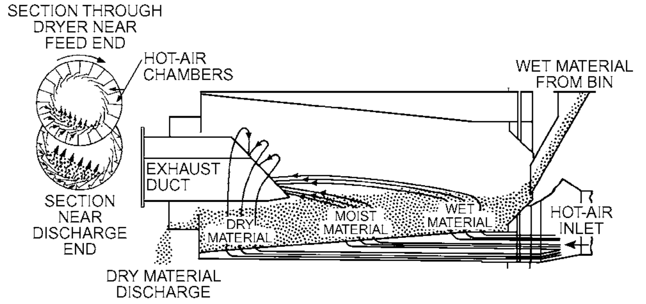

Fig. 4 Cross Section and Longitudinal Section of Rotary Dryer

Microwave Drying

Microwave drying or heating uses ultrahigh-frequency (900 to 5000 MHz) radiation. It is a form of dielectric heating and is used for heating nonconductors. Because of its high frequency, microwave equipment is capable of generating extreme power densities.

Microwave drying is applied to thin materials in strip form by passing the strip through the gap of a split waveguide. Entry and exit shielding make continuous process applications difficult. Its many safety concerns make microwave drying more expensive than dielectric drying. Control is also difficult because microwave drying lacks the self-compensating properties of dielectrics.

Convection Drying (Direct Dryers)

Some convection drying occurs in almost all dryers. True convection dryers, however, use circulated hot air or other gases as the principal heat source. Each means of mechanically circulating air or gases has its advantages.

Rotary Dryers. These cylindrical drums cascade the material being dried through the airstream (Figure 4). The dryers are heated directly or indirectly, and air circulation is parallel or counterflow. The rotating-louver dryer is a variation, introducing air beneath the flights to provide close contact.

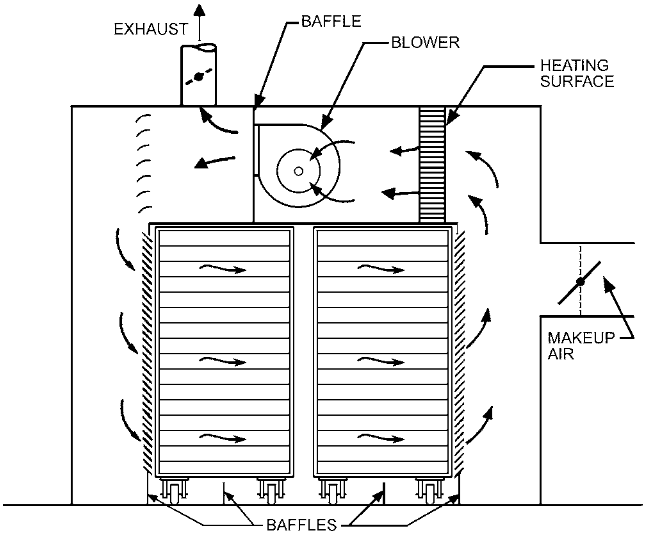

Fig. 5 Compartment Dryer Showing Trucks with Air Circulation

Cabinet and Compartment Dryers. These batch dryers range from the heated loft (with only natural convection and usually poor and nonuniform drying) to self-contained units with forced draft and properly designed baffles. Several systems may be evacuated to dry delicate or hygroscopic materials at low temperatures. Material is usually spread in trays to increase the exposed surface. Figure 5 shows a dryer that can dry water-saturated products.

When designing dryers to process products saturated with solvents, special features must be included to prevent explosive gases from forming. Safe operation requires exhausting 100% of the air circulated during the initial drying period or any part of the drying cycle when solvent is evaporating at a high rate. At the end of the purge cycle, the air is recirculated and heat is gradually applied. To prevent explosions, laboratory dryers can be used to determine the amount of air circulated, cycle lengths, and rate that heat is applied for each product. In the drying cycle, dehumidified air, which is costly, should be recirculated as soon possible. The air *must not* be recirculated when cross-contamination of products is prohibited.

Dryers must have special safety features in case any part of the drying cycle fails. The following are some of the safety design features described in *Industrial Ovens and Driers* (FM Global 2014):

- Each compartment must have separate supply and exhaust fans and an explosion-relief panel.
- The exhaust fan blade tip speed should be 25 m/s for forward-inclined blades, 35 m/s for radial-tip, and 38 m/s for backward-inclined. These speeds produce high static pressures at the fan, ensuring constant exhaust volumes under conditions such as negative pressures in the building or downdrafts in the exhaust stacks.
- Airflow failure switches in both the supply and exhaust ducts must shut off fans and the heating coil and must sound an alarm.
- A high-temperature limit controller in the supply duct must shut off the heat to the heating coil and must sound an alarm.
- An electric interlock on the dryer door must interrupt the drying cycle if the door is opened beyond a set point, such as that wide enough for a person to enter for product inspection.

Tunnel Dryers. Tunnel dryers are modified compartment dryers that operate continuously or semicontinuously. Fans circulate heated air or combustion gas is circulated by fans. The material is handled on trays or racks on trucks and moves through the dryer either intermittently or continuously. The airflow may be parallel, counterflow, or a combination obtained by center exhaust (Figure 6). Air may also flow across the tray surface, vertically through the bed, or in any combination of directions. By reheating or recirculating the air in the dryer, high saturation is reached before the air is exhausted, thus reducing the sensible heat loss.

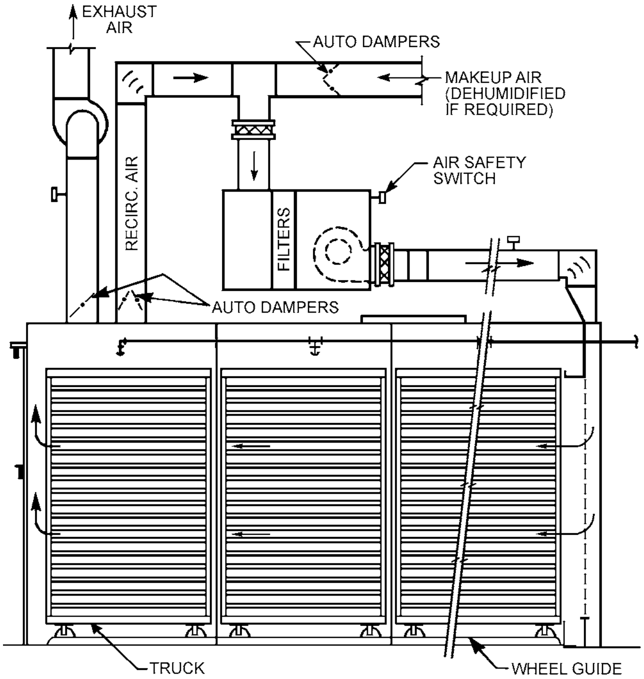

Fig. 6 Explosionproof Truck Dryer Showing Air Circulation and Safety Features

The following problems with tunnel dryers have been experienced and should be considered in future designs:

- Operators may overload product trays to increase output, but this can overtax the system and increase drying time.
- Sometimes air from the drying tunnel is discharged into the production area, increasing the humidity. Air from the drying tunnel should be discharged to the drying system return or outdoors.
- Overloaded product trays add pressure drop, which decreases flow through the dryer. The control panel should indicate validated flow through the tunnel. High and low flow and high moisture levels should trigger alarms.
- Cycle times can be reduced by designing dryers for cross flow rather than end-to-end flow.

A variation of the tunnel dryer is the strictly continuous dryer, which has one or more mesh belts that carry the product through it, as shown in Figure 7. Many combinations of temperature, humidity, air direction, and velocity are possible. Hot air leaks at the entrance and exit can be minimized by baffles or inclined ends, with the material entering and leaving from the bottom.

High-Velocity Dryers. High-velocity hoods or dryers have been used to supplement conventional cylinder dryers for drying paper. When used with conventional cylinder dryers, web instability and lack of process control result. Where internal diffusion is not the controlling factor in the drying rate, applications such as thin permeable webs offer more promise.

Spray Dryers. Spray dryers have been used in producing dried milk, coffee, soaps, and detergents. Because the dried product (in the form of small beads) is uniform and drying time is short (5 to 15 s), this drying method has become more important. When a liquid or slurry is dried, the spray dryer has high production rates.

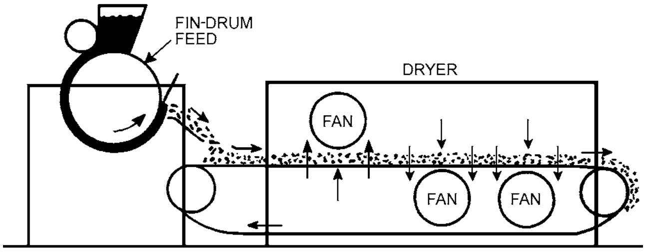

Fig. 7 Section of Blow-Through Continuous Dryer

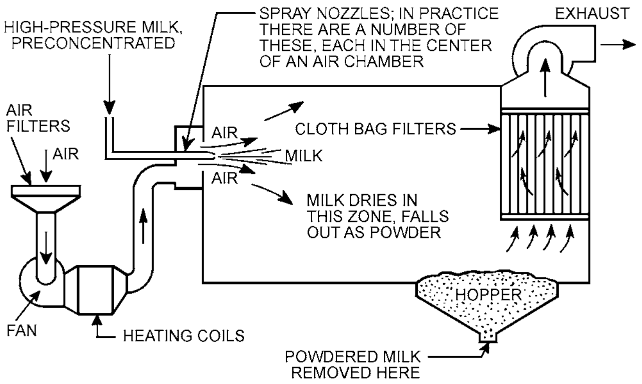

Fig. 8 Pressure-Spray Rotary Spray Dryer

Spray drying involves atomizing a liquid feed in a hot-gas drying medium. The spray can be produced by a two-fluid nozzle, a high-pressure nozzle, or a rotating disk. Inlet gas temperatures range from 93 to 760°C, with the high temperatures requiring special construction materials. Because thermal efficiency increases with the inlet gas temperature, high inlet temperatures are desirable. Even heat-sensitive products can be dried at higher temperatures because of the short drying time. Hot gas flow may be either concurrent or countercurrent to the falling droplets. Dried particles settle out by gravity. Fine material in the exhaust air is collected in cyclone separators or bag filters. Figure 8 shows a typical spray drying system.

The physical properties of the dried product (such as particle size, bulk density, and dustiness) are affected by atomization characteristics and the temperature and direction of flow of the drying gas. The product's final moisture content is controlled by the humidity and temperature of the exhaust gas stream.

Currently, pilot-plant or full-scale production operating data are required for design purposes. The drying chamber design is determined by the nozzle's spray characteristics and heat and mass transfer rates. There are empirical expressions that approximate mean particle diameter, drying time, chamber volume, and inlet and outlet gas temperatures.

Freeze Drying

Freeze drying has been applied to pharmaceuticals, serums, bacterial and viral cultures, vaccines, fruit juices, vegetables, coffee and tea extracts, seafoods, meats, and milk.

The material is frozen, then placed in a high-vacuum chamber connected to a low-temperature condenser or chemical desiccant. Heat is slowly applied to the frozen material by conduction or infrared radiation, allowing the volatile constituent, usually water, to sublime and condense or be absorbed by the desiccant. Most freeze-drying operations occur between –10 and –40°C under minimal pressure. Although this process is expensive and slow, it has advantages for heat-sensitive materials (see Chapter 29 of the 2018 *ASHRAE Handbook—Refrigeration*).

Vacuum Drying

Vacuum drying takes advantage of the decrease in the boiling point of water that occurs as the pressure is lowered. Vacuum drying of paper has been partially investigated. Serious complications arise if the paper breaks, and massive sections must be removed. Vacuum drying is used successfully for pulp drying, where lower speeds and higher masses make breakage relatively infrequent.

Fluidized-Bed Drying

A fluidized-bed system contains solid particles through which a gas flows with a velocity higher than the incipient fluidizing velocity but lower than the entrainment velocity. Heat transfer between the individual particles and the drying air is efficient because there is close contact between powdery or granular material and the fluidizing gas. This contact makes it possible to dry sensitive materials without danger of large temperature differences.

The dried material is free-flowing and, unlike that from convection dryers, is not encrusted on trays or other heat-exchanging surfaces. Automatic charging and discharging are possible, but the greatest advantage is reduced process time. Only simple controls are important: over (1) fluidizing air or gas temperatures and (2) the drying time of the material.

All fluidized-bed dryers should have explosion-relief flaps. Both the pressure and flames of an explosion are dangerous. When toxic materials are used, uncontrolled venting to the atmosphere is prohibited. Explosion suppression systems, such as pressure-actuated ammonium-phosphate extinguishers, have been used instead of relief venting. An inert dryer atmosphere is preferable to suppression systems because it prevents explosive mixtures from forming.

When organic and inflammable solvents are used in the fluidized-bed system, the closed system offers advantages other than explosion protection. A portion of the fluidizing gas is continuously run through a condenser, which strips the solvent vapors and greatly reduces air pollution problems, thus making solvent recovery convenient.

Materials dried in fluidized-bed installations include coal, limestone, cement rock, shales, foundry sand, phosphate rock, plastics, medicinal tablets, and foodstuffs. Leva (1959) and Othmer (1956) discuss the theory and methods of fluidization of solids. Clark (1967) and Vanecek et al. (1966) developed design equations and cost estimates.

Agitated-Bed Drying

Uniform drying is ensured by periodically or continually agitating a bed of preformed solids with a vibrating tray, a conveyor, or a vibrating mechanically operated rake, or, in some cases, by partial fluidization of the bed on a perforated tray or conveyor through which recycled drying air is directed. Drying and toasting cereals is an important application.

Drying in Superheated Vapor Atmospheres

When drying solids with air or another gas, the vaporized solvent (water or organic liquid) must diffuse through a stagnant gas film to reach the bulk gas stream. Because this film is the main resistance to mass transfer, the drying rate depends on the solvent vapor diffusion rate. If the gas is replaced by solvent vapor, resistance to mass transfer in the vapor phase is eliminated, and the drying rate depends only on the heat transfer rate. Drying rates in solvent vapor, such as superheated steam, are greater than those in air for equal temperatures and mass flow of the drying media.

This method also has higher thermal efficiency, easier solvent recovery, and a lower tendency to overdry, and it eliminates oxidation or other chemical reactions that occur when air is present. In drying cloth, superheated steam reduces the migration tendency of resins and dyes. Superheated vapor drying cannot be applied to heat-sensitive materials because of the high temperatures.

Commercial drying equipment with recycled solvent vapor as the drying medium is available. Installations have been built to dry textile sheeting and organic chemicals.

Flash Drying

Finely divided solid particles that are dispersed in a hot gas stream can be dried by flash drying, which is rapid and uniform. Commercial applications include drying pigments, synthetic resins, food products, hydrated compounds, gypsum, clays, and wood pulp.

Constant-Moisture Solvent Drying

In some cases it is desirable to dry organic solvents from a substance without changing moisture content. This is particularly true in drying pharmaceutical products, which are commonly bound with solvents such as isopropyl alcohol (IPA) or acetone. Loss of moisture content can affect the stability of some pharmaceutical compounds, which therefore must be liberated of bound solvents without changing the relative humidity. Most pharmaceutical facilities producing oral solid dosage (OSD) forms manufacture in spaces that range from 30 to 45% rh. To maintain this level of humidity at the temperatures needed to liberate the organic solvents at the required rate, an oven must be fitted with an adequately sized humidifier. Figure 9 shows the compartment dryer from Figure 5 adapted for constant-moisture drying.

It is vital to size the preheat coil to the humidifier to allow enough “room” to provide the humidification level required. The amount of preheat is usually enough to provide makeup air to the oven at 90% rh. This allows the oven heaters to control drying temperature at the more common oven humidity levels of 30 to 45% rh. If electric heat is used, the ability to constantly vary the capacity of the heaters must be provided; silicon-controlled rectifiers (SCRs) are commonly used.

Additional insulation on the outside of the oven and the ductwork from the humidifier section onward should also be considered. Care must be taken to ensure that unwanted condensation does not form inside the oven. Dripping moisture can sometimes ruin the product, causing a substantial economic loss. If the product is pharmaceutical, then the humidifier makeup water source should be deionized or produced to comply with U.S. Pharmacopoeia 34—National Formulary—29 (effective August 2010).

CHAPTER 32

VENTILATION OF THE INDUSTRIAL ENVIRONMENT

Ventilation Design Principles 31.2
General Comfort and Dilution Ventilation 31.2
Heat Control 31.5
Energy Conservation, Recovery, and Sustainability 31.6

INDUSTRIAL environments require ventilation to reduce exposure to excess heat and contaminants that are generated in the workplace; in some situations, cooling may also be required. Ventilation is primarily used to control excess heat, odors, and hazardous particulate and chemical contaminants. These could affect workers' health and safety or, in some cases, become combustible or flammable when allowed to accumulate above their minimum explosive concentration (MEC) or lower flammable limit (LFL) [also called the lower explosive limit (LEL)] (Cashdollar 2000). Excess heat and contaminants can best be controlled by using local exhaust systems whenever possible. Local exhaust systems capture heated air and contaminants at their source and may require lower airflows than general (dilution) ventilation. See Chapter 32 for more information on the selection and design of industrial local exhaust systems.

General ventilation can be provided by mechanical (fan) systems, by natural draft, or by a combination of the two. Combination systems could include mechanically driven (fan-driven) supply air with air pressure relief through louvers or other types of vents, and mechanical exhaust with air replacement inlet louvers and/or doors.

Mechanical (fan-driven) supply systems provide the best control and the most comfortable and uniform environment, especially when there are extremes in local climatic conditions. The systems typically consist of an inlet section, filtration section, heating and/or cooling equipment, fans, ductwork, and air diffusers for distributing air in the workplace. When toxic gases or vapors are not present and there are no aerosol contaminants associated with adverse health effects, air cleaned in the general exhaust system or in packaged air filtration units can be recirculated via a return duct. When applied appropriately, air recirculation can be a major contributor to a sustainable industrial ventilation design and may reduce heating and cooling costs.

In addition, regardless of the method selected, any positive ventilation into an industrial space should be from a source that is essentially free of any contaminants under both normal and abnormal conditions in the surrounding atmosphere. In many cases, this may require a sealed intake stack or ductwork, as opposed to a perimeter wall hood or other air intake device, wherein the source of intake should be from a point well above or beyond the veil of the hazardous space that may surround a ventilated space. Where this cannot be achieved, additional action should be undertaken (e.g., providing particulate or carbon filtration).

A general exhaust system, which removes air contaminated by gases, vapors, or particulates not captured by local exhausts, usually consists of one or more fans, plus inlets, ductwork, and air cleaners or filters. After air passes through the filters, it is either discharged outdoors, or partially recirculated within the building. The air filtration system's cleaning efficiency should conform to environmental regulations and depends on factors such as building location, background contaminant concentrations, type and toxicity of contaminants, and height and velocity of building exhaust discharge.

Many industrial ventilation systems must handle simultaneous exposures to temperature extremes and hazardous substances. In these cases, the required ventilation can be provided by a combination of local exhaust, general ventilation air supply, and general exhaust systems. The ventilation engineer must carefully analyze supply and exhaust air requirements to determine the worst case. For example, air supply makeup for hood exhaust may be insufficient to control heat exposure. It is also important to consider seasonal climatic effects on ventilation system performance, especially for natural ventilation systems. Duct material and its compatibility with the exhaust airstream is also important to consider when ventilating hazardous, abrasive, or corrosive substances.

Most importantly, if the hazardous substances are ignitable gases or dusts, all electrical components of the ventilation system should be rated for the proper electrical classification in the absence of any ventilation, regardless of their locations in the ventilation system.

In specifying acceptable chemical contaminant and heat exposure levels, the industrial hygienist or industrial hygiene engineer must consult the appropriate occupational exposure limits that apply as well as any governing standards and guidelines. The legislated limits for the maximum airborne concentration of chemical substances to which a worker may be exposed are listed as (1) maximum average exposures to which a worker may be exposed over a given work day (generally assumes an 8 to 10 h work day and a traditional 40 h work week); (2) short-term exposure limits, which are the maximum average airborne concentration to which a worker may be exposed over any 15 min period; and (3) ceiling limits, which are the maximum airborne concentration to which a worker may be exposed at any time. However, occupational exposure limits for cold, heat, and contaminants are not lines of demarcation between safe and unsafe exposures. Rather, they represent conditions to which it is believed nearly all workers may be exposed day after day without adverse and/or long-term effects. Because a small percentage of workers may be affected by occupational exposure below the regulated limits, it is prudent to design for control to the most conservative occupational exposure limits (OELs) available.

In the case of exposure to hazardous chemicals, the number of contaminant sources, their generation rates, and the effectiveness of exhaust hoods may not be known. Consequently, the ventilation engineer must rely on industrial hygiene engineering practices when designing toxic and/or hazardous chemical controls. Close cooperation among the industrial hygienist, process engineer, and ventilation engineer is required.

In the case of exposure to flammable or ignitable chemicals, the specific gravity of the contaminant source(s), their concentration, and the rating of all electrical devices in the space, along with any source or point of excessive heat, must be carefully considered to prevent possible loss of life or severe injury. As with all hazardous chemicals, cooperation of knowledgeable experts, including electrical engineers, is required.

This chapter describes principles of ventilation practice and includes other information on industrial hygiene in the industrial environment. Publications from the American Industrial Hygiene Association (AIHA 2011), British Occupational Hygiene Society (BOHS 2002), U.S. Department of Health and Human Services (DHHS 1986), National Safety Council (2012), and U.S. National

The preparation of this chapter is assigned to TC 5.8, Industrial Ventilation Systems.

Institute for Occupational Safety and Health (NIOSH 1986) provide further information on industrial hygiene principles and their application.

1. VENTILATION DESIGN PRINCIPLES

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

General Ventilation

General ventilation supplies and/or exhausts air to provide heat relief, dilute contaminants to an acceptable level, and replace exhaust air. Ventilation can be provided by natural or mechanical supply and/or exhaust systems. Industrial areas must comply with ASHRAE *Standard* 62.1-2013 and other standards as required (e.g., by NFPA). Outdoor air is unacceptable for ventilation if it is known to contain any contaminant at a concentration above that given in ASHRAE *Standard* 62.1. If air is thought to contain any contaminant not listed in the standard, consult relevant federal, state, provincial, or local jurisdictions for acceptable exposure levels. In addition to their role in controlling industrial contaminants, general ventilation rates must be sufficient to dilute the carbon dioxide produced by occupants to a level acceptable under ASHRAE *Standard* 62.2.

For complex industrial ventilation problems, experimental scale models and computational fluid dynamics (CFD) models are often used in addition to field testing.

Makeup Air

When large volumes of air are exhausted to provide acceptable comfort and safety for personnel and acceptable conditions for process operations, this air must be replaced, either through intentional design strategy or through paths of least resistance. A safe and effective ventilation design should be strategic about the mechanism, locations, and physical parameters by which makeup air enters the occupied space. Makeup air, consistently provided by good air distribution, allows more effective cooling in the summer and more efficient and effective heating in the winter. When makeup air design is not incorporated into the ventilation design scheme, it may lead to inefficient operation of local exhaust systems and/or combustion equipment and cross-drafts that affect occupant comfort and environmental control settings. Relying on windows or other air inlets that cannot function in year-round weather conditions is discouraged. Some factors to consider in designs for makeup air include

- Makeup air must be sufficient to replace air being exhausted or consumed by combustion processes, local and general exhaust systems (see Chapter 32), or process equipment. (Large air compressors can consume a large amount of air and should be considered if air is drawn from within the building.)
- Makeup air systems should be designed to eliminate uncomfortable cross-drafts by properly arranging supply air outlets, and to prevent infiltration (through doors, windows, and similar openings) that may make hoods unsafe or ineffective, defeat environmental control, bring in or stir up dust, or adversely affect processes by producing temperature or airflow disturbances. The design engineer needs to consider side drafts and other sources of air movement close to the capture area of a local exhaust hood. In industrial applications, it is common to see large fans blowing air onto workers positioned in front of the hood. This can render the local exhaust hood ineffective to the point that no protection is provided for the worker: Ahn et al. (2008), Caplan and Knutson (1977, 1978), and Tseng et al. (2010) found that air movement in front of laboratory hoods can cause contaminants to escape from the hood and into the operator's breathing zone. Hoods should be located safe distances from doors and openable windows, supply air diffusers, and areas of high personnel traffic (AIHA *Standard* Z9.5; NFPA *Standard* 45).
- Makeup air should be obtained from a clean source with no more than trace amounts of any airborne contaminants or hazardous, ignitable substances. Supply air can be filtered, but infiltration air cannot. For transfer air use, see ASHRAE *Standard* 62.1.
- Makeup air for spaces contaminated by toxic, ignitable, or combustible chemicals may have to be acquired through carefully sealed ductwork from an area know to be free of contamination and be supplied at sufficient rates, pressures, and mixing efficiencies to (1) remove all contamination, and (2) prevent infiltration of similar contaminants from surrounding areas or adjacent spaces.
- Makeup air should be used to control building pressure and airflow from space to space to (1) avoid positive or negative pressures that make it difficult or unsafe to open doors, (2) minimize drafts, and (3) prevent infiltration.
- Makeup air should be used to reduce contaminant concentration, to control temperature and humidity, and minimize undesirable air movement.
- Makeup air systems should be designed to recover heat and conserve energy (see the section on Energy Conservation, Recovery, and Sustainability).

For more information on potential adverse conditions caused by specific negative pressure levels in buildings, see ACGIH (2013) and Chapter 28 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

2. GENERAL COMFORT AND DILUTION VENTILATION

Effective air diffusion in ventilated rooms and the proper quantity of conditioned air are essential for creating an acceptable working environment, removing contaminants, and reducing installation and operating costs of a ventilation system. Ventilation systems must supply air at the proper velocity and temperature, with resulting contaminant concentrations within permissible occupational exposure limits (OELs). For the industrial environment, the most common objective is to provide tolerable (acceptable) working conditions rather than comfort (optimal) conditions.

General ventilation system design is based on the assumption that local exhaust ventilation, radiation shielding, and equipment insulation and encapsulation have been selected to minimize both heat load and contamination in the workplace (see the section on Heat Control). When work operations are generally restricted, such as with equipment operating stations or control booths, spot conditioning of the work environment with clean conditioned air (see the section on Makeup Air) may further reduce the reliance on general ventilation for conditioning or contaminant dilution. In cold climates, infiltration and heat loss through the building envelope may need to be minimized by pressurizing buildings.

For more information on dilution ventilation, see ACGIH (2013).

Quantity of Supplied Air

Sufficient air must be supplied to replace air exhausted by process ventilation and local exhausts, dilute contaminants (gases, vapors, or airborne particles) not captured by local exhausts, prevent the entry of contaminants or hazardous (ignitable) substances from any surrounding atmosphere during ingress or egress, and provide the required thermal environment. The amount of supplied air should be the largest of the amounts needed for temperature control, dilution, and replacement.

Air Supply Methods

Air supply to industrial spaces can be by natural or mechanical ventilation systems. Although natural ventilation systems driven by gravity forces and/or wind effect are still widely used in industrial spaces (especially in hot premises in cold and moderate climates), they are inefficient in large buildings, may cause drafts, and may not sufficiently solve air contamination problems, because the prerequisite environmental conditions may not be available during all required periods of need or there is no practical filtration method available. Thus, most ventilation systems in industrial spaces are either mechanical (fan-driven) or a combination of mechanical supply with natural exhaust, using louvers or doors for air pressure relief (or for air replacement in exhaust systems).

The most common methods of air supply to industrial spaces are mixing, displacement, and localized.

Mixing Air Distribution. In mixing systems, air is normally supplied at velocities much greater than those acceptable in the occupied zone. Supply air temperature can be above, below, or equal to the air temperature in the occupied zone, depending on the heating/cooling load. The supply air diffuser jet mixes with room air by entrainment, which reduces air velocities and equalizes the air temperature. The occupied zone is ventilated either directly by the air jet or by reverse flow created by the jet. Properly selected and designed mixing air distribution creates relatively uniform air velocity, temperature, humidity, and air quality conditions in the occupied zone and over the room height. Note that supply systems should introduce air into the workspace in such a way as to not interfere with contaminant control systems such as ventilation hoods. If possible, ventilation hoods (e.g., fume hoods) should have quiescent air conditions (~0.5 m/s) at their face.

Displacement Ventilation Systems. Conditioned air that is slightly cooler than the desired room air temperature in the occupied zone is supplied from air outlets at low air velocities (~0.5 m/s or less). Because of buoyancy, the cooler air spreads along the floor and floods the room's lower zone. Air close to the heat source is heated and rises upward as a convective air stream; in the upper zone, this stream spreads along the ceiling. The height of the lower zone depends on the air volume and temperature supplied to the occupied zone and on the amount of convective heat discharged by the sources.

Typically, outlets are located at or near the floor, and supply air is introduced directly into the occupied zone. In some applications (e.g., in computer rooms or hot industrial buildings), air may be supplied to the occupied zone through a raised floor. Exhaust or air returns are located at or close to the ceiling or roof.

Displacement ventilation is common in European countries. It is an option when contaminants are released in combination with surplus heat, and contaminated air is warmer (more buoyant) than the surrounding air. It is not a good choice when air turbulence can interfere with convective conveyance of heat and contaminants. Further information on displacement air distribution systems can be found in Chen and Glicksman (2003) and Goodfellow and Tahti (2001).

Localized Ventilation. Air is supplied locally for occupied regions or a few permanent work areas (Figure 1). Conditioned air is supplied toward the occupants' breathing zone to create comfortable conditions and/or to reduce the concentration of pollutants. These zones may have air that is cleaner than the surrounding air, and should generally be compliant with ASHRAE *Standard* 62.1. In localized ventilation systems, air is supplied through one of the following devices:

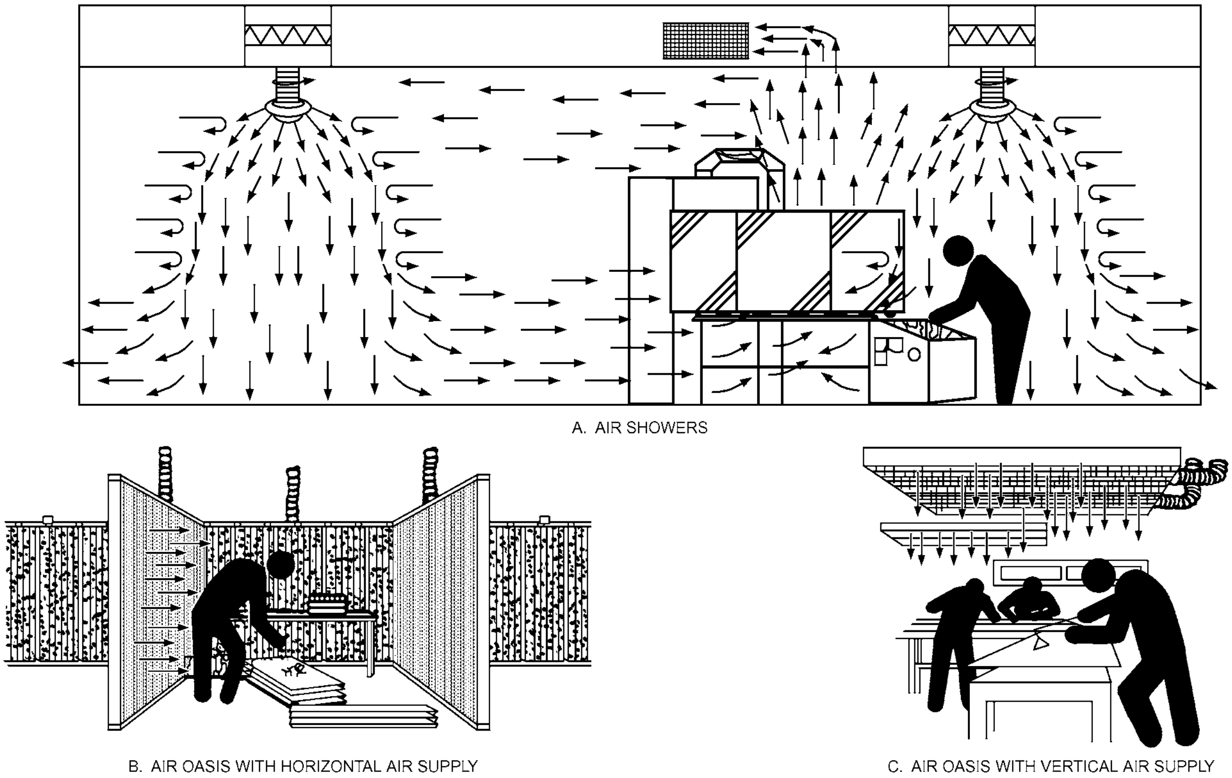

Fig. 1 Localized Ventilation Systems

- Nozzles or grilles (e.g., for spot cooling), specially designed low-velocity/low-turbulence devices
- Perforated panels suspended on vertical duct drops and positioned close to the workstation

Local Area and Spot Cooling

In hot workplaces that have few work areas, it is likely impractical to maintain a comfortable environment in the entire space. However, environmentally controlled cabins, individual cooling, and spot cooling and extraction can improve working conditions in occupied areas. Certain applications require minimum distances from supplied air (and natural ventilation points) to ensure airflow in ventilated hoods and cabinets is not affected.

Environmentally controlled cabins (e.g., operating cabs, pulpits, control rooms, enclosures) can provide thermal comfort, and, when pressurized with a dedicated clean-air supply (either dedicated source or through effective filtration), can improve air quality in occupational environments. There usually are significant economic benefits to properly designing, installing, and maintaining worker-protective environmental enclosures.

Spot cooling, probably the most popular method of improving the thermal environment, can be provided by radiation (changing mean radiant temperature), convection (changing air velocity and/or air supply temperatures), or both. Spot-cooling equipment is fixed at the workstation, whereas in **individual cooling**, the worker wears the equipment.

Local exhaust ventilation (spot extraction) is another method to remove excess heat from a process or source of high temperature, and should be the first step considered for energy saving over spot cooling.

Locker Room, Toilet, and Shower Space Ventilation

Ventilation of locker rooms, toilets, and shower spaces is important in industrial facilities to remove odor and reduce humidity. In some industries, control of workroom contamination requires prevention of both ingestion and inhalation routes of exposure, so adequate hygienic facilities, including appropriate ventilation, may be required in locker rooms, changing rooms, showers, lunchrooms, and break rooms. State, provincial, and local regulations should be consulted early in design.

Supply air may be introduced through doors or wall grilles. In some cases, workplace air may be so contaminated that filtration or a dedicated source of clean supply air is required. When control of workroom contaminants is inadequate or not feasible, reduce employee exposure by positively pressurizing locker rooms, lunchrooms, and break rooms to minimize the level of contamination in those areas. Treated supply air may be ineffective in some applications because it can introduce drafts and outdoor contamination or result in excessive condensation in a humid indoor environment.

When mechanical ventilation of supply air is used, the supply system should have adequate ducting and air distribution devices, such as diffusers or grilles, to distribute air throughout the area.

In locker rooms, take exhaust primarily from the toilet and shower spaces as needed and secondarily from the lockers. Exhausting from the room's open ceiling areas should be a last option. ASHRAE *Standard* 62.1 and many local mechanical codes provide requirements for these areas.

Roof Ventilators

Roof ventilators are heat escape ports located high in a building and should be properly enclosed for weathertightness (Goodfellow 1985). Stack effect and some wind induction are the motive forces for gravity- (buoyancy-) driven operation of continuous and round ventilators. Round ventilators can be equipped with a fan barrel and motor, allowing gravity or forced ventilation operation.

Many ventilator designs are available, including the **low ventilator**, which consists of a stack fan with a rain hood, and a **ventilator with a split butterfly closure** that floats open to discharge air and closes by a counterweight. Both use minimum enclosures and have little or no gravity capacity. Split butterfly dampers tend to increase fan airflow noise and are subject to damage from slamming during strong winds. Because noise is frequently a problem in powered roof ventilators, the manufacturer's sound rating should be reviewed. Sound attenuators should be installed where required to meet the design sound ratings.

Continuous ventilation monitors remove substantial, concentrated heat loads most effectively. One type, the **streamlined continuous ventilator**, is efficient, weathertight, and designed to prevent backdraft; it usually has dampers that may be closed in winter to conserve building heat. Its capacity is limited only by the available roof area and the proper location and sizing of low-level air inlets. Continuous ventilation to achieve a slight pressure above the surrounding atmosphere (referred to as **pressurization** by NFPA) also can be used to reduce or declassify the electrical classification of enclosed spaces. Typically, reductions from class I, zone 1 or division 1 to class I, zone 2 or division 2 can be achieved by following the recommendations of NFPA *Standard* 496. This allows using general-purpose electrical devices instead of zone 2 or division 2 devices, or using zone 2 or division 2 electrical devices instead of zone 1 or division 1 devices, which (1) greatly reduces the cost of electrical equipment and (2) provides a sound alternative when particular devices are not available for the higher (more volatile) electrical area classifications.

Gravity ventilators, also highly effective, have low operating costs, do not generate noise, and are self-regulating (i.e., higher heat release increases airflow through the ventilators). Gravity ventilators can be affected by environmental conditions and thus should only be used for heat control rather than for the control of gaseous or aerosol contaminants. Care must be taken to ensure positive pressure at the ventilators, particularly during the heating season. Otherwise, outside air will enter the ventilators.

Next in order of heat removal capacity are (1) round gravity or wind-band ventilators, (2) round gravity ventilators with fan and motor added, (3) low-hood powered ventilators, and (4) vertical upblast powered ventilators. The shroud for the vertical upblast design has a peripheral baffle to deflect air upward instead of downward. Vertical discharge is highly desirable to reduce roof damage caused by hot air if it contains condensable oil or solvent vapor. Ventilators with direct-connected motors are desirable to avoid belt maintenance. Round gravity ventilators are applicable for warehouses with light heat loads and for manufacturing areas with high roofs and light loads.

Streamlined continuous ventilators must operate effectively without mechanical power. To ensure ventilator performance, sufficient low-level openings must be provided for incoming air; insufficient inlet area and significant space air currents are the most common reasons gravity roof ventilators malfunction. A positive supply of air around hot equipment may be necessary in large buildings where external wall inlets are remote from the equipment. Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals* has additional information on ventilation and infiltration.

The cost of electrical power for mechanical ventilation over that of roof ventilators can be offset by the advantage of constant airflow. Mechanical ventilation can also create the pressure differential necessary for good airflow, even with small inlets. Inlets should be sized correctly to avoid infiltration and other problems caused by high negative pressure in the building. Often, a mechanical system is justified to supply enough makeup air to maintain the work area under positive pressure.

Roof ventilators can comprise either mechanically operated openings or fan-powered mechanical exhaust. Operator-assisted openings or dampers are usually used in shops with high ceilings, and must be installed when natural ventilation is used to provide air to the space.

3. HEAT CONTROL

Ventilation control alone may frequently be inadequate for meeting heat stress standards for industrial work areas. Optimum solutions may involve additional controls such as spot cooling, changes in work/rest patterns, and radiation shielding.

Ventilation for Heat Relief

Many industrial processes release large amounts of heat and moisture to the environment. In such environments, it may not be economically feasible to maintain comfort conditions (ASHRAE *Standard* 55), particularly during summer. Comfortable conditions are not physiologically necessary: the body must be in thermal balance with the environment, but this can occur at temperature and humidity conditions well above the normal comfort zone. In areas where heat and moisture generated by a process are low to moderate, comfort conditions may not have to be provided if personnel exposures are infrequent and brief. In such cases, ventilation may be the only control necessary to prevent excessive physiological heat stress.

The engineer must distinguish between control needs for hot/dry industrial areas and warm/moist conditions. In hot/dry areas, a process gives off only sensible (primarily convective and radiant) heat without adding moisture to the air. This increases the heat load on exposed workers, but the rate of cooling by evaporation of perspiration may not be significantly reduced. Body heat equilibrium may be maintained, but could cause excessive perspiration. Hot/dry work situations occur around furnaces, forges, metal-extruding and rolling mills, glass-forming machines, etc.

In warm/moist conditions, a wet process may generate a significant latent heat load. The rise in sensible heat load on workers may be insignificant, but the increased moisture content of the air can seriously reduce cooling by evaporation of perspiration, making warm/moist conditions potentially more hazardous than hot/dry. Typical warm/moist operations are found in textile mills, laundries, dye houses, and deep mines, where water is used extensively for dust control.

Industrial heat load is also affected by local climate. Solar heat gain and elevated outdoor temperatures increase the heat load at the workplace, but may be insignificant compared to process heat generated locally. The moisture content of outdoor air is an important factor that can affect hot/dry work situations by restricting an individual's evaporative cooling. For warm/moist working environments, solar heat gain and elevated outdoor temperatures are even more important because moisture contributed by outdoor air is insignificant compared to that released by the process.

Both ASHRAE *Standard* 55 and International Organization for Standardization (ISO) *Standard* 7730 specify thermal comfort conditions.

Methods for evaluating the general thermal state of the body both in comfort conditions and under heat and cold stress are based on analysis of the heat balance for the human body, as discussed in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*. A person may find the thermal environment unacceptable or intolerable because of local effects on the body caused by asymmetric radiation, air velocity, vertical air temperature differences, or contact with hot or cold surfaces (floors, machinery, tools, etc.).

Heat Stress—Thermal Standards

Another heat stress indicator for evaluating an environment's heat stress potential is the **wet-bulb globe temperature** (WBGT), defined as follows:

Outdoors with solar load

$$WBGT = 0.7t_{nwb} + 0.2t_g + 0.1t_{db} \quad (1)$$

Indoors, or outdoors with no solar load

$$WBGT = 0.7t_{nwb} + 0.3t_g \quad (2)$$

where

t_{nwb} = naturally ventilated wet-bulb temperature (no defined range of air velocity; different from saturation temperature or psychrometric wet-bulb temperature), °C

t_g = globe temperature (Vernon bulb thermometer, 150 mm diameter), °C

t_{db} = dry-bulb temperature (sensor shaded from solar radiation), °C

Coefficients in Equations (1) and (2) represent the fractional contributions of the component temperatures.

Exposure limits for heat stress for different levels of physical activity are shown in Figure 2 (NIOSH 1986), which depicts the allowable work regime (in terms of rest periods and work periods each hour) for different levels of work over a range of WBGT. When applying Figure 2, assume that the rest area has the same WBGT as the work area. The curves are valid for workers acclimatized to heat. ASHRAE *Standard* 62.1 provides some metabolic rates for different activities that can be used with Figure 2. Refer to NIOSH (1986) for recommended WBGT limits for nonacclimatized workers.

The **WBGT index** is an international standard (ISO *Standards* 7243, 7730, and 7933) for evaluating hot environments. The WBGT index and activity levels should be evaluated on 1 h mean values; that is, WBGT and activity are measured and estimated as time-weighted averages on a 1 h basis for continuous work, or on a 2 h basis when exposure is intermittent. Although recommended by NIOSH, the WBGT has not been accepted as the sole legal standard by the Occupational Safety and Health Administration (OSHA), and it may not apply for non-U.S. jurisdictions. The WBGT is generally used in conjunction with other methods to determine heat stress.

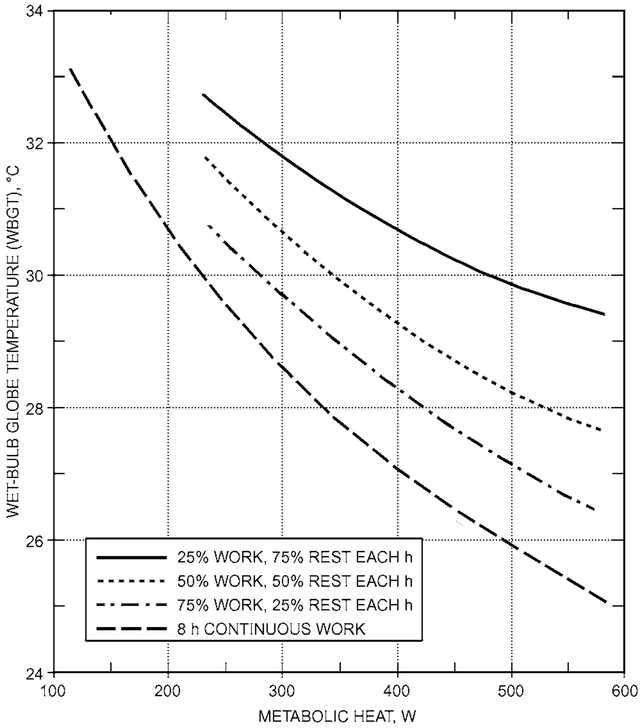

Fig. 2 Recommended Heat Stress Exposure Limits for Heat-Acclimatized Workers
[Adapted from NIOSH (1986)]

Although Figure 2 is useful for evaluating heat stress exposure limits, it is of limited use for control purposes or for evaluation of comfort. Air velocity and psychrometric wet-bulb measurements are usually needed to specify proper controls, and are only measured indirectly in WBGT determinations. Information on other useful tools, including the heat stress index (HSI), can be found in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* and in ISO *Standards* 7243, 7730, and 7933.

The thermal relationship between humans and their environment is determined by four independent environmental variables:

- Air temperature
- Radiant temperatures
- Moisture content of the air
- Air velocity

Together with the rate of internal heat production (metabolic rate) and clothing variables, these factors may combine in various ways to create different degrees of heat stress. The HSI is defined as the percent of the skin that is wetted by perspiration:

$$\text{HSI} = E_{sk}/E_{max} \times 100 \tag{3}$$

where

E_{sk} = evaporative heat loss from the skin, W/m²
E_{max} = maximum possible evaporative heat loss from the skin, W/m²

and incorporates relative contributions of metabolism, radiant heat gain (or loss), convective heat gain (or loss), and evaporative (perspiration) heat gain (or loss). For supplemental information on evaluation and control of heat stress using methods such as reduction of radiation, changes in work/rest pattern, spot cooling, and cooling vests and suits, refer to ACGIH (2013), Brief et al. (1983), Caplan (1980), NIOSH (1986), and Ontario MOL (2009).

Heat Exposure Control

Control at Source. Heat exposure can be reduced by providing sufficient insulation to hot equipment or locating it outdoors or in zones with general or local exhaust ventilation, covering steaming water tanks, providing covered drains for direct removal of hot water, and maintaining tight joints and valves where steam may escape.

Local Exhaust Ventilation. Local exhaust ventilation removes heated air generated by a hot process and/or gases emitted by process equipment, while removing a minimum of air from the surrounding space. Local exhaust systems, including heat exposure control using overhead canopy hoods, are discussed in detail in Chapter 32 and McKernan et al. (2014).

Radiation Shielding. In some industries, the major environmental heat load is radiant heat from hot objects and surfaces, such as furnaces, ovens, furnace flues and stacks, boilers, molten metal, hot ingots, castings, and forgings. Because air temperature has no significant effect on radiant heat flow, ventilation is of little help in controlling such exposure. The only effective control is to reduce the amount of radiant heat impinging on the workers by insulating or placing radiation shields around the source.

Radiation shields are effective in the following forms:

- **Reflective shielding**. Sheets of reflective material or insulating board are temporarily attached to the hot equipment or arranged in a semiportable floor stand.
- **Absorptive shielding (water-cooled)**. These shields absorb and remove heat from hot equipment.
- **Transparent shields**. Heat-reflective tempered plate glass, reflective metal chain curtains, and close-mesh wire screens moderate radiation without obstructing the view of hot equipment.
- **Flexible shielding**. Aluminum-treated fabrics give a high degree of radiation shielding.
- **Protective clothing**. Reflective garments such as aprons, gauntlet gloves, and face shields provide moderate radiation shielding. For extreme radiation exposures, complete suits with vortex tube cooling may be required.

If the shield is a good reflector, it remains relatively cool in severe radiant heat. Bright or highly polished tinplate, stainless steel, and ordinary flat or corrugated aluminum sheets are efficient and durable. Foil-faced plasterboard, although less durable, reflects well on one side. To be efficient, however, the reflective shield must remain bright. Radiation shields are much more efficient when used in multiple layers; they should reflect the radiant heat back to the primary source, where the resulting hot gases can be removed by local exhaust. However, unless the shield completely surrounds the primary source, some infrared energy is reflected into the cooler surroundings and possibly into an occupied area. The direction of reflected heat should be studied to ensure proper shielding installation.

Spot Cooling. If the workplace is located near a source of radiant heat that cannot be entirely controlled by radiation shielding, spot cooling can be used. See Chapter 20 in the 2017 *ASHRAE Handbook—Fundamentals* and data from spot-cooling diffuser manufacturers for further information.

4. ENERGY CONSERVATION, RECOVERY, AND SUSTAINABILITY

Because of the large air volumes required to ventilate industrial plants, energy conservation and recovery should be practiced, and can provide substantial savings if this practice does not compromise overriding life safety concerns. Therefore, after all critical life safety issues have been adequately addressed, energy recovery should be incorporated into preliminary planning for an industrial plant wherever and whenever it is both safe and practical to deploy. When selecting energy recovery equipment, ensure that materials are compatible with all contaminants and hazardous substances that may be exhausted. Verify the acceptability of the energy recovery method with local codes.

In some cases, it is possible to provide unheated or partially heated makeup air to the building. Although most energy conservation and recovery methods in this section apply to heating, the savings possible with cooling systems are similar. The following are some methods of energy conservation and recovery:

- In the original design phase, process and equipment insulation and heat shields should be provided to minimize heat loads. Vaporproofing and reducing the glass area may be required. Exhaust requirements for hoods and processes should be reviewed and kept to a practical, safe minimum; for more on local exhaust systems, see Chapter 32.
- Design the supply and exhaust general ventilation systems for optimal operation throughout the year. Provide air as close to the occupied zone as possible without affecting exhaust operation. Clean, recirculated air can be used in winter makeup if it does not increase the levels of contamination in the space (see the following bullet points for more details and restrictions) (ACGIH 2013). Supply and exhaust systems may be interlocked together to avoid overpressurization of the space by the supply unit if intermittent extracts are used.
- Supply air can be passed through air-to-air, liquid-to-air, or hot-gas-to-air heat exchangers to recover building or process heat. Rotary, regenerative, coil energy recovery (runaround), and air-to-air heat exchangers are discussed extensively in Chapters 25 and 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Energy recovery is also discussed in Chapters 5 and 11 of ACGIH (2013).
- Operate the system for economy if this does not compromise life safety. Although CO_2-based demand control ventilation (DCV) is unsuitable for industrial spaces where human activity is not the

main reason for ventilating the space (DOE 2004), industrial spaces may offer their own kind of demand control ventilation for providing makeup air to offset process and exhaust hood exhaust volumes. If the space does not contain a potential source of toxic contaminants or hazardous (ignitable) substances, shut such systems down at night, on weekends, or whenever possible, and operate makeup air in balance with the needs of process equipment and exhaust hoods. Keep heating supply air temperatures at the minimum, and cooling supply temperatures at the maximum, consistent with process needs and employee comfort. Keep the building in pressure balance so that uncomfortable drafts do not necessitate excessive heating. Increase the deadband/control limits

- If the exhaust air has contaminants that do not pose an unacceptable health risk, and does not contain a potential source of hazardous (ignitable) substances, then recirculation can be considered. However, even then, contaminant concentrations in recirculated air must be determined so that allowable limits in the space are not exceeded. As recirculated air returns to the space, the concentration of contaminants in the partially filtered return air adds to the contaminant levels already existing in the space. It must be determined whether the concentration increases beyond the allowable time-weighted average (TWA) exposure limit during the period for which the worker is exposed. This period is usually assumed to be 8 h for an 8 h work shift, but could be any period of exposure. Once installed, real-time or periodic monitoring is likely required to support this determination. Depending on the contaminant's toxicity, the monitoring system may be required to perform some form of corrective action or shut down once a target level (a percentage of the safe exposure limit) concentration is attained. Predicted energy cost savings from recirculation should be weighed against the necessary costs of air cleaning and monitoring requirements (to include calibration and maintenance of monitoring equipment).

Assuming equilibrium has been established, the predicted TWA concentration at the workers' breathing zone can be calculated (ACGIH 2013):

$$C_B = \frac{Q_B}{Q_A}(C_G - C_M)(1-f) + (C_O - C_M)f + K_B C_R + (1-K_B)C_M \quad (4)$$

where

C_B = TWA worker breathing zone contaminant concentration during recirculation, ppm
Q_B = total ventilation airflow without considering recirculation, m^3/s
Q_A = total ventilation airflow including recirculation, m^3/s
C_G = average space concentration if no recirculation, ppm
f = fraction of time worker spends at workstation
C_O = TWA contaminant concentration at breathing zone of workstation if no recirculation, ppm
K_B = fraction of worker breathing zone air that consists of recirculated air, 0 to 1.0
C_R = recirculated air (after air cleaner) discharge concentration, ppm, or

$$C_R = \frac{(1-\eta)(C_E - K_R C_M)}{1-(1-\eta)K_R} \quad (5)$$

η = fractional air cleaner efficiency for contaminant
C_E = (local) exhaust concentration without recirculation, ppm
K_R = fraction of exhaust air that is recirculated air, 0 to 1.0
C_M = replacement air contaminant concentration, ppm

Other recirculation system examples are given in Chapter 8 of Goodfellow and Tahti (2001).

Example 1. An industrial space uses 4.7 m^3/s for ventilation, of which 2.35 m^3/s is general exhaust and 2.35 m^3/s local exhaust (ACGIH 2013). Local exhaust is recirculated through an air cleaner with an efficiency of 0.75. Recirculated air is directed toward the worker spaces, such that K_B = 0.5 and K_R = 0.8 (more of the recirculated air is locally exhausted than enters the worker's breathing zone). The worker is at the workstation 100% of the time (f = 1). The makeup air has a concentration of 5 ppm (C_M), the local exhaust has a concentration of 500 ppm (C_E), the space has an average concentration of 20 ppm (C_G), and without recirculation the worker's breathing zone is 35 ppm (C_O).

Solution: The concentration C_B at the breathing zone with recirculation is determined from

$$C_R = \frac{(1-0.75)[500-0.8(5)]}{1-(1-0.75)(0.8)} = 155 \text{ ppm}$$

and

$$C_B = \frac{4.7}{2.35}(20-5)(1-1) + (35-5)(1) + 0.5(155) + (1-0.5)5 = 110 \text{ ppm}$$

which may or may not exceed the allowable TWA exposure limit of the worker space, depending on the specific contaminant.

CHAPTER 33

INDUSTRIAL LOCAL EXHAUST SYSTEMS

Local Exhaust Fundamentals 32.2
Air Movement in Vicinity of Local Exhaust 32.3
Other Local Exhaust System Components 32.6
Operation 32.9

INDUSTRIAL exhaust ventilation systems contain, collect, and remove airborne contaminants consisting of particulate matter (dusts, fumes, smokes, fibers), vapors, and gases that can create a hazardous, unhealthy, or undesirable atmosphere. Exhaust systems can also salvage usable material, improve plant housekeeping, and capture and remove excessive heat or moisture. Industrial exhaust systems must comply with ASHRAE *Standard* 62.1 and other standards as required [e.g., National Fire Protection Agency (NFPA) standards].

Special Warning: Certain industrial spaces may contain flammable, combustible and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), Occupational Safety and Health Administration (OSHA), and American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

Local Exhaust Versus General Ventilation

Local exhaust ventilation systems can be the most performance-effective and cost-effective method of controlling air pollutants and excessive heat. For many operations, capturing pollutants at or near their source is the only way to ensure compliance with occupational exposure limits that are measured within the worker's breathing zone. When properly designed, local exhaust ventilation optimizes ventilation exhaust airflow, thus optimizing system acquisition costs associated with equipment size and operating costs associated with energy consumption and makeup air tempering. Chapters 2 and 3 in ACGIH (2013) also discuss this topic at length.

In some industrial ventilation designs, the emphasis is on filtering air captured by local exhausts before exhausting it to the outdoors or returning it to the production space. As a result, these systems are evaluated according to their filter efficiency or total particulate removal. However, if an insufficient percentage of emissions are captured, the degree of air-cleaning efficiency sometimes becomes irrelevant.

For a process exhaust system in the United States, the design engineer must verify if the system is permitted by the 1990 Clean Air Act. For more information, see the Environmental Protection Agency's web site (www.epa.gov/air/caa/).

The pollutant-capturing efficiency of local ventilation systems depends on hood design, the hood's position relative to the source of contamination, temperature of the source being exhausted, and the induced air currents generated by the exhaust airflow. Selection and positioning of the hood significantly influence initial and operating costs of both local and general ventilation systems. In addition, poorly designed and maintained local ventilation systems can cause deterioration of building structures and equipment, negative health effects, and decreased worker productivity.

No local exhaust ventilation system is 100% effective in capturing pollutants and/or excess heat. In addition, installation of local exhaust ventilation system may not be possible in some circumstances, because of the size, mobility, or mechanical interaction requirements of the process. In these situations, general ventilation is needed to dilute pollutants and/or excess heat. Where pollutants are toxic or present a health risk to workers, local exhaust is the appropriate approach, and dilution ventilation should be avoided. Air supplied by the general ventilation system is usually conditioned (heated, humidified, cooled, etc.). Supply air replaces air extracted by local and general exhaust systems and improves comfort conditions in the occupied zone.

Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals* covers definitions, particle sizes, allowable concentrations, and upper and lower explosive limits of various air contaminants. Chapter 31 of this volume, Goodfellow and Tahti (2001), and Chapter 2 of ACGIH (2013) detail steps to determine air volumes necessary to dilute contaminant concentration using general ventilations.

Sufficient makeup air must be provided to replace air removed by the exhaust system. If replacement air is insufficient, building pressure becomes negative relative to atmospheric pressure and allows air to infiltrate through open doors or window cracks, and can reverse flow through combustion equipment vents. A negative pressure as little as 12 Pa can cause drafts and might cause backdrafts in combustion vents, thereby creating potential health and safety hazards. From the sustainability perspective, a negative plant static pressure can also result in excessive energy use. If workers near the plant perimeter complain about cold drafts, unit heaters are often installed. Heat from these units often is drawn into the plant interior, overheating the interior. Too often, this overheating is addressed by exhausting more air from the interior, causing increased negative pressure and more infiltration. Negative plant pressure reduces the exhaust volumetric flow rate because of increased system resistance, which can also decrease local exhaust efficiencies or require additional energy to overcome the increased resistance. Wind effects on building balance may also play a role, and are discussed in Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*.

Positive-pressure plants and balanced plants (those with equal exhaust and replacement air rates) use less energy. However, if there are clean and contaminated zones in the same building, the desired airflow direction is from clean to dirty, and zone boundary construction and pressure differentials should be designed accordingly.

Exhaust system discharge may be regulated under various federal, state, and local air pollution control regulations or ordinances. These regulations may require exhaust air treatment before discharge to the atmosphere. Chapter 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides guidance and recommendations for discharge air treatment.

The preparation of this chapter is assigned to TC 5.8, Industrial Ventilation Systems.

1. LOCAL EXHAUST FUNDAMENTALS

System Components

Local exhaust ventilation systems typically consist of the following basic elements:

- Hood to capture pollutants and/or excessive heat
- Ducted system to transport polluted air to air cleaning device or building exhaust
- Air-cleaning device to remove captured pollutants from the airstream for recycling or disposal
- Air-moving device (e.g., fan or high-pressure air ejector), which provides motive power to generate the hood capture velocity plus overcome exhaust ventilation system resistance
- Exhaust stack, which discharges system air to the atmosphere

System Classification

Contaminant Source Type. Knowing the process or operation is essential before a local exhaust hood system can be designed.

Hood Type. Exhaust hoods are typically round, rectangular, or slotted to accommodate the geometry of the source. Hoods are either enclosing or nonenclosing (Figure 1). **Enclosing hoods** provide more effective and economical contaminant control because their exhaust rates and the effects of room air currents are minimal compared to those for nonenclosing hoods. Hood access openings for inspection and maintenance should be as small as possible and out of the natural path of the contaminant. Hood performance (i.e., how well it captures the contaminant) should ideally be verified by an industrial hygienist.

A **nonenclosing hood** can be used if access requirements make it necessary to leave all or part of the process open. Careful attention must be paid to airflow patterns and capture velocities around the process and hood (under dynamic conditions) and to the process characteristics to make nonenclosing hoods effective. The use of moveable baffles, curtains, strip curtains, and brush seals may allow the designer to increase the level of enclosure without interfering with the work process. The more of the process that can be enclosed, the less exhaust airflow required to control the contaminant(s).

System Mobility. Local exhaust systems with nonenclosing hoods can be **stationary** (i.e., having a fixed hood position), **moveable, portable,** or **built-in** (into the process equipment). Moveable hoods are used when process equipment must be accessed for repair and loading and unloading of materials (e.g., in electric ovens for melting steel).

The portable exhaust system shown in Figure 2 is commonly used for temporary exhausting of fumes and solvents in confined spaces or during maintenance. It has a built-in fan and filter and an exhaust hood connected to a flexible hose. Built-in local exhaust systems are commonly used to evacuate welding fumes, such as hoods built into stationary or turnover welding tables. Lateral exhaust hoods, which exhaust air through slots on the periphery of open vessels, such as those used for galvanizing metals, are another example of built-in local exhaust systems.

Effectiveness of Local Exhaust

The most effective hood design uses the minimum exhaust airflow rate to provide maximum contaminant control without compromising operator capability to complete the work task. **Capture effectiveness** should be high, but it is difficult and costly to develop hoods with efficiencies approaching 100%. Makeup air supplied by general ventilation to replace exhausted air can dilute contaminants that are not captured by the hood. Enclosing more of the process reduces the need to protect against contaminant escape through cross drafts, convective currents, or process-generated contaminant momentum. In turn, this reduces the exhaust airflow required to control the contaminant(s).

Capture Velocity. Capture velocity is the air velocity required to entrain contaminants at the point of contaminant generation upstream of a hood. The contaminant enters the moving airstream near the point of generation and is carried along with the air into the hood. Designers use a designated capture velocity V_c to determine a volumetric flow rate to draw air into the hood. Table 1 shows ranges of capture velocities for several industrial operations. These figures are based on successful experience under ideal conditions. Once capture velocity upstream of the hood and hood position relative to the source are known, then the hood flow rate can be determined for the particular hood design. Velocity distributions for specific hoods must be known or determined.

Hood Volumetric Flow Rate. For a given hood configuration and capture velocity, the exhaust volumetric flow rate (the airflow rate that allows contaminant capture) can be calculated as

$$Q_o = V_o A_o \tag{1}$$

where

Q_o = exhaust volumetric flow rate, m^3/s
V_o = average air velocity in hood opening that ensures capture velocity at point of contaminant release, m/s
A_o = hood opening area, m^2

Low face velocities require that supply (makeup) air be as uniformly distributed as possible to minimize the effects of room air currents. This is one reason replacement air systems must be designed with exhaust systems in mind. Air should enter the hood

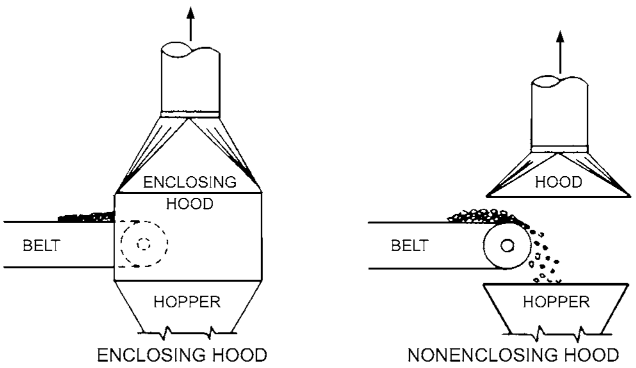

Fig. 1 Enclosing and Nonenclosing Hoods
(Adapted from ACGIH®, *Industrial Ventilation: A Manual of Recommended Practice*, 27th ed. Copyright 2010. Reprinted with permission.)

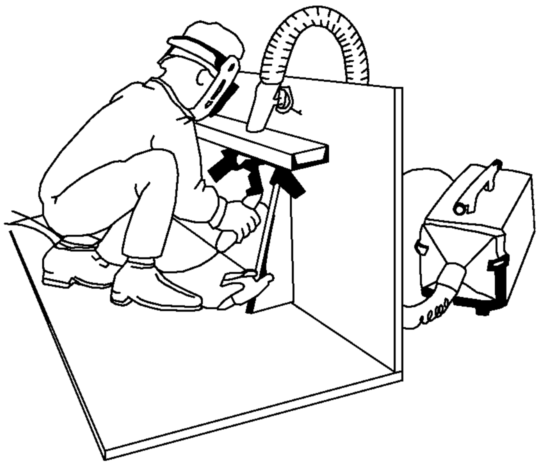

Fig. 2 Portable Fume Extractor with Built-in Fan and Filter

Table 1 Range of Capture (Control) Velocities

Condition of Contaminant Dispersion	Examples	Capture Velocity, m/s
Released with essentially no velocity into still air	Evaporation from tanks, degreasing, plating	0.25 to 0.5
Released at low velocity into moderately still air	Container filling, low-speed conveyor transfers, welding	0.5 to 1.0
Active generation into zone of rapid air motion	Barrel filling, chute loading of conveyors, crushing, cool shakeout	1.0 to 2.5
Released at high velocity into zone of very rapid air motion	Grinding, abrasive blasting, tumbling, hot shakeout	2.5 to 10

Note: In each category above, a range of capture velocities is shown. The proper choice of values depends on several factors (Alden and Kane 1982):

Lower End of Range	Upper End of Range
1. Room air currents favorable to capture	1. Distributing room air currents
2. Contaminants of low toxicity or of nuisance value only	2. Contaminants of high toxicity
3. Intermittent, low production	3. High production, heavy use
4. Large hood; large air mass in motion	4. Small hood; local control only

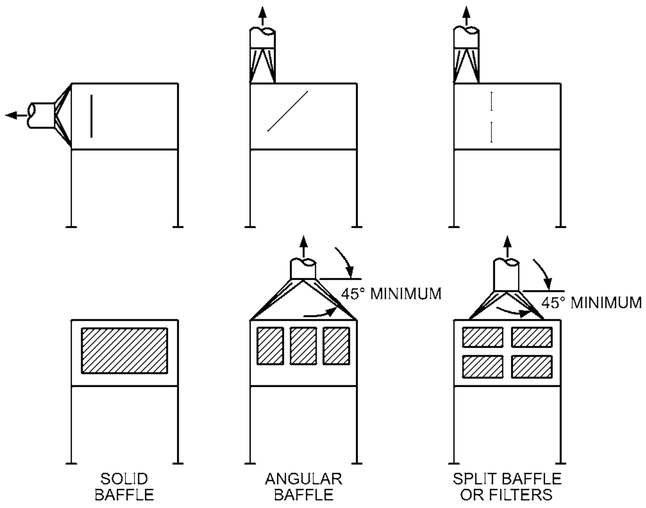

Fig. 3 Use of Interior Baffles to Ensure Good Air Distribution

uniformly. Hood flanges, side baffles, and interior baffles are sometimes necessary (Figure 3).

Airflow requirements for maintaining effective capture velocity at a contaminant source also vary with the distance between the source and hood. Chapter 3 of ACGIH (2013) provides methodology for estimating airflow requirements for specific hood configurations and locations relative to the contaminant source.

Airflow near the hood can be influenced by drafts from supply air jets (spot cooling jets) or by turbulence of the ambient air caused by jets, upward/downward convective flows, moving people, mobile equipment, and drafts from doors and windows. Process equipment may be another source of air movement. For example, high-speed rotating machines such as pulverizers, high-speed belt material transfer systems, falling granular materials, and escaping compressed air from pneumatic tools all produce air currents. These factors can significantly reduce the capturing effectiveness of local exhaust systems and should be accounted for in the exhaust system design.

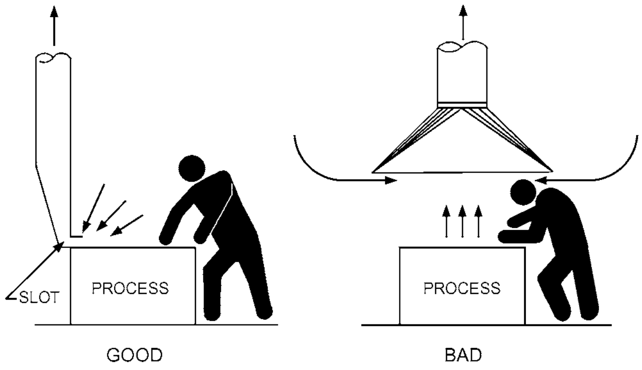

Fig. 4 Influence of Hood Location on Contamination of Air in the Operator's Breathing Zone

(Adapted from ACGIH®, *Industrial Ventilation: A Manual of Recommended Practice*, 28th ed. Copyright 2013.)

Exhausted air may contain combustible pollutant/air mixtures. If it does, the amount by which the exhaust airflow rate should be increased to dilute combustible mixture must be verified to meet the requirements of National Fire Protection Association (NFPA) *Standards* 86 and 329.

Principles of Hood Design Optimization

Numerous studies of local exhaust systems and common practices have led to the following hood design principles:

- Hood location should be as close as possible to the source of contamination.
- The hood opening should be positioned so that it causes the contaminant to deviate the least from its natural path.
- The hood should be located so that the contaminant is drawn away from the operator's breathing zone.
- Hood size must be the same as or larger than the cross section of flow entering the hood. If the hood is smaller than the flow, a higher volumetric flow rate is required.
- Worker position with relation to contaminant source, hood design, and airflow path should be evaluated based on the principles given in Chapters 3 and 10 of ACGIH (2013).
- Canopy hoods (Figure 4) should not be used where the operator must bend over a tank or process (ACGIH 2013).

2. AIR MOVEMENT IN VICINITY OF LOCAL EXHAUST

Air capture velocities in front of the hood opening depend on the exhaust airflow rate, hood geometry, distance from hood face and surfaces surrounding the hood opening. Figure 5 shows velocity contours for an unflanged round duct hood. Studies have established the similarity of velocity contours (expressed as a percentage of the hood entrance velocity) for hoods with similar geometry (DallaValle 1952). Figure 6 shows velocity contours for a rectangular hood with an **aspect ratio** (width divided by length) of 0.333. The profiles are similar to those for the round hood but are more elongated. If the aspect ratio is lower than about 0.2 (0.15 for flanged openings), the flow pattern in front of the hood changes from approximately spherical to approximately cylindrical. Velocity decreases rapidly with distance from the hood; per DallaValle, velocity decreases on the order of 1/(distance from suction inlet squared).

The design engineer should consider side drafts and other sources of air movement close to the capture area of a local exhaust hood. Caplan and Knutson (1977, 1978) found that air movement in front of laboratory hoods can cause contaminants to escape from the

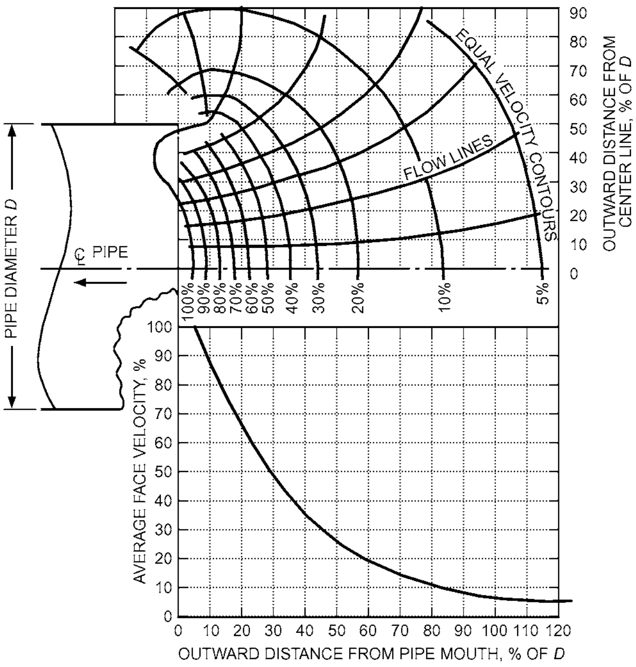

Fig. 5 Velocity Contours for Plain Round Opening
(Alden and Kane 1982; used by permission)

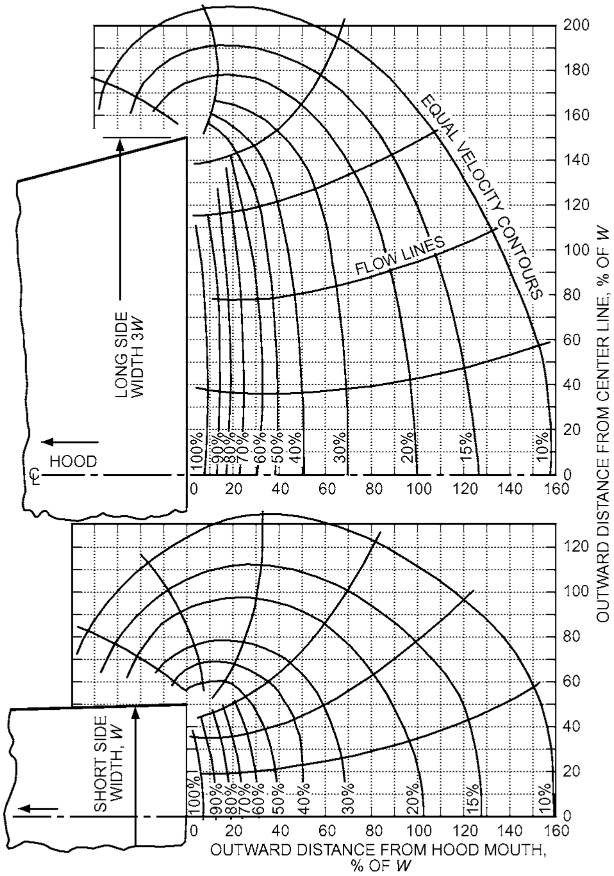

Fig. 6 Velocity Contours for Plain Rectangular Opening with Sides in a 1:3 Ratio
(Alden and Kane 1982; used by permission)

hood and into the operator's breathing zone. In industrial applications, it is common to see large fans blowing air onto workers who are located in front of an exhaust hood. This can render the local exhaust hood ineffective to the point that no protection is provided for the worker and/or their adjacent co-workers.

Pressure Loss in Hoods and Ducts

A vena contracta forms in the entrance of the hood or duct and produces a pressure loss, which can be described using pressure loss coefficient C_o or a static pressure entry loss (ACGIH 2013). When air enters a hood, the pressure loss, called **hood entry loss**, may have several components, depending on the hood's complexity. Simple hoods usually have a single pressure loss coefficient C_L specified, defined as

$$C_L = \sqrt{\frac{P_v}{P_{s,h}}} \tag{2}$$

where

- C_L = pressure loss coefficient depending on hood type and geometry, dimensionless
- P_v = $\rho V^2/2$, dynamic pressure inside duct caused by moving airstream (constant in duct after vena contracta), Pa, where ρ is air density, kg/m^3
- $P_{s,h}$ = static pressure in hood duct because of velocity pressure increase and hood entry loss, Pa

More information on loss factors and the design of exhaust ductwork is in Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals*, ACGIH (2013), and Brooks (2001).

The loss coefficient C_L is different from the hood entry loss coefficient. The entry loss coefficient C_o relates duct total pressure loss to duct velocity pressure. From Bernoulli's equation, hood total pressure is approximately zero at the entrance to the hood, and therefore the static pressure is equal to the negative of the velocity pressure:

$$P_s = -P_v \tag{3}$$

Static pressure in the hood/duct is the static pressure (velocity pressure) plus the head loss, which is expressed as a fraction of the velocity pressure, as

$$P_{s,h} = P_v + C_o P_v \tag{4}$$

Rearranged, the hood/duct static pressure $P_{s,h}$ (hood suction) for hoods is

$$P_{s,h} = (1 + C_o)P_v \tag{5}$$

and the change in total pressure is

$$\Delta P_t = P_{s,h} - P_v = C_o P_v \tag{6}$$

Loss coefficients C_o for various hood shapes are given in Figure 7. For tapered hoods, Figure 5 shows that the optimum hood entry angle to minimize entry loss is 45°, but this may be impractical in many situations because of the required transition length. A 90° angle, with a corresponding loss factor of 0.25 (for rectangular openings), is typical for many tapered hoods.

Example 1. A nonenclosing side-draft flanged hood (Figure 8) with face dimensions of 0.45 by 1.2 m rests on the bench. The required volumetric flow rate is 0.74 m^3/s. The duct diameter is 230 mm; this gives a duct velocity of 17.6 m/s. The hood is designed such that the largest angle of transition between the hood face and the duct is 90°. What is the suction pressure (static pressure) for this hood? Assume air density at 22°C.

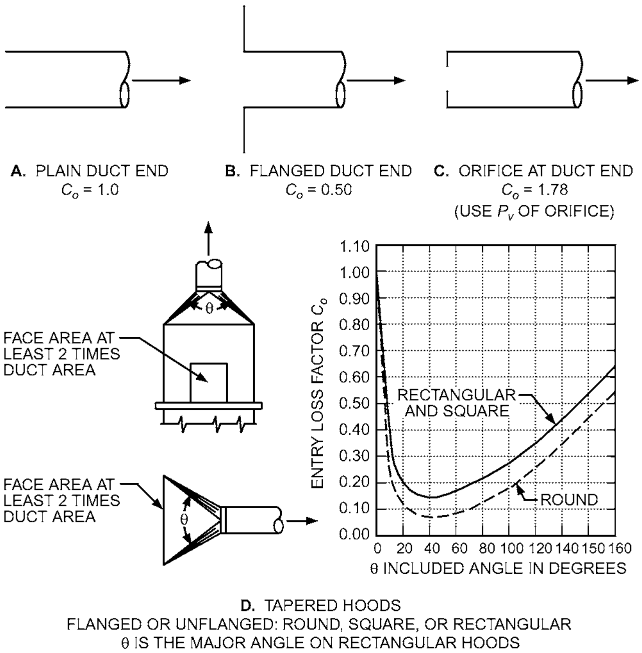

Fig. 7 Entry Losses for Typical Hoods

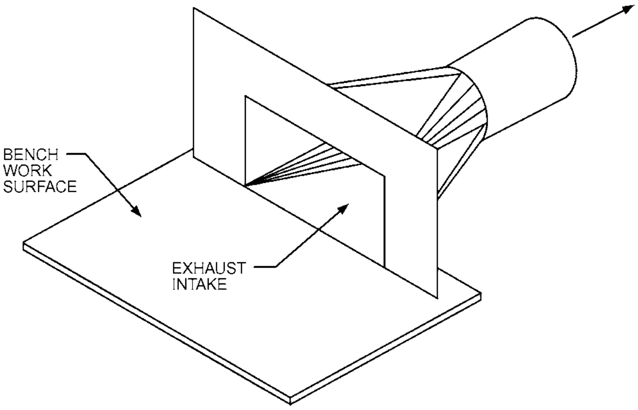

Fig. 8 Hood on Bench

Solution: The two transition angles cannot be equal. Whenever this is true, the larger angle is used to determine the loss factor from Figure 7. Because the transition piece originates from a rectangular opening, the curve marked “rectangular” must be used. This corresponds to a loss factor of 0.25. The duct velocity pressure is

$$P_v = \frac{\rho V^2}{2} = \frac{(1.19)(17.6)^2}{2} = 184 \text{ Pa}$$

From Equation (5),

$$P_{s,h} = (1 + 0.25)(184) = 230 \text{ Pa}$$

Compound Hoods. Losses for multislot hoods (Figure 9) or single-slot hoods with a plenum (compound hoods) must be analyzed somewhat differently. The slots distribute air over the hood face and do not influence capture efficiency. Slot velocity should be approximately 10 m/s to provide required distribution at minimum energy cost; plenum velocities are typically 50% of slot velocities (approximately 5 m/s). Higher velocities dissipate more energy and can cause hot spots in the face of the hood.

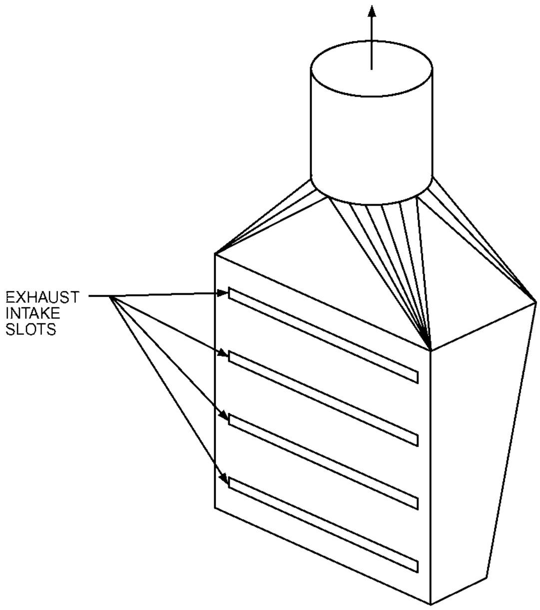

Fig. 9 Multislot Nonenclosing Hood

Losses occur when air passes through the slot and when air enters the duct. Because the velocities, and therefore the velocity pressures, can be different at the slot and at the duct entry locations, the hood suction must reflect both losses and is given by

$$P_{s,h} = P_v + (C_o P_v)_s + (C_o P_v)_d \tag{7}$$

where the first P_v is generally the higher of the two velocity pressures, s refers to the slot, and d refers to the duct entry location.

Example 2. A multislot hood has three slots, each 25 by 1000 mm. At the top of the plenum is a 90° transition into the 250 mm duct. The volumetric flow rate required for this hood is 0.78 m^3/s. Determine the hood suction (static pressure). Assume air density at 22°C.

Solution: The slot velocity V_s is

$$V_s = \frac{Q}{A} = \frac{0.78}{(3)(0.025)(1)} = 10.4 \text{ m/s}$$

which is near the minimum slot velocity of 10 m/s. Substituting this velocity,

$$P_v = \frac{\rho V^2}{2} = \frac{(1.19)(10.4)^2}{2} = 64.4 \text{ Pa}$$

The duct area is 0.0491 m^2. Therefore, duct velocity and velocity pressure are

$$V_d = Q/A$$

$$V_d = \frac{0.78}{0.0491} = 15.9 \text{ m/s}$$

Substituting this velocity,

$$P_v = \frac{(1.19)(15.9)^2}{2} = 150.4 \text{ Pa}$$

For a 90° transition into the duct, the loss factor is 0.25. For the slots, the loss factor is 1.78 (Figure 7). The duct velocity pressure is added to the sum of the two losses because it is larger than the slot velocity pressure. Using Equation (7),

$$P_{s,h} = 150.4 + (1.78)(65) + (0.25)(150.4) = 303.7 \text{ Pa}$$

Exhaust volume requirements, minimum duct velocities, and entry loss factors for many specific operations are given in Chapter 10 of ACGIH (2013).

Overhead Canopy Hoods

If a hot work process cannot be completely enclosed, place a canopy hood above the process so that the contaminant convectively moves toward the hood. Canopy hoods should be applied and designed with caution to avoid drawing contaminants across the operator's breathing zone (see Figure 4). The hood's height above the process should be minimized to reduce total exhaust airflow rate. Efficiencies in ventilation capture can be gained when ventilating heated processes with canopy hoods, because heated air naturally moves upward because of its reduced density (i.e., buoyancy). Canopy hoods are most effective when contaminant is released over a well-defined area, and the contaminant is entrained in the rising, buoyant plume. Room cross drafts can substantially deflect the rising plume when it is created by a low-temperature process, or when cross drafts are greater than 0.25 m/s between the process and the canopy inlet. When determining proper hood selection and design parameters, carefully consider process information, such as required worker access to the process, process-related material movement within the plume, and the hazard potential of the contaminants associated with the process.

Canopy hoods without side walls are the least effective and efficient method of controlling hot process plumes. The limitation of any hood design with distance between the hood face and surface of the source is the ability of cross drafts to interfere with capturing contaminants rising from the hot process. Where cross drafts greater than 0.25 m/s are present, hood designs should include side walls. At a minimum, one side wall should be included in the hood design on the side of the process where the cross draft originates (upstream side).

Canopy Hoods with Sidewalls

When side walls are included, or when the process is close to a structural wall, the plume may attach to the wall. In this event, the plume entrainment volume is reduced compared to that in an unbounded plume, and the resulting flow in the plume is reduced to half the flow of an unbounded plume. If there are two walls attached at a right angle, the flow is reduced to 1/4 of the unbounded plume flow (Nielsen 1993).

Low Canopy Hoods

Whenever the distance between a canopy hood and the hot source is within 0.9 m or the source diameter, whichever is smaller, this hood is considered to be a low canopy hood. Its close proximity to the source does not allow sufficient time for the plume to expand; thus, the diameter or cross section of the hot air column is approximately the same as the source. Under this design scenario, the diameter or side dimensions of the hood need only be about 0.3 m larger than the source diameter at its widest cross-section (Hemeon 1963, 1999). For rectangular sources, rising plumes may be better controlled if the hood shape reflects that of the source. In this circumstance, perform the hood airflow and design calculations as for a circular source, once for the length and once for the width dimensions.

High Canopy Hood Use as Redundant Control Measure

The high canopy hood without side walls is the least favorable canopy design. The design can be used as a redundant measure for controlling large-volume process plumes. High canopy hoods are not recommended as a primary control measure for heated processes, because of the large volumes of air displaced to remove pollutants from the workplace. For example, arc furnace charging has a limited duration, and restricted canopy hood use while the furnace is being charged reduces the required volume of replacement air. Ideally, high canopy hood faces without walls should be round, because rising air from point sources and compact shapes (i.e., not line sources) becomes circular in cross section as it rises (Bill and Gebhart 1975). This occurs because turbulence sweeps the plume edges inward to a minimal volume. However, it is more cost effective to manufacture and install square or rectangular hoods. Baffles are recommended at the face of rectangular canopy hoods to approximate the area of a round hood face.

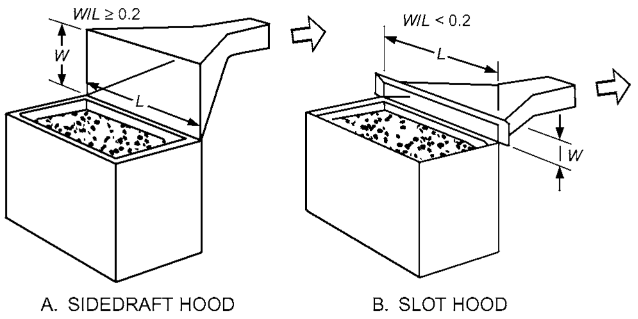

Fig. 10 Sidedraft Hood and Slot Hood on Tank

Ventilation Controls for Large-Scale Hot Processes

Equations to approximate the velocity, area, and volumetric flow of rising air above a large-scale cylindrical heated process with excess air temperatures (Δt < 92°C) are available from several sources (ACGIH 2013; Goodfellow 1985; Hemeon 1963, 1999; U.S. Public Health Service 1973). These equations derive from compilation of empirical research by Hemeon and others, and are useful for traditional large-scale, high-temperature processes (e.g., arc furnaces, tapping operations).

Ventilation Controls for Small-Scale Hot Processes

New equations to approximate the velocity, area, and volumetric flow of the rising air above a small-scale heated process have been validated within a range of excess air temperatures (–1 K < Δt < 30 K) (McKernan and Ellenbecker 2007; McKernan et al. 2007a, 2007b). These equations are based on modern research applicable to designing engineering controls for heated processes, as well as historic work by Hemeon and others (Goodfellow 1985; Hemeon 1963, 1999; U.S. Public Health Service 1973). They are particularly useful for approximating volumetric flow from discrete low-temperature sources. The historic equations of Hemeon and others continue to be useful for the traditional large-scale, high temperature processes (e.g., arc furnaces, tapping operations).

Sidedraft Hoods

Sidedraft hoods typically draw contaminant away from the operator's breathing zone. With a buoyant source, a sidedraft hood requires a higher exhaust volumetric flow rate than a low canopy hood. If a low canopy hood restricts the work process, a sidedraft hood may be more cost effective than a high canopy hood. Examples of sidedraft hoods include multislotted "pickling" hoods near welding benches (Figure 9) and slot hoods on tanks (Figure 10).

3. OTHER LOCAL EXHAUST SYSTEM COMPONENTS

Duct Design and Construction

Duct Considerations. The second component of a local exhaust ventilation system is the duct through which contaminated air is transported from the hood(s). Round ducts are preferred because they (1) offer more uniform velocity to resist settling of material, (2) can withstand the higher static pressures normally found in industrial exhaust systems, and (3) are easier to seal. When design

Table 2 Contaminant Transport Velocities

Nature of Contaminant	Examples	Minimum Transport Velocity, m/s
Vapor, gases, smoke	All vapors, gases, smoke	Usually 5 to 10
Fumes	Welding	10 to 13
Very fine light dust	Cotton lint, wood flour, litho powder	13 to 15
Dry dusts and powders	Fine rubber dust, molding powder dust, jute lint, cotton dust, shavings (light), soap dust, leather shavings	15 to 20
Average industrial dust	Grinding dust, buffing lint (dry), wool jute dust (shaker waste), coffee beans, shoe dust, granite dust, silica flour, general material handling, brick cutting, clay dust, foundry (general), limestone dust, asbestos dust in textile industries	18 to 20
Heavy dust	Sawdust (heavy and wet), metal turnings, foundry tumbling barrels and shakeout, sandblast dust, wood blocks, hog waste, brass turnings, cast-iron boring dust, lead dust	20 to 23
Heavy and moist dust	Lead dust with small chips, moist cement dust, asbestos chunks from transite pipe cutting machines, buffing lint (sticky), quicklime dust	23 and up

Source: Adapted from ACGIH (2013).

limitations require rectangular or flat oval ducts, the aspect ratio (height-to-width ratio) should be as close to unity as possible.

Minimum transport velocity is the velocity required to transport particles without settling. Table 2 lists some generally accepted transport velocities as a function of the nature of the contaminants (ACGIH 2013). The values listed are typically higher than theoretical and experimental values to account for (1) damage to ducts, which increases system resistance and reduces volumetric flow and duct velocity; (2) duct leakage, which tends to decrease velocity in the duct system upstream of the leak; (3) fan wheel corrosion or erosion and/or belt slippage, which could reduce fan volume; and (4) reentrainment of settled particles caused by improper operation of the exhaust system. Design velocities can be higher than minimum transport velocities but should never be significantly lower.

When particle concentrations are low, the effect on fan power is negligible. Using standard duct sizes and fittings decreases cost and delivery time. Information on available sizes and cost of nonstandard sizes can be obtained from the contractor(s).

Duct Losses. Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals* covers the basics of duct design and design of metal-working exhaust systems. Loss coefficients are found in the ASHRAE *Duct Fitting Database* CD-ROM (ASHRAE 2008).

For systems conveying particles, elbows with a centerline radius-to-diameter ratio (r/D) greater than 1.5 are the most suitable. If $r/D \leq 1.5$, abrasion in dust-handling systems can reduce the life of elbows. Elbows, especially those with large diameters, are often made of seven or more gores. For converging flow fittings, a 30° entry angle is recommended to minimize energy losses and abrasion in dust-handling systems (Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals*).

Where exhaust systems handling particles must allow for a substantial increase in future capacity, required transport velocities can be maintained by providing open-end stub branches in the main duct. Air is admitted through these stub branches at the proper pressure and volumetric flow rate until the future connection is installed. Figure 11 shows such an air bleed-in. Using outside air minimizes replacement air requirements, though care must be taken to consider potential adverse effects of temperature or humidity extremes associated with the two air streams. The size of the opening can be calculated by determining the pressure drop required across the orifice from the duct calculations. Then the orifice velocity pressure can be determined from one of the following equations:

$$P_{v,o} = \frac{\Delta P_{t,o}}{C_o} \tag{8}$$

where

$P_{v,o}$ = orifice velocity pressure, Pa
ΔT_o = total pressure to be dissipated across orifice, Pa

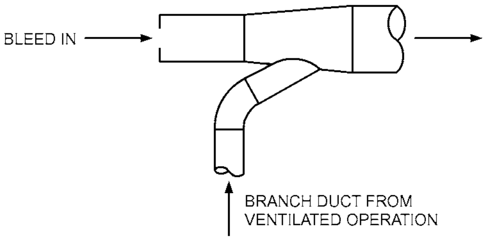

Fig. 11 Air Bleed-In

C_o = orifice loss coefficient referenced to the velocity at the orifice cross-sectional area, dimensionless (see Figure 7)

Once the velocity pressure is known, orifice velocity and size can be determined.

Occasionally, a counterweighted backdraft damper or spring-loaded air admittance valve, configured to allow airflow into the duct but not out, is used as an air bleed in lieu of an orifice in systems that operate under varying airflow conditions. This ensures the proper quantity of transport airflow inside the duct, helping to eliminate material fallout and subsequent duct blockage.

Integrating Duct Segments. Most systems have more than one hood. If the pressures are not designed to be the same for merging parallel airstreams, the system adjusts to equalize pressure at the common point; however, the resulting flow rates of the two merging airstreams will not necessarily be the same as designed. As a result, the hoods can fail to control the contaminant adequately, exposing workers to potentially hazardous contaminant concentrations. Two design methods ensure that the two pressures will be equal. The preferred design self-balances without external aids. This procedure is described in the section on Industrial Exhaust System Duct Design in Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals.* The second design, which uses adjustable balance devices such as blast gates or balancing dampers, is not recommended, especially when abrasive material is conveyed.

Duct Construction. Elbows and converging flow fittings should be made of thicker material than the straight duct, especially if abrasives are conveyed. Elbows with $r/D > 2$ with replaceable wear plates (wear backs) in the heel are often used where particulate loading is extremely heavy or the particles are very abrasive. When corrosive material is present, alternatives such as special coatings or different duct materials (fibrous glass or stainless steel) can be used. Cleanout openings should be located to allow access to the duct interior in the event of a blockage. Certain contaminants may require washdown systems and/or fire detection and suppression systems to comply with safety or fire prevention codes. These requirements should be verified with local code officials and insurance underwriters. NFPA standards provide guidance on fire safety. Industrial duct construction is also described in Chapter 19 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, and in Sheet Metal and Air Conditioning Contractors' National Association (SMACNA) *Standard* 005-1999.

Air Cleaners

Air-cleaning equipment is usually selected to (1) conform to federal, state, or local emissions standards and regulations; (2) prevent reentrainment of contaminants to work areas; (3) reclaim usable materials; (4) allow cleaned air to recirculate to work spaces and/or processes; (5) prevent physical damage to adjacent properties; and (6) protect neighbors from contaminants.

Factors to consider when selecting air-cleaning equipment include the type of contaminant (number of components, particulate versus gaseous, moisture and heat in the airstream, and pollutant concentration), contaminant characteristics (e.g. volatility, reactivity), required contaminant removal efficiency, disposal method, and air or gas stream characteristics. Auxiliary systems such as instrument-grade compressed air, electricity, or water may be required and should be considered in equipment selection. Specific hazards such as explosions, fire, or toxicity must be considered in equipment selection, design, and location. See Chapters 29 and 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for information on equipment for removing airborne contaminants. Consult an applications engineer when selecting equipment.

The cleaner's pressure loss must be added to overall system pressure calculations. In some cleaners, specifically some fabric filters, loss increases as operation time increases. System design should incorporate the maximum pressure drop of the cleaner, or hood flow rates will be lower than designed during most of the duty cycle. Also, fabric collector losses are usually given only for a clean air plenum. A reacceleration to the duct velocity, with the associated entry losses, must be calculated during design. Most other cleaners are rated flange-to-flange with reacceleration included in the loss.

Air-Moving Devices

The type of air-moving device selected depends on the type and concentration of contaminant, the pressure rise required, and allowable noise levels. Fans are usually used. Chapter 21 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* describes available fans; Air Movement and Control Association *Publication* 201 (AMCA 2002) describes proper connection of the fan(s) to the system. The fan should be located downstream of the air cleaner whenever possible to (1) reduce possible abrasion of the fan wheel blades and (2) create negative pressure within the air cleaner and the entire length of dirty duct so that air leaks into the exhaust system throughout its dirty side and control of the contaminant is maintained.

Fans handling flammable or explosive dusts should be specified as spark-resistant. AMCA provides three different spark-resistant fan construction specifications. Consult the fan manufacturer when handling these materials. Multiple NFPA standards give fire safety requirements for fans and systems handling explosive or flammable materials.

When possible, devices such as fans and pollution-control equipment should be located outside classified areas, and/or outside the building, to reduce the risk of fire or explosion.

In some instances, the fan is located upstream from the cleaner to help remove dust. This is especially true with cyclone collectors, for example, which are used in the woodworking industry. If explosive, corrosive, flammable, or sticky materials are handled, an injector (also known as an eductor) can transport the material to the air-cleaning equipment. Injectors create a shear layer that induces airflow into the duct. Injectors should be the last choice because their efficiency seldom exceeds 10%.

Energy Recovery to Increase Sustainability

Energy transfer from exhausted air to replacement air may be economically feasible, depending on the (1) location of the exhaust and replacement air ducts, (2) temperature of the exhausted gas, and (3) nature of the contaminants being exhausted. Heat transfer efficiency depends on the type of heat recovery system used.

If exhausted air contains particulate matter (e.g., dust, lint) or oil mist, the exhausted air should be filtered to prevent fouling the heat exchanger. If exhausted air contains gaseous and vaporous or volatile contaminants, such as hydrocarbons and water-soluble chemicals, their effect on the heat recovery device should be investigated. Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* discusses air-to-air energy recovery systems.

When selecting energy recovery equipment for industrial exhaust systems, cross-contamination from the energy recovery device must be considered. Some types of energy recovery equipment may allow considerable cross contamination (e.g., some heat wheels) from the exhaust into the supply airstream, whereas other types (e.g., runaround coils) do not. The exhaust side of the energy recovery device should be negatively pressured compared to the supply side, so that any leakage will be from the clean side into the contaminated side. This is not acceptable for some applications. The material of the energy recovery device must be compatible with the pollutants being exhausted. If the exhaust airstream destroys the heat exchanger, contamination can enter the supply airstream and cause additional equipment damage as well as increase exposure to workers.

Exhaust Stacks

The exhaust stack must be designed and located to prevent reentraining discharged air into supply system inlets. The building's shape and surroundings determine the atmospheric airflow over it. Chapter 45 covers exhaust stack design. The typical code-required minimum stack height is intended to provide protection for workers near the stack, so discharged air is above their breathing zone. The minimum required stack height does not protect against reentrainment of contaminated exhaust into any outside air intakes.

If rain protection is important, a no-loss stack head design (ACGIH 2013; SMACNA *Standard* 005) is recommended. Weather caps deflect air downward, increasing the chance that contaminants will recirculate into air inlets, have high friction losses, and provide less rain protection than a properly designed stack head. Weather caps should never be used with a contaminated or hazardous exhaust stream.

Figure 12 contrasts flow patterns of weather caps and stack heads. Loss data for stack heads are presented in the *Duct Fitting Database* CD-ROM (ASHRAE 2008). Losses in straight-duct stack heads are balanced by the pressure regain at the expansion to the larger-diameter stack head.

Instrumentation and Controls

Some industrial exhaust systems may require positive verification of system airflow. Indicators of performance failure may require both audible and visual warning indicators. Other instrumentation, such as dust collector level indication, rotary lock valve operation, or fire detection, may be required. Selection of electronic monitoring instruments should consider durability expectations, maintenance, and calibration requirements. Interfaces may be required with the process control system or with the balance of the plant ventilation system. Electrical devices in systems conveying flammable or explosive materials or in a hazardous location may need to meet certain electrical safety and code requirements. These requirements are determined by the owner, process equipment manufacturer, federal and state regulations, local codes, and/or insurance requirements.

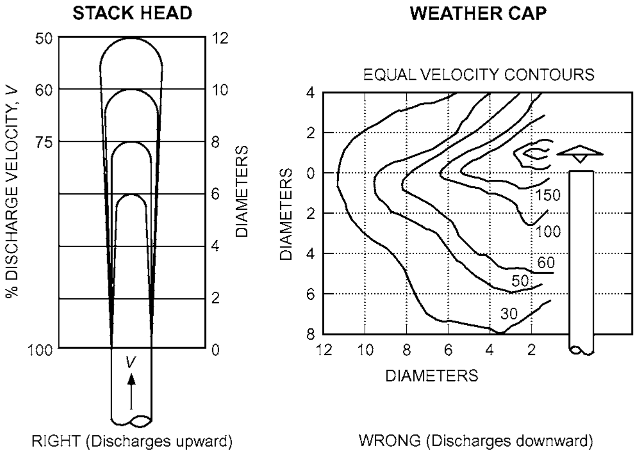

Fig. 12 Comparison of Flow Pattern for Stack Heads and Weather Caps

4. OPERATION

System Testing and Balancing

After installation, an exhaust system should be tested and balanced to ensure that it operates properly, with the required flow rates through each hood. If actual flow rates are different from design values, they should be corrected before the system is used. Testing is also necessary to obtain and document baseline data to determine (1) compliance with federal, state, and local codes; (2) by periodic inspections or real-time monitoring, whether maintenance on the system is needed to ensure design operation; (3) whether a system has sufficient capacity for additional airflow; (4) whether system leakage is acceptable; and (5) compliance with testing, adjusting, and balancing (TAB) standards. AMCA (1990) and Chapter 5 of ACGIH (2007) contain detailed information on preferred methods for testing systems.

Operation and Maintenance

Periodic inspection and maintenance are required for proper operation of exhaust systems. System designers should keep this requirement in mind and account for it through the installation of clean-out/inspection doors and through strategic placement of equipment that ensures access for maintenance activities. Systems are often changed or damaged after installation, resulting in low duct velocities and/or incorrect volumetric flow rates. Low duct velocities can cause contaminants to settle and plug the duct, reducing flow rates at affected hoods. Adding hoods to an existing system can change volumetric flow at the original hoods. In both cases, changed hood volumes can increase worker exposure and health risks. The maintenance program should include (1) inspecting ductwork for particulate accumulation and damage by erosion or physical abuse, (2) checking exhaust hoods for proper volumetric flow rates and physical condition, (3) checking fan drives, (4) maintaining air-cleaning equipment according to manufacturers' guidelines, and (5) confirming that the system continues to meet compliance with worker exposure and environmental pollution requirements. These and other details are also discussed in ACGIH (2007).

RESEARCH 34.43

THIS chapter focuses primarily on commercial kitchen ventilation (CKV) systems in restaurants and institutional food service facilities, and incorporates the research and experience (including all steps of the design process) amassed by TC 5.10 over the past two decades. Although a brief section on residential kitchen ventilation has been retained, only minor updates have been incorporated over the history of this chapter. Given ongoing debate on residential range hood performance, TC 5.10 anticipates sponsoring research to provide a basis for enhanced design of residential kitchen ventilation (RKV) systems.

To provide a means for codifying critical CKV items as well as provide expertise to code-writing authorities, TC 5.10 sponsors Standing Standard Project Committee (SSPC) 154, Ventilation for Commercial Cooking Operations. SSPC-154's scope includes providing the most complete design guidance available on commercial kitchen ventilation components and systems. Specific areas include kitchen hoods, exhaust systems, and replacement air systems.

SSPC-154 relies on the significant field experiences of the manufacturers, designers, and users of kitchen ventilation systems. ASHRAE *Standard* 154 is intended to serve as a template for standardization, harmonization, and ongoing revision of related model and adopted codes and to bring consistency to design requirements and applications of commercial kitchen ventilation systems.

1. COMMERCIAL KITCHEN VENTILATION

Kitchen ventilation is a complex web of interconnected HVAC systems. The main components typically include (1) cooling to address heat from cooking appliances, (2) replacement air to provide proper pressurization during cooking operations, and (3) exhaust to remove heat and effluent generated by cooking appliances. System design includes aspects of air conditioning, fire safety, ventilation, building pressurization, refrigeration, air distribution, and food service equipment. Kitchens are in many buildings, including restaurants and retail malls (see Chapter 2), hotels (Chapter 7), hospitals (Chapter 9), single- and multifamily dwellings (Chapter 1), educational facilities (Chapter 8), and correctional facilities. Each building type has special requirements for its kitchens, but many basic needs are common to all. This chapter provides an understanding of the different components of kitchen ventilation systems and where they can be applied. Additionally, background information is included to provide an understanding of the history and rationale behind these design decisions.

Kitchen ventilation has at least two purposes: (1) to provide a comfortable environment in the kitchen and (2) to ensure the safety of personnel working in the kitchen and of other building occupants. Comfort criteria often depend on the local climate, because some kitchens are not air conditioned. Kitchen ventilation ensures safety by providing the means to remove heat, smoke, and grease (cooking effluent) produced during normal cooking operations.

HVAC system designers are most frequently involved in commercial kitchen applications, in which cooking effluent contains large amounts of grease or water vapor. Residential kitchens typically use a totally different type of hood. The amount of grease produced in residential applications is significantly less than in commercial applications, so the health and fire hazard is much lower.

The centerpiece of almost any kitchen ventilation system is an exhaust hood(s), used primarily to remove cooking effluent from kitchens. Effluent includes gaseous, liquid, and solid contaminants produced by the cooking process, and may also include products of fuel and even food combustion. These contaminants must be removed for both comfort and safety; effluent can be potentially life-threatening and, under certain conditions, flammable. Finally, note that the arrangement of food service equipment and its coordination with the hood(s) can greatly affect the energy used by these systems, which in turn affects kitchen operating costs. Quite often, the hood selection and appliance layout is determined by a kitchen facility designer. To minimize energy use and ensure a properly designed kitchen ventilation system, the HVAC engineer should reach out to the kitchen designer and share the practices and ideas presented in this chapter.

Sustainability

Kitchens are some of the most intensive users of energy for a given floor area when compared to other commercial or institutional occupancies. In addition to energy used during cooking, the kitchen ventilation system must address the large amount of heat emitted or convected into the kitchen from the cooking equipment, and supply and condition the replacement air needed to support the cooking effluent exhaust system as well as ensure acceptable indoor environmental quality (IEQ). An additional factor to be considered is the cooking effluent, and any treatments that may be required before it is discharged into the atmosphere.

Given these factors, it is imperative that the kitchen ventilation system be designed with careful consideration of both first costs and operating costs. Maintenance costs should also be considered, including scheduled equipment service and replacement (e.g., hoods and exhaust duct cleaning, hood filter cleaning, fire protection system inspection, charging, refusing), any corresponding labor, and any production downtime as a result of the maintenance.

To ensure all of these criteria are accounted for in the kitchen ventilation design, the integrated building design approach described in Chapter 60 is recommended.

The preparation of this chapter is assigned to TC 5.10, Kitchen Ventilation.

1.1 COMMISSIONING

Because CKV systems are very complex operational environments, it is strongly recommended that ASHRAE *Standard* 202 and the guidance in Chapter 44 be followed for any commercial kitchen ventilation project. Sections of this chapter contain the technical information necessary to address all four phases of commissioning. Addressing the following topics is recommended when developing and executing any commissioning plan:

1. Owners project requirements (OPR)
   a. System manual outline
      i. System selection: specific kitchen ventilation use requirements (by owner or design team)
      ii. Type of facility (e.g., commissary, quick service, full service, institutional)
      iii. Cooking appliances selection based on menu, type of cooking, and special/unusual considerations
      iv. Other considerations
         1. System cost
         2. Kitchen space comfort targets
         3. Energy use and sustainability targets
         4. Replacement air requirements
         5. Cooking exhaust
            a. Duct routing and egress
            b. Effluent control requirements

1.2 VENTILATION DESIGN

Design Process

Designing a CKV or even a high-end residential kitchen ventilation system requires a different design approach and process than for most traditional HVAC systems. Design considerations include large replacement air requirements, large internal heat gains, kitchen workers' comfort, minimizing HVAC system energy use, and fire safety, all of which are equally high priorities that must be addressed during system design.

Necessary steps to design the ventilation systems for a commercial kitchen are as follows. Details for each step can be found in the subsequent sections in this chapter, or in the other Handbook chapters.

1. **Kitchen facilities design** (including cooking menu and appliance selection and placement). This design is typically performed by the food service consultant (FSC). Additionally, determine which appliances require an exhaust hood.
2. **Exhaust hood selection**, including exhaust air rates. Often overlooked, but one of the most critical design decisions for any CKV system: hood selection directly affects exhaust rates, the corresponding replacement air requirements, CKV system heat gain and loss calculations, and the system's overall energy use. Considerations include
   a. Appliance duty rating, fuel type (e.g., gas, solid fuel, electric, combination), cooking emission, and thermal plume character
   b. Type I or Type II, based on appliance use or process
   c. Hood style (e.g., canopy, island, back shelf)
   d. Energy saving options (e.g., side panels, extra overhang, demand control kitchen ventilation)
   e. Life-cycle cost analysis
3. **CKV system integration and design.** Determine exactly what the CKV system should accomplish, and how to holistically integrate it into the building.
4. **Replacement air design.** Addresses the need for delivering the replacement air into the kitchen. Considerations include
   a. Transfer air, comfort supply air, or direct makeup air (or any combination)
   b. ASHRAE *Standard* 62.1 compliance
   c. Adjacent zone air classifications
   d. Replacement and supply air delivery systems
5. **CKV system controls.** Maintain pressurization and comfort for the kitchen, dining area, and if applicable any adjoining zones. Accommodate any demand control systems, including DCKV and adjacent zones' demand-controlled ventilation (DCV) system(s).
6. **Heat gain and loss calculations**
   a. Appliance heat gains
   b. Replacement air
7. **Exhaust system design**
   a. Duct type selection
   b. Fire safety
   c. Air discharge
   d. Effluent control devices
   e. Fire suppression
8. **HVAC system design**
   a. Equipment selection
   b. Diffuser and return grille layout (very critical)

9. **Hood and replacement air commissioning specifications** (e.g., air balancing, troubleshooting)

Note: the CKV design engineer is recommended to engage the FSC during steps 1 and 2 to identify areas where both designs can be harmonized for optimal CKV performance.

1.3 SYSTEM INTEGRATION AND DESIGN

Ideally, system integration and balancing bring the many ventilation components together to provide the most comfortable, efficient, and economical performance of each component and of the entire system. In commercial kitchen ventilation, the replacement air system(s) must integrate and balance with the exhaust system and/or facility HVAC system(s). Even optimal system designs require field testing and balancing once installed. It is important to verify compliance with design, and equally important to confirm that the design meets the needs of the operating facility. Air balance is a critical step in any CKV commissioning process.

The following fundamentals should be considered and applied to all food service facilities, including restaurants, within the constraints of the particular facility and its location, equipment, and systems.

Principles

Although there are exceptions, the following are the fundamental principles of integrating and balancing food service facility systems for comfort, control, and economical operation:

- The building should always be slightly positively pressurized (e.g. +1.25 Pa) compared to atmosphere to prevent infiltration of outdoor air. Infiltrated air contains contaminants and insects, and adds to the heat load.
- Every kitchen should always be slightly negatively pressurized (–0.25 Pa) to adjacent rooms or areas immediately surrounding it to help contain odors in the kitchen and to prevent odor migration out of the kitchen.
- System HVAC design should prevent air supplied to the kitchen from being returned and supplied to non-kitchen areas. Odor contamination is an obvious potential problem. In addition, in conditions such as seasonal transitions, when adjacent zones may be in different modes (e.g., economizer versus air conditioning or heating), comfort may be adversely affected. Ideally, the kitchen HVAC system should be separate from all other zones' HVAC systems. Three situations to consider are the following:
  - During seasonal transitions, the kitchen zone may require air conditioning or may be served by ventilation air only, while dining areas require heating. Even in kitchens that require cooling when the adjacent dining areas require heating, it is still important to maintain the pressure differential between these spaces and continue transfer of dining-area air into the kitchen.
  - To limit kitchen personnel discomfort, it is important to control the low-temperature MUA set point and prevent drastic temperature variations between the kitchen space and MUA being introduced. If dedicated kitchen MUA requires heating, thermostatic control of the MUA heating source should ideally be based on kitchen space temperature rather than outdoor air temperature. MUA heating should be interlocked with kitchen HVAC cooling to prevent simultaneous heating and cooling. Location of HVAC thermostats in kitchens must account for the potential conflicting temperatures.
  - Ideally, will should be no perceptible drafts in dining areas, and temperature variations of no more than 0.6 K. Kitchens might not be draft free; however, velocities at or near exhaust hoods should be no greater than 0.4 m/s. Kitchen comfort is greatly impacted by radiant heat in work areas, but it is desirable to maintain sensible temperatures within 3 K of design conditions.

    These conditions can be achieved with even distribution and thorough circulation of air in each zone by an adequate number of registers sized to preclude high air velocities. If there are noticeable drafts or temperature differences, dining customers will be uncomfortable and facility personnel are generally less comfortable and less productive.

Both design concepts and operating principles for proper integration and balance are involved in achieving desired results under varying conditions. The same principles are important in almost every aspect of food service ventilation.

In restaurants with multiple exhaust hoods, or hoods with demand control systems, exhaust airflow volume may vary throughout the day. Replacement air must be controlled to maintain proper building and kitchen differential pressures to ensure the kitchen remains negative to adjacent areas at all operating points. The more variable the exhaust, or the smaller and more numerous the zones involved, the more complex the design, but the overall pressure relationship principles must be maintained to provide optimum comfort, efficiency, and economy.

A different application is a kitchen with one side exposed to a larger building with common or remote dining. Examples include a food court in a mall or a small restaurant in a hospital, airport, or similar building. Positive pressure at the front of the kitchen might cause some cooking grease, vapor, and odors to spread into the common building space, which would be undesirable. In such a case, the kitchen area is held at a negative pressure relative to other common building areas as well as to its own back room storage or office space. Such spaces that include direct-vent appliances, such as gas-fired water heaters, must maintain the pressure required for safe appliance operation.

Design Best Practices

Life-Cycle Cost Analysis (LCC). As with any engineering design, many considerations must be taken into account to ensure the CKV system operates properly and with the best interest of end users in mind. Life-cycle cost analysis compares the real cost of owning and operating two or more systems over a given period of time (typically 10 to 20 years). For each system, the total life-cycle cost can be calculated using Equation (1) (Fuller and Peterson 1996):

$$LCC = I + Repl - Res + E + W + OM\&R \tag{1}$$

where

LCC = Total LCC in present-value dollars of given alternative
I = Present-value investment costs
Repl = Present-value replacement costs
Res = Present-value residual (scrap) costs
E = Present-value energy costs
W = Present-value water costs
OM&R = Present-value, nonfuel, operating, maintenance and repair costs

For the kitchen ventilation systems covered in this chapter, the lifetime is typically longer than 10 years; if 10 years is used as the span of the analysis, the replacement costs and scrap costs are zero. For ventilation systems, energy costs could include items such as hood lights, exhaust fans, and the associated HVAC energy to condition supply air; water costs could include heating hot water (if applicable) used for hoods with wash or mist systems; OM&R could include maintenance items, the costs to remove and clean the primary grease extractors in the hood, and periodic replacement of filters in pollution control systems.

For CKV systems, the analysis is typically a comparison of the first cost of the equipment to the operating costs. For CKV systems, the primary operating costs are for conditioning the outdoor air used as replacement air for the kitchen hood exhaust. As such, different climates may yield different LCA values for identical designs.

It is recommended that LCAs be performed on the following items:

- Hoods, including size, type, and options (e.g., increased overhangs and side panels); in some instances, even different manufacturers may yield different results.
- Exhaust fans.
- Makeup air/replacement air designs (comparing untempered to tempered makeup air).
- Cooking effluent reduction technologies to duct cleaning costs.

An example of LCA for a kitchen is selecting the exhaust fan. Table 1 lists several fans that can perform the required, duty. If first cost is considered, the physically smallest (fan A) is the best choice. However, when applying a LCA, the larger fan C is the best option.

Incorporating Variable-Frequency Drives (VFDs) for Exhaust Fan Control

Many kitchen exhaust fans, especially those that are part of a DCKV system, use VFDs to control their speed. If applicable, the VFD will be supplied by the DCKV system supplier, and it should be installed adjacent to the exhaust hood it serves. If the building in which it is installed has the exhaust fans located a considerable distance away, as in tall buildings, the following must be taken into consideration:

- VFDs should have a separate conduit from the VFD to motor. In some cases, VFD output circuits may share conduit for short distances (e.g., in a cable tray, through a roof penetration), for up to 4.6 m.
- If VFD output circuits share conduit for more than 4.6 m, then output reactors should be installed on every VFD.
- No more than two VFD output circuits should share a single conduit for more than 4.6 m.
- Longer VFD-to-motor distances increase the probability that the motor will see higher voltage spikes, which can lead to the motor burning up. The issue gets worse with higher voltages. Methods to address this issue include the following:
  - Specify an inverter-duty motor rated for 1600 V P-P is critical (NEMA *Standard* MG1.1 Part 31)
  - Use a lower switching frequency. This can cause more audible noise at the motor, but is easier on the hardware.
  - Use an output reactor, mounted close to the VFD, to help absorb spikes and reduce reflected wave phenomena on load side of VFD.
  - An output filter, mounted close to the VFD, can also be used, but not in conjunction with output reactors. This provides additional protection to the motor with longer modulated wiring distances.
  - Input reactors, mounted close to the VFD, help smooth out power going to the line side of the VFD and help with rough output voltage on the load side.
- If possible, locate the VFD closer to the motor to reduce the modulated power run from the VFD to the serving motor.
- For retrofit projects, replace existing motors to prevent motor burnout. If existing motor are to be reused, use the following recommended limitations on distance from VFD to motor. Be reasonably conservative, but remember the risk of motor failure always exists.
  - 230 V AC motors: up to 60 m from VFD to motor
  - 460 V AC motors: up to 20 m from VFD to motor
  - 575 V AC motors: up to 12 from VFD to motor
  - If VFD-to-motor wiring distances exceed these limits, then output reactors are recommended
- For new construction and retrofit projects where the motor is replaced, consider the following limitations on distance from VFD to motor:
  - New motors should comply with NEMA *Standard* MG1 Part 31, which states that the motor winding insulation must be able to withstand voltage spikes of 1600 V peak-to-peak in 0.1 µs.
  - Totally enclosed fan-cooled (TEFC) motors should be used if they fit in the housing of the existing fan.
  - Open dripproof (ODP) motors may be used where TEFC motors do not fit.
  - Where the nominal AC voltage is 575 V (e.g., Canada), new motors must have insulation able to withstand 1700 V p-p.
  - Limitations on VFD-to-motor distance when the motor is new and known to meet the standards of NEMA *Standard* MG-1 Part 31 are
    - 230 V AC motors: up to 152 m from VFD to motor
    - 460 V AC motors: up to 60 m from VFD to motor
    - 575 V AC motors: up to 30 m from VFD to motor
    - If VFD-to-motor wiring distance exceeds these limits, then output reactors are recommended

Dedicated Fan Versus Manifold Exhaust Systems. Whether to connect each exhaust hood to its own dedicated exhaust fan is typically dictated by the physical constraints of the building into which the CKV system is being installed. The duct shaft space needed to install multiple exhaust ducts is not permitted on most projects, especially for any multistory building. Additionally, installing multiple exhaust ducts increases the first cost. Thus, many designs use **manifold exhaust systems**, which consist of multiple exhaust hoods served by a single exhaust fan.

The primary advantage of using a manifold exhaust system is first cost. Less ductwork is needed, which also reduces the amount of floor area lost to duct riser shafts. Additionally, fewer exhaust fans are needed, reducing the costs of equipment as well as associated electrical power wiring.

Table 1 Size, First Cost, and Operating Cost of 5 Upblast Exhaust Fans Operating at the Same Design Duty

Design Duty: Belt Drive Upblast Fan: 1888 L/s at 373.2 Pa				
Belt Drive Upblast Fan	**Wheel Diameter, mm**	**Relative Cost**	**Est. Cost**	**Operating Cost/Yr, $**
A	469.9	1	$750	$1082

C	622.3	1.23	$923	$1023
D	565.15	2.09	$1568	$995
E	685.8	2.81	$2108	$937

Table 2 Life-Cycle Analysis of Five Different Exhaust Fans Operating at Same Design Duty*

Belt Drive Upblast Fan	Wheel Diameter (mm)	Cost of Ownership for Years 0 to 10										
		0	1	2	3	4	5	6	7	8	9	10
A	469.9	$750	$1,832	$2,915	$3,997	$5,079	$6,161	$7,244	$8,326	$9,408	$10,490	$11,573
B	543.6	$818	$1,923	$3,029	$4,135	$5,241	$6,347	$7,453	$8,559	$9,665	$10,770	$11,876
C	622.3	$923	$1,945	$2,968	$3,990	$5,013	$6,036	$7,058	$8,081	$9,104	$10,126	$11,149
D	566.4	$1,568	$2,562	$3,557	$4,551	$5,546	$6,540	$7,535	$8,529	$9,524	$10,518	$11,513
E	685.8	$2,108	$3,045	$3,982	$4,919	$5,856	$6,793	$7,730	$8,667	$9,605	$10,542	$11,479

*Energy costs = $0.03/MJ; operating 18 h/day and 7 days/week.

The primary disadvantage of manifolded exhaust systems is the challenge of accurately controlling exhaust airflow at each individual hood. Due to fire codes, air-balancing dampers can only be installed as part of the hood collar, and they must be specifically listed for their intended application. Additionally, if a DCKV system is incorporated, the exhaust airflow can only be reduced when either (1) all cooking equipment under all hoods goes into part-load operation, or (2) specialized control dampers listed for installation and operation in cooking exhaust systems are installed along with the necessary controls to integrate with the DCKV system. These details should be considered when performing a life-cycle cost analysis of a manifolded exhaust system. An additional disadvantage is that, should the fan fail, the entire cooking operation loses function.

For dedicated fan-to-hood systems, first costs are indeed greater for the extra ducts and fans. But the advantages include being able to control exhaust air for each hood simply by changing fan speed. This approach works for both initial balancing and for DCKV control. If a cooking appliance is not being used, the associated fan can be shut off instead of operating at reduced airflow. Finally, should a fan fail, the entire cooking operation will not have to cease.

Multiple-Hood Systems Served by Single Exhaust Fan

Single kitchen exhaust duct/fan systems serving multiple hoods (i.e., manifold exhaust systems) present unique design and balancing challenges. Air balance is one of the main challenges. These systems may be designed with bleed ducts and/or balancing dampers to facilitate balancing the air draw of individual hoods. The dampers can be of blade types that can be set in position manually or operated automatically by a programmable actuator. Balancing dampers must be listed for use with kitchen hoods. Additionally, hood filters are sized to allow pressure loss equalization along the hood for hood containment and capture (C&C). Some filters are adjustable, but should not be used when they can be interchanged between hoods or within the same hood, because such interchange can alter the commissioned air balance of the hoods and exhaust fan. Balancing can also be accomplished by changing the number and/or size of filters.

DCKV in single or manifold applications can automatically provide real-time balancing by using an engineered system listed for use with commercial kitchen hoods, such as one or more of the following: cooking activity sensors, variable-speed exhaust and supply fans, and volume-balancing dampers to modulate hood exhaust. However, the ductwork still must be properly designed to allow each hood to achieve design airflows during full-load cooking operations. When physical space allows, it is good practice to use a separate exhaust fan for each hood. This effectively provides system redundancy and less complexity when balancing.

Exhaust for solid-fuel cooking equipment should be separate from all other exhaust systems. Light-duty smokers, flavoring equipment, or fireboxes that use solid fuel can be installed under the hood serving other cooking equipment, subject to restrictions under NFPA *Standard* 96 and building codes, including size, fuel load and storage, open flame design, and ash removal and disposal.

In some multitenant installations, the duct design may be completed and installed before the tenants have been identified. In cases such as master kitchen-exhaust systems, which are sometimes used in shopping center food courts, no single group is responsible for the entire design. The base building designer typically lays out ductwork to (or through) each tenant space, and each tenant selects a hood and lays out connecting ductwork. Often, the base building designer has incomplete information on tenant exhaust requirements. Therefore, one engineer must be responsible for defining criteria for each tenant's design and for evaluating proposed tenant work to ensure that tenant designs match the system's capacity. The engineer should also evaluate any proposed changes to the system, such as changing tenancy. Rudimentary computer modeling of the exhaust system may be helpful (Elovitz 1992). Given the unpredictability and volatility of tenant requirements, it may not be possible to balance the entire system perfectly. However, without adequate supervision, it is very probable the system will not achieve proper balance.

For greatest success with multiple-hood exhaust systems, minimize pressure losses in ducts by keeping velocities low, minimizing sharp transitions, and using hoods with relatively high pressure drops. When pressure loss in the ducts is low compared to the loss through the hood, changes in pressure loss in the ductwork because of field conditions or changes in design airflow have a smaller effect on total pressure loss and thus on actual airflow.

Minimum code-required air velocity (2.5 m/s) must be maintained in all parts of the exhaust ductwork at all times. If fewer or smaller hoods are installed than the design anticipated, resulting in low velocity in portions of the ductwork, the velocity must be brought up to the minimum. One way is to introduce outdoor air, preferably untempered, through a bleed duct system directly into the exhaust duct (Figure 1). The bypass duct should connect to the top or sides (at least 50 mm from the bottom) of the exhaust duct to prevent backflow of water or grease through the bypass duct when fans are off. This arrangement is also shown in NFPA *Standard* 96 and should be discussed with the authority having jurisdiction.

A fire damper is required in the bleed duct, located close to the exhaust duct. Bypass duct construction should be the same as the exhaust duct construction, including enclosure and clearance requirements, for at least a metre beyond the fire damper or as required by the local authority having jurisdiction (AHJ). Means to adjust the bleed airflow must be provided upstream of the fire damper. All dampers must be in the clean bleed air duct so they are not exposed to grease-laden exhaust air. The difference in pressure between bleed and exhaust air duct may be great; the balancing device must be able to make a fine airflow adjustment against this pressure difference. It is best to provide two balancing devices in series, such as an orifice plate or blast gate for coarse adjustment, followed by an opposed-blade damper for fine adjustment.

Directly measuring air velocities in the exhaust ductwork to assess exhaust system performance may be desirable. Velocity (pitot-tube) traverses may be performed in kitchen exhaust systems, but holes drilled for the pitot tube must be liquidtight to maintain the fire-safe integrity of the ductwork, per NFPA *Standard* 96. Holes should never be drilled in the bottom of a duct, where they may collect grease. Velocity traverses should not be performed when cooking is in progress because grease collects on the instrumentation.

Dynamic Volumetric Flow Rate Effects

Minimum exhaust flow rates for kitchen hoods are determined either by laboratory tests or by building code requirements. Energy codes specify maximum airflow rates. In either case, the installed

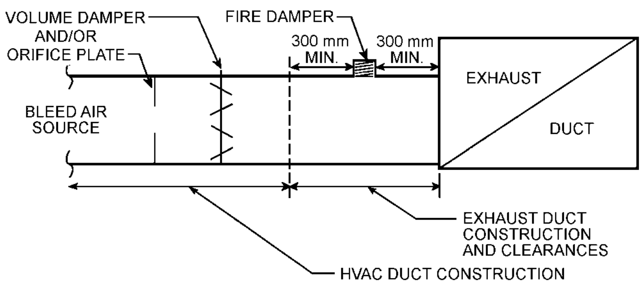

Fig. 1 Bleed Method of Introducing Outdoor Air Directly into Exhaust Duct
(Brohard et al. 2003)

system must ensure proper capture and containment under maximum cooking load conditions. The majority of kitchen exhaust systems use fixed-speed fans, which move the same volume of air at a given speed regardless of air density. Although the air volume remains constant, heat and moisture generated by the cooking process affect mass flow.

Exhaust fans for kitchen ventilation systems, like for other high-temperature exhaust processes, must be selected to provide adequate airflow at standard conditions to meet the mass flow needs of the actual cooking process. Testing for hood listing in accordance with UL *Standard* 710, for example, requires capture and containment testing using actual cooking, with cooking appliance heated to controlled surface temperatures and food product cooked, including flare-ups, to determine airflow. This airflow must be converted to standard air conditions to provide proper design ratings for fan selections.

1.4 ENERGY CONSIDERATIONS

Restaurants and commercial kitchens are the largest consumers of energy per unit of floor area when compared to other commercial or institutional occupancies (Itron and California Energy Commission 2006). Primary drivers of commercial kitchen energy use are the cooking appliances and the HVAC system. Often, the largest energy-consuming component in a commercial food service facility is the kitchen exhaust. However, energy consumption associated with commercial kitchen ventilation (CKV) and HVAC systems, as well the conservation potential, can vary significantly (Fisher 2003). Beyond the design exhaust ventilation rate itself, the magnitude of energy consumption and cost of a CKV system is affected by factors such as geographic location (i.e., climate), system operating hours, static pressure and fan efficiencies, replacement air heating and cooling set points and level of dehumidification, efficiency of heating and cooling systems, level of interaction between kitchen and building HVAC system, appliances under the hood and associated radiant heat gain to space, and applied utility rates. Minimizing the exhaust airflow needed for cooking appliances and reducing radiant load from the appliances are primary considerations in optimizing CKV system design. Because climatic zones vary dramatically in temperature and humidity, energy-efficient designs have widely varying rates of returns on the investment. In new facilities, the designer can select conservation measures suitable for the climatic zone and the HVAC system to maximize the economic benefits.

The operating cost burden has stimulated energy efficiency design concepts and operating strategies discussed in this section and detailed in industry design guidelines (PG&E 2004). It has also impacted changes to ASHRAE *Standard* 90.1.

The Kitchen Exhaust Systems section of ASHRAE *Standard* 90.1 states that if a CKV system has a total exhaust airflow rate greater than 2.4 m^3/s, the design must adhere to maximum exhaust rates specified for the different hood types. These rates apply to listed hoods, and are set 30% below the minimum values for unlisted hoods dictated by the *International Mechanical Code®* (IMC) (ICC 2018). If a kitchen or dining facility has a total kitchen hood exhaust airflow rate greater than 2.4 m^3/s, it must have one of the following:

- At least 50% of all replacement air is transfer air that would otherwise be exhausted
- Demand ventilation system(s) on at least 75% of the exhaust air, capable of at least 50% reduction in exhaust and replacement air system airflow rates, including controls necessary to modulate airflow in response to appliance operation and to maintain full capture and containment of smoke, effluent, and combustion products during cooking and idle
- Listed energy recovery devices with a sensible heat recovery effectiveness of not less than 40% on at least 50% of the total exhaust airflow

Energy Conservation Strategies

Specifying Exhaust Hoods for Minimal Airflow. The type and style of exhaust hood selected depends on factors such as restaurant type, restaurant menu, and food service equipment installed, as well as flexibility for future kitchen upgrades. Exhaust flow rates are largely determined by the food service equipment and hood style. Wall-mounted canopy hoods function effectively at lower exhaust flow rates than single-island hoods. Single- and double-island canopy hoods are more sensitive to replacement air supply and cross drafts than wall mounted canopy hoods (Swierczyna et al. 2010). Engineered back shelf (proximity) hoods may exhibit the lowest capture and containment flow rates. In some cases, a back shelf hood performs the same job as a wall-mounted canopy hood at one-third the exhaust rate. Cooking appliance type and duty rating must be included in the specification process, because not all hoods (particularly back shelf hoods) are rated or designed for all cooking appliance types or duty ratings.

Threshold exhaust rates for a specific hood and appliance configuration may be determined by laboratory testing under the specifications of ASTM *Standard* F1704-17. Similar in concept to the listed airflow rates derived from UL *Standard* 710, the threshold of containment and capture (C&C) for an ASTM *Standard* F1704 test is established under ideal laboratory conditions and is only a reference point for specifying the exhaust airflow rate for a CKV system.

Side Panels and Overhang. In many cases, side (or end) panels allow a reduced exhaust rate because they direct replacement airflow to the front of the hood and cooking equipment. They are a relatively inexpensive way to improve capture and containment and reduce the total exhaust rate. It is important to know that partial side panels can provide almost the same benefit as full panels. Although tending to defy its definition as an “island” canopy, end panels can improve the performance of a double- or single-island canopy hood. A significant benefit of end panels, when hoods are exposed to cross drafts, is mitigation of the negative effect those drafts have on hood performance. However, air distribution designs that eliminate cross drafts are preferred. Increasing overhang is another specification detail that can improve the hood’s ability to capture and allow reduced exhaust rates. It is important that the engineer and food service designers work closely on appliance placement size and type, because they affect hood sizing, which in turn affects lighting, HVAC, and most importantly hood performance. A hood that is too small (i.e., little or no overhang) may often not be capable of working properly at any airflow rate, whereas those with generous overhang may operate well at airflow rates reduced by 30% or more.

Custom-Designed Hoods. Hoods can be custom designed for specific cooking appliances or cooking processes. Customization often reduces exhaust and replacement air quantities and consequently reduces fan sizes, energy use, and energy costs. To operate at flow rates lower than required by code, custom-designed hoods must be either listed or approved by the local code official. The cost involved with custom design makes the process more applicable to chain restaurants, such as quick service, where a specific design may be installed repeatedly. Some single-site establishments may have architectural restrictions that demand a custom solution.

Transfer Air. ASHRAE *Standard* 62.1 specifies the quantity of outdoor air that must be provided to ventilate public spaces, such as dining rooms, in food service establishments. *Standard* 62.1 allows this ventilation air to be reused by transfer from the ventilated public spaces to the kitchen, where it can be used to replace air exhausted by the hood system and assist kitchen comfort. Transfer air must meet the requirements as prescribed in ASHRAE *Standard* 62.1 (section 5.16.3). By maximizing transfer of air from adjoining public spaces to the kitchen, the designer is able to minimize the quantity of dedicated outdoor air supplied to the kitchen as replacement air. This can reduce the energy load on the replacement air system, as well as improve thermal comfort in the kitchen. Most quick-service and fast-casual restaurants do not physically segregate the kitchen from the dining room, so conditioned air can be easily transferred from the dining area to the kitchen. In restaurants where the kitchen and dining room are physically segregated, ducts between the two areas may be required for proper flow of replacement air into the kitchen. Transfer fans may be required to overcome duct losses, because the differential pressure between spaces may be very low (<1.25 Pa). This design can reduce kitchen replacement air requirements and enhance employee comfort, especially if the kitchen is not air conditioned. Codes may restrict transfer of air from adjoining spaces, other than public dining areas, in buildings such as hospitals. Adjoining spaces should not be overventilated to increase transfer airflow, because the heating and cooling conditions for dining and other public spaces are more energy-intense than for conditioning replacement air introduced directly into the kitchen.

Demand-Controlled Kitchen Ventilation

Demand-controlled kitchen ventilation (DCKV) refers to any engineered, automated method of modulating (e.g., variable reduction) the amount of air exhausted for a specific cooking operation in response to a part-load or no-load condition (e.g., by duct temperature, opacity, or appliance surface temperatures).

A DCKV system is different from a DCV system in that the controlling demand factor is the kitchen's cooking operations and not space carbon dioxide (CO_2) levels. In conjunction with this, the amount of replacement air (consisting of makeup, transfer, and outdoor air) is also modulated to maintain the same relative air ratios, airflow patterns, and pressurizations. Failure to integrate systems could cause negative pressure.

The design of all involved ventilation systems must account for DCKV, to create a fully integrated system.

Complete capture and containment of all smoke and greasy vapor must be maintained when a DCKV exhaust system operates at less than 100% of design airflow.

Selection of all components, and design of the DCKV system, must be such that stable operation can be maintained at all modulated and full-flow conditions.

When DCKV is used as the method of compliance with ASHRAE *Standard* 90.1 (section 6.5.7.1.4 part b), it must meet all requirements of that section.

When DCKV is used as the method of compliance with ASHRAE *Standard* 62.1 it must meet the minimum exhaust air rates per Table 6.5 and minimum ventilation air rates per Table 6.2.2.1, ensuring ventilation during periods of occupancy.

The exhaust system configuration and equipment to be served by a DCKV system must be evaluated to determine the feasibility and cost benefits resulting from its use. An example of a situation where a DCKV system may not be appropriate is when gas-underfired broilers are present.

Evaporative Cooling. Direct evaporative coolers are an alternative to mechanical cooling (or, for that matter, no cooling) of replacement air only in dry climates where dehumidification is not required. Indirect evaporative cooling has a wider range in geographical applications. Water costs, availability, and use restrictions should be considered.

Heat Recovery from Exhaust Hood Ventilation Air. High-temperature effluent, often in excess of 200°C, from the cooking equipment mixes with replacement room air, resulting in exhaust air temperatures well over 35°C. It is frequently assumed that this heated exhaust air is suitable for heat recovery; however, over time, smoke and grease in the exhaust air can foul the heat transfer surfaces. Under these conditions, the heat exchangers require regular maintenance (e.g., automatic washdown) to maintain heat recovery effectiveness and mitigate risk of fire. Because heat recovery systems are expensive, food service facilities with large ventilation rates and relatively light-duty cooking equipment are the best candidates for this equipment. Hospitals are a good example, with large exhaust rates and very low levels of grease production from the

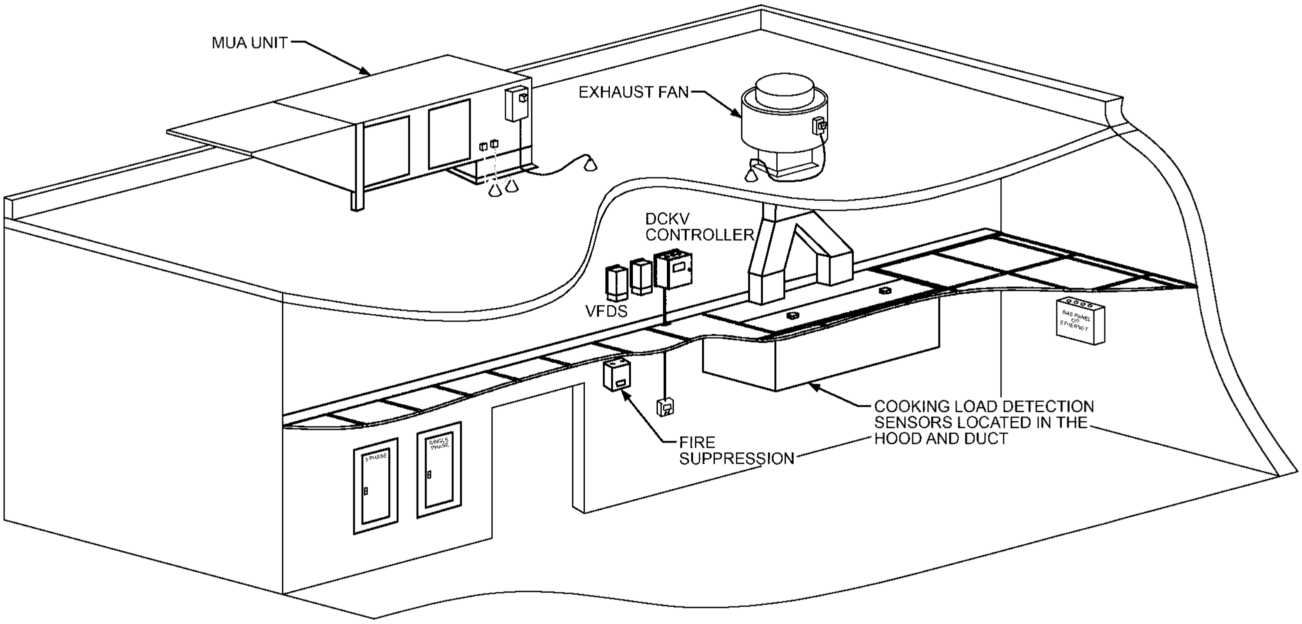

Fig. 2 Typical DCKV Equipment and Configuration

cooking equipment. An exhaust hood equipped with heat recovery is more likely to be cost-effective where the climate has very cold winters (well below 0°C). A mild climate is not conducive to use of this conservation measure. See Chapter 26 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on air-to-air heat recovery.

Optimized Heating and Cooling Set Points. IMC (ICC 2018) requires that replacement air be conditioned to within 5.6 K of the kitchen space, except when replacement air is part of the air-conditioning system and does not adversely affect comfort conditions in the occupied space. The exception is important because it allows the design to be optimized to take advantage of the typically lower heating balance points of commercial kitchens. A commercial kitchen may be considered comfortable at temperatures of up to 29°C when space humidity is ≤60%. During heating seasons, space humidity is typically not an issue if the kitchen exhaust systems are properly designed and operated. During the heating season, space gains from unhooded appliances and radiant gains from hooded appliances, lighting, refrigeration units, and staff make it possible to maintain comfort using lower supply air temperatures. During cooling seasons, in climatic areas that require dehumidification, consideration must be given to all sources that may introduce moisture into commercial kitchens, including internal cooking, holding, and washing as well as local makeup air (MUA) systems or kitchen HVAC systems not designed for continuous dehumidification. Humidity control (≤60%) allows optimization of cooling set points at higher temperatures while maintaining a comfortable working environment.

A dedicated outdoor air system (DOAS) providing conditioned outdoor for kitchen heating, cooling, and dehumidification also optimizes set points by using economizer operation when outdoor air alone (no conditioning) can maintain kitchen set points. Using dedicated outdoor air to heat, cool, and dehumidify outdoor air to control space comfort and humidity and replace air exhausted through the hood has been demonstrated to be an energy-effective design for optimizing heating and cooling set points (Brown 2007).

Accordingly, when local MUA systems are used, it is essential that the heating set point of those units not be set higher than the forecasted heating/cooling balance point (e.g., 13°C) to avoid simultaneous replacement air heating and HVAC cooling. It may be more difficult to control comfort when local MUA (e.g., at 13°C) is introduced into a kitchen being heated by a conventional HVAC system introducing kitchen supply air at temperatures ≥27°C.

Reduced Exhaust and Associated Duct Velocities

Tempering outdoor replacement air can account for a large part of a food service facility's heating and cooling costs. By reducing exhaust flow rates (and the corresponding replacement air quantity) when little or no product is being cooked, energy cost can be significantly reduced when combined with a DCKV system. Field evaluations by one large restaurant chain suggest that cooking appliances may operate under no-load conditions for 75% or more of an average business day (Spata and Turgeon 1995).

However, it has been difficult to reduce exhaust flow rates in a retrofit situation because of the minimum duct velocity restriction. National Fire Protection Association (NFPA) *Standard* 96 had historically required a minimum duct velocity of 7.62 m/s. The common belief was that, if duct velocity were lowered, a higher percentage of grease would accumulate on the ductwork, which would then require more frequent duct cleaning. However, no data or research could be identified to support this assumption. Therefore, ASHRAE research project RP-1033 (Kuehn 2000) was undertaken to determine the true effect of duct velocity on grease deposition.

The project analyzed grease deposition as a function of mean duct velocity, using octanoic acid (commonly found in cooking oils and other foods). The results showed that, for design duct velocities below the traditional 7.5 m/s threshold, grease deposition was not increased; in fact, in isothermal conditions, as duct velocity decreased, grease deposition on all internal sides of the duct also decreased. These results led to NFPA *Standard* 96 and the IMC changing their minimum duct velocity requirements from 7.62 m/s to 2.54 m/s.

Another significant finding in the study was that, if there is a large temperature gradient between exhaust air inside the duct and the external duct wall, the rate of grease deposition increases significantly. Therefore, duct insulation should be considered where there are large temperature variations.

The primary benefit of these code-approved duct velocity changes is the potential for reduced food service energy consumption. By reducing excessive exhaust airflows, while maintaining necessary capture and containment, energy for fans as well as for heating, cooling and/or dehumidifying air that was previously wasted may now be saved. Previously, if a restaurant remodeled their cooking operation and the remodel resulted in reduced exhaust airflows, the owner had to install new, smaller-diameter ductwork to comply with the 7.62 m/s duct velocity requirement. This is often too costly, if not also physically impractical. Now, if a system designed for heavy-duty equipment upgrades to more energy-efficient, lighter-duty equipment, exhaust airflows can be reduced without the expense of modifying ductwork.

Reduced code-approved duct velocity also facilitates application of DCKV systems with less resistance from local code authorities. From a new-facility design perspective, it is recommended that most kitchens be designed for an in-duct velocity between 7.62 and 9.1 m/s. This allows for reducing the airflows to 2.5 m/s if needed in the future or as part of a demand-ventilation control strategy.

Due to a higher risk of duct fires associated with solid-fuel cooking equipment, the DCKV application is typically limited to two-speed on/off fan cycles. Dampers, if used for solid fuel, must adhere to the requirement of liquidtight connection and must not downgrade the ductwork. The dampers are mechanically locked in position and must be approved by a fire inspector. NFPA *Standard* 96 requires listed dampers for the application. Duct sizes for solid fuel typically maintain 7.62 m/s duct velocity.

Exhaust from heavy-duty solid fuel cooking can be treated and cooled down by an in-line water mist duct section. The duct system monitors and cycles water mist to maintain a set exhaust temperature threshold. Listed grease ducts have a threshold not exceeding 260°C for continuous exhaust. The design temperature must consider flammability of creosote buildup on duct walls, produced from solid fuel burning as it mixes with cooking vapor from cooking. Creosote and soot mixtures on duct walls can have a lower flash point than grease alone and pose a fire hazard (see the Fire Safety section).

Dishroom Ventilation

Many different types of dishwashing and warewashing equipment are used in the food service industry: powered sink washers; troughs; undercounter, door-type, conveyor-type, and flight-type warewashers; and rack washers. Ancillary equipment such as pre-rinse valves, scrappers, hoses, and drying dishes are also sources of loads. Each type of equipment operates differently and generates different levels of sensible, latent, and moisture loads to the space. Loads depend on whether the appliance is ventilated, whether sanitization occurs by hot water or chemicals, and the effectiveness of the local ventilation.

Historically, data on heat gains and cooling loads have been scarce. This made it difficult to estimate loads, leading to potentially undersized ventilation and resulting in hot and humid dishrooms with condensation on walls and supply diffusers. ASHRAE research is currently under way to determine heat and moisture loading from these types of equipment. ASHRAE research project

RP-1469 (Stoops et al. 2013) found that dishrooms had latent and sensible loads significantly larger than the spaces were designed for, resulting in hot and humid space conditions and the possibility of mold growth.

International Mechanical Code® (ICC 2014), section 507.3, states that: “type II hoods shall be installed above dishwashers and appliances that produce heat or moisture and do not produce grease or smoke as a result of the cooking process, except where the heat and moisture loads from such appliances are incorporated into the HVAC system design or into the design of a separate removal system.” The only reliable data for the calculations are listed in Table 5F from Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*. The internal heat gain calculation is essentially the same for hooded and unhooded appliances. For unhooded dishwashers, the total latent and sensible (convective and radiant) emissions load the space. The designer cannot assume there is no load from low-temperature and heat recovery models. For hooded dishwashers, the emissions are the sensible radiant load. However, if ventilation is inadequate, an appreciable amount of convective load can spill into the space and create hot and humid conditions.

Only limited heat gain values are available from manufacturers. Manufacturers have only recently begun applying ASTM *Standard* F2474 to determine sensible and latent loads from dishwashers. Underwriters Laboratories’ new listing and labeling program requires heat recovery dishwashers to list and label the sensible and latent loads during heavy-load operations. Heat gain testing per ASTM *Standard* F2474 is a requirement for heat recovery dishwashers as part of a supplement to UL *Standard* 921.

Industry is beginning to realize the opportunities and benefits of heat recovery in a commercial food service facility. The range of application varies from air-to-water heat exchangers above fryer flues, to grease filters incorporating fin-and-tubes to transfer the high-quality heat to preheat water for the dish machine or water heater or to preheat makeup air. In any case, heat exchanger effectiveness ranges between 18 and 63%. The designer must realize that not all the heat is recovered: some amount of heat (both sensible and latent) is released to the space. In the same way, a recirculating or ductless hood system loads the space with nearly the entire plug load from the hood/appliance system. Heat is emitted to the space from heat recovery kitchen equipment, depending on the effectiveness of the heat exchanger. Table 5F in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals* lists the residual heat gain for a few dish machine types. However, as designs become more efficient (e.g., heat pump dish machines releasing 20 to 21°C dry-bulb temperatures), there is always an amount of moisture that must be considered along with elevated dry-bulb temperatures.

Designing for High-Performance Green Building Compliance under ANSI/ASHRAE/USGBC/IES *Standard* 189.1

There are several sections in this standard that any CKV system must comply with in order to be considered a high-performance green building.

Air-Side Economizer Controls for Replacement Air (Makeup Air). Given the large quantities of replacement air typically required for a CKV system, the use of air-side economizers should be evaluated for every location. This evaluation should include comparing the CKV system’s typical daily hours of operation to the number of hours of free cooling available in the local climate. Some locations in ASHRAE climate zones 1A and 1B may still benefit from using air-side economizers, especially if they operate enough hours of the year that they can take advantage of free cooling.

ENERGY STAR Appliances. Commercial food service appliances (e.g., fryers, hot food holding cabinets, refrigerators and freezers, steam cookers, ice machines, dishwashers, griddles, ovens) should bear the ENERGY STAR label. Equipment selection guidance and specifications can be found at www.energystar.gov/.

DCKV for Airflow Greater than 0.9 m³/s. Kitchen/dining facilities with total kitchen hood exhaust airflow rates above 0.9 m^3/s must comply with at least one of the following:

- At least 50% of all replacement air must be transfer air that would otherwise be exhausted.
- At least 75% of kitchen hood exhaust air must be controlled by a demand ventilation system(s), which must (1) be able to reduce exhaust and replacement air system airflow rates by no more than the larger of 50% of total design exhaust and replacement air system airflow rate, or the outdoor airflow and exhaust rates required to meet the ventilation and exhaust requirements of Sections 6.2 and 6.5 of ANSI/ASHRAE *Standard* 62.1 for the zone; (2) include controls to modulate airflow in response to appliance operation and to maintain full capture and containment of smoke, effluent, and combustion products during cooking and idle; (3) include controls that result in full flow when the demand ventilation system(s) fail to modulate airflow in response to appliance operation; and (4) allow occupants to temporarily override the system(s) to full flow.
- Listed energy recovery devices with a sensible heat recovery effectiveness of not less than 40% must be applied on at least 50% of the total exhaust airflow.
- In climate zones 1B, 2B, 3B, 4B, 5B, 6B, 7B, and 8B, when replacement air is uncooled or cooled without mechanical cooling, the capacity of any nonmechanical cooling system(s) (e.g., natural or evaporative cooling) must be demonstrated to be no less than the system capacity of a mechanical cooling system(s) necessary to meet the same loads under design conditions.

Outdoor Airflow Measuring. Each mechanical ventilation system shall have a permanently installed device to measure the minimum outdoor airflow rate that meets the following requirements:

- The device must use methods described in ASHRAE *Standard* 111.
- The device’s accuracy must be ±10% of the minimum outdoor airflow. Where the minimum outdoor airflow varies, as in demand control ventilation systems, the device must maintain this accuracy over the entire range of occupancy and system operation.
- The device must be able to notify the building operator, either by activating a local indicator or by sending a signal to a building monitoring system, whenever an outdoor air fault condition exists. This notification requires manual reset.

  Exception: Constant-volume air supply systems that do not use demand control ventilation and use an indicator to confirm that the intake damper is open to the position needed to maintain design minimum outdoor airflow do not require notification ability.

Energy Measurement Devices. Energy consumption must be measured by devices to track and record energy profiles so that periodic assessments can be made to assure continued future performance. In addition to whole-building monitoring, submetering may be required on specific appliance lineups depending upon capacity. See section 7 of ANSI/ASHRAE/USGBC/IES *Standard* 189.1 for additional information.

Commissioning. Facilities with a gross floor area over 465 m^2 must be commissioned. Commissioning is essential to ensure that the building, including the kitchen exhaust and HVAC systems, functions as intended. For additional information on high performance building commissioning requirements, see section 10 of ANSI/ASHRAE/USGBC/IES *Standard* 189.1.

1.5 THERMAL COMFORT

Due to the many heating, ventilation, and air conditioning operations that can occur (sometimes simultaneously) in a commercial kitchen, determining parameters for a thermally comfortable environment poses a challenge. ASHRAE research project RP-1469 (Stoops et al. 2013) was executed in response to this dilemma. Data were gathered by surveying kitchen workers in over 100 U.S. restaurants, including casual dining, institutional, and quick-service restaurant dishrooms, in different climates, in both summer and winter. The data points were evaluated to quantify thermal comfort in commercial kitchens (Figure 3).

The researchers developed a kitchen comfort zone as a region of the psychrometric chart, including a region with a percent dissatisfied PD < 12%. However, nearly 60% of the temperature and humidity data collected in the study were outside the bounds of the comfort zone. The operative temperature was as high as 42°C, and relative humidity was as high as 78%. Such conditions lead to poor working environment, low productivity, bad morale, and mold growth. Based on these results, it is recommended that commercial kitchen design conditions should align with the results shown on the chart, with maximum dry-bulb temperature of 46°C and humidity 60%.

Dishwashing Area

Previously, there was inadequate design data to calculate the internal loads from dishwashing equipment. This resulted in undersized HVAC equipment and poor air distribution, leading to hot and humid kitchens. The findings of RP-1469 determined that the operative temperatures were as high as 29°C and with 71% rh; the correlating average predicted mean vote was above 2 (warm). The long-term measurements found considerable daily temperature variations in the dishwashing area from 24 to 32°C during working hours. If the dishwashing area was open to the cooking line, the thermal radiation from the hot appliance line raised the operative temperature by an additional 5.6 K, it was reported to peak as high as 39°C. The relative humidity in the kitchen space was recorded during the working hours in the three different kitchen zones (i.e., cook line, prep line, and dishwashing area). The relative humidity was up to 55% higher in the dishwashing area than in the other two zones. Long term data at some quick serve restaurants recorded humidity averages up to 69% in the dishwashing area during the summer.

1.6 COMMERCIAL EXHAUST HOODS

The design, engineering, construction, installation, and maintenance of commercial kitchen exhaust hoods are governed by nationally recognized standards (e.g., NFPA *Standard* 96) and model codes (e.g., the IMC, *International Fuel Gas Code* [IFGC; ICC]). In some cases, local codes may prevail. Before designing a kitchen ventilation system, the designer should identify governing codes and consult the AHJ. Local authorities with jurisdiction may have amendments or additions to these standards and codes.

The type of hood required, or whether a hood is required, is determined by the type and quantity of emissions from cooking. Hoods are not typically required over electrically heated appliances such as microwave ovens, toasters, steam tables, popcorn poppers,

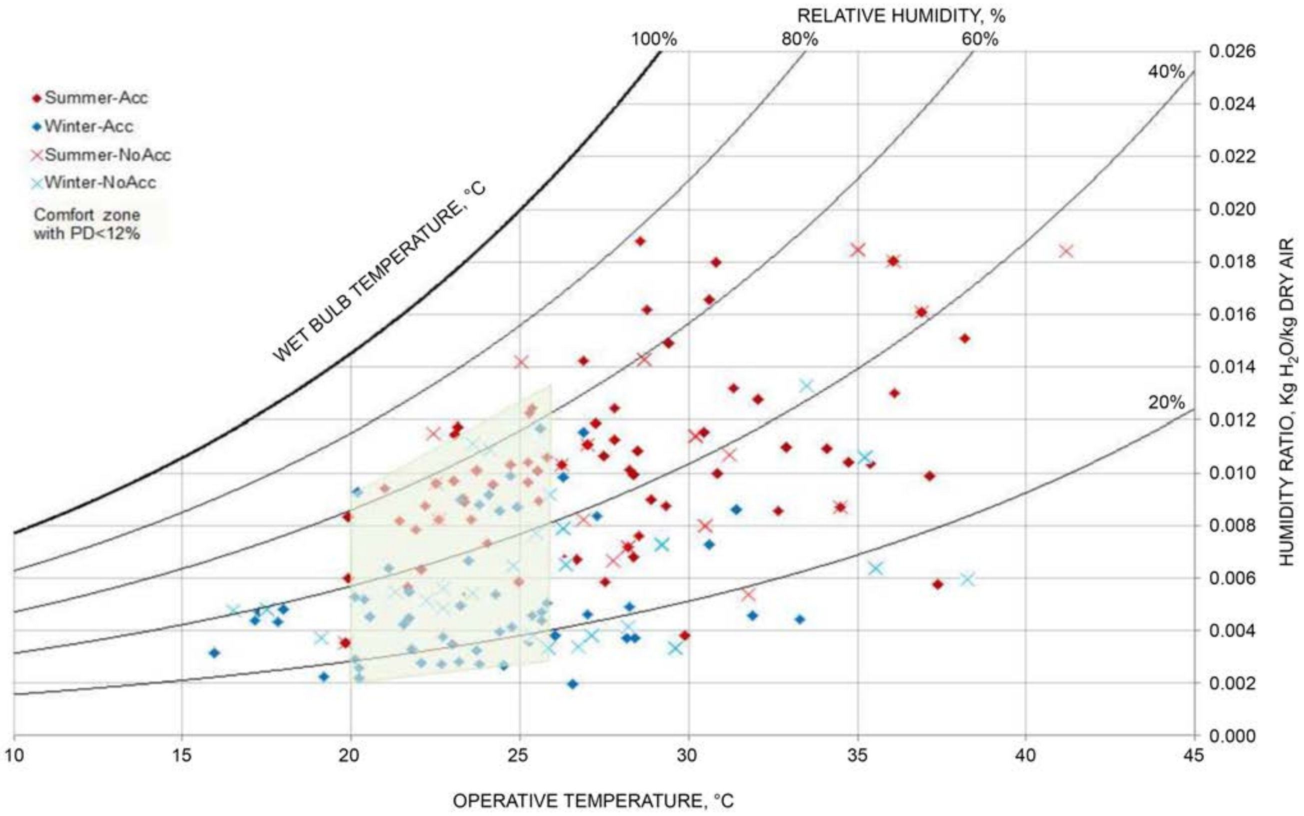

Fig. 3 Thermal Comfort Zone for Commercial Kitchens Work Space Based On the Results From RP-1469: Comfort in Commercial Kitchens
(Stoops et al. 2013)

hot dog cookers, coffee makers, rice cookers, egg cookers, holding/warming ovens (as mentioned in ASHRAE *Standard* 154), or heat lamps. Appliances can be unhooded only if the additional heat and moisture loads have been considered in a thorough load calculation and accounted for in design of the HVAC system. Temperature and humidity in the kitchen space should be based on recommendations of ASHRAE *Standard* 55.

Hood Types

Many types, categories, and styles of hoods are available, and selection depends on many factors. Hoods are classified by whether they are designed to handle grease; Type I hoods are designed for removing grease and smoke, and Type II hoods are not. Model codes distinguish between grease-handling and non-grease-handling hoods, but not all model codes use Type I/Type II terminology. A Type I hood may be used where a Type II hood is required, but the reverse is not allowed. However, characteristics of the equipment and processes under the hood, and not necessarily the hood type, determine the requirements for the entire exhaust system, including the hood.

A **Type I hood** is used for collecting and removing grease particulate, condensable vapor, and smoke. It includes (1) listed grease filters, baffles, or extractors for removing the grease and (2) fire-suppression system. Type I hoods are required over cooking equipment that produce smoke or grease-laden vapors (e.g., ranges, fryers, griddles, gas underfired and electric broilers, ovens).

A **Type II hood** collects and removes steam and heat where grease or smoke is not present. It may or may not have grease filters or baffles and typically does not have a fire-suppression system. It is usually used over dishwashers. A Type II hood is sometimes used over ovens, steamers, or kettles if they do not produce smoke or grease-laden vapor and as authorized by the AHJ.

Type I Hoods

Categories. Type I hoods fall into two categories: unlisted and listed. **Unlisted hoods** are no longer allowed under ASHRAE *Standard* 154. However, if they are used, they must meet the design, construction, and performance criteria of applicable national and local codes and are not allowed to have fire-actuated exhaust dampers. **Listed hoods** are listed in accordance with Underwriters Laboratories (UL) *Standard* 710 and are constructed in accordance with the terms of the hood manufacturer's listing, and are required to be installed in accordance with either NFPA *Standard* 96 or the model codes. Model codes include exceptions for listed hoods to show equivalency with the model code requirements.

The two subcategories of Type I listed hoods, as covered by UL *Standard* 710, are exhaust hoods with and without exhaust dampers. UL listings also distinguish between water-wash and dry hoods.

All listed hoods are subjected to electrical (if applicable), temperature, and cooking smoke and flare-up (capture and containment) tests. A listed exhaust hood with exhaust damper includes a fire-actuated damper, typically at the exhaust duct collar. In the event of a fire, the damper closes to prevent fire from entering the duct. Fire-actuated exhaust dampers are permitted only in listed hoods. Also, listed hoods that incorporate an integral supply air plenum include a fire-actuated damper in that plenum; the damper's location in the supply air plenum depends on plenum configuration. Refer to NFPA *Standard* 96 and UL *Standard* 710 for examples of the damper in exhaust hood supply air plenum.

Grease Removal. Most grease removal devices in Type I hoods operate on the same general principle: exhaust air passes through a series of baffles that create a centrifugal force to throw grease particles out of the airstream as the exhaust air passes around the baffles. The amount of grease removed varies with baffle design, air velocity, temperature, type of cooking, and other factors. NFPA *Standard* 96 does not allow use of mesh-filter as primary grease filter. To date, stand-alone mesh filters have not met the requirements of UL *Standard* 1046, and therefore cannot be used as primary grease filters. For cooking with solid-fuel equipment, embers from wood burning promote duct fires. The grease filters for solid-fuel hoods are supplied with metal screens to protect to some extent against embers entering the exhaust duct. Typically, design practice for heavy-duty solid-fuel cooking equipment evaluates if water mist cooling is required to protect the exhaust system from duct fires.

ASTM *Standard* F2519 provides a test method to determine the grease particle capture efficiency of grease filters and extractors. Grease removal devices generally fall into the following types:

- **Baffle filters** have a series of vertical baffles designed to capture grease and drain it into a container. The filters are arranged in a channel or bracket for easy insertion and removal for cleaning. Each hood usually has two or more baffle filters, which are typically constructed of aluminum, steel, or stainless steel and come in various standard sizes. Filters are cleaned by running them through a dishwasher or by soaking and rinsing. NFPA *Standard* 96 requires that grease filters be listed. Listed grease filters are tested and certified by a nationally recognized test laboratory in accordance with UL *Standard* 1046.
- **Removable extractors** (also called **cartridge filters**) have a single horizontal-slot air inlet. The filters are arranged in a channel or bracket for easy insertion and removal for cleaning. Each hood usually has two or more removable extractors, which are typically constructed of stainless steel and contain a series of horizontal baffles designed to remove grease and drain it into a container. Available in various sizes, they are cleaned by running them through a dishwasher or by soaking and rinsing. Removable extractors may be classified by a nationally recognized test laboratory in accordance with UL *Standard* 1046, or may be listed as part of the hood in accordance with UL *Standard* 710. Hoods that are listed with removable extractors cannot have those extractors replaced by other extractors.
- **Stationary extractors** are integral to the listed water-wash exhaust hoods and are typically constructed of stainless steel and contain a series of horizontal baffles that run the full length of the hood. The baffles are not removable for cleaning, though some have doors that can be removed to clean the extractors and plenum.
- **Water-wash hoods** fall into two classifications: clean-in-place and cold-water mist styles. Clean-in-place hoods reduce or eliminate the need for kitchen staff to manually clean the hood components; these hoods may have fixed stationary or removable grease extractors. These systems may automate the removal of the grease load on the filters, hood plenums, and ductwork. Typical hoods include one or more manifolds with spray nozzles that, when activated, wash out the collected grease with hot, detergent-injected water. The wash cycle is activated periodically, typically after cooking equipment and fans have been turned off. Washdown cycles can lasts 3 to 10 min, depending on the hood manufacturer, type of cooking, duration of operation, water temperature, and pressure. Most water-wash hood manufacturers recommend a water temperature of 54 to 80°C and water pressure of 200 to 550 kPa. Average water consumption varies from 0.1 to 0.3 L/s per linear metre of hood, depending on manufacturer. Most water-wash hood manufacturers provide an optional automatic means of activating the water-wash system in the event of a fire.

  Some water-wash hood manufacturers provide continuous cold water mist as an option. The cold water runs continuously during cooking and may or may not be recirculated, depending on the manufacturer. Typical cold-water usage is 3.5 mL/s per linear metre of hood. The advantage of this method is that it improves grease extraction and removal, partly through condensation of the grease. Many hood manufacturers recommend continuous cold water in hoods located over solid-fuel-burning cooking equipment, because the water acts as a spark arrestor to satisfy code requirements.

- **Multistage filters** use two or more stages of filtration to remove a larger percentage of grease. They typically consist of a baffle filter or removable extractor followed by a higher-efficiency filter, such as a packed bead bed. Each hood usually has two or more multistage filters, which are typically constructed of aluminum or stainless steel and are available in standard sizes. Filters are cleaned by running them through a dishwasher or by soaking and rinsing. NFPA *Standard* 96 requires that grease filters be listed, so these multistage filters must be tested and certified by a nationally recognized test laboratory in accordance with UL *Standard* 1046.

UL *Standards* 710 and 1046 do not include grease extraction efficiency tests. Historically, grease extraction efficiency rates published by filter and hood manufacturers were usually derived from tests conducted by independent test laboratories retained by the manufacturer. Test methods and results therefore have varied greatly.

In 2005, however, a new grease filter and extractor test standard was published: ASTM *Standard* F2519, which determines the grease particle capture efficiency of both removable filters and fixed extractors such as those used in water-wash hoods. The filters are evaluated by pressure drop as well as particulate capture efficiency. The test generates a controlled quantity of oleic acid particles in size ranging from 0.3 to 10 μm that are released into a hood to represent the cooking effluent. The particles are then sampled and counted downstream in the duct with an optical particle counter, with and without the filter or extractor in place. The difference in the counts is used to calculate the particulate capture efficiency graphed versus particle size. ASTM *Standard* F2519 measures particulate capture efficiency only, not vapor removal efficiency. A more detailed explanation is available in the Exhaust Systems section of this chapter.

Styles. Figure 4 shows the six basic styles for Type I hood applications. These style names are not used in all standards and codes but are well accepted in the industry. The styles are as follows:

- **Wall-mounted canopy,** used for all types of cooking equipment located against a wall.
- **Back shelf/proximity,** used for counter-height equipment typically located against a wall, but possibly freestanding.
- **Pass-over,** used over counter-height equipment when pass-over configuration (from cooking side to serving side) is required.
- **Single-island canopy,** used for all types of cooking equipment in a single-line island configuration.
- **Double-island canopy,** used for all types of cooking equipment mounted back-to-back in an island configuration.
- **Eyebrow,** used for direct mounting to ovens and some dishwashers.

Applying Back-Shelf-Style Exhaust Hoods. Due in part to the close proximity of back shelf hoods to the cooking surface, when back shelf hoods are properly applied over appropriate appliances, the exhaust airflow may be reduced to achieve significant energy savings by reducing both exhaust fan motor energy use and makeup air energy. In addition to lower airflows, back shelf hoods can provide health and comfort advantages by exhausting cooking effluent back away from and below the operator's breathing zone. Close proximity to the appliance also creates the potential for a more open ceiling space, which may be used to locate ceiling lighting fixtures to properly illuminate both the kitchen and appliance work surfaces, as well as providing open ceiling spaces to optimize location of HVAC diffusers.

Back shelf hoods operate best when located over appropriate appliances, such as those with flat horizontal cooking surfaces, including griddles, under-fired broilers, and deep fat fryers. However, not all appliances can be properly operated when located under a back shelf hood. Examples are upright appliances such as ovens,

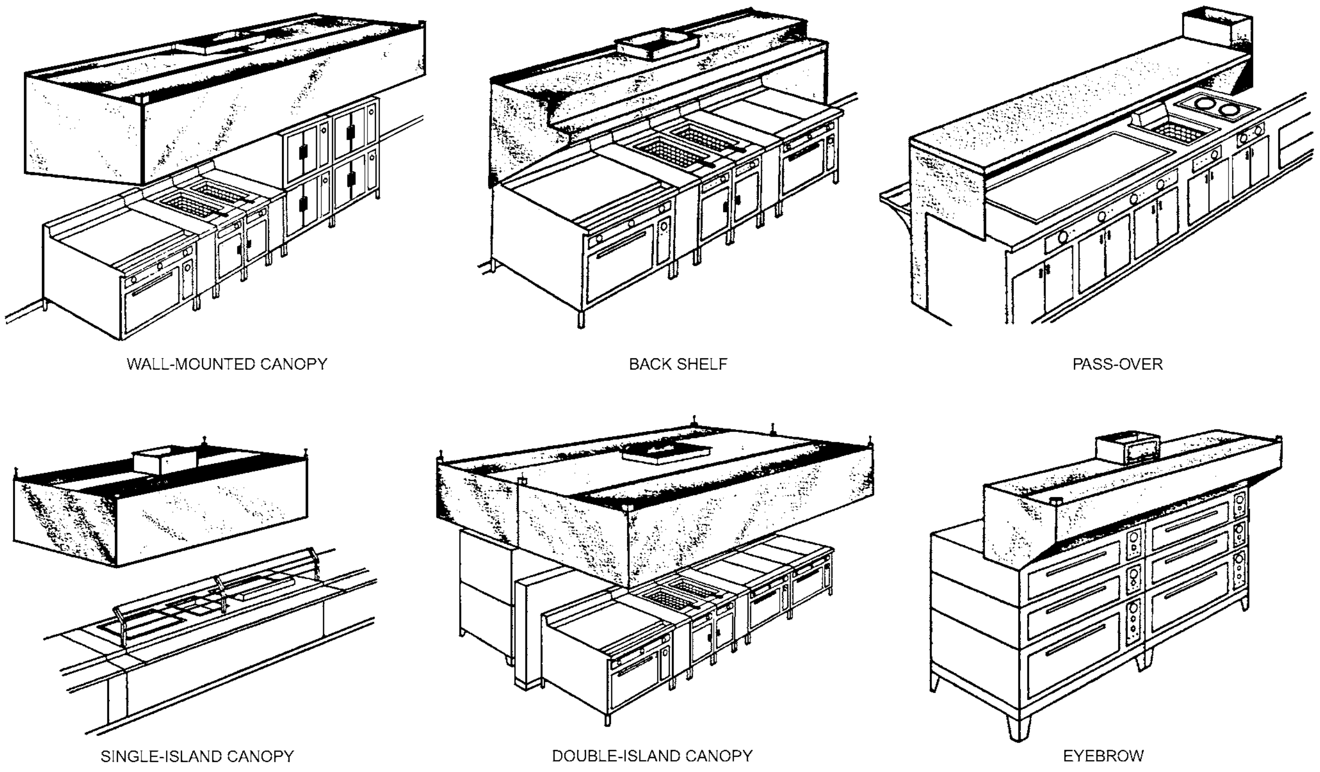

Fig. 4 Styles of Commercial Kitchen Exhaust Hoods

unless specifically design for such use, and appliances with lids that block effluent from entering the hood, such as tilting fry pans.

It is important to match appliance and hood duty ratings, because maintaining proper capture and containment airflow rates is critical for back shelf hoods. Be mindful of how required setback and side overhang will be impacted by final appliance placement. Consider also the impact of gas lines, electrical connection, and even appliance gas regulators on final appliance location. Sometimes these connection points can cause the appliances to be relocated so that they are no longer properly located under the hood.

These hoods require a more detailed analysis of operation and future menu considerations. Additionally, application of back shelf hoods requires more coordination between specifiers and users to be sure selections support food service operations. Attention should also be paid to the need to enclose or trim the connecting exhaust duct runs in a manner that complies with both fire safety and health regulations.

It is also necessary to confirm that a fixed-pipe fire suppression system can be designed and installed to provide proper fire safety protection for the appliances and the exhaust system. Do not specify back shelf hoods over cooking appliances or cooking operations than cannot be properly protected by an approved fire suppression system.

Sizing. The size of the exhaust hood relative to cooking appliances is important in determining hood performance. Usually the hood must extend horizontally beyond the cooking appliances (on all open sides on canopy-style hoods and over the ends on back shelf and pass-over hoods) to capture expanding thermal currents rising from the appliances. For unlisted hoods, size and overhang requirements are dictated by the prevailing code; for listed hoods, by the terms of the manufacturer's listing. **Overhang** varies with hood style, distance between hood and cooking surface, and characteristics of cooking equipment. With back shelf and pass-over hoods, the front of the hood may be kept behind the front of the cooking equipment (**setback**) to allow head clearance for the cooks. These hoods may require a higher front inlet velocity to capture and contain expanding thermal currents. ASHRAE research (Swierczyna et al. 2006, 2010) indicates that an appliance front overhang of 230 to 460 mm for canopy style and a 250 mm setback for back shelf/proximity style are preferable to current code minimums. All styles may have full or partial side panels to close the area between appliances and the hood. This may eliminate the side overhang requirement and generally reduces the exhaust flow rate requirement.

Exhaust Flow Rates. Exhaust flow rate requirements to capture, contain, and remove effluent vary considerably depending on hood style, overhang, distance from cooking surfaces to hood, presence and size of side panels, cooking equipment, food, and cooking processes involved. The hot cooking surfaces and product effluent create thermal air currents that are captured by the hood and then exhausted. The velocity of these currents depends largely on surface temperature and tends to vary from 0.08 m/s over steam equipment to 0.8 m/s over charcoal broilers. The required flow rate is determined by these thermal currents, a safety allowance to absorb cross-currents and flare-ups, and a safety factor for the style of hood.

Overhang and the presence or absence of side panels help determine the safety factor for different hood styles. Gas-fired cooking equipment may require an additional allowance for exhaust of combustion products and combustion air.

Because it is not practical to place a separate hood over each piece of equipment, general practice (reflected in ASHRAE *Standard* 154) is to categorize equipment into four groups, as shown in Table 3. Table 4 lists the required hood type by duty level.

These categories apply to unlisted and listed Type I hoods. ASHRAE *Standard* 154-2016 requires that all Type I hoods be listed; unlisted hoods are not allowed. The exhaust flow rate requirement is based on the group of equipment under the hood. If there is more than one group, the flow rate is based on the heaviest-duty group unless the hood design allows different rates over different sections of the hood.

Though considered obsolete based on laboratory tests and research, some local codes may still require exhaust flow rates for unlisted canopy hoods to be calculated by multiplying the horizontal area of the hood opening by a specified air velocity. Some jurisdictions may use the length of the open perimeter of the hood times the vertical height between hood and appliance instead of the horizontal hood area. Swierczyna et al. (1997) found that these methods of calculation result in higher-than-necessary exhaust flowrates for deeper hoods, because the larger reservoirs of deeper hoods typically increase hood capture and containment performance.

Table 5 lists typical exhaust flow rates for listed hoods. Typical design rates for listed hoods are based on published rates for listed hoods serving single categories of equipment, which vary from manufacturer to manufacturer. Rates are usually lower for listed hoods than for unlisted hoods, and it is generally advantageous to use listed hoods. Actual exhaust flow rates for hoods with internal short-circuit replacement air are typically higher than those in Table 5, although net exhaust rates (actual exhaust less internal makeup air quantity) are lower, which seriously compromises the hood's capture and containment performance (Brohard et al. 2003).

Listed hoods are allowed to operate at their listed exhaust flow rates by exceptions in the model codes. The exhaust flow rates for listed hoods are established by conducting tests per UL *Standard* 710. Typically, exhaust flow rates are much lower than those dictated by the model codes. Note that listed flow rate values are established under draft-free laboratory conditions, and actual operating conditions may compromise listed performance. Thus, manufacturers may recommend design values above their listed values.

Hoods listed in accordance with UL 710 cover one or more cooking duty ratings: light, medium, heavy, and extra heavy. These duty ratings correspond to minimum cooking surface temperatures during tests of 103, 205, 315, and 370°C respectively. In application, these temperature ratings correspond to duty ratings (see Table 4). The total exhaust flow rate is calculated by multiplying the hood exhaust flow rate by hood length.

ASTM *Standard* F1704 details a laboratory flow visualization procedure for determining the capture and containment threshold of an appliance/hood combination. This procedure can be applied to all hood types and configurations installed over any cooking appliances. ASTM *Standard* F2474 also provides a laboratory test procedure for determining heat gain of specific combinations of exhaust hood, cooking equipment, type of foods, and cooking processes. Results from a series of interlab heat gain tests (Fisher 1998; Swierczyna et al. 2008) have been incorporated in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*.

Island Canopy Hoods

Island canopy hoods, particularly single-island style, have become popular in open cafeteria operations such as those found in university food service. In many cases, the food service consultant specifies gas underfired broilers and other heavy-duty cooking equipment as part of the design. For a given line of appliances, a single-island canopy hood requires significantly more exhaust than a wall-mounted canopy hood. Single-island canopy hoods present the most difficult capture and containment challenge in hood applications, and are often the source of the "hood" problem in a kitchen with display cooking. To address the lack of reliable performance data on island canopy hoods, ASHRAE research project RP-1480 (Swierczyna et al. 2010) was undertaken to determine appropriate exhaust airflow rates. The objective was to expand the database for the exhaust rates required for

Table 3 Appliance Types by Duty Category

Light duty (200°C)	Electric or gas	Ovens (including standard, bake, roasting, revolving, re-therm, convection, combination convection/steamer, conveyor, deck or deck-style pizza, pastry) Steam-jacketed kettles Compartment steamers (both pressure and atmospheric) Cheesemelters Re-thermalizers
Medium duty (200°C)	Electric	Discrete element ranges (with or without oven)
	Electric or gas	Hot-top ranges Griddles Double-sided griddles Fryers (including open deep-fat fryers, donut fryers, kettle fryers, pressure fryers) Pasta cookers Conveyor (pizza) ovens Tilting skillets/braising pans Rotisseries
Heavy duty (315°C)	Gas	Open-burner ranges (with or without oven)
	Electric or gas	Gas underfired broilers Chain (conveyor) broilers Wok ranges Overfired (upright) salamander broilers
Extra-heavy duty (370°C)	Appliances using solid fuel such as wood, charcoal, briquettes, and mesquite to provide all or part of the heat source for cooking.	

capture and containment of standardized cook lines under four island canopy hood configurations: rear filter single island, V-bank single island, and 2.4 m deep and 3 m deep double-island hoods. Four side panel designs, four supply air strategies, and two makeup air temperature set points were also evaluated to quantify the effects of these features on island hood performance.

Swierczyna et al. (2010) confirmed that single-island canopy hoods need significantly higher exhaust airflow rates than their wall-mounted counterparts to effectively ventilate cooking equipment for a given duty class. For example, although an exhaust rate of 460 to 620 (L·s)/m can be adequate for complete capture and containment with a wall-mounted canopy hood over a heavy-duty appliance line (ASHRAE *Standard* 154; PG&E 2010), a single-island canopy hood may require an exhaust rate in excess of 770 (L·s)/m in many situations (measured along one side of the canopy hood). In fact, there were several test scenarios for single-island hoods where an exhaust rate in excess of 1080 (L·s)/m was required to achieve capture and containment. This contradicts common design practice, where the specified ventilation rates are often much closer to those for wall-canopy hoods.

Single-island hood performance was improved by the larger hood's V-bank filter configuration over the smaller hood's rear filter configuration for most test configurations. The plume was better aligned with the filters and was drawn toward the center, relative to the front and rear of the hood. The larger V-bank hood was found to be less sensitive to local air replacement. However, aggressive appliance plumes that focused on the flat bottom of the V-bank, or replacement air strategies that were focused at the side of the V-bank, proved challenging and indicated that a change of filter bank profile may improve hood performance.

The performance of a double-island canopy hood, with balanced replacement air, can be comparable to back-to-back wall-mounted canopy hoods for a given duty class of appliances. For example, a heavy-duty front line and a light-duty back line under the double-island hood required an exhaust airflow rate approxi-

Table 4 Type I Hood Requirements[a] by Appliance Type

Appliance Description

Light Duty
- Braising pan/tilting skillet, electric
- Oven, baking, electric and gas
  - Rotisserie, electric and gas
  - Combination, electric and gas
  - Convection, full-size, electric and gas
  - Convection, half-size, electric and gas (protein cooking)
  - Conveyor, electric
  - Deck, electric and gas
  - Duck, electric and gas
  - Revolving rack, electric and gas
  - Rapid cook, electric
  - Roasting, electric and gas
  - Rotisserie, electric and gas
  - Stone hearth, gas
- Range, cook-top, induction
  - Discrete element, electric (with or without oven)
- Salamander, electric and gas

Medium Duty
- Braising pan/tilting skillet, gas
- Broiler, chain conveyor, electric
  - Electric, under-fired
- Fryer, doughnut, electric and gas
  - Kettle, electric and gas
  - Open deep-fat, electric and gas
  - Pressure, electric and gas
- Griddle, double-sided, electric and gas
  - Flat, electric and gas
- Oven, conveyor, gas
- Range, open-burner, gas (with or without oven)
  - Hot top, electric and gas
- Smoker, electric and gas

Heavy Duty
- Broiler, chain conveyor, gas
  - Electric and gas, over-fired (upright)
  - Gas, under-fired
- Grill, plancha, electric and gas
- Oven, tandoor, gas
- Range, wok, gas and electric

Extra-Heavy Duty
- Oven, stone hearth, wood-fired or wood for flavoring
- Solid-fuel cooking appliances combusting a solid fuel (such as wood, charcoal, or coal) to provide all or part of the heat for the cooking process[b]

[a]Where recirculating systems or recirculating hoods are used, the additional heat and moisture loads generated by such appliances should be accounted for in the sensible and latent loads for the HVAC system.
[b]Solid-fuel flavoring cooking appliances should comply with Table 1 as if they do not combust solid fuel.
Source: ASHRAE *Standard* 154-2016; Table 1.

Table 5 Typical Exhaust Flow Rates by Cooking Equipment Category For Listed Type I Hoods

	Exhaust Flow Rate, L/s per linear metre of hood			
Type of Hood	Light Duty	Medium Duty	Heavy Duty	Extra-Heavy Duty
Wall-mounted canopy	230 to 310	310 to 465	310 to 620	540+
Single-island canopy	390 to 465	465 to 620	465 to 930	850+
Double-island canopy (per side)	230 to 310	310 to 465	390 to 620	775+
Eyebrow	230 to 390	230 to 390	—	—
Back shelf/proximity/ pass-over	155 to 310	310 to 465	465 to 620	Not recommended

mately 470 L/(s·m) (measured along both sides of the hood). This rate is comparable to the ventilation rate for similar appliance duty classes under wall-mounted canopy hoods (Swierczyna et al. 2006). The double-island hood configuration performed as if a wall existed between them. Furthermore, the back-to-back appliance lines created a converging thermal plume that helped direct the plume toward the filter bank. However, without a wall between them, the double-island hood system was more susceptible to cross drafts than a wall-mounted hood configuration.

The configuration, volume, and temperature of makeup air was critical to the performance of the double-island canopy hood. Consistent with previous research (Brohard et al. 2003), reducing local makeup airflow rates and velocities corresponded with reduced capture and containment exhaust rates, in most cases. When air volume and associated velocity and turbulence near the hood was minimized, the appliance plumes were more stable and the hood was able to capture and contain at a lower exhaust rate. However, when local makeup air was introduced aggressively through four-way diffusers, perforated diffusers, or a high-flow perforated perimeter supply system, hood performance degraded severely. For double-island configurations, a perforated perimeter supply system operated at a low-flow, low-velocity condition was the best of the local makeup air configurations tested. When the perforated perimeter supply system delivered low-flow, low-velocity air adjacent to the hood (i.e., less than 60% of replacement air requirement), hood performance improved significantly over the high-flow, high-velocity introduction (i.e., greater than 60% of replacement air requirement), and in some cases, better than the exhaust-only configuration with displacement supply. Higher replacement air temperatures from ceiling diffusers also degraded the performance of island hoods. Unbalanced replacement air distribution was extremely detrimental to the performance of the double-island hoods.

Other research highlights the advantages of using side panels for wall-mounted canopy hoods and a variety of replacement air conditions (Brohard et al. 2003; Swierczyna et al. 2006). However, results from the double-island canopy hood testing regarding side panels were inconclusive. A more extensive side panel (and center partition) investigation would need a larger laboratory where replacement air was introduced more uniformly around the hood to eliminate the effect of relatively high, directional local velocities.

A partition between the two appliances lines improved performance of a double-island hood when coupled with a balanced supply on both sides of the hood. However, if as little as 470 L/s was exhausted from the side opposite from the supply air delivery, performance of the double-island hood degraded. This was contrary to the expectation that the partition would be more of a benefit with unbalanced replacement air and its ability to mitigate the effect of cross drafts.

Increased hood overhang was shown to be one of the most effective performance enhancements for island canopy hoods. With a heavy-duty three-broiler appliance line centered front-to-rear under the single island hoods, rather than at a minimum prescriptive front overhang dimension, a 14% exhaust reduction was possible for the smaller rear filter hood, and a 40% exhaust reduction was possible for the larger V-bank hood. Likewise, when side overhang was increased to 610 mm from the minimum of 150 mm, a 41% exhaust rate reduction was found for both single-island hoods. However, the results did not show a significant performance difference between the 2.4 m and 3 m deep double-island hoods. Increased side overhang was found to be one of the most effective performance enhancements for double-island canopy hoods. Increasing the side overhang to 610 mm resulted in a 250 L/(s·m) reduction in exhaust flow rate.

Tailored exhaust bias for double-island hoods may improve hood performance. With more exhaust volume focused over the more challenging appliances, the exhaust rate can be reduced for a given configuration. However, application of a specific bias for other applications or hood dimensions may yield different performance results and should be verified.

Specification of enhanced hood edge geometry should be considered by manufacturers and end-users. Although each design needs to be properly evaluated for its effect on hood performance, the design tested in this project was effective and was typical of edge design currently found in the industry.

Performance in the field should be verified to ensure proper hood capture and containment operation. As shown by RP-1480 (Swierczyna et al. 2010), many factors interact in the kitchen and affect hood performance. These interactions cannot be perfectly predicted for each installation. Therefore, a field test is best to verify proper kitchen ventilation and hood performance.

Wall Canopy Hoods, Appliance Positioning, and Diversity

ASHRAE research project RP-1202 (Swierczyna et al. 2006) quantified the effect of the position and/or combination of appliances under a wall canopy exhaust hood on the minimum C&C exhaust rate. Effects of side panels, front overhang, and rear seal were also investigated. The scope of this laboratory study was to investigate similar and dissimilar appliances under a 3 m wall-mounted canopy hood. The appliances included three full-sized electric convection ovens, three two-vat gas fryers, and three 0.9 m gas underfired broilers, representing the light, medium, and heavy-duty appliance categories, respectively. In addition to various physical appliance configurations, appliances were also varied in their usage: either off, at idle conditions, or at cooking conditions. A supplemental study investigated the effect of appliance accessories (including shelving and a salamander) and hood dimensions (including hood height, depth, and reservoir volume) on the minimum exhaust rate required for complete capture and containment.

The study demonstrated that subtle changes in appliance position and hood configuration could dramatically affect the exhaust rates required for complete capture and containment, regardless of appliance duty and/or usage. The wide range in C&C values for a given hood/appliance setup explains why a similar hood installed over virtually the same appliance line may perform successfully in one kitchen and fall short of expectations in another facility. The following conclusions are specific to the conditions tested by Swierczyna et al. (2006).

Airflow Requirements for Like-Duty Appliance Lines. Evaluation supported widely accepted commercial kitchen ventilation (CKV) design practices: higher ventilation rates are required for progressively heavier-duty appliances (Table 6). For a 3 m wall-mounted canopy hood, at a defined median or good-case installation, the light-duty oven line required 520 L/s (170 L/[s·m]), the medium-duty fryer line required 1130 L/s (370 L/[s·m]), and the heavy-duty broiler line required 2075 L/s (680 L/[s·m]) to achieve C&C. Simply increasing front overhang as noted between the worst- and good-case installations in Table 6 reduced the C&C exhaust rate by 10 to 27%. Installing side panels in addition to the increased front overhang (best-case scenario) reduced the exhaust requirements by an additional 18 to 33%.

Appliance position testing confirmed the exhaust rate of an appliance line is most dependent on the duty of the end appliance. The end appliance drove the exhaust rate more than additional volume from the other two appliances, as they changed from off to cooking conditions or were varied in duty class. In most cases, the lowest exhaust requirements for particular appliance lines were achieved when the lowest-duty appliance was at the end of the appliance line. In other words, hood performance was optimized when the heaviest-duty appliance was in the middle of the appliance line.

Appliance Positioning (Front-to-Back) and Rear Seal. Increasing the front overhang by pushing appliances toward the back

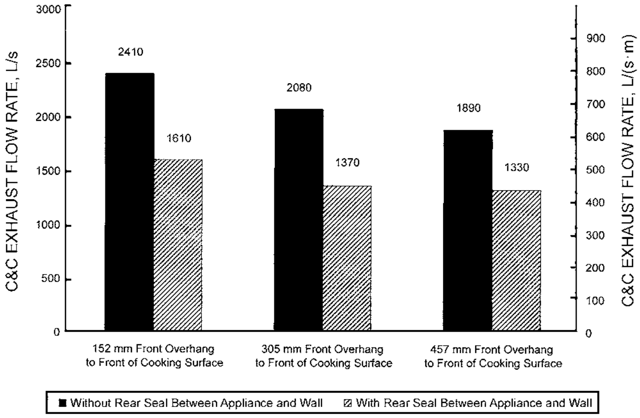

Fig. 5 Capture and Containment Exhaust Rates for Gas Underfired Broilers under 3 m Wall Canopy Hood With and Without Rear Appliance Seal at Various Front Overhangs
(Swierczyna et al. 2006)

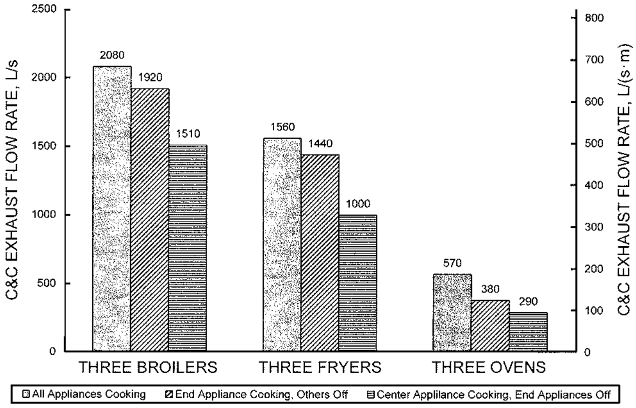

Fig. 6 Exhaust Capture and Containment Rates for One or Three Appliances Cooking from Like-Duty Classes under a 3 m Wall-Canopy Hood
(Swierczyna et al. 2006)

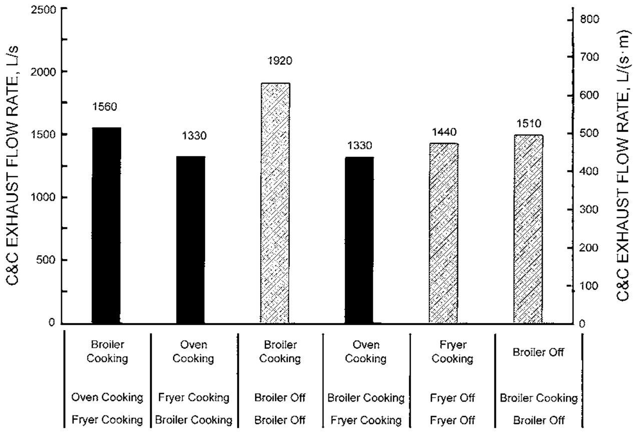

Fig. 7 Capture and Containment Exhaust Rates for Cooking Conditions on Multiduty Appliance Lines (Compared with Single-Duty Lines with Only One Appliance Operating) under 3 m Wall Canopy Hood
(Swierczyna et al. 2006)

wall significantly decreased the required exhaust rates, not only because of the increased distance from the hood to the front of the appliance, but also because of the decreased distance between the back of the appliance and the wall. With a rear seal in place, some of the replacement air, which would have otherwise been drawn up from behind the appliances, was instead drawn in along the perimeter of the hood, helping guide the plume into the hood, as shown in Figure 5.

Diversity in Appliance Usage. Operation diversity was evaluated with cook lines of three similar appliances and included combinations of *cook* and *off* conditions. In most cases, operation correlated directly with the required exhaust rate, with an emphasis on the operation of the end appliances (Figure 6). The capture and containment rate for the end appliance cooking and the other two like-duty appliances off was nearly the same rate as all three appliances cooking.

Changing the condition of end appliances from *off* to cooking had the greatest effect for medium-duty fryers, which required a 450 L/s increase in the exhaust rate. Because the fryers were thermostatically controlled, they responded to cooking operations by firing the burners. This, combined with an aggressive cooking plume, required a significantly increased exhaust rate for C&C. An aggressive thermal plume was present for the three heavy-duty gas underfired broilers; the exhaust rate increased 400 L/s. For the light-duty electric convection oven, there was a 95 L/s difference in turning the end appliances from off to cook. Figure 6 also shows that cooking with only the center appliance, with the two end appliances turned off, greatly reduced the exhaust requirement.

Diversity in Appliance Duty and Position (Side-to-Side). The study found that the capture and containment rate of a multiduty appliance line was less than the rate of the heaviest duty appliance in that line, applied over the length of the hood (Figure 7).

Hood Side Panels. Side panels installed on the 3 m hood improved hood performance dramatically, by preventing the plume from spilling at the side of the hood and by increasing velocity along the front of the hood. Combining side panels (measuring 0.3 by 0.3 m by 45°, 0.6 by 0.6 m by 45°, 0.9 by 0.9 m by 45°, 1.2 by 1.2 m by 45°, or full) with the maximum hood overhang resulted in the lowest exhaust requirement for all cases tested. The example of the three two-vat gas fryer line is shown in Figure 8.

Effect of Shelving on Hood Capture and Containment Performance. Neither solid nor tubular shelving over the six-burner range required an increase in the exhaust rate. In fact, tubular shelving mounted to the back of the appliance showed a slight enhancement compared to having no shelving installed.

Effect of Hood Depth, Reservoir, and Mounting Height on Capture and Containment Performance. Comparing the 1.2 and 1.5 m deep hoods, the deeper hood reduced capture and containment exhaust rates when appliances were positioned with maximum front overhang and minimum rear gap. The deeper hood had a negative effect when appliances remained in the minimum front overhang position. The effect of hood depth in conjunction with front overhang, side panels, and rear seal is shown in Figure 9.

Another advantage of the 1.5 m over the 1.2 m hood was its ability to capture and contain the plume when an oven door was opened. For a 1.2 m hood and a 150 mm front overhang, an exhaust rate of 570 L/s was required for the three electric ovens with the doors closed and 2450 L/s with the doors open. Similarly, for a 1.5 m deep hood with an 460 mm front overhang, 570 L/s was required for three ovens with the doors closed and 1600 L/s with the doors open. The setup and schlieren views are shown in Figure 10.

The reservoir volume of the hood was increased by changing the hood height from 0.6 to 0.9 m. When the gas underfired broiler was operated in the left appliance position, the increased hood volume marginally improved capture and containment performance. In contrast, a significant improvement was found for the appliance in the center position. This improvement indicated the plume was well located in the hood, and the increased hood volume may have allowed the plume to roll inside the hood and distribute itself more evenly along the length of the filter bank.

Minimizing hood mounting height had a positive effect on capture and containment performance. In most cases, a direct correlation could be made between the required exhaust rate and hood height for a given appliance line. The typical 2 m mounting height (for a canopy hood) was increased to 2.1 to 2.3 m. For the gas underfired broiler installed at the end of the hood, increasing the hood height by 0.3 m required a 14% increase in exhaust. However, when the broiler was in the center position, the increased hood height did not compromise capture and containment performance and required exhaust rate was reduced. The dramatic reduction in the exhaust requirement as the hood-to-appliance distance was reduced below the 2 m mounting height illustrated the potential for optimizing CKV systems by using close-coupled or proximity-style hoods. This effect is shown in Figure 11.

Design Guidelines. Swierczyna et al. (2006) illustrated the potential for large variations in the airflow requirements for a specified appliance line and hood configuration. Best-practice design considerations that became evident included the following:

- Position heavy-duty appliances (e.g., broilers) in middle of the line.
- Position light-duty appliances (e.g., ovens) on the end of the line.

Table 7 Exhaust Static Pressure Loss of Type I Hoods for Various Exhaust Airflows*

	Hood Static Pressure Loss, Pa			
Type of Grease Removal Device	230 to 390 L/(s·m)	390 to 540 L/(s·m)	540 to 700 L/(s·m)	700 to 850 L/(s·m)
Baffle filter	60 to 125	125 to 190	190 to 250	250 to 310
Extractor	200 to 340	325 to 425	425 to 750	720 to 1050
Multistage	140 to 275	275 to 425	425 to 720	720 to 1000

*Values based on 500 mm high filters and 7.5 m/s through hood/duct collar.

- Push back appliances (maximize front overhang, minimize rear gap).
- Seal area between rear of appliance and wall.
- Use side panels, end panels, and end walls.
- Installing shelving or ancillary equipment (e.g., salamander) behind or above a range should not negatively affect C&C performance, if other best practices (e.g., maximizing hood overhang) are observed.
- Use larger hoods, both deeper and taller.
- Installing hoods at lowest height practical (or allowed by code) to minimize distance from cooking surface to hood improves C&C performance.
- Introduce replacement air at low velocity. Do not locate four-way diffusers near hood, and minimize use of air curtains.

Replacement (Makeup) Air Options. Air exhausted from the kitchen must be replaced. Replacement air can be brought in through traditional methods, such as **ceiling diffusers**, or through systems built as an integral part of the hood. It may also be introduced using low-velocity displacement diffusers or transfer air from other zones. For further information, see the section on Replacement (Makeup) Air Systems.

Static Pressure. Static pressure drop through hoods depends on the type and design of the hood and grease removal devices, size of duct and duct connections, and flow rate. Table 7 provides a general guide for determining static pressure loss depending on the type of grease removal device and exhaust flow rate. Manufacturers' data should be consulted for actual values. Static pressure losses for exhaust ducts should be calculated for each installation.

Type II Hoods

Type II hoods (Figure 12) can be divided into the following two application categories:

- **Condensate hood.** For applications with high-moisture exhaust, condensate forms on interior surfaces of the hood. The hood is designed to direct the condensate toward a perimeter gutter for collection and drainage, allowing none to drip onto the appliance

Ventilation Rates for Hooded Door Dishwashers

The ventilation rates for high-temperature sanitizing door-type dish machines in the model codes are inadequate to capture and contain the heat and steam from the dishwashing operation. The exhaust rates of 154 and 310 L/s per metre of hood in the IMC and UMC (*Uniform Mechanical Code*; IAPMO 2018), respectively, often do not capture the heat and steam released from the machine. The minimum recommendation is 464 L/s per metre of hood for canopy hoods over high-temperature sanitizing door-type machines. Front and side overhangs are critical for capture of the thermal plume from door-type machines, 305 mm on the side and front are the minimum recommendation.

Door-type machine operations are good candidates for demand control kitchen ventilation (DCKV) systems. The DCKV system should initialize ramp-up at the beginning of the wash cycle, not the end of the cycle, when it is too late to capture the thermal plume from the door opening. Door-type dishwashers are also good candidates for exhaust air heat recovery in the ventilation system. The exhaust air steam is clean and hot and heat exchangers can take advantage of latent heat in addition to sensible heat. Low-temperature sanitizing door-type machines should not be placed directly under return air grilles.

Ventilation for Conveyor Dish Machines

Conveyor dish machines' exhaust ductwork are typically pant-leg connections to vent cowls at the entrance and exit of the dish machine. The exhaust airflow rates at the vent cowls are typically 94 L/s at the entrance and 189 L/s at the exit. The actual airflow rates are difficult to measure in the field and are rarely verified. Therefore, a visual capture and containment assessment is recommended, with field adjustment as necessary to maintain capture and containment at the entrance and exit. Even with a well-balanced airflow, convective loads escape from the curtains, door seals, and drains. These other convective loads could contribute more than 4690 W (with 40% of the load being latent) (PG&E 2011) and should be accounted for in the internal heat load calculation for the dishroom.

As an alternative to a pant-leg exhaust system, a canopy exhaust hood with a minimum ventilation rate of 308 L/s per metre of hood should be considered. The convective load to space can nearly be eliminated if the canopy hood incorporates adequate overhang (305 mm overhang on both sides, and 610 mm overhang on both the front and rear).

Recirculating Systems

A recirculating system, previously called a **ductless hood**, consists of a cooking appliance/hood assembly designed to remove grease, smoke, and odor and to return the treated exhaust air directly back into the room. HVAC design must consider that recirculating systems discharge the total amount of heat and moisture generated by the cooking process back into the kitchen space, adding to the cooling load.

These hoods typically contain the following components in the exhaust stream: (1) a grease removal device such as a baffle filter, (2) a high-efficiency particulate air (HEPA) filter or an electrostatic precipitator (ESP), (3) some means of odor control such as activated charcoal, and (4) an exhaust fan. NFPA *Standard* 96, Chapter 13, is devoted entirely to recirculating systems and contains specific requirements such as (1) design, including interlocks of all critical components to prevent operation of the cooking appliance if any of the components are not operating; (2) fire extinguishing system, including specific nozzle locations; (3) maintenance, including a specific schedule for cleaning filters, ESP, hood, and fan; and (4) inspection and testing of the total operation and interlocks. In addition, NFPA *Standard* 96 requires that all recirculating systems be listed by a testing laboratory. The recognized standard for a recirculating system is UL *Standard* 710B. Recirculating systems should not be used over gas-fired or solid-fuel-fired cooking equipment.

Designers should thoroughly review NFPA *Standard* 96 requirements and contact a manufacturer of recirculating systems to obtain specific information needed for the design and listing information before incorporating this type of system into a food service design.

Downdraft Appliance Ventilation Systems

These systems are intended to remove smoke, grease-laden vapors, odors, and other impurities from the air by drawing the cooking effluents away from cooking appliances and downward into ventilation systems. According to UL *Standard* 710B, these systems are used with electric cooking appliances only. A downdraft system listed to UL *Standard* 710B, for recirculating applications, consists of a fire extinguishing system unit, grease filters, interlocks, etc., all contained within a suitable enclosure.

Downdraft systems operate on a different principle than typical exhaust hoods. With a customary exhaust hood, the buoyant thermal plume from cooking rises into the exhaust hood by gravity, provided overhang is sufficient, cross drafts do not interfere, etc., as explained previously. Thereafter, one or more exhaust fans create a low pressure are in the hood plenum, and the exhaust contents are carried outdoors from the hood.

In contrast, downdraft ventilation systems include an exhaust fan that creates a low pressure at an inlet beside or behind a cooking surface, or between two cooking surfaces. The exhaust fan draws cooking effluents, possibly including combustion products, through a grease filter in the exhaust inlet, to be transported outdoors or recirculated into the cooking space.

Downdraft appliance ventilation systems are described and covered by NFPA *Standard* 96, Chapter 15, and if used for recirculation, are listed to UL *Standard* 710B. If used to ventilate processes producing smoke or grease laden vapor, these systems must comply with NFPA *Standard* 96, Chapter 15, which references other requirements in NFPA *Standard* 96:

- Clearance requirements in Section 4.2
- Hood requirements of Chapter 6
- Grease removal device requirements of Chapter 7
- Special-purpose filters listed in accordance with ANSI/UL *Standard* 1046
- Exhaust duct requirements of Chapter 7
- Air movement requirement of 8.2.1.2 and 8.2.2.3
- Fire-extinguishing requirements of Chapter 10 and Section 15.2
- Maintenance requirements of Chapter 11
- Safety requirements of Chapter 12

Important additional requirements are provided by NFPA *Standard* 96, sections 15.1.2 though 15.4.

Caution is advised for application of downdraft ventilation systems to commercial kitchens. Pulling effluent away from a

flat-surface griddle is one popular application of these systems, particularly in Asian-style steakhouses, where the griddles are used intermittently and the exhaust inlet is slightly close to the edges of the cooking surface. More challenging is trying to pull vapors from the tops of commercial cooking vessels, such as on range tops, because cooking effluents might be emitted above and out of reach of the downdraft inlet suction. For gas appliances, also remember that air movement created by downdraft inlet suction might be sufficient to interfere with the operation of nearby gas burners.

Field Performance Testing

Once kitchen ventilation systems have been installed, it is important to verify that they operate correctly. ASHRAE *Standard* 154 describes performance testing for both Type I and Type II hood applications. For Type II hoods, the requirement is that the hood must be operating at the minimum airflow shown in Table 9. For Type I hoods, all appliances must be turned on and either actual or simulated cooking must be performed to verify that the hood system has achieved proper capture and containment.

1.7 COOKING EFFLUENT GENERATION AND CONTROL

Air quality, fire safety, labor cost, and maintenance costs are important concerns involved with emissions from a commercial cooking operation. Cooking emissions have also been identified as a major component of smog particulate. This has led to regulation in some major cities, requiring reduction of emissions from specific cooking operations.

In a fire, grease deposits within a duct act as fuel. Reducing this grease can help prevent a small kitchen fire from becoming a major structural fire. In the past, the only control of grease build-up in exhaust ducts was frequent duct cleaning, which is expensive and disruptive to kitchen operation. It also depends on frequent duct inspections and regular cleaning. Grease build-up on fans, fire nozzles, roofs, and other ventilation equipment can be costly in additional maintenance and replacement costs. From an energy and sustainability perspective, it is desirable to reduce the atmospheric emissions and achieve the highest grease extraction or destruction with the lowest energy costs possible. For mechanical extractors, the pressure drop of the filters is the predominant driver for energy usage, whereas for other control systems there may be electrical components or water use that needs to be evaluated. Figure 13 presents some design guidance for what filtration may be desirable under various exhaust temperature and/or duty level situations.

Another issue that commonly comes up during kitchen design and operation is how often ductwork needs to be cleaned in restaurants. Table 10 presents inspection schedules adapted from Table 11.4 of NFPA *Standard* 96.

(Kuehn et al. 1999)

Effluent Generation

During cooking operations on appliances, effluent is generated, which includes water vapor and organic material (in both particulate and vapor form) released from the food. The combustion of fuel and grease contributes to the mixture released from the cooking, including condensable and noncondensable gases. For solid-fuel cooking, the effluent mixture contains not only toxic contaminants, but also condensable creosote (which has a lower flash point and increases risk of duct fires).

Particle Size Comparisons (from Exhaust Systems). Effluent from five types of commercial cooking equipment has been measured under a typical exhaust hood (Kuehn et al. 1999). Foods that emit relatively large amounts of grease were selected. Figures 14A and 14B show the measured amount of grease in the plume entering the hood above different appliances and the amount in the vapor phase, particles below 2.5 μm in size ($PM_{2.5}$), particles less than 10 μm in size (PM_{10}), and the total amount of particulate grease. Ovens and fryers generate little or no grease particulate emissions, whereas other processes generate significant amounts. However, gas underfired broilers (referred to as “gas broilers” in Figures 14A and 14B) generate much smaller particulates compared to the griddles and ranges, and these emissions depend on the broiler design. The amount of grease in the vapor phase is significant and varies from 30% to over 90% by mass; this affects the design approach for grease removal systems.

Carbon monoxide (CO) and carbon dioxide (CO_2) emissions are present in solid fuel and natural gas combustion processes but not in processes from electrical appliances. Additional CO and CO_2 emissions may be generated by gas underfired boilers when grease drippings land on extremely hot surfaces and burn. Nitrogen oxide (NO_x) emissions appear to be exclusively associated with gas appliances and related to total gas consumption.

Figure 14C shows the measured plume volumetric flow rate entering the hood. In general, gas appliances have slightly larger flow rates than electric because additional products of combustion must be vented. Gas underfired and electric broilers have plume flow rates considerably larger than the other appliances shown. Effluent flow rates from gas underfired and electric broilers are approximately 100 times larger than the actual volumetric flow rate created by vaporizing moisture and grease from food. The difference is caused by ambient air entrained into the effluent plume before it reaches the exhaust hood.

Thermal Plume Behavior

The most common method of contaminant control is to install an air inlet device (a hood) where the plume can enter it and be conveyed away by an exhaust system. The hood is generally located above or behind the heated surface to intercept normal upward flow. Understanding plume behavior is central to designing effective ventilation systems.

Effluent released from a noncooking cold process, such as metal grinding, is captured and removed by placing air inlets so that they catch forcibly ejected material, or by creating airstreams with sufficient velocity to induce the flow of effluent into an inlet. This technique has led to an empirical concept of capture velocity that is often misapplied to hot processes. Effluent (such as grease and smoke from cooking) released from a hot process and contained in a plume may be captured by locating an inlet hood so that the plume flows into it by buoyancy. Hood exhaust rate must equal or slightly exceed plume volumetric flow rate, but the hood need not actively induce capture of the effluent if the hood is large enough at its height above the cooking operation to encompass the plume as it expands

Fig. 15 Hot-Air Plume from Cooking Appliances under Wall-Mounted Canopy Hood

during its rise. Additional exhaust airflow may be needed to resist cross currents that carry the plume away from the hood.

A heated plume, without cross currents or other interference, rises vertically, entraining additional air, which causes the plume to enlarge and its average velocity and temperature to decrease. If a surface parallel to the plume centerline (e.g., a back wall) is nearby, the plume will be drawn toward the surface by the Coanda effect. This tendency may also help direct the plume into the hood. Figure 15 illustrates a heated plume with and without cooking effluent as it rises from heated cooking appliances. Figure 15A shows two gas underfired broilers cooking hamburgers under a wall-mounted, exhaust-only, canopy hood. Note that the hood is mounted against a clear back wall to improve experimental observation. Figures 15B and 15C show the hot-air plume without cooking, visualized using a schlieren optical system, under full capture and spillage conditions, respectively.

Effluent Control

Effluents generated by cooking include grease in particulate (solid or liquid) and vapor states, smoke particles, and volatile organic compounds (VOCs or low-carbon aromatics, which are significant contributors to odor). Grease vapor is condensable and may condense into grease particulate in the exhaust airstream when diluted with room-temperature air or when it is exhausted into the cooler outdoor atmosphere.

Effluent controls in the vast majority of kitchen ventilation systems are limited to removing solid and liquid grease particles by mechanical grease removal devices in the hood. More effective devices reduce grease build-up downstream of the hood, lowering the frequency of duct cleaning and reducing the fire hazard.

The reported grease extraction efficiency of mechanical filtration systems (e.g., baffle filters and slot cartridge filters) may reflect the particulate removal performance of these devices. These devices are listed for their ability to limit flame penetration into the plenum and duct. Grease extraction performance can be evaluated using ASTM *Standard* F2519. Smaller aerodynamic particles (<2.5 μm) are not easily removed by mechanical extractors. If these particles must be removed, a pollution control unit is typically added, which removes

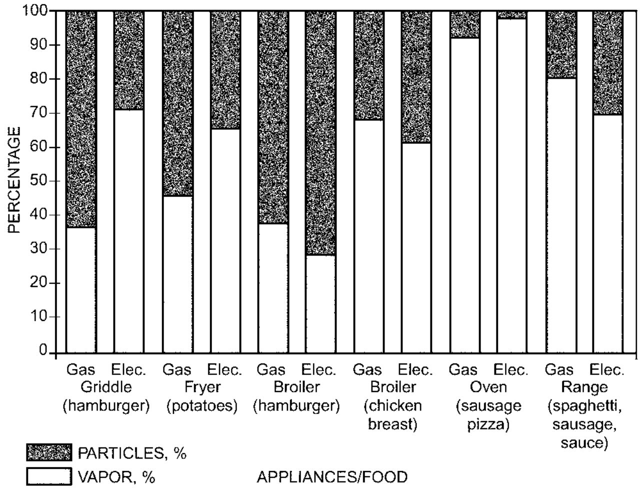

Fig. 16 Particulate Versus Vapor-Phase Emission Percentage per Appliance (Average)
(Gerstler et al. 1998)

a large percentage of the grease that escaped the grease removal device in the hood, as well as smoke particles.

ASHRAE research project RP-745 (Gerstler et al. 1998) found that a significant proportion of grease effluent may be in vapor form (Figure 16), which is not removed by mechanical extractors.

Grease Extraction

The particulate range from cooking operations ranges from 0.01 to 100 μm. Different cooking operations have different ranges of particle sizes in the cooking plume and have been measured for many appliances (Gerstler et al. 1998; Kuehn et al. 2008). Grease particulates larger than 20 μm are too heavy to remain airborne and drop out of the airstream. Figure 17 compares the size of particles from kitchen exhaust to common items.

Each combination of food product, cooking equipment, and cooking temperature creates a unique particle emissions profile, these profiles change over time during the cooking process. For example, the initial drop of French fries into a fryer gives off a short blast of large particles, whereas cooking a hamburger on a griddle gives off a continuous stream of particles and vapor. Burgers cooked on a broiler tend to burn and emit very small particles (< 1 μm in size).

Variations in the food product itself can also change the emissions of a cooking process. Hamburger with 23% fat content produces more grease than a 20% fat burger. Chicken breast may have a different effluent characteristic than chicken legs or thighs. Even cooking chicken with or without the skin changes the properties of emissions.

Figures 18 and 19 show typical particle emission profiles for a gas griddle and gas underfired broiler both cooking hamburgers (Kuehn et al. 1999).

ASTM *Standard* F2519-05 can be used to determine fractional filter efficiency for grease particulate. A fractional efficiency curve is a graph that gives a filter's efficiency over a range of particle sizes. Fractional efficiency curves are created by subjecting a test filter to a controlled distribution of particles and measuring the quantity of particles at each given size before and after the filter. The amount of reduction of particles is used to calculate the efficiency at each given size. The fractional efficiency curve for a typical 510 by 510 mm baffle filter tested at 540 L/(s·m) is shown in Figure 20.

Extraction efficiencies must be compared at the same airflow per linear length of filter. This gives a consistent way of comparing performance of extraction devices that may be built very differently, such as hoods with removable extractors and with stationary extractors. This is also consistent with the way exhaust flow rates for hoods are commonly specified. The airflow rate through a hood changes hood efficiency by changing the velocity at which the air travels through a filter.

To demonstrate what a filter fractional efficiency means with an actual cooking process, the gas underfired broilers (referred to as "charbroiler") emissions curve and the baffle filter efficiency curve have been plotted on one graph in Figure 21. The area under each emission curve is representative of the total particulate emissions for the gas underfired broiler. As can be seen by comparing the graph before and after the baffle filter, there is very little reduction in the amount of grease exhausted to the duct. The area under the "charbroiler after baffle" curve represents the amount of grease particulate exhausted into the duct.

The graphs and efficiencies shown here are only for particulate grease. There is also a vapor component of the grease that is exhausted, which cannot be removed by filtration. Some of the vapor condenses and is removed as particulate before reaching the filter. Some condenses in the duct and accumulates on the duct and fan. However, with elevated temperatures in the exhaust airstream, vapor may pass through and exit to the atmosphere.

Higher efficiency at a specific particle size may not be the only selection criteria for grease extraction. From an energy and sustainability standpoint, the ideal goal would be to have the highest grease extraction at the lowest pressure drop possible. Smaller particles can only be removed by shifting the efficiency curve towards the left.

More effective devices reduce grease build-up downstream of the hood, lowering the frequency of duct cleaning and reducing the fire

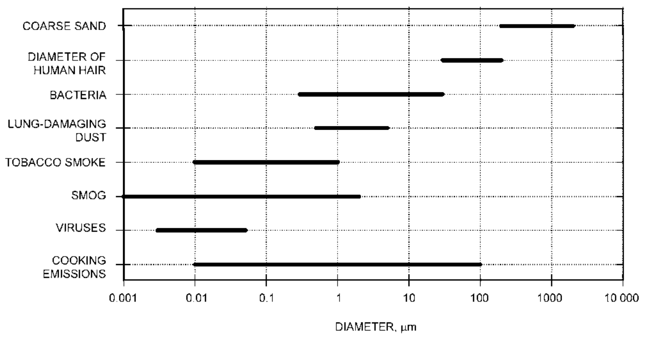

Fig. 17 Size Distribution of Common Particles

(Kuehn et al. 1999)

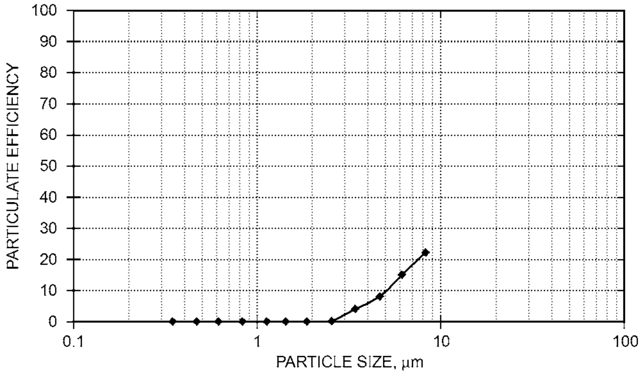

Fig. 20 Baffle Filter Particle Efficiency Versus Particle Size
(Kuehn et al. 1999)

hazard. Having higher-efficiency grease removal devices in the hood reduces the maintenance of downstream control equipment.

Concerns about air quality also emphasize the need for higher-efficiency grease extraction from the exhaust airstream than can be provided by filters or grease extractors in exhaust hoods. Cleaner exhaust discharge to the outdoors may be required by increasingly stringent air quality regulations or where the exhaust discharge configuration is such that grease, smoke, or odors in discharge would create a nuisance. In some cases, exhaust air is cleaned so that it can be discharged inside (e.g., through recirculating systems). Several systems have been developed to clean the exhaust airstream, each of which presents special fire protection issues.

Where odor control is required in addition to grease removal, activated charcoal, other oxidizing bed filters, or deodorizing agents are used downstream of the grease filters. Because much cooking odor is gaseous and therefore not removed by air filtration, filtration upstream of the charcoal filters must remove virtually all grease in the airstream to prevent grease build-up on the charcoal filters. See Chapter 12 of the 2017 *ASHRAE Handbook—Fundamentals* for more information.

The following technologies are applied to varying degrees for control of cooking effluent. They are listed by order of use in the exhaust stream after a mechanical filtration device, with particulate control upstream of VOC control. After the description of each technology are qualifications and concerns about its use. There is no consensus test protocol for evaluating these technologies in kitchen applications.

Electrostatic Precipitators (ESPs). Particulate removal is by high-voltage ionization, then collection on flat plates.

- Condensed grease can block airflow, especially when mounted outdoors.
- As the ionizer section becomes dirty, efficiency drops because the effective ionizer surface area is reduced.
- Under heavy loading, the unit may shut down because of voltage drop.

Ultraviolet (UV) Destruction. This system uses ultraviolet light to chemically convert the grease into an inert substance and ozone. Construction (not performance) is evaluated for safety in accordance with UL *Standard* 710C.

- Requires adequate exposure time for chemical reactions.
- Personnel should not look at light generated by high-intensity UV lamps.
- Exhaust fans should operate when UV lights are on because some forms of UV generate ozone.
- UV is more effective on very small particles and vapor.

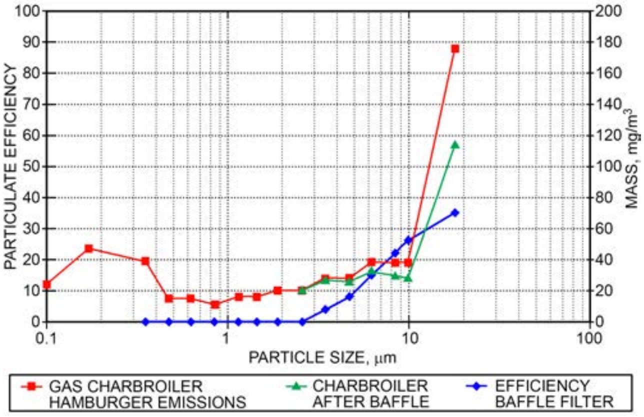

Fig. 21 Baffle Filter Particle Efficiency Versus Particle Size
(Kuehn et al. 1999)

- The required frequency of duct cleaning is reduced.
- Lamps need to be replaced periodically; as lamps become dirty, efficiency drops.

Water Mist, Scrubber, and Water Bath. Passage of the effluent stream through water mechanically entraps particulates and condenses grease vapor.

- High airflow can reduce efficiency of water baths.
- Water baths have high static pressure loss.
- Spray nozzles need much attention; water may need softening to minimize clogging.
- Drains tend to become clogged with grease, and grease traps require more frequent service. Mist and scrubber sections need significant length to maximize exposure time.

Pleated, Bag, and HEPA Filters. These devices are designed to remove very small particles by mechanical filtration. Some types also have an activated-carbon face coating for odor control.

- Filters become blocked quickly if too much grease enters.
- Static loss builds quickly with extraction, and airflow drops.
- Almost all filters are disposable and very expensive.

Activated-Carbon Filters. VOC control is through adsorption by fine activated charcoal pellets or granules.

- Require a large volume and thick bed to be effective.
- Are heavy and can be difficult to replace.
- Expensive to change and recharge. Many are disposable.
- Ruined quickly if they are grease-coated or subjected to water.
- Some concern that carbon is a source of fuel for a fire.

Oxidizing Pellet Bed Filters. VOC and odor control is by oxidation of gaseous effluent into solid compounds.

- Require a large volume and long bed to be effective.
- Are heavy to handle and can be difficult to replace.
- Expensive to change.
- Some concern about increased oxygen available in fire.

Incineration. Particulate, VOC, and odor control is by high-temperature oxidation (burning) into solid compounds.

- Must be at system terminus and clear of combustibles.
- Are expensive to install with adequate clearances.
- Can be difficult to access for service.
- Very expensive to operate.

Catalytic conversion. A catalytic or assisting material, when exposed to relatively high-temperature air, provides additional heat adequate to decompose (oxidize) most particulates and VOCs.

- Requires high temperature (230°C minimum).
- Expensive to operate because of high temperature requirement if integrated into the hood (can be cost-effective at the appliance level).

1.8 REPLACEMENT (MAKEUP) AIR SYSTEMS

In hood systems, where air exhausted through the hood is discharged to the outdoors, the volume of air exhausted must be replaced with uncontaminated outdoor air. Outdoor air must be introduced into the building through properly designed replacement air systems. Proper replacement air volume and distribution allow the hood exhaust fan to operate as designed and facilitate proper building pressurization, which is required for safe operation of direct-vent gas appliances (such as water heaters), prevention of kitchen odors migrating to adjacent building spaces, and/or maintaining a comfortable building environment. Proper pressurization enhances the building environment by preventing suction of unfiltered and/or unconditioned outdoor air into the building envelope through doors, windows, or air

Table 11 Outdoor Air Requirements for Dining and Food Preparation Areas

Facility Type	Airflow Rate, L/s per person	Maximum Occupancy, persons/100 m²
Restaurant dining area	3.8	70
Cafeterias and fast food dining area	3.8	100
Bars/cocktail lounges	3.8	100
Kitchen (cooking) spaces	3.8	20

Note: All areas are assumed nonsmoking.
Source: ASHRAE *Standard* 62.1.

handlers. IMC (ICC 2018a) requires neutral or negative pressurization in rooms with mechanical exhaust. NFPA *Standard* 96 requires enough replacement air to prevent negative pressures from exceeding 5 Pa, which may still be excessive for proper drafting of some direct vent appliances. To ensure pressure control, IMC also requires electrical interlock between exhaust and replacement air sources. This electrical interlock prevents excessive negative or positive pressures created by the exhaust fan or replacement air unit operating independently.

Indoor Environmental Quality

Traditionally, the primary purpose of replacement air has been to ensure proper operation of the hood. Kitchen thermal comfort and indoor environmental quality (IEQ) have been secondary. In some applications, thermal comfort and IEQ can be improved through adequate airflow and proper introduction of replacement air. In many of today's applications, outdoor air that meets IEQ standards is the most energy-efficient source for kitchen hood replacement air. Table 11 gives ASHRAE *Standard* 62.1 requirements for outdoor air per person; these requirements may be increased or decreased in certain areas if approved by the authority having jurisdiction. Outdoor air requirements affect HVAC system sizing and may require another means of introducing outdoor air. A further requirement of *Standard* 62.1, that outdoor air be sufficient to provide for an exhaust rate of at least 3.5 L/s per square metre of kitchen space, is generally easily met due to cooking ventilation rates.

Replacement Air Introduction

Replacement air may be introduced into the building through dedicated makeup air units, conventional HVAC apparatus, dedicated hood-system makeup air units (discussed in the section on Air Distribution), or in very limited climates, ventilators that include no conditioning means.

Dedicated Makeup Air Units. These units are specifically designed to heat, dehumidify, or cool 100% outdoor air. These dedicated units typically include modulating, heating, dehumidification, and cooling systems that react to outdoor air conditions and prevent cycling of these conditioning systems. Cycling leads to space discomfort and higher unit energy consumption. Hot-gas reheat (HGRH) may also be included to aid in continuous dehumidification (when required by outdoor air conditions) while maintaining space comfort. See Chapter 28 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on makeup air units.

Using enthalpy or temperature control for determining dedicated makeup air unit operation is recommended. These controls turn compressor(s), water supply, or heat sources off when outdoor air conditions warrant, while maintaining kitchen comfort, thus conserving energy and saving money without the use of additional economizer damper systems.

Conventional HVAC Units. Conventional HVAC units require fixed outdoor air intakes or economizer-controlled outdoor air dampers when they (1) supply outdoor air to meet spaces' ventilation requirements, (2) are adjacent to the kitchen area, and (3) only secondarily transfer the outdoor component of the total airflow to the kitchen. To alleviate any potential overpressurization occurrences, HVAC units with economizers should have a barometric relief damper either in the return ductwork or in the HVAC unit itself. As the amount of outdoor air increases, the increasing pressure in the system opens the relief damper, so that the return air volumetric rate is only enough to maintain approximately the amount of design supply air. The amount of air required for dedicated replacement air becomes the minimum set point for the economizer damper when the hoods are operating. Fixed outdoor air intakes must be set to allow the required amount of replacement air. Outdoor air dampers should be interlocked with hood controls to open to a preset minimum position when the hood system is energized.

If the zone controls call for cooling, and outdoor conditions are within economizer range, the outdoor damper may be opened to allow greater amounts of outdoor air. The maximum setting for outdoor air dampers in unitary HVAC units is typically 25 to 30% of total unit air volume when the units are operating in their heating or cooling (i.e., noneconomizer) mode. Field experience has shown that large increases in air discharge velocities or volumes can occur at diffusers when HVAC units go into economizer mode. This is because the static loss through the fresh-air intake is considerably less than through the return air duct system, and thus a change from return air to fresh air reduces the overall static through the system, resulting in a relative increase in the total system flow. This can create air balance problems that negatively affect hood performance because of interference with capture and containment supply flow patterns at the hoods.

A large increase in air velocity or volume from supply diffusers indicates a need for better balance between the fresh air and return air static losses. Some HVAC manufacturers state that a relief fan is required to ensure proper air balance if economizer controls call for outdoor air greater than 50% during economizer operation mode. A relief fan addresses static losses in the return duct system, thus helping minimize the static difference with the fresh-air intake. Lack of a barometric relief damper, or constrictions in the return ductwork, also may be the source of the problem.

In smaller commercial buildings, including restaurants and strip centers, individual unitary rooftop HVAC equipment is common. This unitary equipment may not be adequate to supply 100% of the replacement air volume. Outdoor air must be considered during initial unit selection to obtain desired unit operation and space comfort. The space in which the hood is located should be kept at a neutral or negative pressure relative to adjacent spaces. Therefore, HVAC economizers are not recommended for equipment supplying air directly to the space in which the hood is located, unless the economizer installation includes equipment and controls to maintain overall system air balance and to prevent excessive air discharge velocities or volumes.

In climates with higher summer dew-point design conditions, consider adding active dehumidification (such as hot-gas reheat) for units supplying outdoor air for ventilation at rates greater than 10% of unit total airflow.

Replacement Air Categories

Three categories of replacement air have been defined for design of energy-efficient replacement air systems: supply, makeup, and transfer. IAQ engineers must design outdoor air systems to meet total building ventilation requirements. Replacement air for kitchen ventilation must integrate into the total building IAQ design. Total kitchen ventilation replacement air may consist of only dedicated makeup air; however, in many energy-efficient designs, outdoor air required for ventilating the kitchen or adjacent spaces is used as supply or transfer air to augment or even eliminate the need for dedicated makeup air. Typically, replacement air will be a combination of categories from multiple sources. The source of replacement air typically determines its category.

Kitchen supply air is outdoor air introduced through the HVAC or ventilating apparatus, dedicated to the comfort conditioning of the space in which the hood is located. In many cases this may be an ideal source of replacement air because it also provides comfort conditioning for the occupants.

Makeup air is outdoor air introduced through a system dedicated to providing replacement air specifically for the hood. It is typically delivered directly to or close to the hood. This air may or may not be conditioned. When conditioned, it may be heated only; generally only in extreme environments will it be cooled. When included, makeup air typically receives less conditioning than space supply air. The IMC (ICC 2018a) requires makeup air be conditioned to within 5.5 K of the kitchen space, except when introducing replacement air that does not decrease kitchen comfort (see the section on Energy Considerations for additional information). This can be accomplished with proper distribution design. Typical sources of makeup air heating include direct and indirect gas-fired units, hot-water coils (with freeze protection), and, in some cases or geographic areas, electric resistance heating. When cooling is provided, the outdoor air design conditions must be considered. A low-dew-point design is required for effective use of evaporative coolers. Higher-dew-point design temperatures may require water or direct exchange (DX) coils for cooling and/or dehumidification. Temperature of makeup air introduced varies with distribution system and type of operation.

Transfer air is outdoor air, introduced through the HVAC or ventilating apparatus, dedicated to comfort conditioning and ventilation requirements of a space adjacent to the area in which the hood is located. The device providing transfer air must operate and supply outdoor air whenever the hood is operating. Air must not be transferred from spaces where airborne contaminants such as odors, germs, or dust may be introduced into the food preparation or serving areas. Air may be transferred through wall openings, door louvers, or ceiling grilles connected by duct above the ceiling. Depending on grille and duct pressure drop, a transfer fan(s) may be required to avoid drawing transfer air through lower-pressure-drop openings at velocities that may be detrimental to food service processes. When using openings through which food is passed, transfer velocities should not exceed 0.25 m/s to avoid excessive cooling of the food. Transfer air is an efficient source of replacement air because it performs many functions, including ventilating and/or conditioning the adjacent space, replacing air for the hood, and additional conditioning for the space in which the hood is located. Only the portion of air supplied to the adjacent space that originated as outdoor air may be transferred for replacement air. The IMC (ICC 2018a) recognizes the use of transfer air as a replacement air source. In large buildings such as malls, supermarkets, and schools, adequate transfer air may be available to meet 100% of hood replacement air requirements. Malls and multiple-use-occupancy buildings may specify a minimum amount of transfer air to be taken from their space to keep cooking odors in the kitchen, or they may specify the maximum transfer air available. Code restrictions may prevent the use of corridors as spaces through which transfer air may be routed. Conditions of transfer air are determined by conditioning requirements of the space into which the air is initially supplied.

Air Distribution

The design of a replacement air distribution system may enhance or degrade hood performance. Systems that use a combination of kitchen supply, makeup, and transfer air include various components of distribution. Distribution from each source into the vicinity of the hood must be designed to eliminate high velocities, eddies, swirls, or stray currents that can interrupt the natural rising of the thermal plume from cooking equipment into the hood, thus degrading the performance of the hood. Methods of distribution may include conventional diffusers, compensating hood designs, transfer devices, and simple openings in partitions separating building spaces. Regardless of the method selected, it is important to always deliver replacement air to the hood (1) at proper velocity and (2) uniformly from all directions to which the hood is open. This minimizes excessive cross-currents that could cause spillage. Proper location and/or control of HVAC return grilles is therefore critical. The higher air velocities typically recommended for general ventilation or spot cooling with unconditioned air (0.4 to 1.0 m/s at worker) should be avoided around the hood. Hood manufacturers offer a variety of compensating hoods, plenums, and diffusers designed to introduce replacement air effectively.

Hood-Supplied Replacement Air (Compensating Hoods). A common way of distributing replacement air is through compensating systems that are integral with the hood. Figure 22 shows four typical compensating hood configurations. Because actual flows and percentages may vary with hood design, the manufacturer should be consulted about specific applications. The following are typical descriptions of configurations that include perimeter supply.

Brohard et al. (2003) investigated the effects of six methods of introducing replacement air on three hood styles, Three hood types were tested: (1) wall-mounted canopy, (2) island-mounted canopy, and (3) proximity (back shelf). Gas underfired broilers and gas griddles, respectively representing heavy-duty and medium-duty appliances, were tested. Idle and emulated cooking conditions were also tested. The MUA strategies included (1) displacement ventilation (base case), (2) ceiling diffuser, (3) hood face diffuser, (4) air curtain diffuser, (5) back wall supply, and (6) short-circuit supply. The influences of air mass disturbances (drafts) and tapered side panels were also investigated. Each replacement air strategy and specific configuration tested compromised the exhaust hood's ability to completely capture and contain the thermal plume and/or effluents at higher replacement airflow rates (expressed as a percentage of the threshold exhaust rate). Temperature of locally supplied makeup air also affected hood performance, because air density affects the dynamics of air movement around the hood. Generally, hotter makeup air temperatures (e.g., greater than 32°C) affect hood performance more adversely than cooler air (e.g., less than 24°C).

Air Curtain Supply. This method is typically used for spot-cooling the cooking staff to counter the severe radiant heat generated from equipment such as gas or electric broilers. The air must be heated and/or cooled, depending on local climate. Air curtain discharge can be along the length of the hood front only or along all open sides of the

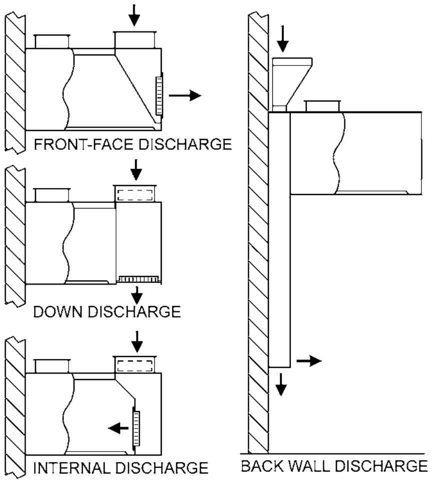

Fig. 22 Compensating Hood Configurations

hood. When discharge velocity is too low, air tends to enter the hood directly and may have little effect on hood performance. When discharge velocity is too high, air entrains the cooking plume and spills it into the room. Ideal velocity and throw can improve hood performance and redirect the thermal plume toward the filters. Discharge velocities must be carefully selected to avoid discomfort to personnel and cooling of food.

Limit the percentage of makeup air supplied through an air curtain to less than 20% of the hood's exhaust flow. At these low air velocities, an air curtain may enhance capture and containment, depending on design details. However, at higher makeup airflow rates, the air curtain is one of the worst performing makeup air strategies. The negative effect of an air curtain is clearly illustrated in Figure 23 by the schlieren flow visualization recorded during a test of a wall-mounted canopy hood operating over two gas underfired broilers.

Introducing makeup air through an air curtain is a risky option. An air curtain (by itself or in combination with another pathway) is not recommended, unless velocities are minimized and the designer has access to performance data on the actual air curtain configuration being specified. Typical air curtains are easily adjusted, which could cause cooking effluent to spill into the kitchen by inadvertently creating higher-than-specified discharge velocities.

Back-Wall Supply. A makeup air plenum is installed between the back of the hood and wall. The full-length plenum typically extends down the wall to approximately 150 mm below the cooking surface or 600 to 900 mm above the floor. The depth of the plenum is typically 150 mm. Makeup air is discharged behind and below the cooking equipment. The bottom of the plenum is provided with diffusers and may also include a balancing damper. As with front-face discharge, air volume and discharge velocity dictate how far into the space the makeup air will travel. The amount of travel and local climate dictate the amount of heating and/or cooling needed. Support for wall shelves, salamander broilers, or cheesemelters mounted under the hood must be considered. The plenum structure typically does not provide sufficient support for mounting these items.

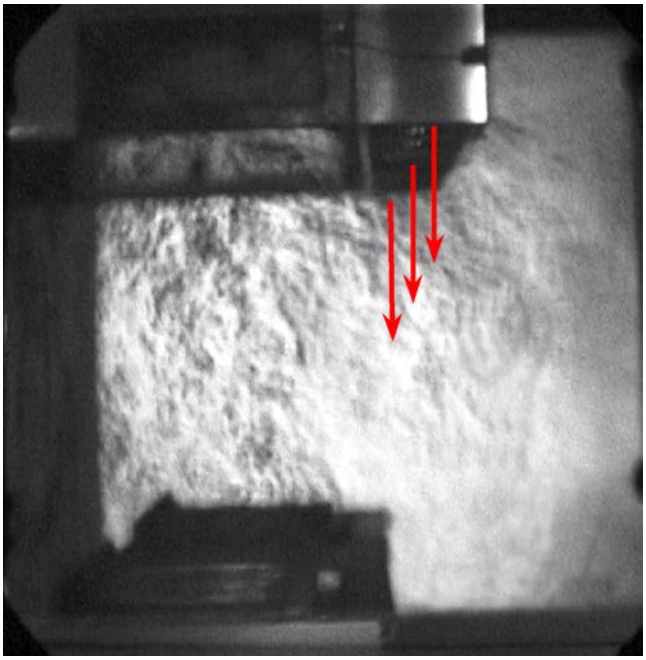

Fig. 23 Schlieren Image Showing Thermal Plume Being Pulled Outside Hood by Air Curtain
(Brohard et al. 2003)

Back-wall supply can be an effective strategy for introducing makeup air (Figure 24). In most cases, it allows significant amounts of air to be locally supplied without a detrimental effect on hood C&C performance. Local makeup air mostly enters the kitchen space, rather than remaining contained in the cooking zone. This potentially creates an additional heat and moisture load on the kitchen, particularly because most replacement air supplied is mixed with room air before being exhausted.

To help ensure proper performance, the discharge of the back-wall supply should be at least 300 mm below cooking surfaces of appliances, to prevent the relatively high-velocity makeup air from interfering with gas burners and pilot lights. Back-wall plenums with larger discharge areas may provide increased airflow rates as long as discharge velocities remain below maximum thresholds. The quantity of air introduced through the back-wall supply should be no more than 60% of the hood's exhaust flow.

Front-Face Supply. Supplying air through the front face of the hood is a configuration recommended by many hood manufacturers. In theory, air exits the front-face unit horizontally into the kitchen space. However, a front-face discharge with louvers or perforated face can perform poorly, if its design does not consider discharge air velocity and direction. Figure 25 presents a poorly designed perforated face supply, which can negatively affect hood capture performance in the same way as an air-curtain or four-way diffuser. To improve front-face performance, internal baffling and/or a double layer of perforated plates may be used improve the uniformity of airflow. In addition, greater distance between the lower capture edge of the hood and the bottom of the face discharge area may decrease the tendency of the replacement air supply to interfere with hood capture and containment. In general, face discharge velocities should not exceed 0.75 m/s (i.e., replacement air flow rate divided by gross discharge area) and should exit the front face in a horizontal direction.

Internal Makeup Air. This method, also known as **short-circuit,** introduces makeup air directly into the exhaust hood cavity. This design has limited application, and the amount of air that can be introduced varies considerably with the type of cooking equipment and exhaust flow rate. As noted previously, thermal currents from

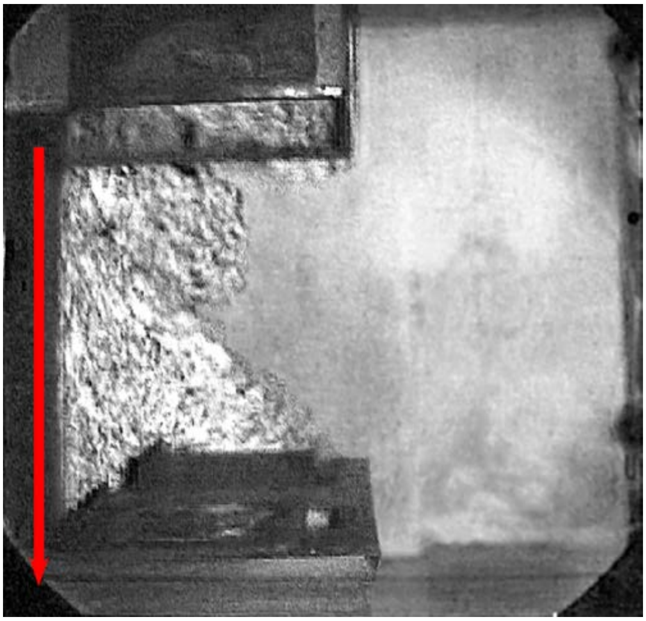

Fig. 24 Schlieren Image Showing Thermal Plume Being Captured with Back-Wall Supply
(Brohard et al. 2003)

cooking equipment create a plume of a certain volume that the hood must remove. The hood must therefore draw at least this volume of air from the kitchen, in addition to any internal makeup. If the net exhaust flow rate (total exhaust less internal makeup air) is less than the plume volume, part of the plume may spill out of the hood. Internal makeup air is typically not conditioned; however, depending on local climate, manufacturer's design, type of cooking equipment, and local codes, conditioning may be required. Some local authorities approve internal discharge hoods, and some do not. For unlisted hoods, IMC (2018a) requires the net quantity of exhaust air to be calculated by subtracting any airflow supplied directly to a hood cavity from the total exhaust flow rate of a hood. Listed hoods are operated in accordance with the terms of the listing. All applicable codes must be consulted to ensure proper criteria are followed.

When short-circuit hoods are operated with excessive internal makeup air, they typically fail to capture and contain the cooking effluent (Figure 26). ASHRAE *Standard* 154 limits the quantity of internal replacement air to no more than 10% of the exhaust airflow. Additionally, the introduction of untempered makeup air results in uncomfortable kitchen conditions. Independent research (Brohard et al. 2003) recommends not using this compensating hood design; therefore, there is no additional design information in this chapter.

Multiple Discharge. This method may combine internal, perimeter, air curtain, and/or front face. Each may be served by a separate or common plenum. Balancing dampers may be provided for one or both discharge arrangements. These dampers may be used to fine-tune the amount of air discharged through the air curtain or front face. However, this method inherits the performance problems of each of the individual types, and combining them tends to compound these issues.

Perforated Perimeter Supply. Perforated perimeter supply is similar to a front-face supply, but the air is directed downward, as in Figure 27, toward the hood capture area. This may be advantageous under some conditions, because air is directed downward into the hood capture zone.

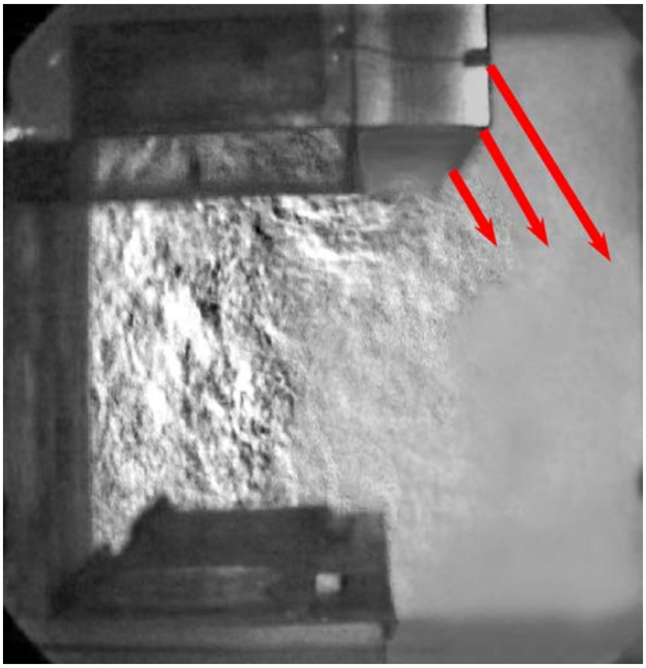

Fig. 25 Schlieren Image Showing Thermal Plume Being Pulled Outside Hood by Front Face
(Brohard et al. 2003)

For proper hood performance, discharge velocities should not exceed 0.75 m/s (i.e., makeup airflow rate divided by gross discharge area) from any section of the diffuser, and the distance to lower edge of the hood should be no less than 460 mm, or the system begins to act like an air curtain. An increase in the plenum discharge area

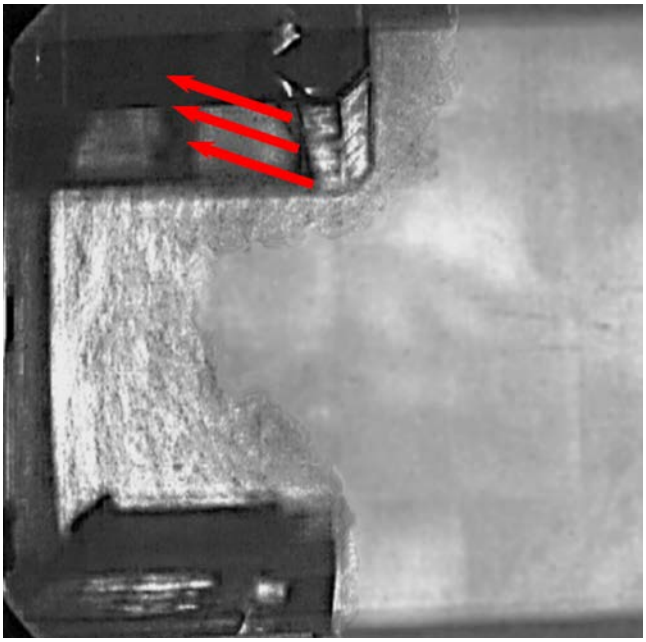

Fig. 26 Schlieren Image Showing Thermal Plume Being Displaced by Short-Circuit Supply, Causing Hood to Spill
(Brohard et al. 2003)

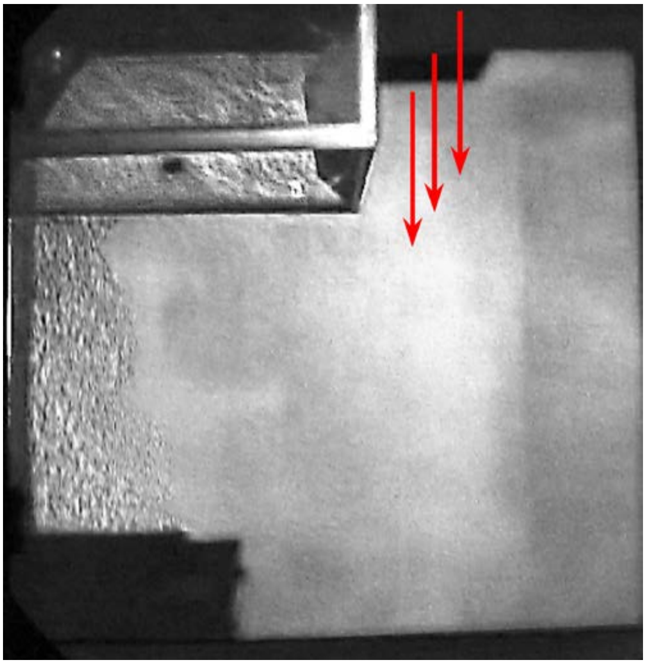

Fig. 27 Schlieren Image Showing Effective Plume Capture with Replacement Air Supplied Through 400 mm Wide Perforated Perimeter Supply, Shown with Additional Front Overhang
(Brohard et al. 2003)

lowers the velocity for a given flow of replacement air and reduces the chance of it affecting capture and containment. If the perforated perimeter supply is extended along the sides of the hood as well as the front, the increased area allows proportionally more makeup air to be supplied. In all cases, the velocity downward 50 mm above the lower edge of the hood should not exceed 0.4 m/s.

Room-Supplied Makeup Air (Diffusers and Grilles). There are various ways to distribute replacement air in the vicinity of the hood to avoid cross currents that degrade hood performance. Non-aspirating diffusers are recommended, especially adjacent to the hood. For more information on diffusers, see Chapter 20 of the 2017 *ASHRAE Handbook—Fundamentals*, Chapter 20 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, and Chapter 58 of this volume. Typical devices include the following.

Directional Ceiling Diffusers. Air from these two- or three-way diffusers should not be directed toward exhaust hoods, where it might disturb the thermal plume and adversely affect hood performance. The diffuser should be located so that the jet velocity at the lip of the hood does not exceed 0.4 m/s.

Four-Way Directional Ceiling Diffusers. Four-way directional diffusers located close to kitchen exhaust hoods (Figure 28) can have a detrimental effect on hood performance, particularly when flow through the diffuser approaches its design limit. They are not recommended within 4.5 m of the hood.

Perforated Ceiling Diffusers. These nonaspirating, perforated-face diffusers may have internal deflecting louvers, but should not be capable of directing the airflow toward the hood. The diffuser should be located so that the jet velocity at the lip of the hood does not exceed 0.4 m/s. In some code jurisdictions, when conventional ceiling diffusers are used, only perforated diffusers are allowed in commercial kitchens. Perforated ceiling diffusers can be used near the hood, although a greater number of these diffusers may be required to reduce air velocities for a given supply rate. To help ensure proper hood performance, air from a perforated diffuser near the hood should not be directed toward the hood. If ceiling-supplied air must be directed toward a hood, air discharge velocity at the diffuser face should be selected so that the terminal velocity does not exceed 0.4 m/s at the edge of the hood capture area.

Slot Diffusers. Because the slot opening of these devices is generally small compared to air volume, air velocity is often higher than that which would be obtained with two-, three-, and four-way diffusers. Also, because airflow is mostly downward, the potential for negatively affecting hood performance is quite high if outlets are near the hood. If used with relatively high ceilings, the potential for negative impact is less because the velocity diminishes as air diffuses downward. Slot diffusers are usually nonaspirating.

Displacement Diffusers. These devices, designed to provide low-velocity laminar flow over the diffuser surface, typically supply air from 10 to 21°C in a kitchen, depending on equipment loads. Hotter, stratified air is removed from the ceiling through exhaust ducts or returned to the HVAC system to be conditioned. In contrast with ceiling diffusers, which require complete mixing to be effective, stratification is the desired effect with displacement diffusers.

Displacement diffusers were used to determine the baseline for Brohard et al.'s (2003) replacement air study, because they provided a uniform, nearly laminar bulk airflow. This low-velocity bulk airflow is optimal for attaining C&C with the lowest exhaust rate. Therefore, supplying replacement air through displacement diffusers (Figure 29) may be an effective strategy for introducing replacement air. Adequate wall or floor space is required to accommodate displacement diffusers.

Other Factors That Influence Hood Performance.

Hood Style. Wall-mounted canopy hoods function effectively with a lower exhaust flow rate than single-island hoods. Island canopy hoods are more sensitive to makeup air supply and cross drafts than wall-mounted canopy hoods. Back-shelf/proximity hoods generally exhibit lower capture and containment exhaust rates, and in some cases, perform the same job at one-third of the exhaust rate required by a wall-mounted canopy hood.

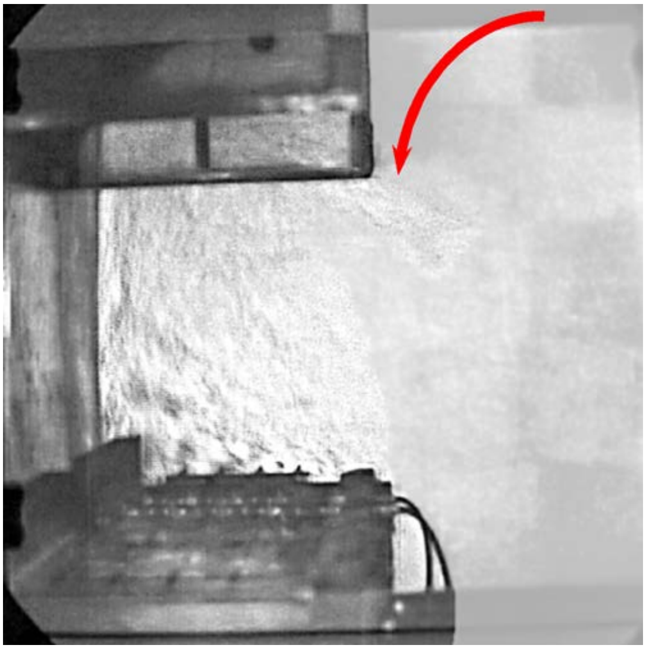

Fig. 28 Schlieren Image Showing Thermal Plume Being Pulled Outside Hood by Air Discharged from Four-Way Diffuser
(Brohard et al. 2003)

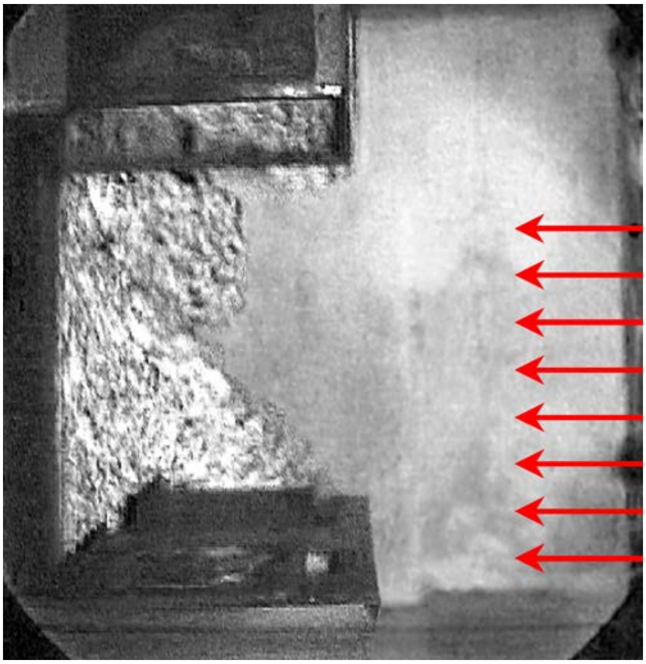

Fig. 29 Schlieren Image Showing Plume Being Effectively Captured when Replacement Air Is Supplied at Low Velocity from Displacement Diffusers
(Brohard et al. 2003)

Cross Drafts. Cross drafts have a detrimental effect on all hood/appliance combinations. Cross drafts adversely affect island canopy hoods more than wall-mounted canopy hoods. A fan in a kitchen, especially pointing at the cooking area, severely degrades hood performance and may make capture impossible. Cross drafts required at least a 37% increase in exhaust flow rate; in some cases, C&C could not be achieved with a 235% increase in exhaust rate (Brohard et al. 2003). Cross drafts can result from portable fans, movement in the kitchen, or an unbalanced HVAC system, which may pull air from open drive-through windows or doors.

Side Panels. Side (or end) panels allow a reduced exhaust rate in most cases, because they direct replacement airflow to the front of the hood. Installing side panels improved C&C performance for static conditions an average 10 to 15% and up to 35% for dynamic (cross-draft) conditions. They are a relatively inexpensive way to enhance performance and reduce the total exhaust rate. Partial side panels can provide virtually the same benefit as full panels. One of the greatest benefits of side panels is to mitigate the negative effect of cross drafts.

Brohard et al. (2003) recommend reducing the impact that locally supplied makeup air may have on hood performance by minimizing makeup air velocity as it is introduced near the hood. This can be accomplished by minimizing the volume of makeup air through any single distribution system or by distributing through multiple configurations. The chances of makeup air affecting hood performance increase as the percentage of the locally supplied makeup air (relative to the total exhaust) is increased. In fact, the 80% rule of thumb for sizing airflow through a makeup air system may be a recipe for trouble.

Effective introduction of replacement air (whether supplied through displacement ventilation diffusers, perforated diffusers located in the ceiling, and/or as transfer air from adjacent spaces) should be designed to limit velocities approaching the hood to less than 0.4 m/s.

Design Recommendations. The first step to reducing the replacement air requirement is lowering the design exhaust rate, which can be accomplished by prudent selection and application of UL *Standard* 710 listed hoods. Using side panels on canopy hoods may increase effectiveness and mitigate cross drafts, and is highly recommended where applicable. The next step is to take credit for outdoor air that must be supplied by the HVAC system to meet code requirements for space or occupant ventilating. Depending on the architectural layout, it may be practical to transfer most of this air to the kitchen. Assuming the transfer air is conditioned and properly introduced, it may enhance hood performance and improve the kitchen environment.

For more information, see the sections on Energy Considerations and Commercial Exhaust Hoods in this chapter.

1.9 HVAC SYSTEM DESIGN

As mentioned previously, one purpose of kitchen ventilation is to provide a comfortable environment for employees. Engineers who are used to designing HVAC loads for more traditional spaces (e.g., offices) may not realize how different the kitchen environment can be: kitchens require a much greater quantity of outdoor air as makeup, and have much higher internal loads (including sensible radiated heat gain from appliances underneath hoods, sensible and latent loads from unhooded equipment including warewashers, and sometimes outdoor air loads).

Hooded and Unhooded Appliance Loads

One of the challenges in performing cooling and heating load calculations for a kitchen is determining the space heat gains from the cooking appliances. Given that many of the largest cooking appliances include exhaust hoods to remove the smoke, grease, and heat, determining the heat gain can be challenge. There may also be a large number of smaller appliances that do not include exhaust hoods and which reject all their heat directly to the space.

Table 12 Appliance Heat Gain Reference

Appliance Location	Fuel Source	Chapter 18, 2017 *ASHRAE Handbook—Fundamentals* Table Reference
Unhooded	All	5A and 5B
Hooded	Electric	5C
Hooded	Gas	5D
Hooded	Solid Fuel	5E
Hooded and unhooded dishwashers	All	5F

Table 13 Heat Gain from Outdoor Air Infiltration

Type of Heat Gain	Equation	Chapter 18, 2017 *ASHRAE Handbook—Fundamentals* Equation Reference
Sensible	$q_s = 1.23Q_s\Delta t$	(9)
Latent	$q_l = 3010Q_s\Delta W$	(10)
Total (Sensible + Latent)	$q_t = 1.2Q_s\Delta t$	(7)

Notes: Q_s is flow in m³/s, t is °C, W is kg water per kg air, h is kJ/kg, and q is heat gain in W. Δ is the difference between outdoor and space-neutral (room design) conditions.

Tables 5A to 5F in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals* list typical equipment and the heat rejected into the kitchen. The data contained in these tables were updated as part of ASHRAE research project RP-1362 (Swierczyna et al. 2008). Table 12 summarizes which tables to use for what type of equipment.

For the majority of appliances, table heat gain values were determined during idle or standby condition: that is, the appliance was fully warmed up and in its ready-to-cook condition. (Typically, an appliance is in standby for as much as 70% of the day.) For appliances installed under an exhaust hood, the amount of heat emitted as radiation is listed, because this heat ends up heating nearby objects. For the appliances that are not installed under a hood because of their low energy consumption or lack of cooking effluent, the amount of both sensible and latent heat is listed, in addition to the radiation.

The greatest challenge with using these data is determining the diversity or usage factor of the appliances. It may be difficult to anticipate how often the appliance will be at full cooking or at some standby condition. Any assumptions made can be rendered incorrect by a change in kitchen throughput or sales. Determining the correct heat gain is an involved procedure that requires input from the entire kitchen design team.

Outdoor Air Loads

If the outdoor air is not conditioned to a space-neutral (or space design) condition, then the sensible and latent loads from this volume of air will impact the existing HVAC system at least to some extent because however the air is introduced into the kitchen some of it will enter the kitchen space especially if that air is hot and humid. Table 13 summarizes the relevant equations from Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*. It is recommended that the load from at least 50% of the outdoor air brought into the kitchen to replace the exhaust air be used in the heat gain calculations.

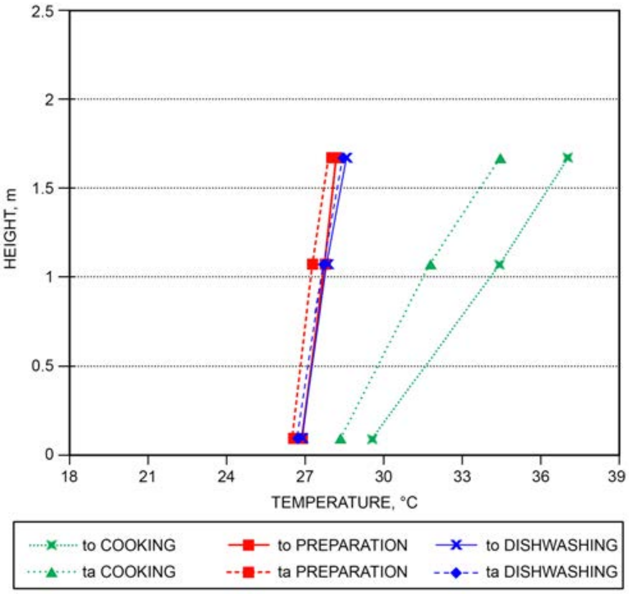

Fig. 30 Summer Temperatures by Height and Kitchen Zone in Casual Kitchens

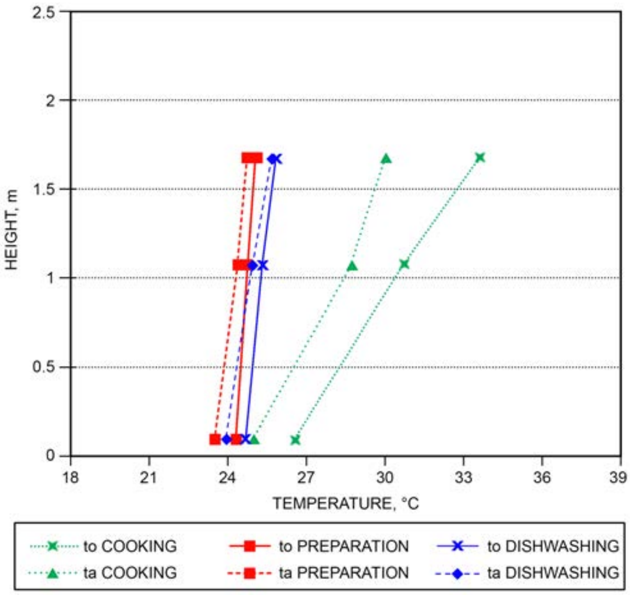

Fig. 31 Summer Temperatures by Height and Kitchen Zone in Institutional Kitchens

The remaining heat gains from lighting, envelope, and people can be calculated following the procedure described in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*.

Thermal Comfort Research Results

ASHRAE research project RP-1469 (Stoops et al. 2013) conducted a large field survey on kitchens in the United States to identify how well engineers are satisfying design kitchen conditions. Researchers monitored space conditions in 105 kitchens during the summer. Figures 30 to 32 show the resulting temperatures in three areas of the restaurant (kitchen, food preparation, and warewashing) as a function of height above the floor.

Stoops et al. found that temperature increases with height above the floor: although floor-level temperatures ranged from approximately 24 to 28°C, at head level for staff temperatures ranged from 30 to 37°C. Higher temperatures at increasing heights can be partially attributed to radiated heat gain from the appliances underneath hood(s), but there is no question that the space conditions were not being met on average for most of the kitchens monitored in this study, even at the floor level. See Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* for more information.

1.10 EXHAUST SYSTEMS

Exhaust systems remove effluent produced by appliances and cooking processes to provide fire and health safety, comfort, and aesthetics. Typical exhaust systems simultaneously incorporate fire prevention designs and fire suppression equipment. In most cases, these functions complement each other, but in other cases they may seem to conflict. Designs must balance these functions. For example, fire-actuated dampers may be installed to minimize the spread of fire to ducts, but maintaining an open duct might be better for removing smoke of an appliance fire from the kitchen.

Duct Systems

Exhaust ducts convey exhaust air from the hood to the outdoors, along with any grease, smoke, VOCs, and odors that are not extracted from the airstream along the way. These ducts may also be used to exhaust smoke from a fire. To be effective, ducts must be greasetight; it must be clear of combustibles, or combustible material must be protected so that it cannot be ignited by a fire in a duct; and ducts must be sized to convey the volume of airflow necessary to remove the effluent.

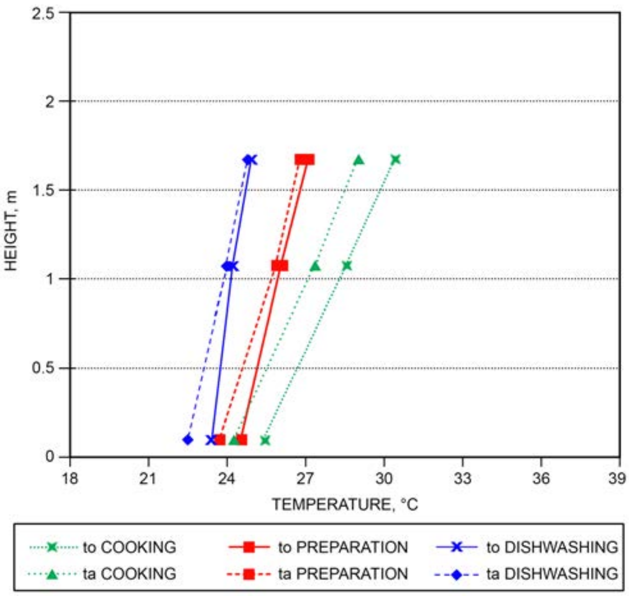

Fig. 32 Summer Temperatures by Height and Kitchen Zone in Quick-Service Restaurant Kitchens

Model building codes, such as the IMC (ICC 2018a), and standards, such as NFPA *Standard* 96, set minimum air velocity for exhaust ducts at 2.5 m/s. Maximum velocities are limited by pressure drop and noise and typically do not exceed 12.5 m/s. Until recently, NFPA *Standard* 96 and the IMC had set the minimum air velocity through the duct at 7.5 m/s. However, based on ASHRAE research (Kuehn 2000) that indicated that there is no basis for specifying 7.5 m/s minimum duct velocity for commercial kitchen ventilation and that grease deposition in ducts does not increase when duct velocity is lowered to 2.5 m/s, NFPA and IMC requirements were changed to 2.5 m/s. This allows flexibility for design of variable-speed exhaust systems and retrofitting older systems, though because of spatial and cost constraints, current design practice for new single-speed systems generally is to design duct velocity between 7.6 and 9 m/s.

Ducts should have no traps that can hold grease, which would be an extra fuel source in the event of a fire, and ducts should pitch toward the hood or an approved reservoir for constant drainage of liquefied grease or condensates. On long duct runs, allowance must be made for possible thermal expansion because of fire, and the slope back to the hood or grease reservoir must conform to local code requirements.

Single-duct systems carry effluent from a single hood or section of a large hood to a single exhaust termination. In multiple-hood systems, several branch ducts carry effluent from several hoods to a single master duct that has a single termination. See the section on Multiple-Hood Systems for more information.

Ducts may be round or rectangular. Standards and model codes contain minimum specifications for duct materials and construction, including types and thickness of materials, joining methods, and minimum clearance of 460 mm to combustible materials. Listed factory-built modular grease duct systems are available as an alternative to code-prescribed welded systems. These listed systems typically incorporate stainless steel liners and double-wall, insulated construction, allowing reduced clearances to combustibles and non-welded joint construction.

When fire-rated enclosures are required for grease ducts, either fired-rated enclosures are built around the duct or the newer listed, field-applied grease duct enclosures can be used directly on the grease duct, or the newer listed, factory-built, modular grease ducts with insulated construction can be used as an integral fire-rated enclosure. Most of these listed systems allow zero clearance to combustibles and also provide 1 h or 2 h fire resistance rating, and can be used in lieu of a fire-rated enclosure required in NFPA *Standard* 96 and IMC (ICC 2018a). See Chapter 19 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and the Fire Safety section in this chapter for more information on grease duct construction.

1.11 EXHAUST FANS

Types of Exhaust Fans

Exhaust fans for kitchen ventilation must be capable of handling hot, grease-laden air. The fan should be designed to keep the motor out of the airstream and should be effectively cooled to prevent premature failure. To prevent roof damage, the fan should contain and properly drain all grease removed from the airstream. See Chapter 21 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and the Fire Safety section in this chapter for more information on fans.

The following types of exhaust fans are commonly used; all have centrifugal wheels with backward-inclined blades:

- **Power roof ventilator (PRV).** Also known as **upblast** fans, PRVs are designed for mounting at the exhaust duct outlet (Figure 33), and discharge upward or outward from the roof or building. Aluminum upblast fans must be listed for the commercial kitchen exhaust application in compliance with UL *Standard* 762, and must include a grease drain, grease collection device, and integral hinge kit to permit access for duct cleaning.
- **Centrifugal fan.** Also known as a **utility set**, this is an AMCA Arrangement 10 centrifugal fan, including a field-rotatable blower housing, blower wheel with motor, drive, and often a motor/drive weather cover (Figure 34). These fans are typically constructed of steel and roof-mounted. Where approved, centrifugal fans can be mounted indoors and ducted to discharge outdoors. The inlet and outlet are at 90° to each other (single width, single inlet), and the outlet can usually be rotated to discharge at different angles around a vertical circle. The lowest part of the fan must drain to an approved container. When listed in accordance with UL *Standard* 762, a grease drain, grease collection device, and blower housing access panel are required.
- **Tubular centrifugal.** These fans, also known as **inline** fans, have the impeller mounted in a cylindrical housing discharging the gas in an axial direction (Figure 35). Where approved, these fans can be located in the duct inside a building if exterior fan mounting is not practical for wall or roof exhaust. They are always constructed of steel. The gasketed flange mounting must be greasetight yet removable for service. The lowest part of the fan must drain to an approved container. When listed in accordance with UL *Standard* 762, a grease drain, grease collection device, and blower housing access panel are required.

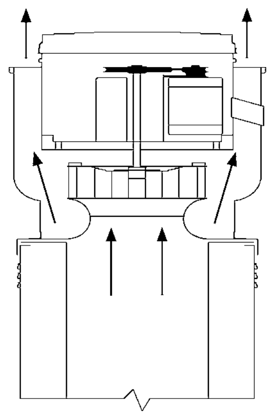

Fig. 33 Power Roof Ventilator (Upblast Fan)

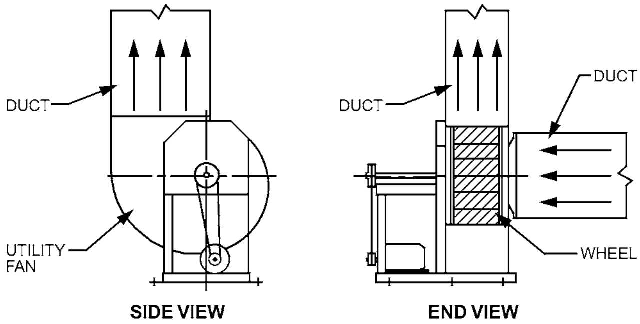

Fig. 34 Centrifugal Fan (Utility Set)

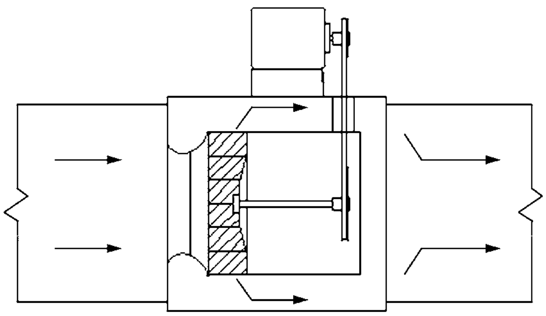

Fig. 35 Tubular Centrifugal (Inline) Fan

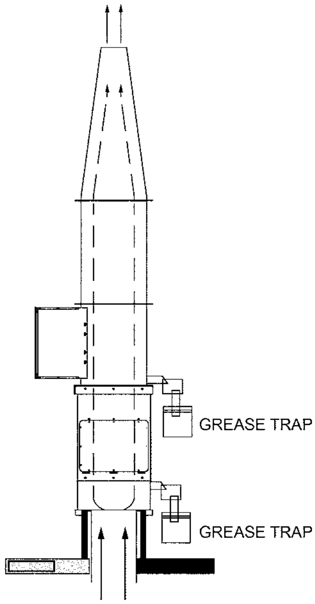

Fig. 36 High-Plume Fan

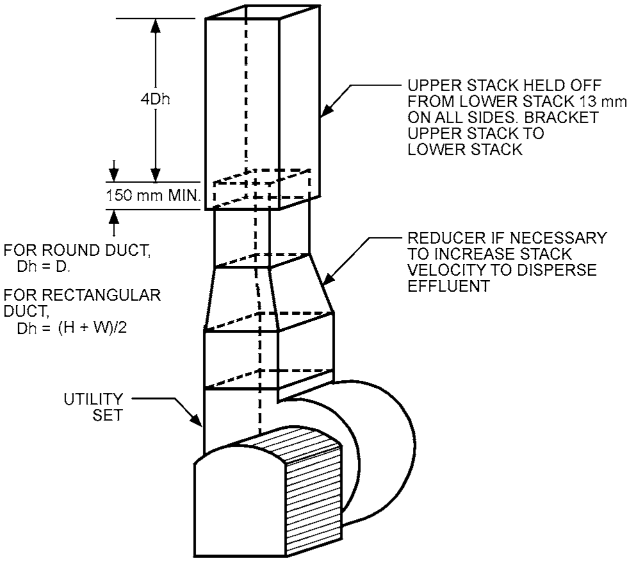

Fig. 37 Rooftop Centrifugal Fan (Utility Set) with Vertical Discharge

- **High-plume fan.** These fans may be used for kitchen applications when the requirements for a high exhaust plume are required (Figure 36). These fans generate a high nozzle exit velocity, which forces the exhaust plume to higher elevations and thus discharges smoke and grease laden vapors into the atmosphere. This fan is applicable when the intent is to prevent re-entraining smoke and grease-laden kitchen exhaust into the building makeup air system, or to discharge it over neighboring buildings or structures. When listed in accordance with UL *Standard* 762, a grease drain, grease collection device, and blower housing access panel are required. Because of the size and weight of these fans, the installation should be verified for structural integrity by a structural engineer. Items to be evaluated may include roof load, wind load, and seismic conditions.

Exhaust Terminations

Rooftop. Rooftop terminations are preferred because discharge can be directed away from the building, the fan is at the end of the system, and the fan is accessible. Common concerns with rooftop terminations are as follows:

- Exhaust system discharge should be arranged to minimize reentry of effluent into any fresh-air intake or other opening to any building. This requires not only separating the exhaust from intakes, but also knowledge of the direction of the prevailing winds. Some codes specify a minimum distance to air intakes. See Chapter 46 of this volume for more information on exhaust discharge principles and considerations.
- In the event of a fire, neither flames, radiant heat, nor dripping grease should be able to ignite the roof or other nearby structures.
- All grease from the fan or duct termination should be collected and drained to a remote closed container to preclude ignition.
- Rainwater should be kept out of the exhaust system, especially out of the grease container. If this is not possible, then the grease container should be designed to separate water from grease and drain the water back onto the roof. Figure 37 shows a rooftop utility set with a stackhead fitting, which directs exhaust away from the roof and minimizes rain penetration. Discharge caps should not be used because they direct exhaust back toward the roof and can become grease-fouled.

Outside Wall. Wall terminations are less common today but are still occasionally used in new construction. The fan may or may not be the terminus of the system, located on the outside of the wall. Common concerns with wall terminations are as follows:

- Discharge from the exhaust system should not be able to enter any fresh-air intake or other opening to any building.
- Adequate clearance to combustibles must be maintained.
- To avoid grease draining down the side of the building, duct sections should pitch back to the hood inside, or a grease drain should be provided to drain grease back into a safe container inside the building.
- Discharge must not be directed downward or toward any pedestrian areas.
- Louvers should be designed to minimize their grease extraction and to prevent staining of the building facade.

Recirculating Systems. With these units, it is critical to keep components in good working order to maintain optimal performance. Otherwise, excessive grease, heat, and odors will accumulate in the premises.

As with other terminations, containing and removing grease and keeping the discharge as far as possible from combustibles are the main concerns. Some units are fairly portable and could be set in an unsafe location. The operator should be made aware of the importance of safety in locating the unit. These units are best for large, unconfined areas with a separate outdoor exhaust to keep the environment comfortable.

1.12 FIRE SAFETY

The combination of flammable grease vapor and particulates carried by kitchen ventilation systems and the potential of cooking equipment to be an ignition source creates a higher hazard level than normally found in HVAC systems. Design of an exhaust system serving commercial cooking equipment that may produce grease-laden vapors (i.e., a Type I exhaust system) must include a fire suppression system, as required by NFPA *Standard* 96 and the *International Mechanical Code* (IMC; ICC 2018a). The IMC further requires that the fire suppression system comply with the *International Building Code* (IBC; ICC 2018c) and the *International Fire Code* (IFC; ICC 2018d). By further reference, these codes and standards require that automatic fire suppression systems for Type I hoods must be listed to UL *Standard* 300.

Replacement air systems, air-conditioning systems serving a kitchen, and exhaust systems serving cooking equipment that does not produce grease-laden vapor have no specific fire protection requirements beyond those applicable to similar systems not located in kitchens. However, an exhaust system serving any grease-producing cooking equipment must be considered a grease exhaust system even if it also serves non-grease-producing equipment.

Fire safety starts with proper design, followed by proper operation and maintenance of the cooking equipment and the exhaust system, including frequent and thorough cleaning of grease deposits in the area of appliances, and exhaust filters, hoods, and ducts. After that, the three primary aspects of fire protection in a grease exhaust system are (1) to extinguish a fire quickly once it has started, (2) to prevent the spread of fire from or to the grease exhaust system, and (3) to prevent heat transfer to building components from a grease duct fire if the fire-extinguishing system fails. Additionally, UL *Standard* 300 requires that the fire suppression system not disperse burning grease outside the fire zone, and that, after a fire is suppressed by a fire suppression system, it must remain suppressed for at least 20 min.

Solid-Fuel Cooking. When solid-fuel cooking is used in commercial kitchens, fire risk is increased by the formation and deposition of combustible creosote in exhaust systems. Creosote is formed when unburnt vapors from solid-fuel combustion condense in exhaust systems. Creosote production is increased when moisture is present in solid-fuel combustion, such as when green or wet wood is burned, or when solid fuel is burned in the presence of fuel gas combustion products, one of which is water vapor. Chapter 14 of NFPA *Standard* 96 provides extensive requirements for solid-fuel cooking operations. Note that solid-fuel cooking appliances are referred to as “extra-heavy-duty cooking appliances” in the IMC and are defined as those using open-flame combustion of solid fuel at any time during the cooking process.

Fire Suppression Systems

NFPA *Standard* 96 requires that exhaust systems serving grease-producing equipment must include a fire-extinguishing system that protects the cooking equipment, hood interior, hood filters or grease extractors, ducts, and any other grease-removal devices in the system.

Actuation of any fire-extinguishing system must not depend on building electricity. If actuation relies on electricity, it must be supplied with standby power, usually in the form of battery backup.

Listed fire suppression systems must also automatically shut off all supplies of fuel and energy to all equipment protected by that system. Any gas appliance not requiring protection but located under the same ventilating equipment must also be shut off. On operation of an extinguishing system, all electrical sources located under the ventilating equipment, if subject to exposure to discharge from the fire-extinguishing system, must be shut off. If the exhaust system is in a building with a fire alarm system, actuation of the fire-extinguishing system should send a signal to the fire alarm system. With solid-fuel cooking, there is no practical means of stopping combustion of the burning fuel, and consequently, detection, activation, and performance of fire suppression systems are especially important.

Dry and Wet Chemical Systems. Wet chemical and combinations of wet chemical and water fire-extinguishing systems have comprised the majority of fire suppression systems since the publication of UL *Standard* 300 in 1994 and its subsequent citation by codes and standards. Dry chemical systems were popular through the early 1990s, but their use declined because they do not meet the requirements of UL *Standard* 300 and must be replaced with UL *Standard* 300 listed systems. Wet chemical systems are covered in NFPA *Standard* 17A, and though obsolete since UL *Standard* 300 was published, dry chemical systems are covered in NFPA *Standard* 17. Both standards provide detailed application information.

Fire suppression systems are tested for their ability to extinguish fires in cooking operations in accordance with UL *Standard* 300. Wet chemical systems extinguish fires by reacting with fats and grease to **saponify**, or form a soapy foam layer, which prevents oxygen from reaching the burning surface. This suppresses the fire and prevents reignition. Saponification is particularly important with deep fat fryers, where the frying medium may be hotter than its autoignition temperature for some time after the fire is extinguished. If the foam layer disappears or is disturbed before the frying medium has cooled below its autoignition temperature, the fat can reignite.

Frying media commonly used today, which contain a high percentage of vegetable oils, have autoignition points of about 360 to 375°C when new. Contamination and deterioration through normal use lowers the autoignition point. In addition to the formation of a foam blanket instead of a thin layer of powder, another advantage of wet chemical systems over dry chemical systems is that the former cools the frying media, bringing it below the autoignition point more quickly. With solid-fuel cooking, the flash point of liquid creosote ranges from 74 to 92°C and the autoignition temperature for solid creosote ranges from 233 to 360°C. These temperatures suggest that creosote in ducts from solid-fuel cooking can be a greater fire hazard than grease alone.

For a wet chemical system protecting the entire exhaust system, fire-extinguishing nozzles are located over the cooking equipment being protected, in the hood to protect grease-removal devices and the hood plenum, and at the duct collar (downstream from any fire dampers and pointing in the direction of effluent flow) to protect the grease duct.

Two types of nozzle arrangements are common for protecting appliances. Appliance specific coverage is provided by nozzles that are usually directed at the centers of individual appliances. Overlapping coverage is provided by a generally greater number of evenly spaced nozzles. Although overlapping coverage is slightly more expensive to install and maintain, this arrangement solves the common problem of appliances being periodically rearranged under hoods to meet operational needs.

The duct nozzle is rated to protect an unlimited length of duct, so additional nozzles are not required further downstream in the duct. Additional nozzles and piping in ducts would also make periodic duct cleaning more difficult.

Listed fire-extinguishing systems are available as pre-engineered (packaged) systems, installed by authorized exhaust hood manufacturers or local authorized fire suppression system distributors/dealers. In either case, required periodic maintenance of fire suppression systems is performed by local authorized fire suppression system distributors/dealers.

Chemical systems typically consist of one or more tanks of chemical agent, a propellant gas cartridge, piping to the suppression nozzles, fire detectors, and auxiliary equipment. Auxiliary equipment may include manual actuation (“pull”) stations, gas shutoff valves (spring-loaded or solenoid-actuated), and auxiliary electric contacts.

Fire detection is required at the entrance to each duct (or ducts, in hoods with multiple duct takeoffs). The fire detectors are typically fusible links that melt at a set temperature associated with a fire, although electronic detection with battery back-up is also available.

Actuation of chemical suppression systems is typically mechanical, requiring no electric power, by means of a spring-loaded device that pierces the seal on a propellant canister. Fire detectors are typically interconnected with the system actuator by steel cables in tension, so that melting of any fusible links, in series configuration, releases the tension on the steel cables, causing the spring-loaded actuator to release the propellant and force suppressant through pipes and nozzles.

The total length of the steel cable and number of pulley elbows allowed in the detection system are limited. A manual pull station is typically connected to the system actuator by steel cable. If a mechanical gas shutoff valve is used, it is also typically connected to the system actuator by steel cable. System actuation also switches auxiliary dry electrical contacts, which can be used to shut off electrical cooking equipment, operate an electric gas valve, shut off a replacement air fan, keep the related exhaust fan running, and/or send an alarm signal to the building fire alarm system. With electrically actuated fire suppression systems, detection is by electronic temperature sensors, and manual pulls are electric, in place of fusible links, cables, pipes, and pulleys.

Manual pull stations are generally required to be at least 3 m from the cooking appliance and in a path of egress. Some code authorities may prefer that the pull station be installed closer to the cooking equipment for faster response; however, if it is too close, it may not be possible to approach it once a fire has started. Refer to the applicable code requirements for each jurisdiction to determine specific requirements for location and mounting heights of pull stations.

Water Systems. Water can be used for protecting cooking equipment, hoods, and exhaust systems. Standard fire sprinklers may be used throughout the system, except over deep-fat fryers, where special automatic spray nozzles specifically listed for the application must be used. These nozzles must be aimed properly and supplied with the correct water pressure. Many hood manufacturers market a pre-engineered water spray system that typically includes a cabinet containing the necessary plumbing and electrical components to monitor the system and initiate fuel shutoff and building alarms.

Application of standard fire sprinklers for protection of cooking equipment, hoods, and exhaust systems is covered by NFPA *Standard* 13. NFPA *Standards* 25 and 96 cover maintenance of sprinkler systems serving an exhaust system. The sprinklers must connect to a wet-pipe building sprinkler system installed in compliance with NFPA *Standard* 13.

One advantage of a sprinkler system is that it has virtually unlimited capacity, whereas chemical systems have limited chemical supplies. Where sprinklers are used in ducts, the duct should be pitched to drain safely. NFPA *Standard* 13 requires that sprinklers used to protect ducts be installed every 3 m on center in horizontal ducts, at the top of every vertical riser, and in the middle of any vertical offset. Any sprinklers exposed to freezing temperatures must be protected.

Combination Systems. Hoods that use water either for periodic cleaning (water-wash) or for grease removal (cold-water mist) can use this feature in conjunction with the fire-extinguishing system to protect the hood, grease-removal devices, and/or ducts in the event of a fire, if listed to UL *Standard* 300. The water supply for these systems may be from the kitchen water supply if flow and pressure requirements are met. Examples include (1) an approved water-wash or water-mist system to protect the hood in combination with a listed wet chemical system to protect ducts and the cooking appliances (2) a listed chemical fire suppression system in the hood backed up by water sprinklers in the duct, or (3) a listed wet chemical system for appliances, with simultaneous use of a hood water-wash system, with foam-forming chemical injected into the water, for hood plenum and duct.

Hybrid Systems. Several types of hybrid systems have been developed to improve upon conventional fire suppression system designs. One type connects to the domestic water system and then discharges this water on the protected areas following initial activation and wet chemical agent discharge, but it retains fusible links for detection. A second type provides electronic detection in place of fusible links, cables, cable conduit, pulley elbows, and tees, though it retains conventional wet chemical fire suppressant. Another UL *Standard* 300 equivalent system (based on UL *Outline of Investigation* 199E) relies on the water supplied by the building's NFPA *Standard* 13 compliant sprinkler system. Suppression is handled by the activation of sprinklers and hybrid water/aqueous film-forming foam (AFFF) sprinklers directly over the fire location.

Electronic Systems. These systems include electronic detection, activation, monitoring, annunciation of issues with readiness for suppression, and battery back-up. Connection to building management systems or other networks is optionally available. Surfactant is added to the supplied water suppressant to improve water coating of surfaces. Newer systems can also combine cold water and surfactant fire suppression with daily hood and lower duct cleaning by hot water and surfactant. With electronic detection, detectors can be mounted high in ducts, using listed duct penetrations, to better detect fires that autoignite in ducts, such as from solid-fuel cooking and related creosote deposits.

Multiple-Hood Systems. All hoods connected to a multiple-hood exhaust system must usually meet several requirements. In the IMC (ICC 2018a), for example, the hoods must be on the same floor of the building, all interconnected hoods must be in the same room or in adjoining rooms, interconnecting ducts must not penetrate assemblies required to be fire-resistance rated, and the grease duct system must not serve solid-fuel-fired appliances.

The multiple-hood exhaust system must be designed to (1) prevent a fire in one hood or in the duct from spreading through the ducts to another hood and (2) protect against a fire starting in the common duct system. Of course, the first line of protection for the ducts is keeping them clean. Especially in a multiple-tenant system, a single entity must assume responsibility for cleaning the common duct frequently.

Each hood must have its own fire-extinguishing system to protect the hood and cooking surface. A single system might serve more than one hood, but in the event of fire under one hood, the system would discharge its suppressant under all hoods served, resulting in unnecessary cleanup expense and inconvenience. A water-mist system could serve multiple hoods if sprinkler heads were allowed to operate independently.

Because of the possibility of a fire spreading through ducts from one hood to another, the common duct must have its own fire extinguishing system. The appendices of NFPA *Standards* 17 and 17A present detailed examples of how common ducts can be protected, either by one system or by a combination of separate systems serving individual hoods. Different types of fire-extinguishing systems may be used to protect different portions of the exhaust system; however, in any case where two different types of system can discharge into the common duct at the same time, the agents must be compatible.

As mentioned earlier, actuation of the fire-extinguishing system protecting any hood must shut off fuel or power to all cooking equipment under that hood, but fuel shutoff is not possible with solid-fuel cooking. When a common duct, or portion thereof, is protected by a chemical fire-extinguishing system that activates from a fire in a single hood, NFPA *Standards* 17 and 17A require shutoff of fuel or power to the cooking equipment under every hood served by that common duct, or every portion of it protected by the activated system, even if there is no fire in the other hoods served by that duct.

From an operational standpoint, it is usually most sensible to provide one or more fire-extinguishing systems to detect and protect against fire in common ducts and a separate system to protect each hood and its connecting ducts. This prevents a fire in the common duct from causing discharge of fire suppressant under an unaffected hood and it allows unaffected hoods to continue operation in the event of a fire under one hood unless the fire spreads to the common duct.

Preventing Fire Spread

The exhaust system must be designed and installed both to prevent a fire started in the exhaust system from damaging the building or spreading to other building areas, and to prevent a fire in one building area from spreading to other parts of the building through the exhaust system. This protection has three main aspects: (1) maintaining clearance from the duct to other portions of the building, (2) either enclosing the duct in a fire-resistance-rated enclosure, or wrapping the duct with a listed fire-rated product, and (3) designing, constructing, and testing to ensure integrity of the duct before and during a fire. These methods are sometimes addressed by a listed insulated grease duct system that incorporates an integral fire resistance.

Clearance to Combustibles. A grease fire can generate gas temperatures of 1100°C or greater in the exhaust hood and duct. In such a grease fire, heat radiating from the hot surface can ignite combustible materials near the hood or duct. Additionally, if the hood or duct is not fully welded and liquidtight as required by codes and standards, grease liquid or vapor leaking from the hood or duct can ignite and spread fire to nearby combustible structure. Most codes require a minimum clearance of 460 mm from the hood and grease duct to any combustible material. However, even 460 mm may not be sufficient clearance to prevent ignition of combustibles in the case of a major grease fire, especially with large volumes of grease in larger ducts.

Several methods to protect combustible materials from the radiant heat of a grease fire and allow reduced clearance to combustibles are described in NFPA *Standard* 96 and the IMC (ICC 2018a). Based on testing and listing of grease ducts provided with integral insulation or wrapped with insulation, NFPA *Standard* 96 and other codes now allow listed insulation to be applied to the duct or a listed factory-built grease duct with integral insulation. For hoods, the clearance can be reduced as prescribed.

Listed grease ducts, typically with insulation between double walls or on the outside of single-wall ducts, may be installed with reduced clearance to combustibles in accordance with locally adopted codes and standards, if installed per manufacturers' instructions, which should include specific information regarding the listing. Listed grease ducts are tested and evaluated in accordance with UL *Standard* 1978.

NFPA *Standard* 96 requires a minimum clearance of 75 mm to "limited combustible" materials (e.g., gypsum wallboard on metal studs). The IMC (ICC 2018a) allows reduced clearance of ducts to 75 mm in proximity to noncombustibles on noncombustible structure, such as gypsum wallboard on metal studs. Clearance reduction is also available for hoods, but may differ by local code, so local codes and standards should be consulted accordingly.

Note that clearance-to-combustible issues are often seen in inspections of restaurant sites after grease fires. Many instances of inappropriate clearance reduction have been seen in which gypsum wallboard was mistakenly applied to wood studs and joists. In many of these cases, surrounding structure was ignited by heat from a grease fire, in spite of the gypsum wallboard barrier. The issue here is autoignition of the combustible material behind the gypsum wallboard from the high heat of the grease fire, even in cases where the gypsum wallboard layer is intact after the fire. Note that in some codes and standards, gypsum board is considered to be a combustible or limited-combustible material.

A simple means of complying with most building codes and standards' clearance requirements is the specification and installation of metal beams, joists, studs, and trusses within 457 mm of appliances, hoods, and ducts.

Enclosures. Normally, when a HVAC duct penetrates a fire-resistance-rated wall or floor, a fire damper is used to maintain the integrity of the wall or floor. Because fire dampers cannot be installed in a grease duct unless specifically approved for such use, there must be an alternative means of maintaining the integrity of rated walls or floors. Therefore, grease ducts that penetrate a fire-resistance-rated wall or floor/ceiling assembly must be continuously enclosed in a fire-rated enclosure from the point the duct penetrates the first fire barrier until the duct leaves the building. Listed grease ducts are also subject to these enclosure requirements. The requirements are similar to those for a vertical shaft (typically 1 h rating if the shaft penetrates fewer than three floors, 2 h rating if it penetrates three or more floors), except that the shaft can be both vertical and horizontal. In essence, the enclosure extends the room containing the hood through all the other compartments of the building without creating any unprotected openings to those compartments.

Where a duct is enclosed in a rated enclosure, whether vertical or horizontal, clearance must be maintained between the duct and the shaft. NFPA *Standard* 96 and the IMC (ICC 2018a) require a minimum 150 mm clearance and that the shaft be vented to the outdoors. IMC requires that each exhaust duct have its own dedicated enclosure.

Some listed grease ducts are designed and tested for use without shaft enclosure. Listed grease ducts of this type use fire barrier insulation and provide integral fire-rated resistance, which serves the same function as the shaft enclosure. These products are tested and listed in accordance with UL *Standard* 2221. They must be installed in accordance with the manufacturer's installation instructions.

Some insulation materials are listed to serve as a fire-resistance-rated enclosure for a grease duct when used to cover a duct. These insulations are tested and listed in accordance with ASTM *Standard* E2336. These listed insulations must be applied in accordance with the manufacturer installation instruction.

Insulation materials that have not been specifically tested and approved for use as fire protection for grease ducts should not be used in lieu of rated enclosures or to reduce clearance to combustibles. Even insulation approved for other fire protection applications, such as to protect structural steel, may not be appropriate for grease ducts because of the high temperatures that may be encountered in a grease fire.

Duct Integrity. Ducts must retain integrity and stability during a grease fire so that the fire does not spread through unintended openings (poor welds or duct collapse). Factory-built stainless steel ducts are tested and listed to UL *Standards* 1978 and 2221 and are often dual listed to other high-temperature related all-fuel chimney standards (UL *Standards* 103 and 2561). A listed duct system is recommended for exhaust systems that are four stories in height or greater. Specification of listed ducts is recommended for all exhaust systems serving solid-fuel cooking. The model codes require testing for all duct joint/seam leakage, though for listed ducts, this testing is only required for duct joints assembled in the field.

Exhaust and Supply Fire-Actuated Dampers. Because of the risk that the damper may become coated with grease and become a source of fuel in a fire, balancing and fire-actuated dampers are not allowed at any point in a exhaust system except where specifically listed for use or required as part of a listed device or system. Typically, fire dampers are found only at the hood collar and only if provided by the hood manufacturer as part of a listed hood.

Opinions differ regarding whether any fire-actuated dampers should be provided in the exhaust hood. On one hand, a fire-actuated damper at the exhaust collar may prevent a fire under the hood from spreading to the exhaust duct. However, like anything in the exhaust airstream, the fire-actuated damper and fusible link may become coated with grease if not properly maintained, which may impede damper operation. On the other hand, without the fire-actuated damper, the exhaust fan draws smoke and fire away from the hood. Although this cannot be expected to remove all smoke from the kitchen during a fire, it can help to contain smoke in the kitchen and minimize migration of smoke to other areas of the building.

A fire-actuated damper will generally close only in the event of a severe fire; most kitchen fires are extinguished before enough heat is released to trigger the fire-actuated damper. Thus, the hood fire-actuated damper remains open during relatively small fires, allowing the exhaust system to remove smoke, but can close in the event of a severe fire, helping to contain the fire in the kitchen area.

Fan Operations. If replacement air flow rates exceed 940 L/s, the replacement air supply to the kitchen might be required by some codes and standards to be shut down during fire to avoid feeding air to the fire. However, if the exhaust system is intended to operate during a fire to remove smoke from the kitchen (as opposed to just containing it in the kitchen), the replacement air system must operate as well. If the hood has an integral (internal) replacement air plenum such as with short-circuit hoods, a fire-actuated damper must be installed in the replacement air plenum to prevent a fire in the hood from entering the replacement air duct. NFPA *Standard* 96 details the instances where fire-actuated dampers are required in a hood replacement air plenum.

Regardless of whether fire-actuated dampers are installed in the exhaust system, NFPA *Standard* 96 calls for the exhaust fan to continue to run in the event of a fire unless fan shutdown is required by a listed component of the exhaust system or of the fire-extinguishing system. Listed fire-extinguishing systems protecting ducts are tested both with and without airflow, and exhaust airflow is not necessary for proper operation.

Control Systems. The IMC (ICC 2018a) requires that Type I (grease and smoke) hoods be designed and installed to automatically activate related exhaust fans whenever cooking operations occur.

1.13 SYSTEM COMMISSIONING AND AIR BALANCING

ANSI/ASHRAE/IES *Standard* 202 defines commissioning as "a quality-focused process for enhancing delivery of a project. The process focuses upon verifying and documenting that all of the commissioned systems and assemblies are planned, designed, installed, tested, operated, and maintained to meet the owner's project requirements."

For commercial kitchen ventilation (CKV), commissioning may involve validation of system components that are designed, supplied, and/or installed by multiple design professionals, vendors and building trades. This chapter's sections on Commissioning and Ventilation Design include steps that may be used to develop the owner's project requirements (OPR), including system design and installation.

It is not unusual for CKV systems to be treated as independent building systems, even though these systems can affect the safety and IEQ (including comfort and odor control) of the entire facility. Some locations may limit the effects the CKV system is allowed to have on the outdoor environment surrounding the facility. Given the CKV system's potential impacts, it is critical the OPR identifies responsibilities for system performance and its impacts on the facility and its environments. Refer to the System Integration and Design section of this chapter for more information.

Air Balancing

Kuehn (2010) demonstrated that a high degree of correction is required to achieve accurate airflow measurements with many of the instruments commonly used in the field to balance hood systems. Because of the level of correction required, hot-wire anemometers are not recommended. Therefore, balancing is best performed when the manufacturers of all system components provide a certified reference method of measuring the airflow of their equipment, rather than depending on generic measurements of duct flows or other forms of measurement in the field, which, again, can be erroneous. The equipment manufacturer should be able to develop a reference method of measuring airflow in a portion of the equipment that is dynamically stable in the laboratory as well as in the field. This method should relate directly to airflow by graph or formula.

Basic tools for balancing include the following:

- Volumetric flow hood
- Rotating vane anemometer
- Velocity grid
- Pitot tube/anemometers
- Manometer/pressure meter
- Voltage/amperage meter(s)
- Tachometer

Using instruments with current calibration certification or new instruments is recommended.The general steps for air balancing in restaurants are as follows:

1. Verify all exhaust and HVAC equipment is installed correctly and operating correctly, including (but not limited to) verifying that exhaust ducts are fully welded and inspection doors are in place, HVAC and supply ducts are complete and sealed, fans are rotating the correct direction, all exhaust hood grease filters are installed and properly sized, and thermostats are set up correctly and set to on or occupied mode.
2. Tabulated results of measurements should be kept and used to create a balance chart to show the building's net exfiltration or infiltration.
3. Exhaust hoods should be set to their proper flow rates, with supply and exhaust fans on.
4. Next, supply airflow rate, whether part of combined HVAC units or separate replacement air units, should be set to design values through the coils and the design supply flows from each outlet, with approximately correct settings on the outdoor airflow rate. Then, correct outdoor and return airflow rates should be set proportionately for each unit, as applicable. These settings should be made with exhaust on, to ensure adequate relief for the outdoor air. Where outdoor air and return air flows of a particular unit are expected to modulate, there should ideally be similar static losses through both airflow paths to preclude large changes in total supply air from the unit. Such changes, if large enough, could affect the efficiency of heat exchange and could also change airflows within and between zones, thereby upsetting air distribution and balance. See Chapter 39 for general HVAC testing, adjusting, and balancing information.
5. Next, outdoor air should be set with all fans (exhaust and supply) operating. Pressure difference between indoors and outdoors should be checked to confirm that (1) nonkitchen zones of the building are at a positive pressure compared to outdoors and (2) kitchen-zone pressure is negative compared to the surrounding zones, and positive or neutral compared to outdoors.
6. For applications with DCKV systems, proper capture and containment, as well as differential pressures between zones and atmosphere, should be confirmed at minimum and at maximum flow rates. This requires that the replacement airflow rate compensate automatically with each increment of exhaust. It may require some adjustments in controls or in damper linkage settings to get the correct proportional response.

System Tests

Cooking Exhaust Duct Leakage. ASHRAE *Standard* 154 outlines methods of test for exhaust system duct leakage. In most installations, the hood, exhaust fans, and replacement air equipment will be listed and labeled for its intended use. Exhaust duct systems may be field fabricated or listed factory-built systems. Either system requires joining sections in the field and may include field-installed cleanouts and inspections ports. It is critical to the fire safety of the facility and the performance of the CKV system that these duct systems be tested to assure they are properly installed. See Chapter 19 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for information on HVAC duct construction and leakage criteria.

Fire Suppression. Like the duct system, the hood fire suppression system requires some field work to complete the system installation. Typically, the local AHJ requires an operating test of the installed suppression system. Test requirements vary. If the local AHJ does not require such a performance test of the completed system, the OPR should specify that such a test be conducted.

DCKV. When a DCKV system is installed to control the CKV systems, a system test should be conducted. This test should include the full range of the DCKV modulation, including the effects on exhaust and replacement air system performance throughout that full range. Examples include, at DCKV modulation extremes, (1) heating/cooling performance, (2) effective airflow distribution, and (3) maintaining proper pressure balance between the kitchen, adjacent spaces, and atmosphere.

Building Automation System. The CKV system for controlling the temperature and proper pressurization of food preparation spaces and zones must be tested to ensure it operates properly as designed. If other spaces and zones outside of the food preparation zone provide replacement air for the CKV system, then they must also be tested to ensure their proper operation.

Performance Test

After initial airflows are verified to be at design values and the building is balanced, a performance evaluation of all exhaust hoods should be performed to verify capture and containment (C&C) at the design conditions. ASHRAE *Standard* 154 outlines performance test methods.

Conduct Type I and II hood field testing with all appliances under the hood at operating temperatures, with all the hoods operating at design airflows, with all sources providing replacement air for the hood operating at design airflows, and with all sources of recirculated air in the space operating at design airflows. C&C is verified visually by observing smoke or steam produced by actual cooking or dishwashing operation.

Simulating devices such as smoke candles or smoke puffers are good for detecting air currents moving inward at the lower edge of the hood, but generally do not produce enough smoke to simulate full-load cooking operation. Note that smoke bombs typically create new effluent from a point source, and though they may create a volume of effluent that is equivalent to that of cooking effluent, their use to determine whether actual cooking effluent would be captured by the hood is not always reliable. Actual cooking at the full load or at the highest production rate is the most reliable method of generating smoke. Note that many health department rules for new facilities typically do not allow food to be brought into the facility until all safety and health inspections are complete and approved. Actual cooking may require special arrangements with the AHJ and should be considered in lieu of simulation methods, or as a final method to verify capture as part of the commissioning process for a hood's ventilation system.

Hood systems with DCKV should be tested in auto mode to verify that the system responds appropriately to the changes in cooking operation. Begin with the cooking appliances off and confirm that the system is at minimum airflow. Then, turn cooking appliance on and verify that the airflow increases with increasing temperature. Once the appliances reach cooking temperature, generate smoke through actual cooking and verify C&C or simulation, as described previously. The evaluation should be performed at light, medium, and heavy-load conditions to verify C&C.

If hoods fail the performance test, examine the systems and correct any capture problems. Close attention should be given to the design considerations and guidelines in this chapter to correct any performance problems.

Follow-Up: Records

1. A punch list of any remaining issues encountered during installation, air balancing, or performance testing should be recorded and submitted to the facility management and any affected contractors so that these items can be corrected.
2. When the preceding steps are complete, the system is properly integrated and balanced. At this time, all fan speeds and damper settings (at all modes of operation) should be permanently marked on the equipment and in the test and balance report. Air balance records of exhaust systems, replacement air systems, HVAC supply and return serving the hood area, and individual diffuser and/or grille airflows must also be completed. If the unit includes a fan, records must include fan or unit model(s) and size(s), fan wheel and motor rpm, and fan motor amp draw. These records should be kept by the food service facility for future reference.
3. For new facilities, after two or three days in operation, all belts in the system should be checked and readjusted to correct new belt run-in wear. This examination should take place no later than a week after initial operation, and before the facility opens if possible. Obviously, direct-drive systems do not require this inspection or replacement.
4. Once the facility is operational, check performance of the ventilation system to verify that the design is adequate for actual cooking operation, particularly at maximum cooking and at outdoor environmental extremes. Any necessary changes should be made, and all the records should be updated to show the changes.
5. Rechecking the air balance should not be necessary more than once every two years. If there are any changes, such as adding a new type of cooking equipment or deleting exhaust connections, the system should be modified, rebalanced, and retested accordingly. Recommend a rebalance/retest whenever components of the kitchen ventilation and HVAC systems are replaced/modified (e.g., when an exhaust or supply fan is replaced or when supply/return air outlets are added or relocated within the kitchen). The system should also be rebalanced/retested whenever a cooking appliance is relocated or replaced with an appliance of different function. For example, if a fryer was replaced with a broiler, the ventilation would have to be rebalanced and retested for the broiler. Modifications should be recorded, added to owner's records, and marked on affected equipment.
6. All final operational measurements and recording shall be retained as a reference for future energy audit field surveys.

1.14 OPERATIONS AND MAINTENANCE

Sustainability Impact

Proper operation and maintenance of all kitchen ventilation systems is an often overlooked requirement, but is one of the most critical, especially given the large amount of resources used in CKV operation. Typically, most attention is focused on the production of food, which is the primary role of any commercial kitchen. Given the kitchen ventilation system's role in providing replacement air, heating and cooling, and cooking effluent extraction, ensuring it is properly operated and maintained is critical for minimizing both overall system energy use and any environmental impacts both inside and outside the restaurant caused by effluent produced during cooking. Systems that are not operated or maintained correctly are likely to consume excessive energy, may create uncomfortable conditions in the kitchen area, may create an environmentally hazardous condition in the kitchen (e.g., hoods that do not capture and contain cooking effluent), and may affect outdoor environmental conditions (e.g., when pollution control devices are not operating properly). Additionally, given the fire hazards associated with commercial cooking, improper operation and maintenance of a kitchen's ventilation system(s) can even create a life safety hazard. Maintaining a proper air balance is part of a kitchen ventilation system's necessary maintenance. See Chapter 40 for more information on the costs associated with building operations and maintenance.

Finally, as part of any total commissioning process, the impact of operations and maintenance must be taken into account, especially ensuring that any related tasks can be performed with minimal disruption to food service production. If the system's proper operations and associated maintenance are not easily performed, they will most likely be deferred or not performed at all.

Operation

All components of the kitchen's ventilation system, and in some instances the entire building's ventilation system, are designed to operate in balance with each other, even under variable loads, to properly capture, contain, and remove cooking effluent and heat and maintain proper space temperature control in the most efficient and economical manner. Deterioration in any of these components unbalances the system, affecting one or more of its design concepts

The ventilation system's design intent should be fully understood by the owners and operators, so that any deviations in operation can be noted and corrected. *This is especially critical when a DCKV system is used.* In addition to creating health and fire hazards, normal cooking effluent deposits can also unbalance the system, so they must be regularly removed.

All components of exhaust and replacement air systems affect proper capture, containment, and removal of cooking effluent. In the exhaust system, this includes the cooking equipment itself, exhaust hood, all filtration devices, ducts, exhaust fan, and any dampers. In the replacement air system, this includes the air-handling unit(s) with intake louvers, dampers, filters, fan wheels, heating and cooling coils, ducts, and supply registers. In systems that obtain their replacement air from the general HVAC system, this also includes return air registers and ducts.

When the system is first set up and balanced in new condition, these components are set to optimum efficiency. In time, all components become dirty; filtration devices, dampers, louvers, heating and cooling coils, and ducts become restricted; fan blades change shape as they accumulate dirt and grease; and fan belts loosen. In addition, dampers can come loose and change position, even closing, and ducts can develop leaks or be blocked if internal insulation sheets fall down.

All these changes deteriorate system performance. The operator should know how the system performed when it was new, to better recognize when it is no longer performing the same way. This knowledge allows problems to be found and corrected sooner and the peak efficiency and safety of system operation to better be maintained.

Maintenance

Maintenance may be classified as preventive or emergency (breakdown). **Preventive maintenance** keeps the system operating as close as possible to optimal performance, including maximum production and least shutdown. It is the most effective maintenance and is preferred.

Preventive maintenance can prevent most emergency shutdowns and emergency maintenance. It has a modest ongoing cost and fewer unexpected costs. Clearly the lowest-cost maintenance in the long run, it keeps the system components in peak condition, maximizes the system's energy efficiency, and extends the operating life of all components.

Emergency maintenance must be applied when a breakdown occurs. Sufficient staffing and money must be applied to the situation to bring the system back on line in the shortest possible time. Such emergencies can be of almost any nature. They are impossible to predict or address in advance, except to presume the type of component failures that could shut the system down and keep spares of these components on hand or readily accessible, so they can be quickly replaced. Preventive maintenance, which includes regular inspection of critical system components, is the most effective way to avoid emergency maintenance.

Following are brief descriptions of typical operations of various components of kitchen ventilation systems and the type of maintenance and cleaning required to bring the abnormally operating system back to normal. Many nontypical operations are not listed here. Any maintenance should include a check of the building automation system (BAS) as it relates to the kitchen ventilation system to ensure it is operating per its original design.

Cooking Equipment

Normal Operation. Produces properly cooked product, of correct temperature, within expected time. Minimum smoke during cooking.

Abnormal Operation. Produces undercooked product, of lower temperature, with longer cooking times. Increased smoke during cooking.

Cleaning/Maintenance. Clean solid cooking surfaces between each cycle if possible, or at least once a day. Baked-on product insulates and retards heat transfer. Filter frying medium daily and change it on schedule recommended by supplier. Check that (1) fuel source is at correct rating, (2) thermostats are correctly calibrated, and (3) conditioned air is not blowing on cooking surface.

Solid-fuel appliances are listed as "Extra-Heavy Duty" (see Table 4) and require additional attention. A hood over a solid-fuel appliance must be individually vented and therefore not be combined at any point with another duct and fan system. Using a UL *Standard* 762 upblast, in-line, or utility set fan listed to 205 to 260°C is suggested because the airstream temperature may be hotter without cooler air combining from other, typically lower-temperature cooking appliances. Design, installation, and maintenance precautions for the use of and emissions from solid fuel include monthly duct cleaning with weekly inspections, spark arrestors, and additional spacing to fryers. Refer to NFPA *Standard* 96, Chapters 5 to 10 and 14, and IMC, sections 507 and 906, for additional direction.

Exhaust Systems (e.g., Hoods)

Normal Operation. All cooking vapors are readily drawn into the exhaust hood, where they are captured and removed from the space. The environment immediately around the cooking operation is clear and fresh.

Abnormal Operation. Many cooking vapors do not enter the exhaust hood at all, and some that enter subsequently escape. The environment around the cooking operation, and likely in the entire kitchen, is contaminated with cooking vapors and a thin film of grease.

Cleaning/Maintenance. Clean all grease removal devices in the exhaust system. Hood filters should be cleaned at least daily. High-efficiency grease extractors may require frequent cleanings during each shift. For other devices, follow the minimum recommendations of the manufacturer; even these may not be adequate at very high flow rates or with products producing large amounts of effluent. Check that (1) all dampers are in their original position, (2) fan belts are properly tensioned, (3) the exhaust fan is operating at the proper speed and turning in the proper direction, (4) the exhaust duct is not restricted, and (5) the fan blades are clear.

NFPA *Standard* 96 design requirements for access to the system should be followed to facilitate cleaning the exhaust hood, ductwork, and fan. Cleaning should be done if the combustibles' depth is greater than 2 mm in any part of the system, and by a method that leaves no more than a 0.05 mm depth deposit of combustibles. Cleaning agents should be thoroughly rinsed off, and all loose grease particles should be removed, because they can ignite more readily. Agents should not be added to the surface after cleaning, because their textured surfaces merely collect more grease more quickly. Fire-extinguishing systems may only be disarmed by properly trained and qualified service personnel before cleaning, to prevent accidental discharge, and then reset by authorized personnel after cleaning. All access panels removed must be reinstalled after cleaning, with proper gasketing in place to prevent grease leaks and escape of fire.

Supply, Replacement, and Return Air Systems

Normal Operation. The environment in the kitchen area is clear, fresh, comfortable, and free of drafts and excessive air noise.

Abnormal Operation. The kitchen is smoky, choking, hot, and humid, and perhaps very drafty with excessive air noise.

Cleaning/Maintenance. Check that the replacement air system is operating and is providing the correct amount of air to the space. If it is not, the exhaust system cannot operate properly. Check that dampers are set correctly, filters and exchangers are clean, the belts are tight, the fan is turning in the correct direction, and supply and return ductwork and registers are open, with supply air discharging in the correct direction and pattern. If drafts persist, the system may need to be rebalanced. If noise persists in a balanced system, system changes may be required.

Filter cleaning or changing frequency varies widely depending on the quantity of airflow and contamination of local air. Once determined, the cleaning schedule must be maintained.

With replacement air systems, the air-handling unit, coils, and fan are usually cleaned in spring and fall, at the beginning of the seasonal change. More frequent cleaning or better-quality filtering may be required in some contaminated environments. Duct cleaning for the system is on a much longer cycle, but check local codes because stricter requirements are sometimes invoked. Ventilation systems should be cleaned by professionals to ensure that none of the expensive system components are damaged. Cleaning companies should be required to carry adequate liability insurance. The Power Washers of North America (PWNA) and the International Kitchen Exhaust Cleaning Association (IKECA) provide descriptions of proper cleaning and inspection techniques and lists of their members.

Recommended Frequency of Maintenance

Proper preventative maintenance and periodic recommissioning and rebalancing is necessary for achieving the designed performance and life cycle of the CKV systems. The following recommendations are based on field experience:

- Recommission and rebalance CKV systems, at minimum, every five years.
- Recommission and rebalance CKV systems any time changes are made to the CKV equipment, related HVAC equipment, or to the cooking operations. For example, replacing exhaust or makeup fans, relocating supply or return air grilles, relocating cooking equipment, or replacing cooking equipment with equipment of a different function (e.g., a fryer replaced with a broiler). These new or altered systems need to be tested, balanced, and commissioned for the new usage.
- Recommission and rebalance CKV systems any time performance issues arise, such as smoke or heat loss from the kitchen hoods, abnormal space temperatures, high-velocity air currents at pass-through windows, condensation, negative building pressure, etc.
- Performance verification check of all control systems related to the CKV system every two years.
- Capture and containment verification check of kitchen exhaust hoods every year.
- Verify proper outside air quantities every two years.

Preventative maintenance is key to maintaining designed performance and life cycle cost of a CKV system. As grease builds up inside the kitchen exhaust ductwork, so does the static pressure and the corresponding potential for a fire. Depending on the available static that the exhaust fan was selected, pressure loss increase could become more than the fan can handle, which would reduce the required airflow rate, creating poor smoke and heat capture as well as overloading the fan.

2. RESIDENTIAL KITCHEN VENTILATION

Although commercial and residential cooking processes can be similar, their ventilation requirements and procedures are different. Differences include exhaust airflow rate and hood installation height. In addition, residential kitchen ventilation is less concerned with replacement air, and energy consumption is comparatively insignificant because of lower airflow, smaller motors, and intermittent operation.

Equipment and Processes

Although the physics of cooking and the resulting effluent are about the same, residential cooking is usually done more conservatively. Heavy-duty and extra-heavy-duty equipment, such as upright broilers and solid-fuel-burning equipment (described in Table 3), are not used. Therefore, the high ventilation rates of commercial kitchen ventilation and equipment for delivering these rates are not often found in residential kitchens. However, some residential kitchens are designed to operate with commercial-type cooking equipment, with higher energy inputs rates than usually found. In these cases, the required hood may be similar to a commercial hood, and the required ventilation rate may approach that required for small commercial facilities.

Cooking effluent and by-products of open-flame combustion must be more closely controlled in a residence than in a commercial kitchen, because any escaping effluent can be dispersed throughout a residence, whereas a commercial kitchen is designed to be negatively pressurized relative to surrounding spaces. By-products of cooking and natural gas burning processes, such as $PM_{2.5}$, CO_2, CO, and HCHO (formaldehyde), can negatively impact indoor air quality and respiratory health and should be considered during system design. A residence also has a much lower outdoor air ventilation rate, making the presence of any escaped contaminant more persistent. This situation makes residential kitchen ventilation a different kind of challenge, because problems cannot be resolved by simply increasing the ventilation rate at the cooking process. Active research is being conducted to better understand the health risks that can be caused by the effluent produced from residential cooking, and the best means for mitigating those risks.

Residential cooking always produces a convective plume that carries with it cooking effluent, often including grease vapor and particles, as well as water vapor, and by-products of combustion when natural gas is the energy source. Sometimes there is spatter as well, but those particles are so large that they are not removed by ventilation. Residential kitchen hoods depend more on thermal buoyancy than mechanical exhaust to capture cooking effluent and by-products of combustion.

2.1 EXHAUST SYSTEMS

Hoods and Other Ventilation Equipment

Wall-mounted, conventional range hoods ventilate most residential kitchens. There are unlimited style-based variations of the conventional range hood shape. Deep canopy hoods are somewhat more effective because of their capture volume. Other styles have less volume, or a more flat bottom, and may be somewhat less effective at capturing effluent. To the extent that residential range hoods are often mounted between cabinets, with portions of the cabinets extending below the sides of the hood, performance may be improved because the cabinet sides help contain and channel the exhaust flow into the hood.

An increasingly popular development in residential kitchen ventilation is using a ventilating microwave oven in place of the typical residential range hood. Microwave ovens used for this purpose typically include small mesh filters mounted on the bottom of the oven and an internal exhaust fan. Means are usually provided to direct the exhaust flow in two directions: back into the kitchen or upward to an exhaust duct leading outdoors. The latter is more expensive, but highly preferred; otherwise, if directed back to the kitchen, walls, ceiling, and cabinet surfaces are likely to become coated with grease from condensed grease vapor, and grease residue can damage paint and varnish. Additionally, typical microwave oven ventilators do not include vertical surfaces that provide a reservoir volume to contain the convective plume during transient effects, such as removing the lid from a cooking vessel. Consequently, microwave oven ventilators often provide lower exhaust capture and containment performance than standard range hoods.

Downdraft range-top ventilators have also become more popular. Functionally, these are an exception, because they capture contaminants by producing velocities over the cooking surface greater than those of the convective plume. With enough velocity, their operation can be satisfactory; however, velocity may be limited to prevent adverse effects such as gas flame disturbance and cooking process cooling. Additionally, this method is more effective for exhaust from cooking near the range surface, and it is usually much less effective for capturing the convective plume from taller cooking vessels, because the convective plume is too far above the ventilator intake to be affected by it.

Ironically, many high-end kitchens have less efficient ventilation than standard range hoods. Inefficient methods include

- Mounting range tops in cooking islands with no exhaust hood or other means of ventilation
- Mounting ovens in cabinets, separate from rangetops, without any way to remove heat and effluents from the oven
- Using low-profile exhaust devices with insufficient overhang over the appliance and no reservoir to contain convective plume during dynamic effects
- Having duct runs, particularly in larger homes, with very high static pressure losses, so that the actual exhaust flow rate is much lower than the nominal exhaust fan rating

Whole-kitchen exhaust fans were more common in the past, but they are still used. Mounted in the kitchen wall or ceiling, they ventilate the entire kitchen volume rather than capturing contaminants at the source. For kitchen exhaust fans not above the cooking surface, and without a capturing hood, 15 air changes per hour (ach) is recommended; for ceiling-mounted fans, this is usually sufficient, but for wall-mounted fans, it may be marginal.

Residential exhaust hoods are often furnished with multiple-speed fans, so that users can match exhaust fan speeds (and noise) with the cooking process and resultant convective plume. Carrying this concept further, there are high-end residential exhaust hood manufacturers that provide an automatic two-speed control that increases fan speed when higher convective plume temperature is sensed.

Continuous low-level, whole-building ventilation is increasingly used to ensure good indoor air quality in modern, tightly built houses with less infiltration. ASHRAE *Standard* 62.2 requires kitchen ventilation in most residences. Some whole-building ventilation systems can intermittently increase airflow to achieve the needed reduction in cooking effluent. In that case, there must be provision to avoid introducing and accumulating grease and other cooking effluent that may cause undesirable growth of microorganisms.

Differences Between Commercial and Residential Equipment

Safety requirements covering residential cooking area fans are contained in UL *Standard* 507. These fans and accessories are intended for use in conjunction with residential gas and electric cooking appliances only, and are investigated to determine the effects of increased air temperature and grease on electrical components. The filters provided as a part of the fan are also checked for flammability and smoke propagation. Products include hood fans intended to mount directly over (but not directly on) ranges, separate hoods provided with lights or other wiring and intended for use over ranges in conjunction with a remote blower, downdraft fans, and oven ventilators for use over wall-insert ovens. Fans intended for mounting directly on cooking equipment are investigated in conjunction with the cooking appliances, and are typically listed as part of the accessory to the cooking appliance. Fans installed in close proximity to a stove, range, or oven where fumes, grease-laden air, or the like may be present and intended to discharge air away from the cooking area should be installed to discharge air to the exterior of the building and not into concealed walls or ceiling spaces or into the attic. Ductless fans intended for use in cooking areas are not required to discharge air to the building exterior.

Fire-actuated dampers are never part of the hood and are almost never used. Grease filters in residential hoods are much simpler, and grease collection channels are rarely used because inadequate maintenance could allow grease to pool, creating a fire and health hazard.

Conventional residential wall hoods usually have standard dimensions that match the standard 75 mm modular grid of residential cabinets. Heights of 150, 230, 300, and 610 mm are common, as are depths from 430 to 520 mm. Width is usually the same as the cooking surface, with 760 mm width nearly standard in the United States. Current U.S. Housing and Urban Development (HUD) Manufactured Home Construction and Safety Standards call for 75 mm overhang per side.

Hood mounting height is usually 460, 610, or 760 mm, and sometimes even higher with a sacrifice in collection efficiency. A lower-mounted hood captures more effectively because there is less opportunity for lateral air currents to disrupt the convective plume. Studies show 460 mm is the minimum height for cooking surface access. Some codes require a minimum of 760 mm from the cooking surface to combustible cabinets. In that case, the bottom of a 150 mm hood can be 610 mm above the cooking surface.

A minimum airflow rate (exhaust capacity) of 60 L/s per linear metre of hood width has long been recommended by the Home Ventilating Institute (HVI 2004), and confirmed by field tests. Additional capacity, with speed control, is desirable for handling unusually vigorous cooking and cooking mistakes, because airflow can be briefly increased to clear the air, and speed can be reduced to a quieter level for normal cooking.

Recommended minimum exhaust airflow rates vary among model codes. A minimum airflow rate (exhaust capacity) of 60 L/s per linear metre of hood width has long been recommended by the Home Ventilating Institute (HVI 2004), and confirmed by field tests. ASHRAE *Standard* 90.2 requires a minimum exhaust rate of 47 L/s intermittent. IMC (ICC 2018a) requires a minimum exhaust rate of 47 L/s intermittent or 12 L/s continuous. Additional capacity, with speed control, is desirable for handling unusually vigorous cooking and cooking mistakes, because airflow can be briefly increased to clear the air, and speed can be reduced to a quieter level for normal cooking.

In some instances, commercial cooking equipment is used in residential applications. In these instances, special care should be taken for using adequate Type I or Type II exhaust hoods, ducting, and air flow requirements that are more in line with commercial or mechanical codes, because residential codes do not address this scenario.

Exhaust Duct Systems

Residential hoods offer little opportunity for custom design of an exhaust system. The range hood has a built-in duct connector and the duct should be the same size, whether round or rectangular. A hood includes either an axial or a centrifugal fan. The centrifugal fan can develop higher pressure, but the axial fan is usually adequate for low-volume hoods. The great majority of residential hoods in the United States have HVI-certified airflow performance. In all cases, it is highly preferable to vent the exhaust hood outdoors through a roof cap, rather than venting back into the home, whether into the kitchen or elsewhere.

Replacement (Makeup) Air

The exhaust rate of residential hoods is generally low enough and natural infiltration sufficient to avoid the need for replacement air systems. Although this may cause slight negative pressurization of the residence, it is brief and is usually less than that caused by other equipment. Still, backdrafts through the flue of a combustion appliance should be avoided and residences with gas furnace and water heater should have the flue checked for adequate flow. NFPA *Standard* 54 provides a method of testing flues for adequate performance. Sealed-combustion furnaces and water heaters are of less concern.

Sometimes commercial-style cooking equipment approved for residential use is installed in residences. IMC (ICC 2018a) requires that exhaust hood systems capable of exhausting 189 L/s or greater be provided with makeup air at a rate equal to the exhaust rate. Additionally, the makeup air system is to be equipped with a means of closure and operated simultaneously with the exhaust system to ensure proper building pressurization.

High-Rise Systems

Multistory structures with a common exhaust system serving multiple kitchen areas have additional requirements, as detailed in the Domestic Kitchen Exhaust Equipment section of the IMC. Typically, each resident's hood fan discharges into a common exhaust riser duct, at the top of which is a large fan rated for kitchen exhaust duty. A diversity factor is included in the sizing of this duct and fan, because not all of the kitchen hoods will operate simultaneously. Static pressure sensor(s) located in the duct riser controls the speed of this fan so that a small but continuous negative duct pressure is maintained regardless of the number of hoods being operated. Makeup air for this kitchen exhaust is typically provided by a central makeup air unit that serves the entire building's makeup air needs, including those for other exhausts (e.g., toilets, clothes dryers). Commissioning of these makeup and exhaust air systems is required to ensure each area has sufficient exhaust airflow to remove convective heat and effluent generated by the cooking process.

Energy Conservation

The energy cost of residential hoods is quite low because of the few annual running hours and the low rate of exhaust. For example, it typically costs less than $10 per heating season in Chicago to run a hood and heat replacement air, based on running at 70 L/s for an hour a day and using gas heat.

Fire Protection for Residential Hoods

Residential hoods must be installed with metal (preferably steel) duct, positioned to prevent grease pooling. Residential hood exhaust ducts are almost never cleaned, and there is no evidence that this causes fires.

There have been some attempts to make fire extinguishers available in residential hoods, but none has met with broad acceptance. However, grease fires on the residential cooking surface, almost always the result of unattended cooking, continue to occur. There is no industry-accepted standard of design in residential fire-extinguishing equipment. When extinguishing systems are installed over residential range tops, the system should comply with UL *Standard* 300A.

Table 14 Summary of TC 5.10 Research Projects

Year(s)	ASHRAE Project	Title
1993 to 1994	RP-623	A Field Test Method for Determining Exhaust Rates in Grease Hoods for Commercial Kitchens (Gordon and Parvin 1994)
1996 to 1997	RP-851	Determining the Efficiency of Grease-Removal Devices in Commercial Kitchen Applications (Schrock 1998)
1998 to 1999	RP-745	Identification and Characterization of Effluents from Various Cooking Appliances and Processes as Related to Optimum Design of Kitchen Ventilation Systems (Gerstler et al. 1998)
2000 to 2001	RP-1033	Effects of Air Velocity on Grease Deposition in Exhaust Ductwork (Kuehn 2000)
2001 to 2003	RP-1151	Development of a Draft Method of Test for Determining Grease Removal Efficiencies (Welch 2004)
2003 to 2005	RP-1202	Effect of Appliance Diversity and Position on Commercial Kitchen Hood Performance (Swierczyna et al. 2006)
2007 to 2008	RP-1375	Characterization of Effluents from Additional Cooking Appliances (Kuehn 2008)
2008 to 2009	RP-1362	Revised Heat Gain and Capture and Containment Exhaust Rates from Typical Commercial Cooking Appliances (Swierczyna 2008)
2008 to 2010	RP-1376	Method of Test to Evaluate Field Performance of Commercial Kitchen Ventilation Systems (Kuehn 2010)
2008 to 2009	RP-1480	Island Hood Energy Consumption and Energy Reduction Strategies (Swierczyna et al. 2010)
2010 to 2013	RP-1469	Thermal Comfort in Commercial Kitchens (Stoops 2013)
2013 to 2015	RP-1631	Countertop Commercial Appliance Emissions (Zhang 2015)
2017 to present	RP-1614	Developing a Test Method to Determine the Effectiveness of UVC Systems on Commercial Cooking Effluent

Maintenance

All listed hoods and kitchen exhaust fans are designed for cleaning, which should be done at intervals consistent with the cooking practices of the user. Although cleaning is sometimes thought to be for fire prevention, the health benefits of removing nutrients available for the growth of organisms can be more important.

3. RESEARCH

Research Overview

ASHRAE Technical Committee TC 5.10, Kitchen Ventilation, has been active in research related to kitchen ventilation, as shown in Table 14. This research has tended to focus on answering questions related to field-related issues, such as how to measure exhaust airflow rates for hood and replacement air systems (RP-623 and RP-1376) and how much grease is produced by cooking appliances (RP-745 and RP-1375), and a current project is evaluating the grease and heat gain from unhooded countertop cooking appliances (RP-1631). Some of the research focused on design aspects of kitchen ventilation systems, from optimizing exhaust hood performance (RP-1202 and RP-1480), to evaluating the grease removal efficiency of filtering devices (RP-851 and RP-1151) and reducing the velocity of airflow in the exhaust ductwork (RP-1033). Other projects evaluated relationships between appliances and ventilation systems and the HVAC system in the space (RP-1362).

A comprehensive study has been conducted using both field measurements and field surveys regarding thermal comfort in commercial kitchens (RP-1469), and a research project (RP-1614) has been initiated on developing a method of test to determine the effectiveness of UVC systems installed in commercial kitchen ventilation systems.

Benefits to the HVAC Industry

Many of the research projects that TC 5.10 sponsored have affected energy use and sustainability in the food service industry. RP-1033 data showed that grease deposition on the walls of duct actually decreased when the duct velocity was lowered from 7.6 m/s to 2.5 m/s. These data allowed both NFPA *Standard* 96 and the International Mechanical Code (ICC 2009) to allow lower duct velocities. These changes allow demand-controlled ventilation systems (in which airflow is lowered during noncooking periods of the day) to be used across the United States to achieve significant energy savings.

The two projects related to hood performance (RP-1202 and RP-1480) not only evaluated how wall canopy and island hoods perform with various appliances, but also evaluated methods of reducing the exhaust airflows required for the hoods to capture the cooking effluent more efficiently. These include items such as optimizing the appliance position underneath the hoods, installing side panels, and designing hoods to use larger overhangs if possible. If exhaust air is reduced, this also generally reduces how much conditioned air needs to be brought back into the space to replace the air that is exhausted, leading to large energy savings in restaurants. RP-1362 measured the heat gain from appliances underneath hoods, and these data can be used to more accurately size the HVAC equipment needed to condition the kitchen space.

Earlier projects related to grease emissions (RP-851, RP-745, and RP-1151) were used to help develop ASTM *Standard* F2519. Data from these research projects, along with *Standard* F2519 and data from RP-1375, revolutionized the kitchen ventilation industry with regard to how mechanical filters actually perform in the field and the ASTM *Standard* provides a framework for making more efficient filters that help reduce the amount of grease built up in ductwork, on exhaust fans, and on the roof of buildings.

Another project (RP-1631) evaluated the appliance emissions and heat gain to space from countertop commercial cooking appliances to help determine whether these processes require a ventilation hood or can be vented to the space

RP-623 and RP-1376 both examined how to accurately measure the exhaust and replacement air in food service establishments. By being able to more accurately measure the airflows, restaurants can be properly balanced to the design conditions so that excess energy is not consumed.

THE use of geothermal resources can be subdivided into three general categories: ground-source heat pump applications (generally <32°C, which usually require a heat pump to provide useful energy), intermediate- and low-temperature (<150°C) direct-use applications, and high-temperature (>150°C) electric power production. This chapter covers only ground-source heat pumps and intermediate- and low-temperature direct use. Design aspects of the building heat pump loop may be found in Chapter 9 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. GROUND-SOURCE HEAT PUMPS

Ground-source heat pumps (GSHPs) were originally developed to heat and cool residential buildings but are also now widely applied in the commercial sector, with a primary goal of improving energy performance over conventional systems. Many installation recommendations and design guides appropriate to residential design must be amended for large buildings. In large buildings, GSHPs save not only energy but also water, because they often displace cooling towers for cooling. Kavanaugh and Rafferty (2014) provide a more complete overview of design of ground-source heat pump systems. Kavanaugh (1991) and Oklahoma State University (1988a, 1988b) discuss design and installation of ground-source heat pumps in more detail, but their focus is primarily residential and light commercial applications. For comprehensive coverage of commercial and institutional design and construction of ground-source heat pump systems, see ANSI/CSA/IGSHPA *Standard* C448-16.

1.1 TERMINOLOGY

The term **ground-source heat pump (GSHP)** is applied to a variety of systems that use the ground, groundwater, or surface water as a heat source and sink. The general terms include **ground-coupled (GCHP)**, **groundwater (GWHP)**, and **surface-water (SWHP) heat pumps**. Many parallel terms exist (e.g., **geothermal heat pumps [GHPs]**, **geo-exchange**, and **ground-source [GS] systems**) and are used to meet a variety of marketing or institutional needs (Kavanaugh 1992). See Chapter 9, Applied Heat Pump and Heat Recovery Systems, of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for a discussion of the merits of various other non-geothermal heat sources/sinks.

This chapter focuses primarily on the ground heat exchanger portion of GSHP systems, although the heat pump units used in these systems are unique to GSHP technology as well. GSHP systems typically use extended-range water-source heat pump units, in most cases of water-to-air configuration. Extended-range units are specifically designed for operation at entering water temperatures between –5°C in heating mode and 40°C in cooling mode. Units not meeting extended-range criteria are not suitable for use in GSHP systems (except for some groundwater heat pump systems). Some applications (e.g., groundwater loops, deep-surface-water loops, interior core zones of ground-coupled loops when perimeter zones require heating) include a free-cooling mode when water-loop temperatures fall near or below 13°C. This is typically accomplished by inserting a water coil in the return air stream before the refrigerant coil.

Ground-Coupled Heat Pump Systems

The GCHP is a subset of the GSHP and is often called a closed-loop heat pump. A GCHP system consists of a reversible vapor compression cycle that is linked to a closed ground heat exchanger (also called a **ground loop**) buried in soil (Figure 1). The most widely used unit is a water-to-air heat pump, which circulates water or a water/antifreeze solution through a liquid-to-refrigerant heat exchanger and a buried thermoplastic piping network. Heat pump units often include desuperheater heat exchangers (shown on the left in Figure 1). These devices use hot refrigerant at the compressor outlet to heat water. A second type of GCHP is the **direct-exchange configuration (DXGCHP)**, which circulates the refrigerant directly (rather than a secondary heat transfer fluid) in a network of buried copper piping.

The GCHP is further subdivided by whether its ground heat exchanger design is vertical or horizontal. **Vertical GCHPs** (Figure 2) generally consist of two small-diameter, high-density polyethylene (HDPE) tubes placed in a vertical borehole that is subsequently filled with a solid medium. The tubes are thermally fused at the bottom of the bore to a close return U-bend. Vertical tubes range from 20 to 40 mm nominal diameter. Bore depths normally range from 15 to 120 m depending on local drilling conditions and available equipment, but can go to 180 m or more if procedures for deep boreholes are followed (see the section on Pump and Piping System Options). Boreholes are typically 100 to 150 mm in diameter.

To reduce thermal interference between individual bores, a minimum borehole separation distance of 6 m is recommended when loops are placed in a grid pattern. This distance may be reduced when bores are placed in a single row, the annual ground load is balanced (i.e., energy released in the ground is approximately equal to the energy extracted on an annual basis), or water movement or evaporation and subsequent recharge mitigates the effect of heat build-up in the loop field.

The preparation of this chapter is assigned to TC 6.8, Geothermal Heat Pump and Energy Recovery Applications.

Advantages of the vertical GCHP are that it (1) requires relatively small plots of ground, (2) is in contact with soil that varies very little in temperature and thermal properties, (3) requires the smallest amount of pipe and pumping energy, and (4) can yield the most efficient GCHP system performance. Disadvantages are (1) typically higher cost because expensive equipment is needed to drill the borehole and (2) the limited availability of contractors to perform such work.

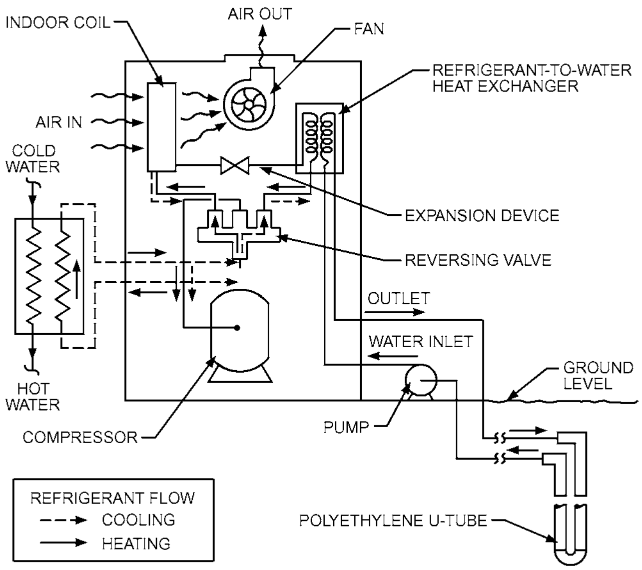

Fig. 1 Vertical Closed-Loop Ground-Coupled Heat Pump System
(Kavanaugh 1985)

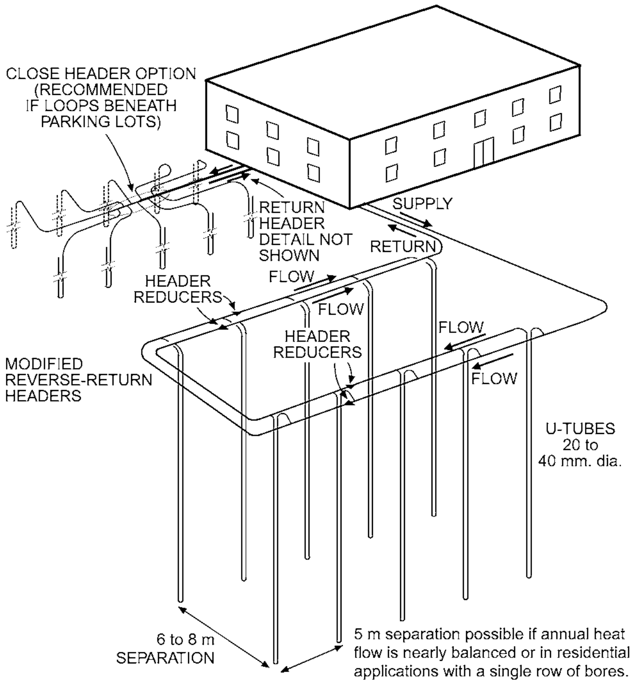

Fig. 2 Vertical Ground-Coupled Heat Pump Piping

Hybrid systems are a variation of ground-coupled systems in which a smaller ground heat exchanger is used, augmented in cooling mode by a fluid cooler or a cooling tower. This approach can have merit in large cooling-dominated applications. The ground heat exchanger is sized to meet the heating requirements. The downsized loop is used in conjunction with the fluid cooler or cooling tower with an isolation heat exchanger to meet the heat rejection load. Using the cooler reduces the capital cost of the ground heat exchanger in such applications, but somewhat increases maintenance requirements. For heavily heating-dominant applications, a downsized loop also can be augmented with an auxiliary heat source such as electric resistance, solar collectors, or fossil fuel.

Horizontal GCHPs (Figure 3) include single-pipe, multiple-pipe, spiral (see Figure 23), and horizontally bored layouts. Single-pipe horizontal GCHPs are placed in narrow trenches at least 1.2 m deep. These designs require the greatest amount of ground area. Multiple pipes (usually two, four, or six), placed in a single trench, can reduce the amount of required ground area. Trench length is reduced with multiple-pipe GCHPs, but total pipe length must be increased to overcome thermal interference from adjacent pipes. The spiral coil further reduces required ground area. These horizontal ground heat exchangers are made by stretching small-diameter polyethylene tubing from the tight coil in which it is shipped into an extended coil that can be placed vertically in a narrow trench or laid flat at the bottom of a wide trench. Recommended trench lengths are much shorter than those of single-pipe horizontal GCHPs, but pipe lengths must be much

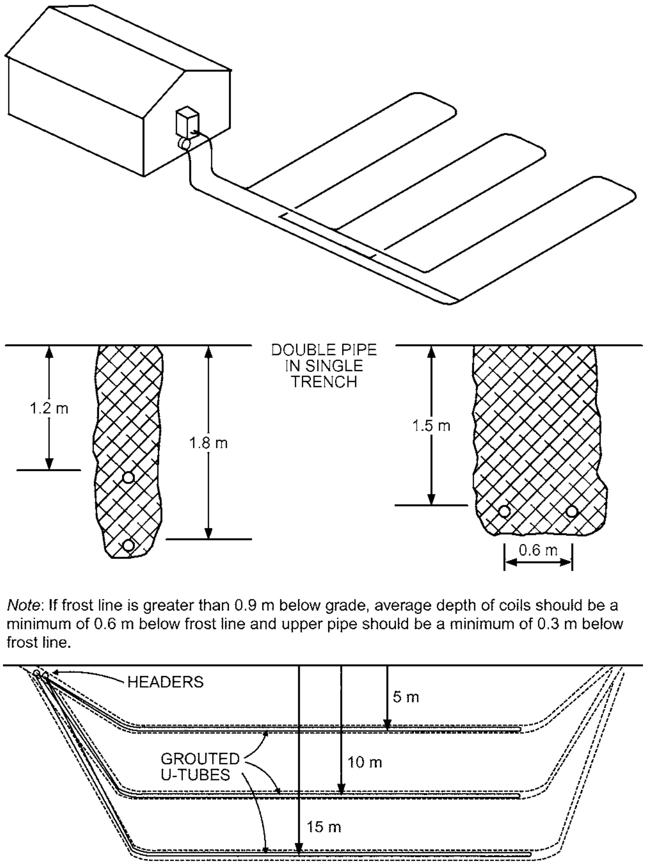

Fig. 3 Trenched Horizontal (top) and Horizontally Bored (bottom) Ground-Coupled Heat Pump Piping

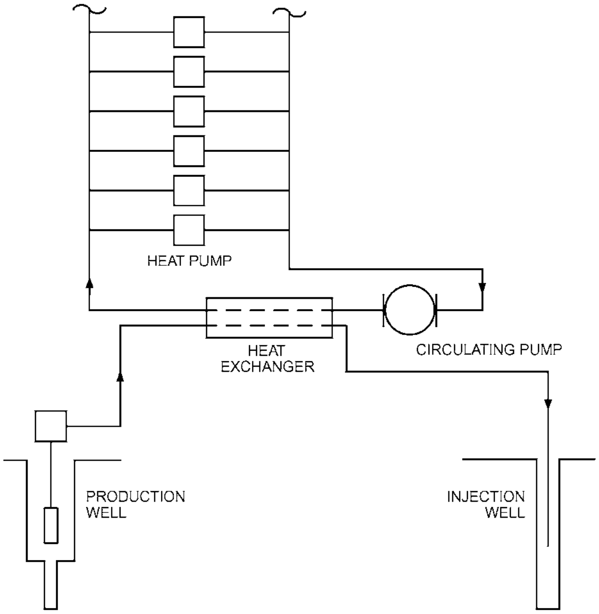

Fig. 4 Unitary Groundwater Heat Pump System

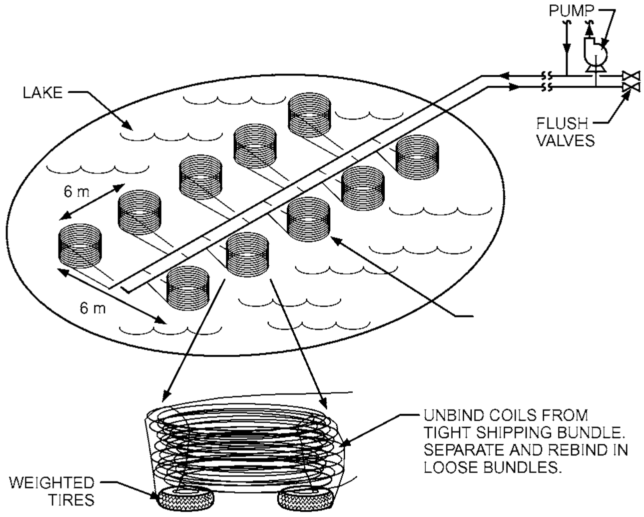

Fig. 5 Lake Loop Piping

longer to achieve equivalent thermal performance. When horizontally bored loops are grouted and placed in the deep earth, as shown in the bottom of Figure 3, design lengths are near those for vertical systems, because annual temperature and moisture content variations approach deep-earth values.

Advantages of horizontal GCHPs are that (1) they are typically less expensive than vertical GCHPs because relatively low-cost installation equipment is widely available, (2) many residential applications have adequate ground area, and (3) trained equipment operators are more widely available. Disadvantages include (1) a larger ground area requirement; (2) greater adverse variations in performance because ground temperatures and thermal properties fluctuate with season, rainfall, and burial depth; (3) slightly higher pumping-energy requirements; and (4) lower system efficiencies. Oklahoma State University (1988a, 1988b), Remund and Carda (2014), and Svec (1990) discuss design and installation of horizontal GCHPs.

Groundwater Heat Pump (GWHP) Systems

The second subset of GSHPs is groundwater heat pumps (Figure 4). Until the development of GCHPs, they were the most widely used type of GSHP. In the commercial sector, GWHPs can be an attractive alternative because large quantities of water can be delivered from and returned to relatively inexpensive wells that require very little ground area. Whereas the cost per unit capacity of the ground heat exchanger is relatively constant for GCHPs, the cost per unit capacity of a well water system is much lower for a large GWHP system. A pair of high-volume wells can serve an entire building. Properly designed groundwater loops with correctly developed water wells require no more maintenance than conventional air and water central HVAC. When groundwater is injected back into the aquifer by a second well, net water use is zero.

One widely used design places a central water-to-water heat exchanger between the groundwater and a closed water loop, which is connected to water-to-air heat pumps in the building. A second possibility is to circulate groundwater through a heat recovery chiller (isolated with a heat exchanger), and to heat and cool the building with a distributed hydronic loop.

Both types and other variations may be suited for direct preconditioning in much of the United States. Groundwater below 15°C can be circulated directly through hydronic coils in series or in parallel with heat pumps. The cool groundwater can displace a large amount of energy that would otherwise have to be generated by mechanical refrigeration.

Advantages of GWHPs under suitable conditions are (1) they cost less than GCHP equipment, (2) the space required for the water well is very compact, (3) water well contractors are widely available, and (4) the technology has been used for decades in some of the largest commercial systems.

Disadvantages are that (1) local environmental regulations may be restrictive, (2) water availability may be limited, (3) fouling precautions may be necessary if groundwater is used directly in the heat pumps and water quality is poor, and (4) pumping energy may be high if the system is poorly designed or draws from a deep aquifer.

Surface Water Heat Pump Systems

Surface water heat pumps are included as a subset of GSHPs because of the similarities in applications and installation methods. SWHPs can be either closed-loop systems similar to GCHPs or open-loop systems similar to GWHPs. However, the thermal characteristics of surface water bodies are quite different than those of the ground or groundwater. Some unique applications are possible, though special precautions may be warranted.

Closed-loop SWHPs (Figures 5 and 36) consist of water-to-air or water-to-water heat pumps connected to a piping network (also called a **surface water loop**) placed in a lake, river, or other open body of water. A pump circulates water or a water/antifreeze solution through the heat pump water-to-refrigerant heat exchanger and the submerged piping loop, which transfers heat to or from the body of water. The recommended piping material is thermally fused HDPE tubing with ultraviolet (UV) radiation protection.

Advantages of closed-loop SWHPs are (1) relatively low cost (compared to GCHPs) because of reduced excavation costs, (2) low pumping-energy requirements, (3) low maintenance requirements, and (4) low operating cost. Disadvantages are (1) the possibility of coil damage in public lakes and (2) wide variation in water temperature with outdoor conditions if lakes are small and/or shallow. Such variation in water temperature would cause undesirable variations in efficiency and capacity, though not as severe as with air-source heat pumps.

Open-loop SWHPs can use surface water bodies the way cooling towers are used, but without the need for fan energy or frequent maintenance. In warm climates, lakes can also serve as heat sources during winter heating mode, but in colder climates where water temperatures drop below 7°C, closed-loop systems are the only viable option for heating.

Lake water can be pumped directly to water-to-air or water-to-water heat pumps or through an intermediate heat exchanger that is connected to the units with a closed piping loop. Direct systems tend to be smaller, having only a few heat pumps. In deep lakes (12 m or more), there is often enough thermal stratification throughout the year that direct cooling or precooling is possible. Water can be pumped from the bottom of deep lakes through a coil in the return air duct. Total cooling is possible if water is 10°C or below. Precooling is possible with warmer water, which can then be circulated through the heat pump units. Large-scale cooling-only systems have been deployed successfully in some locations, including Cornell University and the city of Toronto (Cornell University 2006; Enwave [no date]).

1.2 GENERAL INFORMATION

Site Characterization

Site characteristics influence the type of GSHP system most suitable for a particular location. Site characterization is the evaluation of a site's geology and hydrogeology with respect to its effect on GSHP system design. Important issues include presence or absence of water, depth to water, water (or soil/rock) temperature, groundwater quality, depth to rock, rock type, and the nature and thickness of unconsolidated materials overlying the rock. Information about the nature of water resources at the site helps to determine whether an open-loop system may be possible. Depth to water affects pumping energy for an open-loop system and possibly the type of rig used for drilling closed-loop boreholes. Groundwater temperature in most locations is the same as the undisturbed ground temperature. These temperatures are key inputs to the design of GSHP systems. The types of soil and rock allow a preliminary evaluation of the range of thermal conductivity/diffusivity that might be expected. The thickness and nature of the unconsolidated (soil, gravel, sand, clay, etc.) materials overlying the rock affect whether casing is required in the upper portion of boreholes for closed-loop systems, a factor that increases drilling cost.

After the GSHP system type has been decided, specific details about the subsurface materials' (rock/soil) thermal conductivity and diffusivity, water well static and pumping levels, drawdown, etc., are necessary to design the system. There are many sources for gathering site characterization information: geologic and hydrologic maps, state geology and water regulatory agencies, the U.S. Geological Survey (USGS 2000), and geotechnical studies of the site. Among the best sources of information are completion reports for nearby water wells. These reports are filed by the driller upon completion of a water well and provide a great deal of information of interest for both open- and closed-loop designs. The most thorough versions of well completion reports (level of detail varies by state) cover all of the issues of interest to GSHP designers. Information about access to and interpretation of these reports and other sources of information for site characterization is included in Rafferty (2000a) and Sachs (2002).

Once the type of system has been selected, more site-specific tests (e.g., ground thermal properties test for GCHP, well flow test for GWHP) can be used to determine the parameters necessary for system design. In many areas, ground heat exchangers are regulated by the state or other jurisdictions and under the jurisdiction of a state water rights authority, department of natural resources or environmental quality, or possibly a federal agency such as the U.S. Army Corps of Engineers. The regulation scope may include any type of ground-coupled system. The engineer or designer should be aware of and versed in regulatory issues affecting the project site. More recently, the U.S. Department of Homeland Security has required that certain activities, especially those close to drinking water sources, be excluded or stringently regulated. For security reasons, resource protection zones may not be found in public records archives. The simplest solution may be to contact the permitting authority.

Commissioning GSHP Systems

The design phase of GSHP commissioning requires a thorough site survey and characterization, accurate load modeling, and ensuring that the design chosen (and its documentation) meets the design intent.

The construction phase is dominated by observation of installation and verification of prefunctional checks and tests. It also involves planning, training development, and other activities to help future building operators understand the HVAC system.

The acceptance phase starts with functional tests and verification of all test results. It continues with full documentation: completing the commission report to include records of design changes and all as-built plans and documents, and completing the operations and maintenance manual and system manual. Finally, after system testing and balancing is complete, the owner's operating staff are trained. The acceptance phase ends at substantial completion, at which date the warranty period begins.

Table 1 provides information on tasks and participants involved in the GSHP commissioning process. Additional details on this topic, along with preventive maintenance and troubleshooting information, are included in Caneta Research (2001). Also, per ANSI/CSA/IGSHPA *Standard* C448-16, the contractor must provide the owner with a written maintenance procedure.

Codes and Standards

Current *Uniform Code* and *International Code* revisions now address ground-source heat pump systems. The *Uniform Code* now contains an independent volume, the *Uniform Solar Electric and Hydronic Code* (IAPMO 2015), which discusses ground-source piping for geothermal systems in Chapters 4 (Hydronics) and 7 (Geothermal Energy Systems). The *International Code*'s Chapter 12 (Hydronic Piping) covers geothermal piping and geothermal systems; ground-source specific information is included in the last section (1210). In addition to standards issued by the International Ground Source Heat Pump Association (IGSHPA 2017), the Canadian Standards Association, in conjunction with U.S. industry and professional organizations, has released a binational standard, ANSI/CSA/IGSHPA *Standard* C448-16, which covers most forms of open- and closed-loop GSHP and GWHP systems.

1.3 GROUND-COUPLED HEAT PUMP SYSTEMS USING WATER-BASED HEAT TRANSFER FLUIDS

Ground-coupled heat pumps commonly use a secondary water-based heat transfer fluid to extract/reject heat from/to the ground. The fluid exchanges heat with the refrigerant in the heat pump and circulates through the ground in buried thermoplastic tubing. This section discusses how to design different configurations of the ground heat exchanger, considering building loads and the related zone heat pump operations.

Table 1 Example of GSHP Commissioning Process for Mechanical Design

System	Function	Performed By	Witnessed By
Heat pump piping	Pressure test, clean, and fill	Contractor	A/E
Ground source piping	Pressure test, clean, fill, and purge air; check for compliance with ICC (2012) sections 1207 and 1208	Contractor Contractor	A/E —
Pumps	Inspect, test, and start up	Contractor	—

Vertical Design

This section provides an overview of a suggested design procedure for vertical, ground-coupled systems; related information and equations are discussed in more detail in Kavanaugh and Rafferty (2014). Several public software programs are available for performing the repetitive computations necessary for system optimization. Shonder et al. (1999, 2000) tested the accuracy of these programs, and agreement was attained with several programs in subsequent evaluations.

A more recent publication (Kavanaugh 2008) updates the design recommendations for GCHP systems as follows:

1. Calculate peak zone cooling and heating loads, and estimate off-peak loads.
2. Estimate annual heat rejection into and absorption from the ground heat exchanger to account for potential ground temperature change (see Table 5).
3. Select preliminary loop operating temperatures and flow rate to begin optimization of first cost and efficiency (selecting temperatures near normal ground temperature results in high efficiencies but larger and more costly ground heat exchangers).
4. Correct heat pump performance at rated conditions to actual design conditions (see Table 14)
5. Select heat pumps to meet cooling and heating loads, and locate units to ensure accessibility for maintenance and to minimize duct cost and fan power and noise.
6. Arrange heat pump into ground heat exchanger circuits to minimize system cost, pump energy and electrical demand (see Figures 15 to 17).
7. Conduct site survey to determine ground thermal properties and drilling conditions (see following recommendations).
8. Determine and evaluate possible loop field arrangements that are likely to be optimum for the building and site (bore depth, separation distance, completion methods, annulus grout/fill, and header arrangements); include subheader circuits (typically 5 to 15 U-tubes on each) with isolation valves to allow air and debris flushing of sections of loop field through a set of full-port purge valves.
9. Determine optimum ground heat exchanger dimensions with Equations (4) and (5) or software; one or more alternatives (depth, number of bores, grout/fill material, etc.) that provide equivalent performance may yield more competitive bids.
10. Iterate to determine optimum operating temperatures, flows, loop field arrangement, depth, bores, grout/fill materials, etc.
11. Lay out interior piping and compute head loss through critical path.
12. Select pumps and control method, determine system efficiency, and consider modifying water distribution system if pump demand exceeds 8% of the system total demand or air distribution system if fan demand exceeds 12% of the system total.

Deliverables from this process that are necessary to adequately describe a GCHP installation include, as a minimum,

- Heat pump specifications at rated conditions
- Pump(s) specifications, expansion tank size, and air separator
- Fluid specifications: system volume, inhibitors, antifreeze concentration (if required), water quality, etc.
- Design operating conditions: entering and leaving ground heat exchanger temperatures, return air temperatures (including wet bulb in cooling), airflow rates, and liquid flow rates
- Pipe header details with ground heat exchanger layout, including pipe diameters, spacing, and clearance from building and utilities
- Bore depth and approximate bore diameter
- Piping material specifications, and visual inspection and pressure testing requirements
- Grout/fill specifications: thermal conductivity and acceptable placement methods to eliminate voids
- Purge provisions and flow requirements to ensure removal of air and debris without reinjecting air when switching to adjacent subheader circuits
- Instructions on connecting to building loop(s) and coordinating building and ground heat exchanger flushing
- If applicable, a drilling report from the thermal properties test borehole that includes the type of equipment used (rig, bit, etc.), drilling fluid (air, foam, drilling mud), depth of hole, description of drilled soil or rock, time needed to drill the borehole, any special conditions encountered.
- Sequence of operation for controls

Thermal Property Testing. In the design of vertical GCHPs, accurate knowledge of soil/rock formation thermal properties is

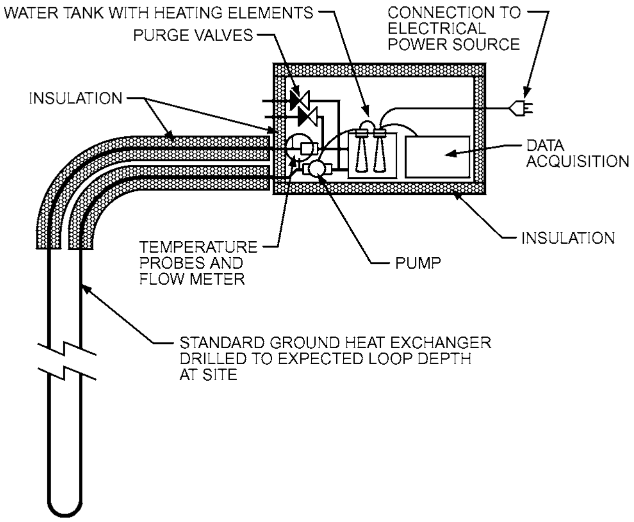

Fig. 6 Thermal Properties Test Apparatus

critical. These properties can be estimated in the field by installing a loop of approximately the same size and depth as the heat exchangers planned for the site. The test loop location should be chosen with care, and designed to be used for the eventual full borefield, especially if geothermal is a likely final system choice (this may require the test loop to meet all local ground heat exchanger standards). Heat is added in a water loop at a constant rate, and data are collected as shown in Figure 6. Inverse methods are applied to find thermal conductivity, diffusivity, and temperature of the formation. These methods are based on either the line source (Gehlin 1998; Mogensen 1983; Witte et al. 2002), the cylindrical heat source (Ingersoll and Zobel 1954), or a numerical algorithm (Austin et al. 2000; Shonder and Beck 1999; Spitler et al. 1999). More than one of these methods should be applied, when possible, to enhance reported accuracy. Recommended test specifications are as follows (Kavanaugh 2000, 2001):

- Thermal property tests should be performed for 36 to 48 h.
- Heat rate should be 50 to 80 W/m of bore, which are the expected peak loads on the U-tubes for an actual heat pump system.
- Standard deviation of input power should be less than ±1.5% of the average value and peaks less than ±10% of average, or resulting temperature variation should be less than ±0.3 K from a straight trend line of a log (time) versus average loop temperature.
- Accuracy of temperature measurement and recording devices should be ±0.3 K.
- Combined accuracy of the power transducer and recording device should be ±2% of the reading.
- Flow rates should be sufficient to provide a differential loop temperature of 3.7 to 7.0 K. This is the temperature differential for an actual heat pump system.
- A waiting period of five days is suggested for low-conductivity soils ($k < 1.7$ W/[m·K]) after the ground heat exchanger has been installed and grouted (or filled) before the thermal conductivity test is initiated. A delay of three days is recommended for higher-conductivity formations ($k > 1.7$ W/[m·K]).
- The initial ground temperature measurement should be made at the end of the waiting period by directly inserting a probe inside a liquid-filled ground heat exchanger at three locations, representing the average, or by temperature measurement as liquid exits the loop during the period immediately after start-up.
- Data collection should be at least once every 10 min.
- All aboveground piping should be insulated with a minimum of 13 mm closed-cell insulation or equivalent. Test rigs should be enclosed in a sealed cabinet that is insulated with a minimum of 25 mm fiberglass insulation or equivalent.
- If retesting a bore is necessary, loop temperature should be allowed to return to within 0.3 K of the pretest initial ground temperature. This typically requires a 10- to 12-day delay in mid- to high-conductivity formations and 14 days in low-conductivity formations if a complete 48 h test has been conducted. Waiting periods can be proportionally reduced if tests are shorter.

Ground Heat Exchanger Sizing. This is perhaps the most critical step in the design of a vertical GCHP. Ground-loop design methods must proceed with limited information; a major missing component is long-term, field-monitored data, which are needed to further validate the design method to address effects of water movement and long-term heat storage more fully. The conservative designer can assume no benefit from water movement; designers who assume maximum benefit must ignore annual imbalances in heat rejection and absorption.

Two design methods are presented in the following section. Both methods have been implemented in design software tools, and are based on the assumption that heat transfer in the ground is governed by conduction only. The **concentric cylinder source** method is based on the solution of the equation for heat transfer from a cylinder buried in the earth. This equation was developed and evaluated by Carslaw and Jaeger (1947) and was suggested by Ingersoll and Zobel (1954) as an appropriate method of sizing ground heat exchangers. Kavanaugh (1985) adjusted the method to account for the U-bend arrangement and hourly heat rate variations. Alternative design methods are described by Eskilson (1987), Morrison (1997), Philippe et al. (2010), Spitler (2000), and Spitler et al. (2000). A second method, attributed to Eskilson, is presented after this first method. Finally, a review of vertical borehole ground heat exchanger design methods has been presented by Spitler and Bernier (2016).

Vertical Ground Heat Exchanger Sizing using the Concentric Cylinder Source Method. The method of Ingersoll and Zobel (1954), based on the following steady-state heat transfer equation, can be used to size vertical ground heat exchangers:

$$q = \frac{L(t_g - t_w)}{R_{ov}} \tag{1}$$

where

q = heat transfer rate, W
L = required total bore length, m
t_g = ground temperature, °C
t_w = liquid temperature, °C
R_{ov} = overall resistance of ground and bore, (m·K)/W

The heat rate delivered to the ground in the cooling mode by the condenser includes the heat of the heat pump and auxiliary equipment. Thus, q_{cond} can be calculated to be

$$q_{cond}/q_{lc} = \frac{\text{COP}_c + 1.0}{\text{COP}_c} \tag{2}$$

where

COP_c = cooling coefficient of performance, W/W
q_{cond} = heat pump condenser heat rejection rate to ground, W
q_{lc} = building design cooling block load, W
q_{lh} = building design heating block load, W

However, the heat of the heat pump and auxiliary equipment in heating mode is delivered to the building. Thus the heat removed from the ground by the evaporator is

Table 2 Thermal Properties of Selected Soils, Rocks, and Bore Grouts/Fills

	Dry Density, kg/m³	Conductivity,* W/(m·K)	Diffusivity, m²/day
Soils			
Heavy clay, 15% water	1920	1.4 to 1.9	0.042 to 0.060
5% water	1920	1.0 to 1.4	0.047 to 0.060
Light clay, 15% water	1280	0.7 to 1.4	0.033 to 0.047
5% water	1280	0.5 to 0.9	0.033 to 0.056
Heavy sand, 15% water	1920	2.8 to 3.8	0.084 to 0.112
5% water	1920	2.1 to 3.3	0.093 to 1.200
Light sand, 15% water	1280	1.4 to 2.1	0.047 to 0.093
5% water	1280	0.9 to 1.9	0.056 to 0.121
Rocks			
Granite	2640	2.2 to 3.6	0.084 to 0.130
Limestone	2400 to 2800	2.4 to 3.8	0.084 to 0.130
Sandstone		2.1 to 3.5	0.065 to 0.112
Shale, wet	2560 to 2720	1.4 to 2.4	0.065 to 0.084
dry		1.4 to 2.1	0.056 to 0.074

Grouts/Backfills	Liquid Density, kg/m³	Conductivity,* W/(m·K)
Bentonite (20 to 30% solids)	1106.1 to 1175.4	0.73 to 0.74
10-25% bentonite/20-50% SiO_2 sand/ 35-55% mix water	1350.4 to 1618.8	0.99 to 1.64
8-12% bentonite/55-65% SiO_2 sand/ 28-34% mix water	1724.2 to 1788.9	1.73 to 2.08
Low-density bentonite/graphite (plus additives)*	1198.3 to 1438.0	1.37 to 2.77
Neat cement (not recommended)	1246.2 to 1773.4	1.52 to 2.77
30% concrete/70% SiO_2 sand (plus plasticizer)	1653.6 to 1917.2	0.69 to 0.78

*Intermediate densities and thermal conductivities can be obtained by mixing silica sand and graphite in different proportions. Contact grout manufacturer for additional information on thermal properties and density of various grout silica sand/graphite mixtures.

$$q_{evap}/q_{lh} = \frac{\text{COP} - 1}{\text{COP}} \tag{3}$$

where q_{evap} is the heat pump evaporator heat extraction rate from ground, W; q_{lh} is the building design heating block load, W; and COP is the heating coefficient of performance, W/W. The design (e.g., peak) block load is the average building load during the block (e.g., a specified time period, usually a few hours) on design day (e.g., worst-case weather and occupancy conditions). Ground heat exchanger design also requires calculation of the monthly part-load factors (PLFs), which are the actual monthly loads divided by the monthly load if the building operated continuously at the design block load. Both the design block load and PLFs can be computed using building simulations or design guidelines (see ACCA [2008, 2016] and Chapters 17 and 18 of the 2017 *ASHRAE Handbook—Fundamentals*).

Equation (1) can be rearranged to solve for the required bore length L. The steady-state Equation (1) is modified to represent the variable heat rate of a ground heat exchanger by dividing the heat transfer q into a series of constant-heat-rate pulses. The thermal resistance R_{ov} is divided into contributions from the ground and borehole. The effective thermal resistance of the ground per unit length is calculated as a function of time corresponding to the time span over which a particular heat pulse occurs (annual R_{ga}, monthly R_{gm}, or peak short-term R_{gst}); the effective resistance is different from a steady-state resistance in that it accounts for the transient heat flow in the ground. The borehole thermal resistance R_b includes the thermal resistance of the pipe wall and interfaces between the pipe and fluid and the pipe and the ground. The resulting equation takes the following form for the required length to satisfy cooling loads:

$$L_c = \frac{q_a R_{ga} + (q_{lc} - W_c)(R_b + \text{PLF}_m R_{gm} + F_{sc} R_{gst})}{t_g - \dfrac{t_{wt} + t_{wo}}{2} - t_p} \tag{4}$$

The required length for heating is

$$L_h = \frac{q_a R_{ga} + (q_{lh} - W_h)(R_b + \text{PLF}_m R_{gm} + F_{sc} R_{gst})}{t_g - \dfrac{t_{wt} + t_{wo}}{2} - t_p} \tag{5}$$

where

F_{sc} = short-circuit heat loss factor
L_c = required total bore length for cooling, m
L_h = required total bore length for heating, m
PLF_m = part-load factor during design month
q_a = net annual average heat transfer to ground, W
R_{ga} = effective thermal resistance of ground (annual pulse), (m·K)/W
R_{gst} = effective thermal resistance of ground (peak short term) 1 to 6 h recommended, (m·K)/W
R_{gm} = effective thermal resistance of ground (monthly pulse), (m·K)/W
R_b = borehole thermal resistance, (m·K)/W
t_g = undisturbed ground temperature, °C
t_p = temperature penalty for interference of adjacent bores, °C
t_{wi} = liquid temperature at heat pump inlet, °C
t_{wo} = liquid temperature at heat pump outlet, °C
W_c = system power input at design cooling load, W
W_h = system power input at design heating load, W

Note: Heat transfer rate, building loads, and temperature penalties are positive for heating and negative for cooling.

Equations (4) and (5) consider three different pulses of heat to account for long-term heat imbalances, average monthly heat rates during the design month, and maximum heat rates for a short-term period during a design day. This period could be as short as 1 h, but a 4 to 6 h block is recommended.

The required total bore length is the larger of the two lengths L_c and L_h calculated with Equations (4) and (5). The heat exchanger will be oversized during the season with shorter calculated L; the resulting increase in efficiency lowers operating costs for that season. However, oversizing the heat exchangers increases first costs, so designers may consider using the shorter calculated L, and supplementing the GSHP system with season-specific equipment (e.g., a cooling tower for cooling, a boiler for heating) to address loads for the season with the longer L. See the section on Hybrid System Design for more information about these configurations.

Thermal resistance of the ground is calculated from ground properties, pipe dimensions, grout/fill thermal conductivity, and operating periods of the representative heat rate pulses. Table 2 lists typical thermal properties for soils and fills for the annular region of the boreholes. Type of fill material depends on thermal, regulatory, and economic considerations. Historically, a relatively low-thermal-conductivity bentonite grout common in the water well industry had been used. More recently, thermally enhanced grouts have been developed to supplement or replace conventional grouts. Thermally enhanced grout has three primary components:

- **Bentonite** provides sealing properties to the mixture and suspends the thermal additive in the bore column to provide uniform heat transfer from top to bottom.
- **Thermal additive** (either silica sand or graphite) improves overall grout thermal conductivity (TC) and subsequent heat transfer capabilities.
- **Mix water** amounts are specified by the manufacturer to ensure that the grout will perform as advertised.

Table 3 Summary of Potential Completion Methods for Different Geological Regime Types

	Grout				Two-Fill with	
Geological Regime Type	**0.6 < k ≤ 1.4 W/(m·K)**	**1.4 < k ≤ 2.1 W/(m·K)**	**k > 2.1 W/(m·K)**	**Backfill with Cuttings or Sand/Gravel Mix**	**Cuttings or Sand/Gravel Mix Below Aquifers**	**Other* Below Aquifers**
Clay or low-permeability rock,

single-aquifer	—	Yes	Yes	—	—	Yes
multiple-aquifer	Yes	Yes	Yes	Yes	Yes	Yes
Permeable rock,						
no shallow aquifers	—	Yes	Yes	Yes	Yes	Yes
single-aquifer	—	Yes	Yes	Yes	Yes	Yes
multiple-aquifers	—	Yes	Yes	Yes	—	—
Karst terrains with secondary permeability	—	Yes	Yes	Yes	—	—
Fractured terrains with secondary permeability	—	Yes	Yes	Yes	Yes	Yes

*Use of backfill material that has thermal conductivity of $k \geq 2.4$ W/(m·K) Yes = Recommended potentially viable backfill methods

As with any engineered product, the components must be mixed according to manufacturer specifications to meet the minimum thermal performance and permeability requirements for a given project.

In some cases, such as when voids, fissures, or caverns are present, drill cuttings or manufactured sand/gravel mixes have been placed instead of bentonite or thermally enhanced grout. Note that placing such fill material from the surface may cause the borehole to bridge, leaving voids or ungrouted sections of the borehole. Also, thermal performance of drill cuttings or manufactured sand/gravel mix is subject to factors such as final placement density and height of the static water table, and is thus difficult to quantify. Because thermal properties of the fill material are critical to overall system performance, use of a tremie pipe to inject grout from the bottom upward is recommended. Nutter et al. (2001) contains a detailed evaluation of potential fills and grouts for vertical boreholes. Also, Jenkins (2009), Sachs (2002), and Skouby (2011) have additional recommendations regarding grout and grout placement.

Table 3 summarizes potential completion methods for various geological conditions. “Two-fill” refers to the practice of placing a low-permeability material in the upper part of the hole and/or at intervals where needed to separate individual aquifers, and a more thermally advantageous material in the remaining intervals. When backfill completion methods are allowed in lieu of pressure-tremie grouting, the designer should be aware that thermal properties and subsequent system performance is subject to final backfill density and the location/height of the static water table, as previously mentioned.

Borehole thermal resistance, from the fluid to the borehole wall, considers the effects of pipe resistance R_p and bore annulus grout resistance R_{grt}:

$$R_b = R_p + R_{grt} \tag{6}$$

Pipe resistance includes the fluid’s convective film resistance and the conductive resistance of the pipe walls. Contact resistances are negligible compared to the high resistance of plastic pipe walls and annular grouts. For a single U-tube (two tubes) the pipe resistance is

$$R_p = (R_{film} + R_{tube})/2 = [1/(\pi d_i h_{conv}) + \ln(d_o/d_i)/2\pi k_p]/2 \tag{7}$$

where h_{conv} is the convection coefficient inside the pipes, k_p is pipe thermal conductivity, d_o is the tube outer diameter, and d_i is the tube inner diameter.

A correlation for the grout’s thermal resistance has been developed using shape factor correlations (Remund 1999):

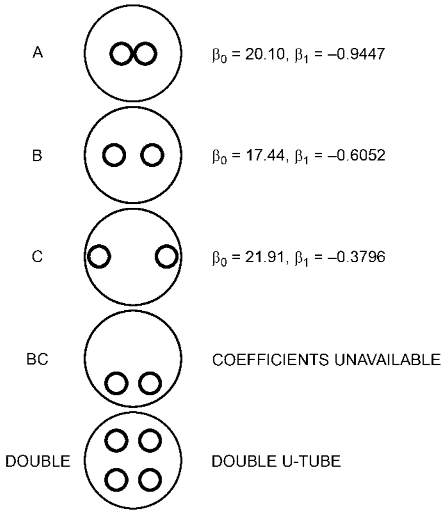

Fig. 7 Coefficients for Equation (8)

$$R_{grt} = \left[\beta_0 \left(\frac{d_b}{d_o}\right)^{\beta_1} \times k_{grt}\right]^{-1} \tag{8}$$

where k_{grt} is the grout’s thermal conductivity and d_b is bore diameter. Coefficients β_0 and β_1 in Equation (8) have been developed for three locations of the tubes, as shown in Figure 7: centered in the bore and in contact each other (A), centered and spaced evenly in the bore (B), and centered and in contact with the bore wall (C). However, the most likely location of the U-tubes is BC, and coefficients for this location are unavailable. A similar but slightly more detailed solution was developed by Hellström (1991) and applied to a few design and simulation tools (Liu 2008; Philippe et. al. 2010). More recently, Javed and Spitler (2017) examined the accuracy of various methods to calculate borehole thermal resistance.

Because locations of U-tubes cannot be determined even when spacers are installed, exact computation of bore thermal resistance values is somewhat uncertain. It is possible to apply the results from thermal property tests to calculate the bore thermal resistance if the U-tube dimensions, grout conductivity, and borehole diameter are known (Kavanaugh 2010). Thermal property tests were conducted at 15 installations where these values were known and the bore resistance was calculated. The field calculated bore resistances best matched the values computed with Equations (6) to (8) using

Table 4 Thermal Resistance of Bores R_b for Locations B, C, and Double

- Location C at 4 (27%) of the sites
- An average of location B and location C at 5 (33%) of the sites
- Location B at 5 (33%) of the sites, and
- Location A at 1 (7%) site

Table 4 provides the bore resistances computed using Equations (6) to (8) for three different grout conductivities, three different fluid flow regimes (Reynolds number = 2000 [laminar], 4000 [transition], and 10 000 [fully turbulent]), three different U-tubes sizes, and three different bore diameters for locations B and C. Resistance is also computed for a double U-tube in a bore. These values were calculated with a value of k_p equal to 0.42 W/(m·K). Designers can choose to use the values of location B (conservative), BC (average), C (risky), or Double.

The most difficult parameters to evaluate in Equations (4) and (5) are the equivalent thermal resistances of the ground. The solutions of Carslaw and Jaeger (1947) require that the time of operation, bore diameter, and thermal diffusivity of the ground be related in the dimensionless Fourier number (Fo):

$$\text{Fo} = \frac{4\alpha_g \tau}{d_b^2} \tag{9}$$

where

α_g = thermal diffusivity of ground, m²/day
τ = time of operation, days
d_b = bore diameter, m

The method may be modified to allow calculation of equivalent thermal resistances for varying heat pulses. A system can be modeled by three heat pulses: a 10 year (3650 day) pulse of q_a, a 1 month (30 day) pulse of q_m, and a 4 h (0.167 day) pulse of q_{st}. Three times are defined as

$$\tau_1 = 3650 \text{ days}$$

$$\tau_2 = 3650 + 30 = 3680 \text{ days}$$

$$\tau_f = 3650 + 30 + 0.167 = 3680.167 \text{ days}$$

The Fourier number is then computed with the following values:

$$\text{Fo}_f = 4\alpha\tau_f / d_b^2$$

$$\text{Fo}_1 = 4\alpha(\tau_f - \tau_1)/d_b^2$$

$$\text{Fo}_2 = 4\alpha(\tau_f - \tau_2)/d_b^2$$

An intermediate step in computing the ground's thermal resistance using the methods of Ingersoll and Zobel (1954) is to identify a G-factor, which is determined from Figure 8 for each Fourier value. The algorithm proposed by Cooper (1976) provides an alternative to using Figure 7.

$$R_{ga} = (G_{\text{Fo}_f} - G_{\text{Fo}_1})/k_g \tag{10}$$

$$R_{gm} = (G_{\text{Fo}_1} - G_{\text{Fo}_2})/k_g \tag{11}$$

$$R_{gm} = G_{\text{Fo}_2}/k_g \tag{12}$$

Correlations for the values of R_{ga}, R_{gm}, and R_{gst} were presented by Philippe et al. (2010) for a wide range of conditions.

Ranges of the ground thermal conductivity k_g are given in Table 4. State geological surveys are a good source of soil and rock data. However, geotechnical site surveys are highly recommended to determine load soil, rock types, and drilling conditions.

Performance degrades somewhat because of short-circuiting heat losses between the upward- and downward-flowing legs of a conventional U-bend loop. This degradation can be accounted for by introducing the short-circuit heat loss factor F_{sc} in Equations (4) and (5), in the following table. Normally U-tubes are piped in parallel to the supply and return headers. Occasionally, when bore depths are shallow, two or three loops can be piped in series. In these cases, short-circuit heat loss is reduced; thus, the values for F_{sc} are smaller than that for a single bore piped in parallel. Alternatively, F_{sc} can be set to 1.0 and thermal short-circuiting can be included in Equations (4) and (5) by replacing R_b with an effective borehole thermal resistance R_b^* (Claesson and Hellström 2011). As noted by Javed and Spitler (2016), R_b^* values start to be significantly different from R_b for long boreholes and low flow rates.

Bores per Loop	F_{sc}	
	0.036 L/(s·kW)	0.054 L/(s·kW)
1	1.06	1.04
2	1.03	1.02
3	1.02	1.01

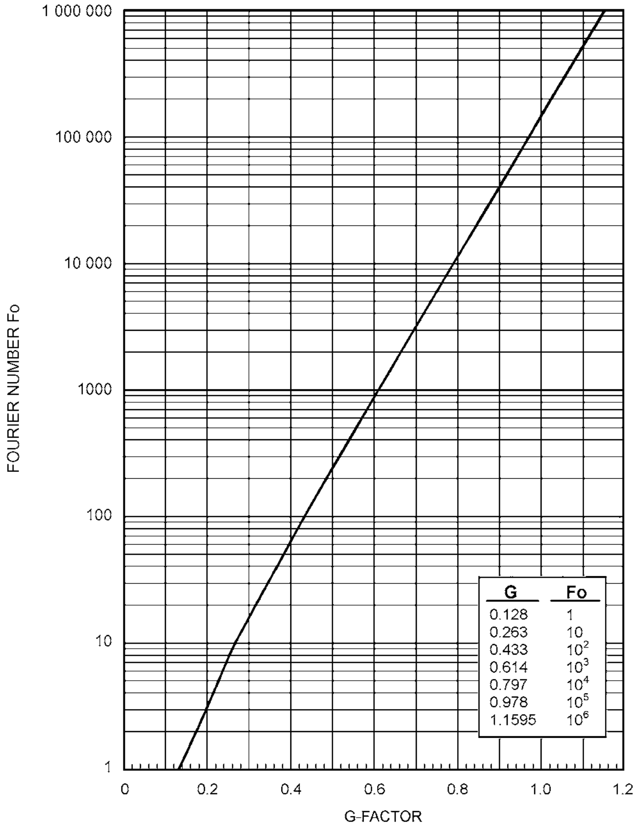

Fig. 8 Fourier/G-Factor Graph for Ground Thermal Resistance
(Kavanaugh and Rafferty 2014)

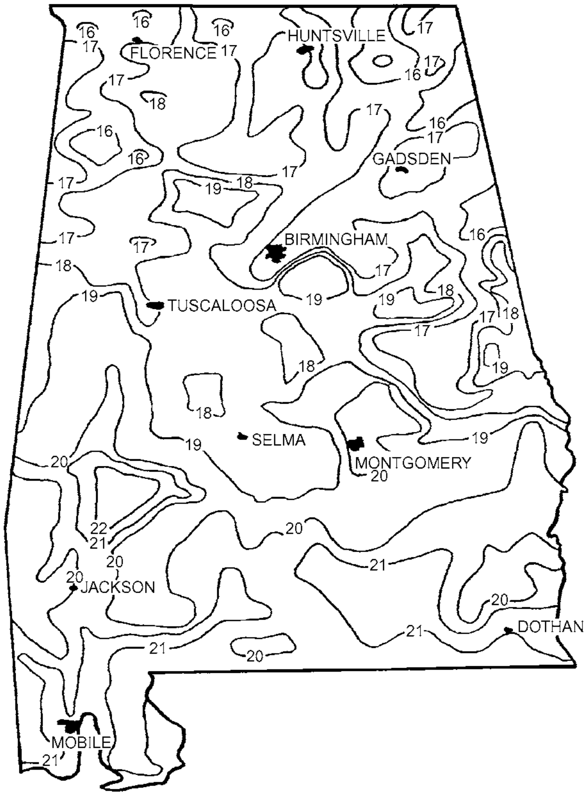

Fig. 9 Water and Ground Temperatures in Alabama at 15 and 45 m Depth
(Chandler 1987)

The remaining terms in Equations (4) and (5) are temperatures. The local deep-ground temperature t_g can best be obtained from local water well logs and geological surveys. A second, less accurate source is a temperature contour map, similar to Figure 9, prepared by state geological surveys. A third source, which can yield ground temperatures within 2 K, is a map with contours, such as Figure 10. Comparing Figures 9 and 10 indicates the complex variations that would not be accounted for without detailed contour maps.

Selecting the temperature t_{wi} of water entering the unit is critical in the design process. Choosing a value close to ground temperature results in higher system efficiency, but makes the required ground coil length very long and thus unreasonably expensive. Choosing a value far from t_g allows selection of a small, inexpensive ground coil, but the system's heat pumps will have greatly reduced capacity and increased electric demand. Selecting t_{wi} to be 11 to 17 K higher than t_g in cooling and 6 to 11 K lower than t_g in heating is a good compromise between first cost and efficiency in many regions of the United States. The value for t_{wo} can be selected by adding/subtracting the temperature change through the heat pump with t_{wi}, where the temperature change is based on the flow rate and heat capacity of the water and the heat rejected/absorbed by the heat pump.

A final temperature to consider is the temperature penalty t_p, which is added to the undisturbed earth temperature to represent the build-up or reduction of thermal energy around each borehole over a period of forecast years. If annual cooling and heating ground loads are balanced, the temperature penalty will be zero. The t_p increases the bore length (L_c, L_h) required to achieve desired performance, and t_p increases for closely spaced boreholes; therefore, the designer must select a reasonable separation distance to balance required land area and bore length. The minimum recommended vertical bore separation distance is 6 m.

The temperature penalty approximation method presented here is adapted from Kavanaugh and Rafferty (2014). The net annual heat transfer into and out of the ground q_a is a key factor. At the initial design phase, q_a can be computed using estimated **equivalent full-load hours (EFLHs)**, which are equal to the annual load divided by the heat pump capacity; final designs should use a more thorough analysis of site loads. In the EFLH method, the ground thermal load at full heat pump capacity is multiplied by the estimated EFLH values corresponding to the location, building type, and internal loads (Table 5), and these values are summed and divided by 8760 h to determine q_a:

$$q_a = \{\text{capacity}[(\text{COP}_c + 1)/\text{COP}_c] \times \text{EFLH}_c + \text{capacity}[(\text{COP}_h - 1)/\text{COP}_h] \times \text{EFLH}_h\}/8760 \text{ h} \qquad (13)$$

where capacity is nominal heat pump capacity, which is positive for heating and negative for cooling, in W.

To the extent that annual loads are proportional to peak loads, the equivalent full-load hours method provides a simple estimate of annual loads from peak loads. The EFLHs in Table 5 provide a quick means to estimate annual loads needed to size ground heat exchangers at the initial feasibility study phase of a project; the final design should use a more thorough analysis of the site loads. Because EFLHs vary with changes in both annual and peak loads, not all building parameters' effects are included in EFLHs. For instance, building operating hours change annual loads by increasing the amount of time that internal gains are at elevated levels, but they do not change the peak load. Occupancy hours can add load without increasing the installed capacity, thereby changing the EFLHs. Furthermore, changes in other parameters,

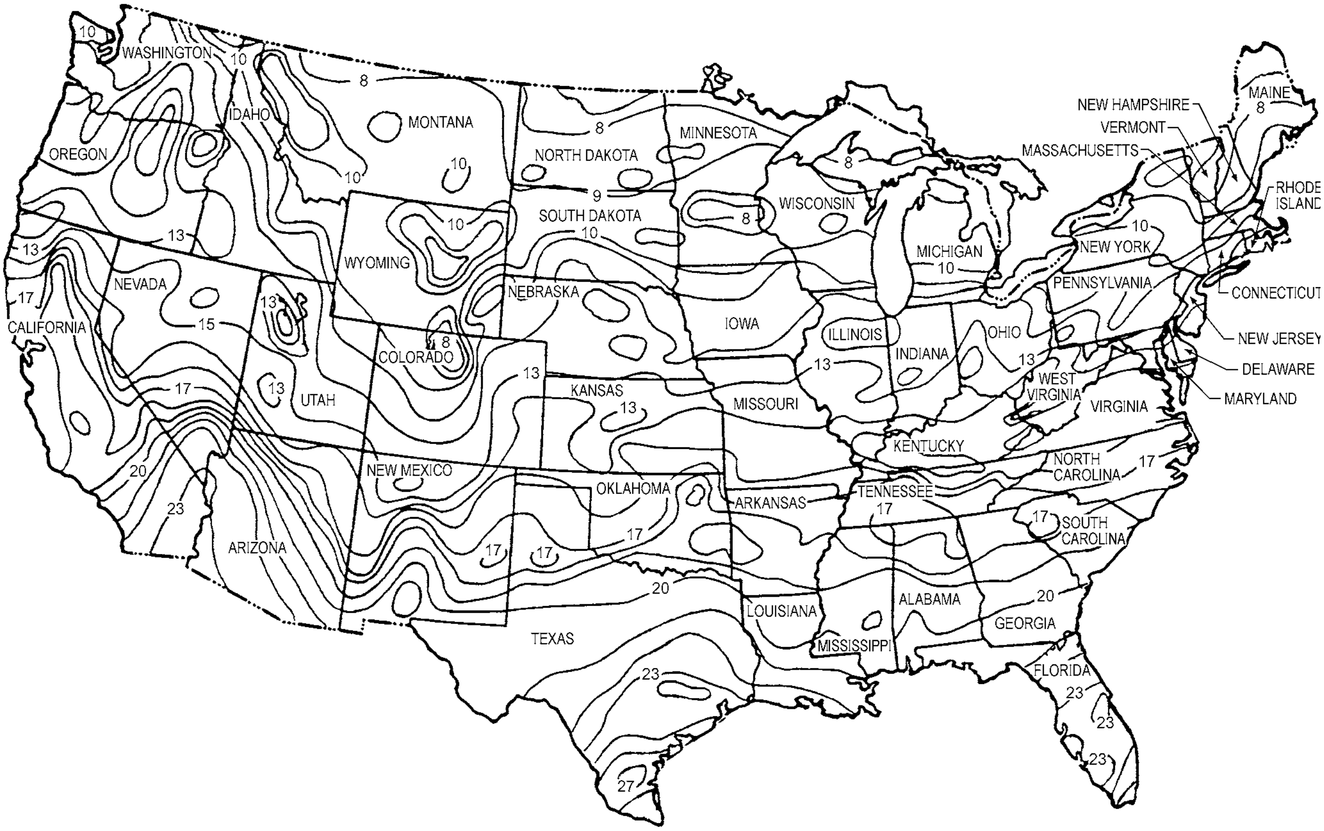

Fig. 10 Approximate Groundwater Temperature (°C) in the Continental United States

such as internal gains, do not necessarily scale with system capacity in the same proportion as annual load, again leading to changing EFLHs. Potential users of EFLHs must understand these sources of variability to use them effectively (Carlson 2001).

Adjacent boreholes thermally interfere with each other, effectively restricting the volume of soil available to diffuse heat from/to the bore. Consider an internal bore surrounded by adjacent bores on all four sides (Figure 11). Assuming equal heat exchange from each bore, an adiabatic symmetry boundary exists at half the separation distance between each bore, $S_{bore}/2$. Net annual energy that would otherwise be diffused beyond the boundary (if the bore were not surrounded by any other bore) is stored in/extracted from and, over time, results in the temperature penalty. The temperature penalty for an internal bore is computed by dividing the stored energy by the heat capacity of the soil within the rectangular prism symmetry boundary:

$$t_{p,\,int} = \frac{Q_{stored}}{\rho c_p S^2_{bore} L} \qquad (14)$$

where

Q_{stored} = energy stored (or extracted from) within adiabatic symmetry boundary, kWh
ρc_p = $k\alpha$ = soil volumetric capacity, kJ/(m³·K)
S_{bore} = bore separation distance, m
L = total bore length (either L_c or L_h), m

An initial guess value is required for L and can be found using Equation (4) or (5) with a reasonable value for t_p (e.g. –6 to 6°C). Values for L and t_p are iterated to find the final solution. The energy that would have otherwise been stored in imaginary hollow cylinders of soil beyond the symmetry boundary is

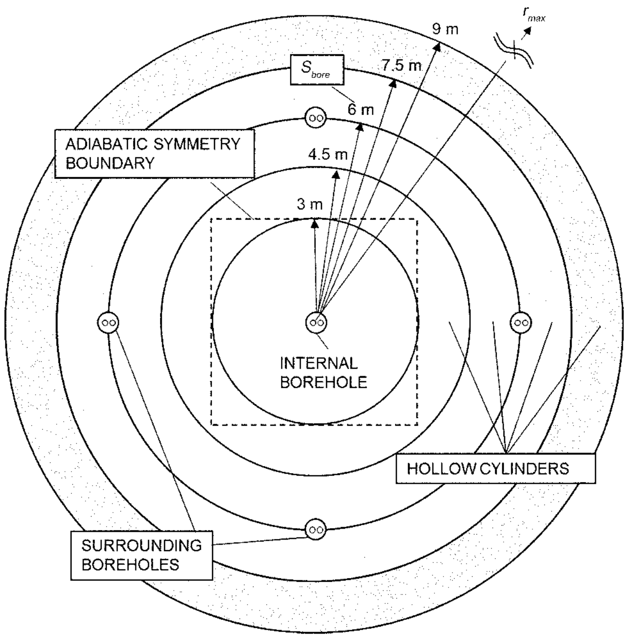

Fig. 11 Representative Soil Cylinders and Adiabatic Symmetry Boundary for Heat Storage

Source: Carlson (2001).
Notes: 1. The ranges in values are from internal gains at 6.5 at 27 W/m^2.
2. Operating with large temperature setbacks during unoccupied periods (effectively turning off the system) reduces heating EFLHs by 20% and cooling EFLHs by 5%.

Equations relating EFLH to Heating and Cooling Degree Days allowing calculation of EFLH for locations other than those listed here can be found in Carlson (2001).

$$Q_{stored} = \sum_{r = S_{bore}/2}^{T_{max}} \rho c_p \pi L(r_o^2 - r_i^2) \times \Delta t_r \qquad (15)$$

where

r_o = outer radius of hollow soil cylinder, m
r_i = inner radius of hollow soil cylinder, m
r_{max} = maximum considered radius
Δt_r = soil temperature change at average radius $r = (r_o + r_i)/2$, °C

Note that, because there is some overlap of the innermost hollow cylinder with the symmetry boundary, the impact of the overlap is neglected. The value for r_{max} is increased until the temperature rise in the outermost cylinder is negligible (<0.3 K); beyond this distance, the storage effect is offset with evaporative cooling and moisture recharge mechanisms. Porous soil with high moisture content may require $r_{max} = S_{bore}$, whereas low-porosity soil may require as much as $r_{max} = 5 \times S_{bore}$ (Kavanaugh and Rafferty 2014). For a nominal configuration (Figure 11) with S_{bore} of 6 m, four hollow cylinders with a 1.5 m width, $r_o - r_i$, gives sufficiently resolved results; other separation distances may require different numbers and width of cylinders. The average soil temperature change for each cylinder is computed at the average radius, $r = (r_o + r_i)/2$, using the line source method (Carslaw and Jaeger 1959; Ingersoll and Zobel 1954; Kavanaugh and Rafferty 2014):

$$\Delta t_r = \frac{q_a I(X)}{2\pi k_g L} \qquad (16)$$

where the $I(X)$ function is formed from the exponential integral; an approximation with less than 1% error for $X < 0.7$ is

$$I(X) = -\frac{1}{2}Ei(-X^2) \approx \ln\left(\frac{1}{X}\right) + \frac{X^2}{2} - \frac{X^4}{8} - \frac{\gamma}{2} \tag{17}$$

where γ is Euler's constant (0.57722....), *Ei* is the exponential integral, and the *X* term is

$$X = \frac{1}{2\sqrt{\text{Fo}}} = \frac{r}{2\sqrt{\alpha_v \tau}} \tag{18}$$

where

$r = (r_o + r_i)/2$, average radius of soil cylinder, m
τ = time duration, days

The value for τ is the designer's choice and can be based on expected groundwater movement; τ_2 (from the preceding Fourier number calculations, value is usually about 10 years) can be used for minimal groundwater movement and vertical percolation of water through the borefield, whereas 365 days can be used for more substantial water movement. Finally, t_p is calculated by prorating $t_{p,int}$ based on the number of bores with a particular adjacency: interior, side, corner, midrow, and end (Figure 12), as well as accounting for heat diffusion at the bottom of the borefield:

$$t_p = \frac{N_{int} + 0.75N_{side} + 0.5N_{corner} + 0.5N_{midrow} + 0.25N_{end}}{(N_{int} + N_{side} + N_{corner} + N_{midrow} + N_{end}) + C_{fHoriz}} \times t_{p,\,int} \tag{19}$$

where

N_{int} = number of interior boreholes, surrounded by four other bores
N_{iside} = number of side boreholes, surrounded by three other bores
N_{corner} = number of corner boreholes, surrounded by two other bores
N_{midrow} = number of boreholes in middle of row, surrounded by two other bores (only for borefield with a single row)
N_{end} = number of end boreholes, surrounded by one other bore (only for borefield with a single row)
C_{fHoriz} = bottom diffusion factor

The bottom diffusion factor is the ratio of surface area of the sides and bottom of the borefield to the surface area of the sides:

$$C_{fHoriz} = \frac{[2L_{bore}(W_{field} + L_{field})] + W_{field}L_{field}}{2L_{bore}(W_{field} + L_{field})} \tag{20}$$

where the individual bore length L_{bore} is found by dividing L by the number of bores. The borefield length and width are

$$L_{field} = S_{bore}(N_{long} - 1) \tag{21}$$

$$W_{field} = S_{bore}(N_{wide} - 1) \tag{22}$$

where the borefield has N_{long} bores in the length direction and N_{wide} bores in the width direction (Figure 12).

Temperature Penalty Uncertainty. Calculating the temperature penalty is one of the more uncertain parts of heat exchanger length selection. Temperature penalties computed using the concentric cylinder source method presented here (Kavanaugh and Rafferty 2014) differ significantly from those obtained using the *g*-function approach (see the section on Alternative Sizing Method, after Example 1), as discussed by Bernier et al. (2008). The *g*-function method accounts for the ground heat conduction with more rigor; it includes both radial and axial heat transfer, rather than only radial heat transfer, and computes the temperature penalty from interfering boreholes at the borehole wall, rather than using the average soil temperature change. Both approaches only consider conductive heat transfer and therefore represent worst-case scenarios, where the actual temperature change is usually mitigated by groundwater recharge (vertical flow), groundwater movement (horizontal flow), and evaporation (and condensation) of water in the soil. Further research is needed to understand which ground heat exchanger sizing method best captures the temperature penalty related to long-term operation in applied systems. Note that, despite the uncertainty in long-term temperature penalty, the concentric cylinder source method has been used in many successful installations of GSHP systems.

Groundwater movement strongly affects long-term temperature change in a densely packed bore field (Chiasson et al. 2000a). A related factor is the evaporative cooling effect experienced with heat addition to the ground. Although thermal conductivity is somewhat reduced with lower moisture content (see Table 2), the net effect is beneficial in porous soils when water movement recharges the ground to original moisture levels. A similar effect may be experienced in cold climates when soil moisture freezes and the heat of solidification mitigates excessive temperature decline. Because these effects have not been thoroughly studied, the design engineer must establish a range of design lengths between one based on minimal groundwater movement, as in very tight clay soils with poor percolation rates, and a second based on the higher rates characteristic of porous aquifers.

Kavanaugh and Kavanaugh (2012a, 2012b) examined ground heat exchanger performance in 40 commercial buildings with vertical ground heat exchangers and between 5 and 25 years of operation. They calculated maximum approach temperature (difference between average loop temperatures t_{wi} and t_{wo} and initial ground temperature t_g) for all of the buildings; higher approach temperatures as years of operation increased would indicate an increase in ground temperature and raise concern about the expected life of ground heat exchangers with imbalanced cooling loads compared to heating loads.

In fact, the data suggested that older GSHP systems had lower approach temperatures. Results were not adjusted for many important factors such as vertical bore length, ground thermal properties, and vertical bore separation distance. Newer systems tended to have slightly shorter ground heat exchangers, but this was offset somewhat by the older systems' tendency to have smaller vertical bore separation distances and lower-conductivity grout and fill. Of the loops with the largest approach, three of the newer systems had vertical bore lengths less than 10.4 m/kW. Two systems with long loops but large approach temperatures had low thermal conductivity grout (0.66 W/[m·K]), 4.6 m bore separation, and indoor air temperatures below 21°C.

The study's data set is small, and significant long-term temperature change cannot be excluded at this point. Although

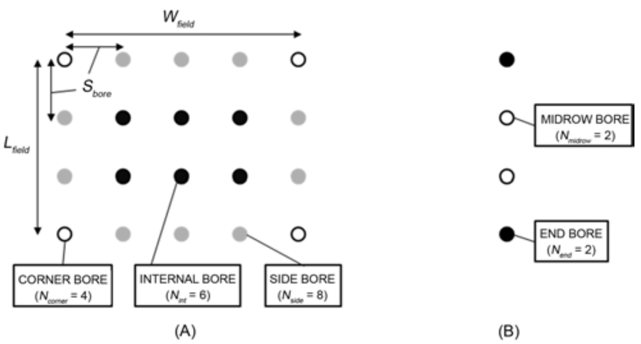

Fig. 12 Borefield with (A) 20 Boreholes, N_{wide} = 5, N_{long} = 4, and (B) 4 Boreholes, N_{wide} = 1, N_{long} = 4 (i.e., Single Row)

much more field study is desirable, the absence of any significant trend of increased ground temperature (noted by elevation of maximum approach temperature) with increased years of GSHP operation suggests that long-term ground temperature change is not prevalent in properly designed GSHPs.

Results from this project cannot be applied to long-term temperature decline in which the amount of heat removed from the ground in heating far exceeds the heat rejected in cooling. In cold climates the heat capacity available at the freeze point of water is significant, but the impact on grout thermal and physical properties also needs further field study.

Example 1. Size a vertical ground-coupled heat pump system for a six-zone classroom addition in Atlanta, GA. The addition has a peak cooling (block) load q_{lc} of 72 kW and a peak heating (block) load q_{lh} of 47 kW. The design monthly part-load factor PLF_m is 0.28.

Ground temperature t_g = 18°C

Ground conductivity k_g and diffusivity a_g = 2.4 W/(m·K), 0.1 m²/day

Bore fill conductivity k_{grt} = 1.7 W/(m·K)

Vertical U-tube = 32 mm, DR11, HDPE, 125 mm borehole diameter

2 × 10 grid (20 vertical bores) with S_{bore} = 6 m separation

Bores per loop = 1, flow is 0.054 L/(s·kW), so F_{sc} = 1.04

Reynolds number = 4000 (transition flow)

Heat pump inlet and outlet temperatures t_{wi} and t_{wo} = 30 and 36°C

Heat pump capacity = 72 kW (maximum of peak block cooling and heating loads)

Heat pump cooling and heating efficiency (COP_c, COP_h) = 4.2, 4.4

10 year (3650 day), 1 month (30 day), and 4 h (0.167 day) heat pulse analysis:

$EFLH_c$ = 760 h, $EFLH_h$ = 245 h (Table 5)

$$q_{cond} = (Q_{lc} + W_c) = q_{lc} \times \frac{COP_c + 1}{COP_c} = -72\text{ kW} \times \frac{4.2 + 1}{4.2}$$

$$= -89.1\text{ kW}$$

$$q_{evap} = (Q_{lh} - W_h) = q_{lh} \times \frac{COP_h + 1}{COP_h} = 47\text{ kW} \times \frac{4.4 - 1}{4.4} = 36.3\text{ kW}$$

$$q_a = \frac{\text{capacity}\left(\frac{COP_c + 1}{COP_c}\right) \times EFLH_c + \text{capacity}\left(\frac{COP_h - 1}{COP_h}\right) \times EFLH_h}{8760}$$

$$= \frac{-72\left(\frac{4.2 + 1}{4.2}\right) \times 760 + 72\left(\frac{4.4 - 1}{4.4}\right) \times 245}{8760} = -6.2\text{ kW}$$

Fo_f = (4 × 0.1 m²/day × 3680.167 days)/(0.125 m)² = 94,200;
from Fig. 8, G_{Fof} = 0.97

Fo_1 = [4 × 0.1 m²/day × (3680.167 – 3650) days]/(0.125 m)² = 772;
from Fig. 8, G_{Fo1} = 0.60

Fo_2 = [4 × 0.1 m²/day × (3680.167 – 3680) days]/(0.125 m)² = 4.28;
from Fig. 8, G_{Fo2} = 0.21

R_{ga} = (0.97 – 0.60)/2.4 W/(m·K) = 0.154 (m·K)/W

R_{gm} = (0.60 – 0.21)/2.4 W/(m·K) = 0.1625 (m·K)/W

R_{gst} = 0.21/2.4 W/(m·K) = 0.088 (m·K)/W

R_b = 0.11 (m·K)/W (average of Locations B and C, interpolated between k_{grout} = 1.4 and 2.1 W/(m·K), transition flow for Re = 4000).

The required total bore length, assuming no long-term ground temperature change (t_p = 0) caused by moisture evaporation and subsequent groundwater recharge through porous soil is

$$L_c = \frac{(-6200 \times 0.154) - 89\ 100(0.11 + 0.28 \times 0.163 + 1.04 \times 0.088)}{18 - \frac{30 + 36}{2} - (-0)}$$

= 1528 m = 1528 m/20 bores = 76 m/bore

For nonporous soils, a temperature penalty is computed. The annual heat imbalance q_a is applied for the 10 years plus one month time duration (3680 days). For the internal bore temperature penalty, the average temperature change for four (the temperature change of a fifth cylinder is less than 0.3 K, so it is not considered) 1.5 m wide hollow cylinders extending beyond the symmetry boundary are computed, beginning with the inner hollow cylinder ($r_i = S_{bore}/2$ = 6/2 m = 3 m, $r_o = r_i$ + 1.5 m = 4.5 m, and $r = [r_o + r_i]/2$ = [4.5 + 3]/2 = 3.75 m):

For r = 3.75 m,

$$X = \frac{r}{2\sqrt{\alpha_g \tau}} = \frac{3.75}{2\sqrt{0.1 \times 3680}} = 0.098$$

$$I(X) = \ln\left(\frac{1}{X}\right) + \frac{X^2}{2} - \frac{X^4}{8} - \frac{\gamma}{2}$$

$$= \ln\left(\frac{1}{0.098}\right) + \frac{0.098^2}{2} - \frac{0.098^4}{8} - \frac{0.5772}{2} = 2.042$$

Repeating for r = 5.25 m: X = 0.137, $I(X)$ = 1.710.

Repeating for r = 6.75 m: X = 0.176, $I(X)$ = 1.464.

Repeating for r = 8.25 m: X = 0.215, $I(X)$ = 1.271.

For the first iteration, a small value of –0.6 K is used as an initial guess, because the building is slightly cooling dominated (recall that negative values are used for cooling loads):

$$L_c = \frac{(-6200 \times 0.154) - 89\ 100(0.11 + 0.28 \times 0.163 + 1.04 \times 0.088)}{18 - \frac{30 + 36}{2} - (-0.6)}$$

= 1592 m, or L_{bore} = 1592 m/20 bores = 80 m/bore

So the average temperature changes of the hollow cylinders are, for the hollow cylinder with r = 3.75 m,

$$\Delta t_r = \frac{q_a I(X)}{2\pi k_g L_c} = \frac{-6200 \times 2.042}{2\pi \times 2.4 \times 1592} = -0.52°C$$

Repeating for r = 5.25 m: Δt_r = –0.44 K.

Repeating for r = 6.75 m: Δt_r = –0.38 K.

Repeating for r = 8.25 m: Δt_r = –0.33 K.

The volumetric heat capacity is $\rho c_p = k_g/\alpha_g$ = 2.4 W/(m·K)/(0.1 m²/day) × 24 h/day = 576 W·h/(m³·K), and the energy stored in the hollow cylinders is

r_o, r_i	$\rho c_p L_c \pi(r_o^2 - r_i^2)\Delta t_r$	Q_{stored}
3.0 m, 4.5 m	576 × 1592π(4.5² – 3.0²)(–0.52)	–17.0 × 10⁶ W·h
4.5 m, 6.0 m	576 × 1592π(6.0² – 4.5²)(–0.44)	–20.0 × 10⁶ W·h
6.0 m, 7.5 m	576 × 1592π(7.5² – 6.0²)(–0.38)	–22.0 × 10⁶ W·h
7.5 m, 9.0 m	576 × 1592π(9.0² – 7.5²)(–0.33)	–23.3 × 10⁶ W·h
		–82.3 × 10⁶ W·h

$$t_{p,int} = \frac{Q_{stored}}{\rho c_p S_{bore}^2 L_c} = \frac{-82.3 \times 10^6}{576 \times 6^2 \times 1592} = -2.5°C$$

$$L_{field} = S_{bore}(N_{long} - 1) = 6\text{ m }(10 - 1) = 54\text{ m}$$

$$W_{field} = S_{bore}(N_{wide} - 1) = 6\text{ m }(2 - 1) = 6\text{ m}$$

$$C_{fHoriz} = \frac{[2L_{bore}(W_{field} + L_{field})] + W_{field} \times L_{field}}{2L_{bore}(W_{field} + L_{field})}$$

$$= \frac{[2 \times 80(6 + 54)] + 6 \times 54}{2 \times 80(6 + 54)} = 1.034$$

$$t_p = \frac{N_{int} + 0.75N_{side} + 0.5N_{corner}}{(N_{int} + N_{side} + N_{corner}) \times C_{fHoriz}} \times t_{p,\,int}$$

$$= \frac{0 + 0.75 \times 16 + 0.5 \times 4}{(0 + 16 + 4) \times 1.034} \times -2.5 = -1.69°\text{C}$$

For the second iteration, this t_p is substituted back into the equation for L_c, which yields 1722 m, and a new corresponding t_p is calculated, –1.56 °C. The solution is fully converged after four iterations with

$$L_c = 1708 \text{ m} \qquad L_{bore} = 85 \text{ m} \qquad t_p = -1.58°\text{C}$$

Repeat the process using Equation (5) to find the bore length for heating L_h. The design bore length is the larger value of L_c and L_h.

Alternative Sizing Method. The traditional concentric cylinder source design method can be solved using a relatively simple procedure, because the effective ground thermal resistances R_{ga}, R_{gm}, and R_{gst} are calculated independent of borehole length. In contrast, the ***g*-function** method, discussed here and used in some software design tools, is more complex and requires a more involved iteration process to evaluate the design length. The benefit of using the *g*-function method is that it accounts for both radial and axial conduction, and effectively applies the long-term temperature penalty to the borehole wall (rather than using the average soil temperature change).

Thermal response factors, also known as ***g*-functions** (not to be confused with the *G*-factor) may be used as an alternative to calculate the ground thermal resistance required in Equations (4) and (5). The concept was first introduced by Eskilson (1987) and extended to short-time steps by Yavuzturk and Spitler (1999). The *g*-functions give a relation between the heat extracted (or rejected) from the ground per unit borehole length q_L and the borehole wall temperature T_b. The borehole wall temperature is given by

$$T_b = T_g - \frac{q_L}{2\pi k_g}\, g(t/t_s, r_b/H, B/H) \qquad (23)$$

where *g* represents the *g*-function. As shown in Equation (23), the *g*-function depends on three non-dimensional parameters: B/H, the ratio of the borehole spacing over the borehole length; r_b/H, the ratio of the borehole radius over the borehole length; and t/t_s, a nondimensional time where t_s is a characteristic time ($= H^2/9\alpha_g$). Typical *g*-functions curves are presented in Figure 13 for a 3 × 2 bore field.

The *g*-function curves are presented graphically in Figure 13 as a function of $\ln(t/t_s)$ for six bore field spacings (B/H) and for a value of r_b/H = 0.0005. The curve for $B/H = \infty$ corresponds to the *g*-function of a single borehole. One of the major advantages of these nondimensional curves is that they apply to any 3 × 2 bore field.

Eskilson (1987) provides *g*-function curves for a number of bore field geometries. Design software tools that use the *g*-function concept have a relatively large data set of *g*-function curves to choose from. Eskilson (1987) calculated *g*-functions using two-dimensional transient finite-difference equations on a radial-axial coordinate system for a single borehole in homogeneous ground. The temperature fields from a single borehole were superimposed in space to obtain the response from a borehole field with a certain configuration.

Example 2. Boreholes in a 3 × 2 bore field have the following characteristics: r_b = 0.05 m, H = 100 m, and B = 5 m. The undisturbed ground temperature is 15°C, the thermal conductivity is 1.5 W/(m·K), and the thermal diffusivity is 1.12e^{-6} m^2/s. What is the resulting borehole wall temperature after 10 years of heat extraction at an average rate of 5 W per metre of bore?

Evaluation of the three non-dimensional parameters lead to: r_b/H = 0.0005, B/H = 0.05, t_s = 31.5 years and $\ln(t/t_s)$ = –1.15. According to

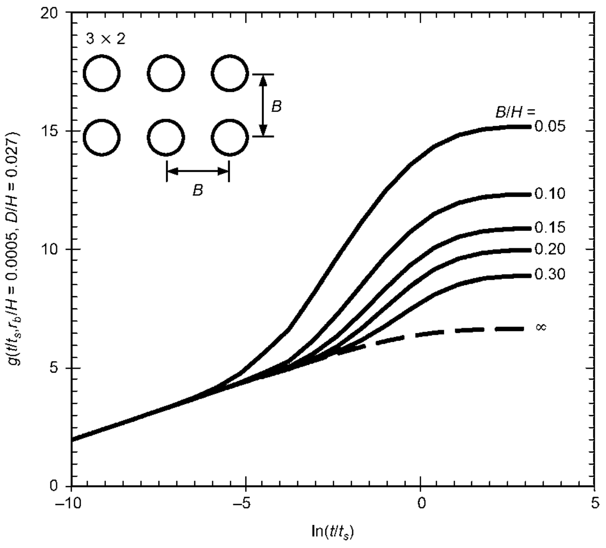

Fig. 13 Typical *g*-Function Curves for 3 × 2 Bore Field

Figure 13, the resulting *g*-function is 12.3. Using Equation (23), the borehole wall temperature is then equal to 8.5°C.

The *g*-functions can be used to determine the design length of a bore field. One possible approach is to use Equations (4) and (5) but with two modifications. First, when *g*-functions are used, thermal interference among boreholes is implicitly accounted for and t_p can be eliminated. Second, the values of R_{ga}, R_{gm}, and R_{gst} are now based on *g*-functions. Hence, Equations (24) to (26) take the following forms:

$$R_{ga} = \frac{g_{(t_f)} - g_{(t_f - t_1)}}{2\pi k_g} \qquad (24)$$

$$R_{gm} = \frac{g_{(t_f - t_1)} - g_{(t_f - t_2)}}{2\pi k_g} \qquad (25)$$

$$R_{gst} = \frac{g_{(t_f - t_2)}}{2\pi k_g} \qquad (26)$$

where $g_{(t_x - t_y)}$ is the *g*-function evaluated at $\ln[(t_x - t_y)/t_s]$ for a given bore field and B/H ratio. Note that determining L (i.e., $n_b \times H$, where n_b is the number of boreholes) is an iterative process because R_{ga}, R_{gm}, and R_{gst} depend on H, which is unknown beforehand. Thus, software tools are often required to accomplish this task. Because *g*-functions account for 3D heat transfer in the borefield, they are considered to be more accurate than the *G*-factors, which derive from a radial-only heat transfer model. Borehole thermal capacity can be accounted for by using the short-time-step *g*-functions (Yavuzturk and Spitler 1999).

Example 3. A building has a cooling block load of 52 kW with a corresponding value of q_{cond} = –66.0 kW. The annual ground imbalance q_a = –3.0 kW, PLF$_m$ = 0.30, and F_{SC} = 1.0. The 3 × 2 bore field has the following characteristics: r_b = 0.05 m, B = 5 m, and R_b = 0.1 (m·K)/W. The undisturbed ground temperature is 10°C, the thermal conductivity is 3.34 W/(m·K), and the thermal diffusivity is 1.12 × 10^{-6}m^2/s. Calculate the equivalent thermal resistances R_{ga}, R_{gm}, and R_{gst} for three consecutive heat pulses of 10 years, 1 month, and 6 hours and the total required length if the maximum mean fluid temperature in the borehole is to be kept below 35°C.

From the problem statement, t_f = 3680.25 days, t_2 = 3680 days, and t_1 = 3650 days. After iterations, this leads to $g_{(t_f)}$ = 12.34, $g_{(t_f - t_1)}$ = 3.99, and $g_{(t_f - t_2)}$ = 1.55; and R_{ga} = 0.398 (m·K)/W, R_{gm} = 0.116 (m·K)/W, and R_{gst} = 0.074 (m·K)/W; and

$$L_c = \frac{-3000 \times 0.398 - 66\,000(0.1 + 0.3 \times 0.116 + 0.074)}{10 - 35} = 600 \text{ m}$$

Thus, 100 m per bore is required with a borehole spacing of 5 m. This represents a length of 11.52 m per kilowatt.

Simulation of Ground Heat Exchangers

After the design length has been determined, it is often necessary to evaluate the outlet fluid temperature of a bore field as a function of time, generally on an hourly basis, and estimate the annual heat pump energy consumption. Energy simulation can be used to compute this temperature (they can also be used iteratively to assist in sizing the ground heat exchanger). Some energy simulation programs use the duct ground storage (DST) model introduced by Hellström (1989) to evaluate the outlet fluid temperature of a bore field as a function of time. Yavuzturk and Spitler (1999) describe the calculation method behind the DST model.

The DST model calculates the transient thermal process in densely packed borehole fields. The boreholes are assumed to be evenly distributed within a cylindrical storage region in the ground. Although the DST model was originally intended to simulate borehole thermal energy storage (BTES) systems, it has been used to simulate ground source heat pump systems.

Other energy simulation programs have a *g*-function-based routine to evaluate the outlet fluid temperature of a bore field as a function of time (Fisher et al. 2006; Liu 2008). The following analysis is intended to give only the salient features of an hourly simulation based on *g*-functions. As an example, assuming that $F_{SC} = 1$ and that the borehole length and the inlet fluid temperature are known, and that the heat transfer rates for three consecutive time intervals (0 to t_1, t_1 to t_2, and t_2 to t_3) are given by Q_1, Q_2, and Q_3, then, using temporal superposition, the mean fluid temperature at the end of the third time interval is given by

$$T_m = T_g - \left[\frac{Q_1[g_{(t_3-0)} - g_{(t_3-t_1)}] + Q_2[g_{(t_3-t_1)} - g_{(t_3-t_2)}] + Q_3 g_{(t_3-t_2)}}{2\pi k_g L} + \frac{Q_3 R_b}{L}\right] \quad (27)$$

with $T_m = (T_{wi} + T_{wo})/2$.

Based on the work of Yavuzturk and Spitler (1999), Equation (27) can be generalized for *n* time steps as follows:

$$T_m = T_g - \sum_{i=1}^{n} \frac{(Q_i - Q_{i-1})}{2\pi k_g L} g\left(\frac{t_n - t_{i-1}}{t_s}, \frac{r_b}{H}, \frac{B}{H}\right) - \frac{Q_n R_b}{L} \quad (28)$$

Solving Equation (28) can be computationally intensive if the number of time steps is large, because there is no recurrence in the summation term. In other words, the calculations performed at time step $n - 1$ cannot be used at time step *n*, and the ground loop loading history must be updated at each time step. Load aggregation is typically used to reduce the number of terms in the summation without sacrificing accuracy. It is based on the fact that recent ground loads have a more significant effect on the current mean fluid temperature than distant ground loads. For example, in the case of hourly simulations, the determination of T_m at the end of a year would require a summation of 8760 hourly terms according to Equation (28). One possible alternative is to aggregate (i.e., average) the ground loads of the first 8000 hours, then aggregate the next 730 hours and keep intact the last 30 hours. The summation term would then be reduced to 32 terms. Other aggregation schemes have been proposed by Bernier et al. (2004), Liu (2005), and Yavuzturk and Spitler (1999).

Hybrid System Design

The design methods described previously size the ground loop for the larger of the heating or cooling loads, including a temperature penalty for the amount of imbalance (which can be large in severe climates). An alternative approach for imbalanced buildings is to partially balance the load on the ground, both at peak and annual scale, by adding a supplemental device to help meet the larger of the two peak loads. This is a hybrid geothermal (or **hybrid ground-coupled**) system. Hybrids can provide several benefits for buildings with a load imbalance. The biggest economic effect is in decreasing the ground heat exchanger size/cost. First-cost savings have been reported of 6 to 16% of total HVAC system cost, with little consequence reported on operating cost (Hackel and Pertzborn 2011; Singh and Foster 1998) because the HVAC systems operates for the vast majority of the year at a fraction of peak design. More balanced loads resulting from hybrids can reduce the long-term ground temperature penalty associated with multiyear operation.

In most U.S. commercial buildings, the cooling load is dominant both annually and at the peak because of high internal loads, ventilation heat recovery, and good building envelopes. Heat from compressors, pumps, and fans also plays a factor; in heating mode, this heat is delivered to the building, so less heat is required from the ground. As a result, achieving annual thermal balance requires heat pumps in a geothermal system to operate in heating mode 1.6 to 1.8 h for every hour in cooling.

The ideal configuration of the ground heat exchanger and supplemental cooling device in a hybrid depends on many factors, such as climate, building peak load, and building annual loads. Carefully analyze which approach may work best for a specific building. One common configuration for cooling-dominated systems, a series hybrid, is shown in Figure 14A. This approach could also be taken with a closed-circuit cooling tower (i.e., fluid cooler) downstream of the ground heat exchanger (GHX). In general, it is most effective to place the lower-temperature heat sink downstream; an energy model can help determine which order most often results in this scenario throughout the year. As a rule of thumb, in drier climates with warmer ground (e.g., desert southwestern United States) the tower is almost always the lower-temperature sink, whereas in humid climates with moderate-temperature ground (e.g. southeastern United States), the ground is often the lower-temperature sink. The hybrid can also be configured in parallel, as shown in Figure 14B, which is especially desirable if the ground heat exchanger is small in comparison to the building peak cooling load (a series system in this example would require a more complex partial GHX bypass). In either case, there are two guidelines for design and operation of hybrid systems:

- A valve can be used to bypass the ground heat exchanger when the system is balanced; a dead band of 13 to 24°C can be used for this purpose. This valve can be three-way as shown, or two-way where appropriate.
- Cooling towers are optimal when they are oversized, use a variable-speed fan, and minimize fan speed across cells.

Control of a cooling-dominated hybrid depends on the configuration. If equipment is placed as shown in Figure 14A, the temperature downstream of the tower can be used to control the use and speed of the tower based on a high limit (some additional savings are possible if the tower is controlled by the Δt between entering fluid and ambient wet-bulb temperatures, though this method depends on a difficult measurement of wet bulb). If the tower is located upstream of the ground heat exchanger, the temperature exiting the tower and the ground heat exchanger should both be used in tower control (to ensure the ground is not being cooled). For parallel configurations (Figure 14B), one practical tower control sequence bases tower operation on a calculation of the

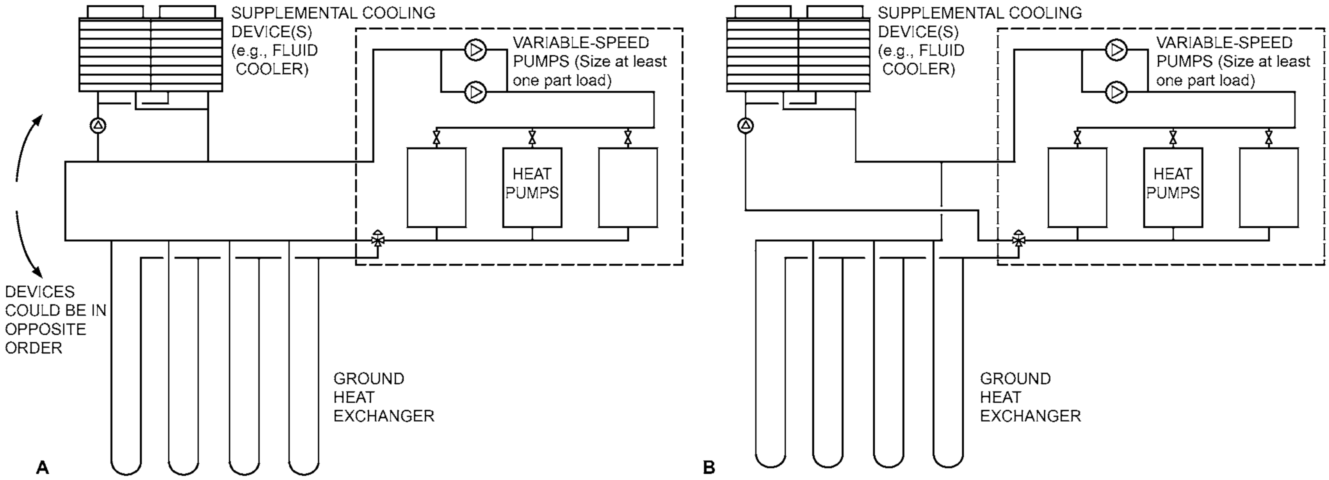

Fig. 14 Hybrid System Configuration Options, (A) Series and (B) Parallel

average of fluid temperature entering the heat pumps over the previous week (Xu 2007). Xu also suggests a strategy for controlling the parallel three-way valve.

For hybrid systems that require cooling towers, design also needs to consider water efficiency. Proper controls, as discussed previously, are a good start in minimizing water usage. Sequences can include a stage of cooling in which the spray pump is off (for when ambient temperatures are moderate). If the tower is run to precool the ground, this should be done carefully (Pertzborn et al. 2012) to avoid overusing the tower, which could result in significant energy and water penalties. Finally, operators should still follow the fundamental guidance for efficient tower operation (see Chapter 40 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*).

A heating-dominated hybrid with a boiler instead of a cooling tower can use a series configuration, with the boiler downstream of the loop (because of the boiler's high temperature output). The boiler is ideally controlled based on the temperature leaving the heat pumps.

Sizing hybrid components is a bit more complex than standard systems. For cooling dominated hybrids, Kavanaugh and Rafferty (2014) suggest that heat exchanger length for heating L_h be determined using Equation (5) with heating-mode loop temperatures t_{wi} and t_{wo} as low as possible to minimize L_c. A tower with an isolation heat exchanger is sized to meet the capacity difference between the required cooling length L_c from Equation (4) and the heating length L_h. Kavanaugh (1998) revised this method to include an additional iteration to size the ground heat exchanger only after estimating the annual heat rejection from the tower: q_{tower}(rated L/min) = L/min$_{system}$$(L_c - L_h)/L_c$, where L_c is calculated from Equation (5) but based on reduced EFLH$_c$ to account for tower operation rejecting an estimated amount of the annual load. The strategy suggests eliminating long-term ground temperature change with additional tower operation.

A more detailed study (Hackel et al. 2009) included assumptions about typical installation and operating costs to demonstrate an optimized design strategy for cooling dominated hybrids. Based on life-cycle cost, this approach was roughly attractive whenever the peak heating load was less than 80% of the cooling load; savings increased logarithmically as the ratio decreased below 80%. A variety of cases were modeled, and the simplified best-fit regression for the hybrid ground heat exchanger length L_{hyb} in a cooling-dominated scenario was found to be proportional to heating load:

$$L_{hyb} = C_1 \times q_h/(t_g - t_{wo}) \quad (29)$$

where C_1=147 (m·K)/kW, at k =2.4 W/(m·K). For other ground conductivities, the change in ground heat exchanger size is approximately inversely proportional to the change in conductivity. In choosing t_{wo}, Hackel et al. (2009) also suggest in cooler climates it is often economical to include antifreeze in the system and allow the entering fluid temperature to drop to 2°C or lower. The supplemental cooling device (closed-circuit tower) should then be sized to meet the fraction of the cooling load that this smaller hybridized ground heat exchanger cannot. The study suggests that the tower should even be oversized slightly and its fan put on variable-speed control, to achieve optimal performance. Furthermore, tower sizing should be completed using the local peak wet-bulb and design entering fluid temperature for the hybrid.

This basic strategy of sizing hybrids was found to be valid for a wide range of economic scenarios. This economically justifies the general concept laid out in Kavanaugh (1998); however, results showed that it is generally not economically optimal to balance the load on the ground, and some increase in ground temperature can be accepted. Preliminary research showed that running the tower at night or in winter before there was significant cooling load (precooling the ground) to balance the ground load is not always necessary, and if done without care (i.e., in-depth energy analysis) could possibly lead to increased energy consumption (Pertzborn et al. 2012).

Regardless of the calculation method used, detailed building load calculation is critical when sizing and configuring a hybrid, to determine the impacts of heating and cooling loads across time scales from peak to annual. Further refinement of hybrid sizing (and control) can be done through energy simulation software, including some of the design software mentioned earlier, as well as a tool created as a result of ASHRAE research project RP-1384 (Hackel et al. 2009). Building energy simulation can estimate loads at every hour of the year, establishing better understanding of annual ground loads as well as the load sharing between ground heat exchanger and supplemental device.

Heating-Dominated Hybrids. These hybrids are needed in only very cold climates. In heating-dominated buildings in such climates (i.e., with approximately twice as much annual heating load as cooling load), however, a heating-dominated hybrid could decrease the size of the ground heat exchanger. Optimally, the ground heat exchanger is sized to meet the cooling load and a supplemental device meets the remaining heating load through a supplemental heat coil on the ground-coupled fluid loop. Coil energy could be supplied

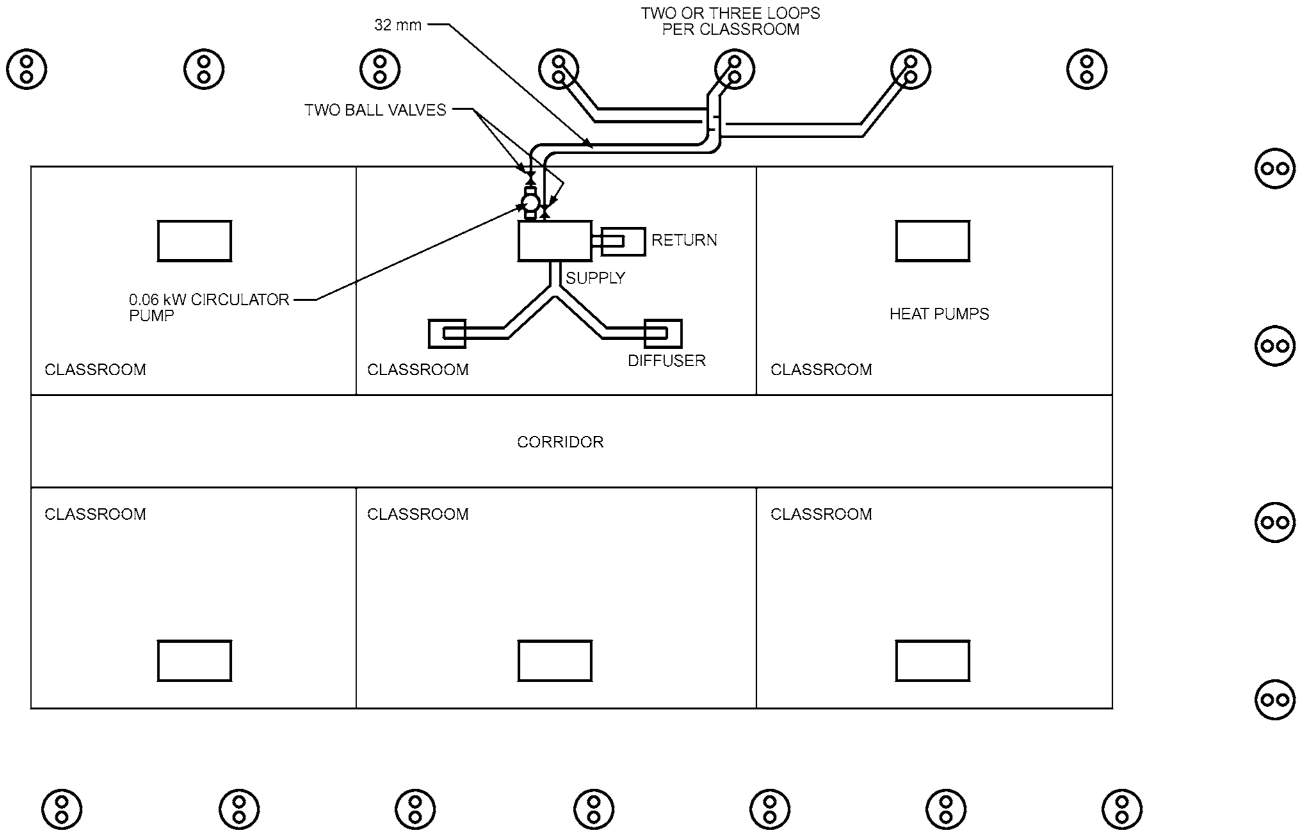

Fig. 15 Unitary GCHP Loops with On/Off Circulator Pumps

by gas boiler, solar panels, electric resistance, or another source. Several things need to be considered if using this approach:

- The potentially high temperatures of the heating coil are not covered by typical ground heat exchanger warranties.
- Controls must be maintained correctly. Place boiler in series, downstream of ground heat exchanger, with control of boiler and ground heat exchanger coordinated so that heat is never rejected to the ground while the boiler operates (very little of such heat would be recovered).
- The heat pumps operate whenever heating is needed, even though a high-temperature coil is also operating, reducing efficiency.

An alternative strategy for heating dominated buildings that poses some advantages is to simply remove some loads in the building from the ground-coupled loop and serve them by boilers, solar panels, or some other source which provides high enough temperatures to heat without added heat pump energy. Baseboard, unit heaters, and preheat coils can be good applications for this approach. This may alleviate some of the complications with boiler hybrids discussed previously.

Pump and Piping System Options

Loop design can have a substantial effect on both pumping power requirements and system installed cost. A GSHP survey (Caneta Research 1995a, 1995b) reported that installed pumping power varied from 0.0085 to 0.045 kW_{elect}/kW_{therm} of heat pump power. This represents 4 to 21% of the total demand of typical GSHP systems and up to 50% of the total energy for some pump control schemes. Table 6 gives a recommended set of guidelines for minimizing the power of closed-loop GSHPs and maximizing system efficiency.

Good grades (Table 6) can be obtained by minimizing extensive piping arrangements with long interior and exterior piping runs, high-head-loss fittings, valves, and control devices. Designers must compare the costs and advantages of large central piping loops and larger pumps with those of multiple smaller loops and smaller pumps. Pumping rates greater than 0.05 L/s·kW in closed-loop systems result in marginal equipment capacity gains in modern water-to-air heat pumps, and typically decrease overall system efficiency.

Kavanaugh et al. (2002) found the total cost of vertical GCHP ground-loop systems (including headers) ranged from $19 to $82 per metre of vertical bore. The cost of headers is a significant portion of the total and in many cases exceeded the cost of the vertical bore. The savings in vertical loop costs because of central systems' load diversity often is not warranted because of the increased cost of large-diameter piping networks connecting equipment inside the building and below-grade circuits connecting exterior ground heat exchangers.

In low-rise buildings with large footprints, such as a school, multiple unitary loop systems (Figure 15) are an effective option to offset the high cost of central interior piping and ground-loop header costs. Although the total length of vertical bore for unitary systems is greater than for central loop systems, the high cost of interior piping, exterior headers, and valve vaults often offsets the bore cost savings. Additionally, pump demand is substantially reduced in the unitary system because of the short header runs, so low-wattage on/off circulator pumps are suggested.

A compromise in applications with significant load diversity is to group ground heat exchangers into multiple smaller subcentral loops in different areas of the building (Figure 16). Subcentral loops can be served by on/off circulator pumps located on each heat pump if a

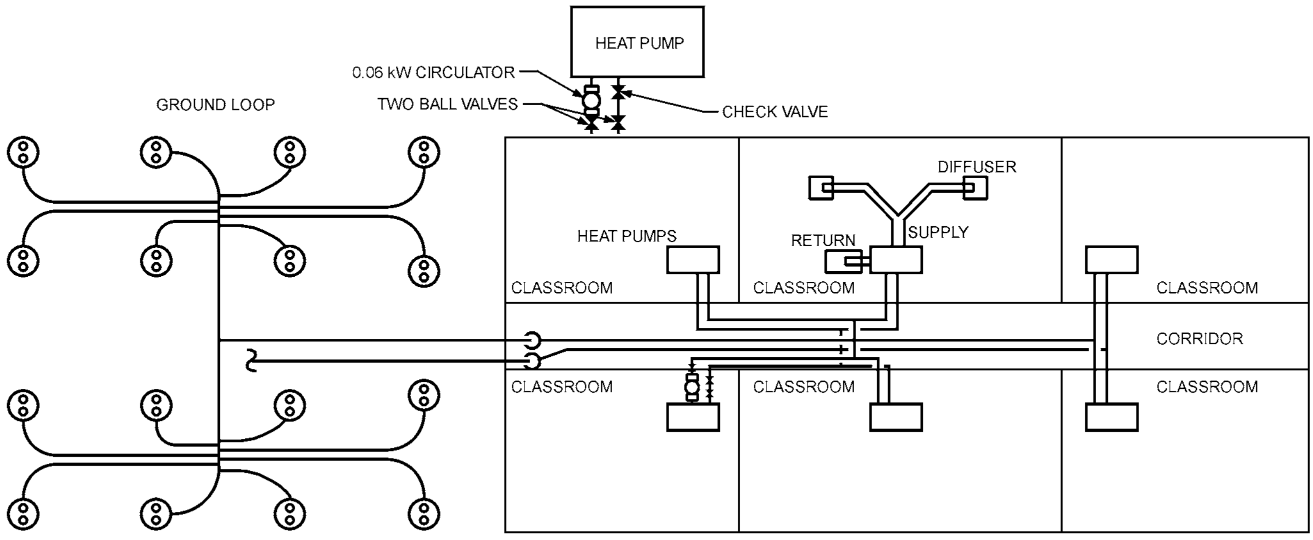

Fig. 16 Subcentral GCHP Loop with On/Off Circulator Pumps

check valve is installed on each heat pump to prevent reverse water circulation through idle units.

Figure 17 is an example of a central loop that can effectively reduce the cost of the required vertical bore in buildings with higher load diversities. The central ground heat exchanger consists of several subheader sets, each having 6 to 20 vertical U-tube heat exchangers. The subheaders are gathered into a valve manifold located either near the center of the loop field in a below-grade vault or in the building equipment room. Each subheader set has isolation valves for independent purging of air and debris. Interior piping is similar to conventional water-source heat pump systems in which interior piping is routed to individual water-to-air heat pumps in each zone and/or heat pump water heaters and water-to-water heat pumps.

Variable-speed drives (VSDs) are recommended for central loop systems because they offer substantial energy savings compared to primary/secondary pump schemes in GSHP applications. However, in buildings with primary occupancy of less than 60 h per week, measures should be incorporated to turn off the main VSD pump and provide some alternative means of pumping water to critical building zones during low-occupancy or unoccupied periods.

Several projects examined installation costs of nonresidential ground source heat pumps beginning in the mid 1990s: a large survey from an ASHRAE-sponsored research project (Caneta 1995) and a condensed report (Caneta 1998) studied systems located in colder climates, and Zimmerman (2000) looked at costs in several Tennessee Valley GSHP schools (Figure 18). Kavanaugh et al. (2012) also studied costs for the complete system

Table 7 Average Costs for Three GSHP Systems

(Caneta 1995; Zimmerman 2000)

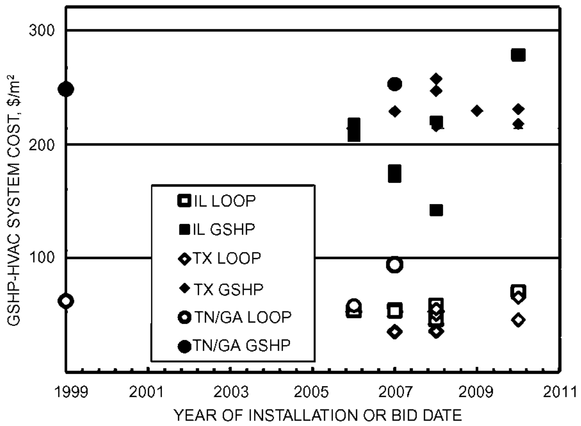

Fig. 19 GSHP System and Ground Loop Cost Based on Building Floor Area

and ground loop (Figure 19). Table 7 compiles the average, maximum, and minimum costs for these studies.

As Table 7 shows, the percentage of ground loop costs to total GSHP system cost declined from 38.5% in 1995 to 25.5% in 2011. Results indicate there was a 177% increase in HVAC component costs compared to a 52% increase in ground loop costs during this 16 year period. The TX Loop (cost for ground loop installed in Texas) costs are an example of how multiple unitary loops can be very cost effective.

Figure 20 shows the results of a cost comparison of a GSHP system with two four-pipe water-cooled chilled/hot-water systems

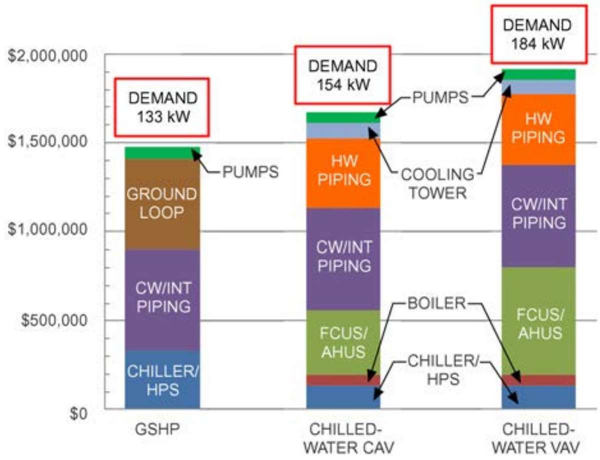

Fig. 20 Project Installation Cost Comparison of 530 kW GSHP with Four-Pipe Systems

for a 6700 m^2 school in Birmingham, Alabama with a 530 kW cooling requirement. The installation cost of the GSHP system was 11.7% lower than that of the constant-air-volume (CAV) system and 31.9% less than the variable-air-volume (VAV) system. Installation costs were based on 2014 data (Means 2014) but assumed the ground loop cost was $49/m of vertical ground heat exchanger. Costs include controls for components (thermostats, VAV actuators, sensors, etc.) but not building automation systems (BAS) or energy recovery units (ERUs).

Additional cost data for regions across the United States are available in Battocletti and Glassley (2013).

GSHP Piping Materials. It is an industry standard that the buried ground-loop piping materials be fusion welded. For this reason, the current IGSHPA design and installation standards lists only high-density polyethylene (HDPE), and most recently an exception for cross-linked polyethylene (PEX-a) as approved materials for buried pipe. (IGSHPA 2011). ANSI/CSA/IGSHPA *Standard* C448-16 only discusses HDPE and PEX-a as approved materials for closed-loop buried pipe. In most cases, this pipe is buried without insulation.

Distribution systems in a building need to be carefully chosen and not solely driven by cost or ease of installation. As with any system, piping materials must be compatible with system design temperatures and with the fluids conveyed. Closed-loop systems typically use potable water and may also include antifreeze and/or water treatment chemicals. With newer refrigerants, care is needed to ensure the piping materials are compatible with the oils used in the refrigeration system and that equipment seals are compatible with the heat transfer fluids conveyed; for instance, polyolester (POE) oil used with R-410A is not compatible with PVC pipe. Consult chemical resistance charts provided by materials manufacturers.

Whether designing a new system or retrofitting an existing one, it is the design engineer's responsibility to size and select the proper piping materials for each application and to select only those materials allowed by code (ICC 2012). In large building systems, the aboveground piping specifications commonly include steel, iron, copper or PVC. Where the hydronic mains are 100 mm or larger, it is often more cost effective to specify steel pipe. Specifying steel pipe may require some type of water treatment to inhibit general corrosion and dielectric isolation when connected to geothermal heat pumps.

Water Quality, Heat Transfer Fluids, and Water Treatment. When engineers introduce dissimilar metals into closed-loop hydronic piping systems, improperly address water treatment requirements for their designs, or are not properly informed of the local groundwater regulations, water quality problems may result. Poor water quality contributes to a decline in mechanical system performance, increased maintenance, and can reduce the useful lifetime of mechanical system components.

The standard working fluid in small residential closed-loop piping systems is either potable water or, in colder regions, an antifreeze solution. Where required, the antifreeze solution is introduced after the ground loop is properly pressure tested, flushed, and purged of debris and air. There has been little problem with or concern about water quality in these GSHP systems, because piping materials have historically been HDPE, copper, or stainless steel hose kits for final connection at the heat pumps.

Quality of potable water can vary, depending upon the source, and rules on its use vary from state to state. The chemistry of this water is one of the contributors to corrosion and water quality problems in closed-loop piping systems, so engineers need to be precise with hydronic piping and water treatment system specifications. Chapter 50 offers some guidance on understanding the consequences of water quality on both open- and closed-loop hydronic systems.

The type of chemical used for water treatment in closed-loop systems is based on several criteria, including the materials being protected, the quality of the water in the piping system, local regulations, and cost. These systems are typically specified to include a rigorous process for cleaning the distribution piping, flushing the piping systems of air and debris, and then adjusting the water quality of the final local water to meet the long-term performance requirements of the building systems. Chemicals used to adjust water quality for these systems, including corrosion inhibitors, are often not acceptable for use when the circulating fluid is also connected to a ground loop. This is not a problem unless there is a pipe failure or problem with the ground loop, but a potential leak is a concern of the regulatory agencies that protect groundwater in each state.

Flush and Purge. To ensure that a geothermal heat pump system provides trouble-free operation, all ground-loop systems must be properly flushed and purged prior to connection to the building piping system (IGSHPA 2011). The current standard of care is defined by IGSHPA as providing a minimum velocity of 0.6 m/s through each piping system (but not in excess of the maximum flow velocity recommended by the pipe and fittings manufacturer) to remove air from the system. Flushing and purging each supply and return circuit in the forward and reverse directions for long enough to remove all debris and air from the system is also recommended. To attain proper flow velocity, appropriately sized and located purge ports and valves should be included in the mechanical design, preferably in a location where manipulation of the valve(s) allows independent flush and purge of the building and/or the ground loop. Special care should be taken to ensure that air is not pumped from the building into the ground loop.

Recommendations for Good GSHP Piping System Design.

- Before beginning design, consult the local regulatory agency for guidance on requirements related to the ground-loop portion. In many locations, this may be the Departments of Health or Environmental Services. Drilling for a vertical closed-loop system may not be allowed. Local groundwater conditions may limit the use of certain working fluids due to the sensitive nature of the resource and the concern for contamination.
- Conform to applicable codes on adding nonpotable chemicals to building mechanical piping systems and for any discharge to public sewage systems. Good piping designs minimize the need for chemical treatment and any potential impact to the environment.
- Note that corrosion occurs at some level in all hydronic systems. The best GSHP distribution system from a corrosion standpoint is one that includes only HDPE. Breaking down the system into the subcentral or individual loops may accommodate the use of only HDPE in large buildings.
- Review pressure ratings of all piping materials specified for the system design temperatures.
- Minimize the number of fittings, valves, and specialties where practical. Fittings, valves, specialties, and pumps perform best when stainless steel or bronze fitted.
- Even in a closed-loop piping system, it is possible for air to be introduced by expansion and contraction of the pipe and occasional addition of make-up water. For suspended gases, air separators installed upstream of the pumps with an expansion tank can provide deaeration. For dissolved gases, particularly oxygen, the problem can only be addressed with chemical treatment.
- It is very important that all ground-loop and building systems are properly flushed and purged of debris. Not only can debris clog equipment, but biological material contributes to a drop in water pH as it decays.
- Take a water sample of the local potable water supply if it is planned to be the hydronic system's working fluid. If dissimilar metals are used and/or the local water quality is poor, a water-treatment specialist can help select a water treatment regimen for the system. Alert the owner to the requirement for periodic monitoring of water quality.
- If a chemical pot feeder is added into the system as a place to introduce the chemicals for the hydronic system, include an integral filter. The filter will help to maintain water quality and remove residual debris that may break lose after the system has been properly flushed and purged.
- If propylene glycol is to be used as an antifreeze, note that concentrations less than 20% may promote bacterial growth. Check this percentage with the supplier (NGWA 2010).

Pressure Considerations in Deeper Vertical Boreholes

In deep vertical boreholes, it is especially important for the designer to be aware of conditions that may lead to pipe failure. The hydrostatic pressure exerted on both the inner and outer wall of the U-bend piping during installation should be considered.

Internal Pressure Considerations. Pressure is exerted on the inner pipe wall during installation but before grout placement, because the pipe is filled with water to offset its buoyancy in a water- or mud-filled bore. Equation (30) may be used to determine the **internal working pressure (IWP)** during vertical loop installation. (Note that the depth to the static water table, which is site specific, must be known.)

$$IWP = 9.806 \times Depth \tag{30}$$

where

IWP = internal working pressure, kPa
Depth = depth to static water table, m

The internal pressure caused by water column height is offset in the portion of the loop that is installed below the static water table.

Once the internal working pressure is known, the designer should ensure that the **internal pressure rating (IPR)** of the pipe is not exceeded. The IPR of HDPE is a function of pipe material type (cell classification), wall thickness (DR), and temperature. The IPR for HDPE 3408/3608 and 4710 at 23°C for DR-11 and DR-9 are shown in Table 8; compensating factors to account for other temperatures are shown in Table 9. To determine the IPR at the pipe's actual working temperature, simply multiply the IPR at 23°C by the appropriate temperature compensating multiplier.

External Pressure Considerations. Pressure is exerted on the outer pipe wall by the liquid grout slurry as it is pumped into the

bore. As a liquid, grout rests against the outer pipe wall, exerting pressure until it hardens (sets). In general, the maximum working time for most grouts is 30 to 45 min, depending on factors such as makeup water temperature and chemistry, borehole temperature, etc. After this amount of time, the grout begins to set into its permanent state as a semirigid plug. Note that grouting is not required in some jurisdictions and not addressed in others; this has given rise to substituting a manufactured fill material, which may be acceptable in some cases.

After it sets, grout can partially support its own weight. It still exerts some pressure on the outer pipe wall, but the amount is far less compared to when in its liquid state. The amount of pressure exerted by the liquid grout column increases with depth, and is at maximum at the bottom of the bore. Equation (31) calculates the pressure exerted on the outer pipe wall after grout placement and before setting. The external pressure is due to density differences between the liquid grout column on the outer and the fluid (water) on the inner pipe wall:

$$EWP = 0.00981(\rho_{grout} - \rho_{water}) \times \text{Depth} \tag{31}$$

where

EWP = external working pressure, kPa
ρ_{water} = density of internal fluid, which is typically water during grout installation, kg/m^3
ρ_{grout} = density of the external grouting fluid, kg/m^3
Depth = borehole depth, m

Once the external working pressure is known, the designer should ensure that the **external pressure rating (EPR)** of the pipe is not exceeded. The EPR of HDPE is a function of pipe material type (cell classification), wall thickness (DR), temperature, percent deflection (pipe ovality), and duration of exposure to external pressures. The EPR for HDPE 3408/3608 and 4710 at 23°C for DR-11 and DR-9 are shown in Table 10, and compensating factors to account for other temperatures are shown in Table 9. Compensation factors to account for pipe ovality are shown in Figure 21 and Table 11, and those to account for duration of sustained pressure on the outer wall of the HDPE pipe are shown in Table 12. Note that the 1 h correction factor is appropriate for bentonite-based grouts, whose working time is generally 30 to 45 minutes. Cement-based grouting materials usually require use of 10 or 24 h compensation factors. Contact the manufacturer for more information.

To determine the EPR at the actual working temperature of the pipe for a given ovality, multiply the EPR at 23°C by the appropriate temperature, ovality, and sustained pressure duration compensating multipliers. Additionally, the percent deflection must be lower than the limits specified in Table 11.

As shown in Figure 21, HDPE EPR is very sensitive to ovality, which is determined by calculating the percentage reduction in pipe diameter along the deformed section of pipe (when applicable):

$$\text{Ovality, \%} = \frac{OD_{nom} - OD_{min}}{OD_{nom}} \times 100 \tag{32}$$

where

OD_{nom} = nominal U-bend pipe diameter, mm
OD_{min} = U-bend pipe diameter along deformed section, when applicable, mm

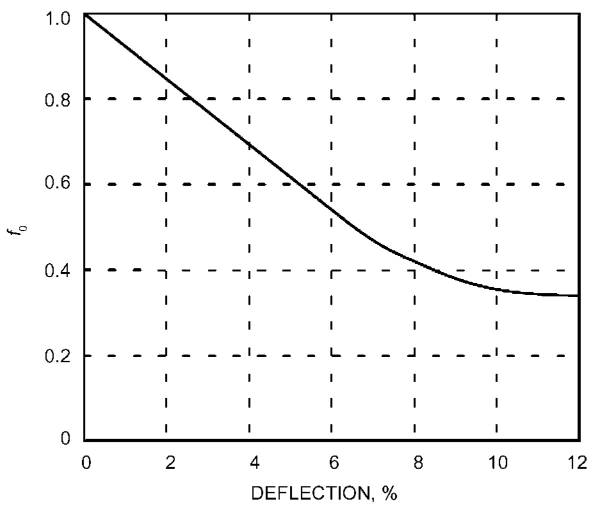

Fig. 21 Ovality Compensation Factors for HDPE
(PPI 2018)

Note that any section of pipe that exhibits ovality greater than the recommended limit shown in Table 9 should be removed from the system and discarded.

If exceeding the U-bend EPR becomes a concern, there are three primary ways to minimize the potential for issues to occur:

- Use a heavier pipe wall thickness. Remember that thicker-walled pipe is more expensive and may not be as readily available; its use also effectively reduces the inside pipe diameter, which increases system head loss and associated pumping power requirements
- Pressurize the U-bend from the surface before pumping grout into the bore to counteract external pressures during grout placement. Do not pressurize the loop above its IPR. Additionally, if the bore is completely dry, adding pressure to the loop from the surface will not be an option. Without water in the bore to counteract the pressure applied to the inside pipe wall, the U-bend's internal pressure rating will quickly be exceeded (burst pressure).
- Reduce grout density by using graphite in place of silica sand (without sacrificing thermal performance). Densities of graphite-based mixes are typically low enough that bore collapse should no longer be a concern for common bore installation depths. Contact the grout manufacturer for additional information.

Example 4. Calculate the external pressure rating of HDPE 4710 and the external hydrostatic pressure exerted on the outer pipe wall during grout placement. Assume the pipe will be DR-11 and is perfectly round (0% ovality), that a bentonite-based grouting material is used in the bore annulus, and that the 1 h apparent modulus is appropriate.

Ground temperature, t_g = 16°C
Grout density, ρ_{grout} = 1809.4 kg/m^3
Internal fluid (water) density, ρ_{water} = 1000 kg/m^3
Borehole depth = 152.4 m
Bore fill conductivity k_{grt} = 1.7 W/(m·K)
Percent deflection (pipe ovality) compensation factor = 1.00
Temperature compensation factor = 1.18

$$\text{EPR} = (1349\text{ kPa})(1.18) = 1591.8\text{ kPa}$$

$$\text{EWP} = (0.00981)(1809.4\text{ kPa} - 1000\text{ kPa})(152.4\text{ m}) = 1210.1\text{ kPa}$$

The external pressure rating (EPR) exceeds the external working pressure (EWP) of the piping system during grout placement (assuming no safety factor, N_s = 1.00).

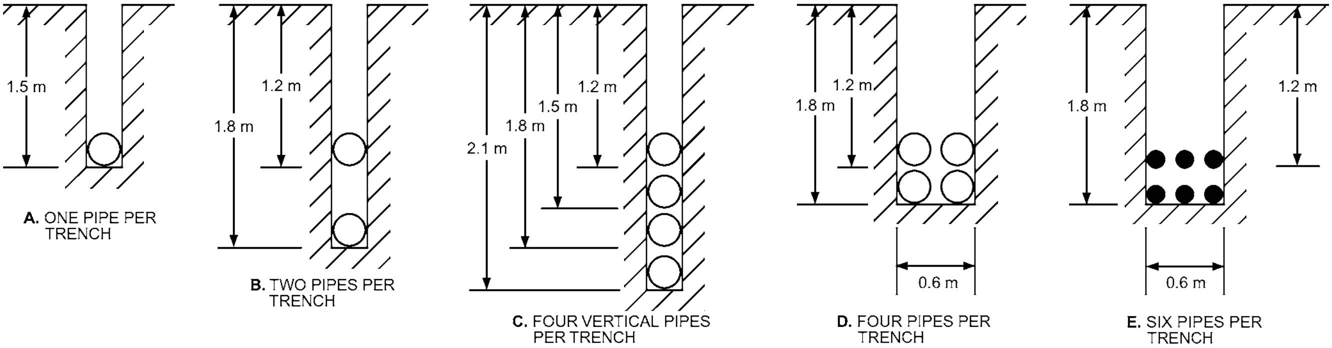
Effect of GSHP Equipment Selection on Heat Exchanger Design

The ground heat exchanger must absorb the heat of compression and heat from auxiliary equipment (e.g., fans, pumps) in cooling mode. In heating mode, heat from auxiliary equipment reduces the amount of heat required from the ground. Therefore, the cooling- and heating-mode power values W_c and W_h in Equations (4) and (5) must include the auxiliary input.

Rated values for GSHPs published in compliance with ANSI/ARI/ASHRAE/ISO *Standard* 13256-1 do not include the auxiliary power required to circulate air and water through the distribution systems. Furthermore, the auxiliary power required to distribute chilled air (and water) can have a substantial negative effect on the equipment's cooling capacity.

Table 13 summarizes the air and water temperatures used to generate the rated performance of water-to-air heat pumps. Table 14 summarizes the conditions for ANSI/ARI/ASHRAE/ISO *Standard* 13256-2, which rates water-to-water heat pumps.

Actual heat pump performance can be substantially different from rated conditions. Designers must convert rated performance to design conditions by accounting for the effect of auxiliary power input and for design ELTs and EWTs. When water-to-water heat pumps or chillers are used in this application, corrections should include power for the pump(s) of the source/sink loop and the chilled-/hot-water loop, and power for fans in the air distribution system. Table 15 demonstrates the difference between rated GSHP efficiency and actual system efficiencies for various options when the effect of auxiliary components is considered. Note that using a high-static-pressure air handler for air distribution significantly reduces cooling efficiency. In heating, 49°C hot water also lowers heating COP compared to direct condensation and hydronic systems (e.g., in-floor heating) that use lower-temperature water.



Note: If frost line is greater than 0.9 m below grade, average depth of coils should be a minimum of 0.6 m below frost line and upper pipe should be a minimum of 0.3 m below frost line.

Horizontal and Small Vertical System Design

The buried pipe of a closed-loop GSHP may theoretically produce a change in temperature in the ground up to 5 m away. For all practical purposes, however, the ground temperature is essentially unchanged beyond about 1 m from the pipe loop. For that reason, the pipe can be buried relatively near the ground surface and still benefit from the moderating temperatures that the earth provides. Because the ground temperature may fluctuate as much as 5 K at a depth of 2 m, an antifreeze solution must be used in most heating-dominated regions. The critical design aspect of horizontal applications is to have enough buried pipe loop in the available land area to serve the equipment. The design guidelines for residential horizontal loop installations can be found in OSU (1988b).

Limitations on selecting a horizontal loop design include the following:

- The minimum land area needed for most nonspiral horizontal loop designs for an average house is about 2000 m^2. Horizontal systems are not feasible for most urban houses, which are commonly built on smaller lots.
- The larger length of pipe buried relatively near the surface is more susceptible to being cut during excavations for other utilities.
- Soil moisture content must be properly accounted for in computing the required ground heat exchanger length, especially in sandy soils or on hilltops that may dry out in summer.
- Rocks and other obstructions near the surface may make excavation with a backhoe or trencher impractical.
- Multiple pipes are often placed in a single trench to reduce the land area needed for horizontal loop applications. Some common multiple-pipe arrangements are shown in Figure 22. When pipes are placed at two depths, the bottom row is placed first, and then the trench is partially backfilled before the upper row is put in place. Rarely are more than two layers of pipe used in a single trench because of the extra time needed for the partial backfilling. Higher pipe densities in the trench provide diminishing returns because thermal interference between multiple pipes reduces the heat transfer effectiveness of each pipe. The most common multiple-pipe applications are the two-pipe arrangement used with chain trenchers and the four- or six-pipe arrangements placed in trenches made with a wide backhoe bucket.

An overlapping spiral configuration (Figure 23) has also been used with some success. However, it requires special attention during backfilling to ensure that soil fills all the pockets formed by the overlapping pipe.Large quantities of water must be added to compact the soil around the overlapping pipes. The backfilling must be performed in stages to guarantee complete filling around the pipes and good soil contact. The high pipe density (up to 10 m of pipe per linear metre of trench) may cause problems in prolonged extreme weather conditions, either from soil drying during cooling or from freezing during heating. This spiral design has been used in vertical trenches cut with a chain trencher as well as in laying the coil flat on the bottom of a large pit

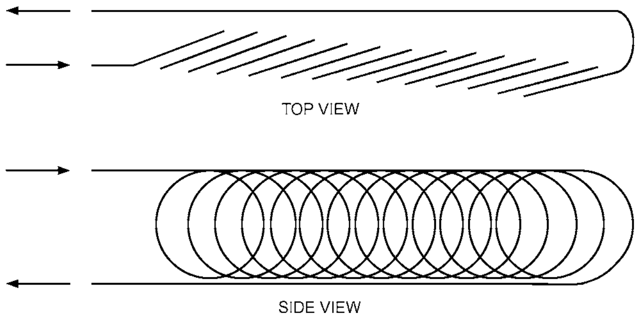

Fig. 23 General Layout of Spiral Earth Coil

excavated with a bulldozer. Installations using the horizontal spiral coil on the bottom of a pit have generally performed better than those with spiral coils that were stood upright in a vertical trench.

The extra time needed to backfill and the extra pipe length required make spiral configurations nearly as expensive to install as straight pipe configurations. However, the reduced land area needed for the more compact design may allow use on smaller residential lots that are too small for conventional horizontal-pipe ground-loop designs. The spiral pipe configuration laid flat in a horizontal pit arrangement is used commonly in the northern Midwest of the United States, where sandy soil causes vertical trenches to collapse. A large open pit is excavated by a bulldozer, and then the overlapping pipes laid flat on the bottom of the pit. The bulldozer is also used to cover the pipe, being careful to not run over them with the bulldozer tread.

Although most horizontal closed-loop systems (see Figure 3) are installed with either a chain trencher or a backhoe, horizontal boring machines are also now available for this application. Developed for buried utility applications such as electric or potable water service, these devices simply bore through the ground parallel to the ground surface. A detector at the surface can show the exact point where the boring head is located underground so that the bore does not penetrate other known utilities or cross over into a neighbor's lot.

Most horizontal loop installations place the pipe loops in a parallel rather than a single (series) loop to reduce pumping power (Figure 24). Splitting the flow into parallel loops increases the fluid-to-soil temperature difference and subsequent heat transfer. Parallel loops may require slightly more pipe, but may use smaller pipe and thus have smaller internal volumes, requiring less antifreeze (if needed). Also, smaller pipe is typically much less expensive for a given length, so total pipe cost should be less for parallel loops. An added benefit is that parallel loops can be flushed out with a smaller purge pump than is required for a larger single-pipe loop. A disadvantage of parallel loops is the potential for unequal flow in the loops and thus nonuniform heat exchange efficiency.

The time required to install a horizontal loop is not much different from that for a vertical system. For the arrangements described, a two-person crew can typically install the ground heat exchanger for an average house in a single day.

Soil characteristics are an important concern for any ground heat exchanger design. With horizontal loops, the soil type can be more easily determined because the excavated soil can be inspected and tested. EPRI (1990) lists criteria and simple test procedures that can be used to classify soil and rock for horizontal ground-loop design.

Although soil type and moisture content are important considerations in sizing the ground heat exchanger, some design guidelines have been developed based on extensive analysis of monitored systems in mostly southern climates (Kavanaugh and Calvert 1995). Table 16 gives recommended trench lengths for the various types of

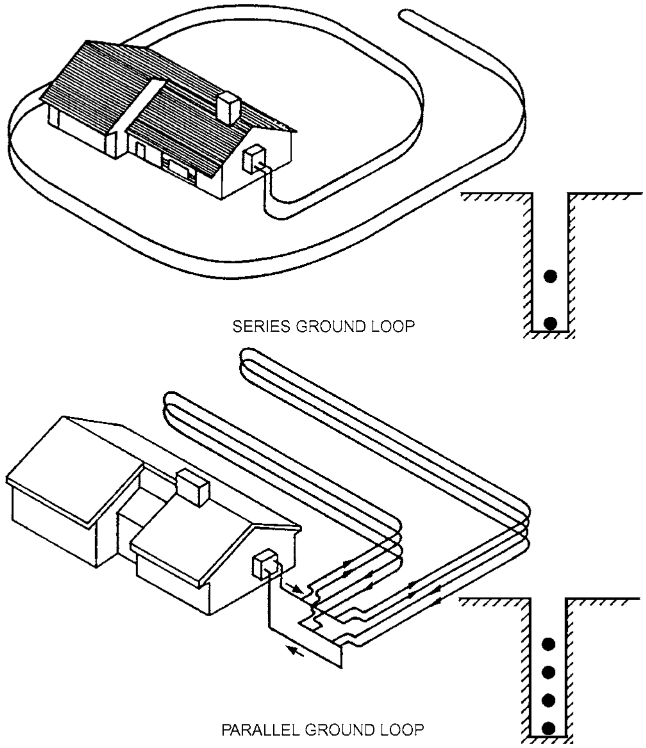

Fig. 24 Parallel and Series Ground Heat Exchanger Configurations

commonly used excavation methods. Heating-mode run times approaching 100% on a daily basis would be the norm at heating design conditions in heating-dominated climates. In contrast, daily run times of no more than 50% would be encountered at design cooling conditions in cooling-dominated climates. The combination of long run times and ice formation around the pipes makes performance of horizontal systems dependent on both the loop field design and how the system is matched to the building load. Though many thousands of these systems have been installed in heating climates, no comparable analysis has been performed to determine proper design guidelines. The loop length data in Table 16 for soil temperatures below 13°C are based on nominal heat pump capacity and use of supplemental resistance heat at design conditions. If installing such a system for the first time, contact several experienced contractors in the area to determine successful design lengths for the local climate and soil types.

Trench lengths in Table 16 are based on a minimum trench separation of 3 m and minimum horizontal loop average burial depth of the greater of 1.5 m or 0.6 m below the frost line. Bore lengths are based on a vertical bore separation of 6 m. Design ground heat exchanger temperatures are a maximum of 32°C return and 38°C entering in warm climates and a minimum of –2°C return and –6°C entering in cold climates.

Additional considerations for horizontal loop systems in colder climates arise from the potential for ice formation around the pipe loop. The loop should not pass within 0.6 m of any buried water line (potable, sewer, or rainwater). If such proximity cannot be avoided, the GCHP loop can be insulated in that area. Horizontal loops should not be placed closer than 2 m from a basement or crawl space wall when buried parallel to the wall. Heaving from ice formation could cause structural damage if placed in close proximity to the wall.

Leaks in heat-fused plastic pipe are rare when attention is paid to pipe cleanliness and proper fusion techniques. Should a leak occur, it is usually best to try to isolate the leaking parallel loop

Table 16 Recommended Lengths of Trench or Bore per kW for Residential GCHPs

Note: Based on k = 1.0 W/(m·K) for horizontal loops and k = 2.1 W/(m·K) for vertical loops. Figures for soil temperatures < 13°C based on modeling using nominal heat pump capacity and assumption of auxiliary heat at design conditions.

Multiply Table 16 Values by Bold Values Below to Correct for Other Values of Ground Conductivity

	Ground Thermal Conductivity in W/(m·K): 0.7	1.0	1.4	1.7	2.1	2.4	2.8	3.1	3.5
Horizontal loop	**1.22**	**1.0**	**0.89**	**0.82**	—	—	—	—	—
Vertical loop*	—	—	**1.23**	**1.10**	**1.0**	**0.93**	**0.87**	**0.83**	**0.79**

*Vertical loop values based on an annular fill with k = 1.5 W/(m·K). Multiply lengths by 1.2 for $k_{annulus}$ = 0.7 W/(m·K) and 0.95 for $k_{annulus}$ = 1.9 W/(m·K).

and abandon it in place. The effort required to find the source of the leak usually far outweighs the cost of replacing the defective loop. Because the loss of as little as 0.9 L of water from the system causes the system to lose pressure and shut down, leaks cannot be located by looking for wet soil, as is commonly done with water lines.

Although leaks should be rare with properly thermally fused pipe, some states have adopted restrictions against the use of certain types of antifreeze mixtures in GCHP systems; check local water-quality regulations before selecting a mixture. Methanol has been used extensively because of its low cost and good physical properties when cold. Comprehensive studies by Heinonen and Tapscott (1996) and Heinonen et al. (1997) showed that propylene glycol is a good alternative when issues of flammability or environmental safety are important considerations. A more thorough discussion of antifreeze solutions is given in the Antifreeze Requirements section of this chapter.

Fluid Flow and Loop Circuiting. Residential systems, like commercial applications, sometimes have excessive pumping power. This trend may result from undersized piping, excessive amounts of viscous antifreeze solutions, or conservative pump sizing. Because a 10.5 kW heat pump with an energy efficiency ratio (EER) of 15 requires a total power (compressor and fan) of 2400 W, the addition of a second 0.12 kW pump (which draws 245 W) reduces system efficiency by 10%. Table 17 provides a guideline to ensure adequate liquid flow rate with the least possible number of pumps. It should be used in conjunction with Table 16 and applies to loops with 0 to 15% propylene glycol solutions (by volume; note that caution and additional treatment may be needed for solutions lower than 20%, because of risks of corrosion and biological growth below this level). This solution has the reputation of being the most difficult of the commonly used solutions to pump when cold. However, it is no more difficult to pump than ethyl alcohol, and pumping penalties can be mitigated by adding only the required amount of antifreeze. Shorter loops may require higher levels of antifreeze solutions. See the section on Antifreeze Requirements for more details. Any exposed piping above the frost line must be insulated with closed-cell insulation with ultraviolet (UV) protection (paint or wrap).

Example 5. Design the vertical ground coupling grid and the pumping loop for a 14 kW residential heat pump system. The home is located in Nashville, Tennessee, and the header pipes can be brought into the equipment room where the unit will be located. The driller can bore 115 mm holes to a depth of 53 m in the light limestone and clay at the site. The owner wants the drilling site to be located 23 m from the house. Thermally enhanced grout with thermal conductivity of 1.5 W/(m·K) is used to fill the annular region between the U-tubes and borehole walls.

Solution: The soil temperature is estimated to be 14.5°C in Nashville. Table 16 suggests bore lengths of 15 m/kW for 19 mm U-bends, 14 m/kW for 25 mm, and 13 m/kW for 32 mm (bores are deep, greater than 30 m). However, 32 mm U-bends are very difficult to install in a 115 mm borehole, and are not considered. Therefore, either 210 m (15 m/kW × 14 kW) of 19 mm U-bend coupling or 196 m (14 m/kW × 14 kW) of 25 mm coupling is required. The latter is used in this example. Also, Table 16 is based on a soil conductivity of 2.1 W/(m·K), which is an approximate

average between limestone and clay, and a bore fill (or grout) conductivity of 1.5 W/(m·K). If the ground conductivity is higher (i.e., more limestone than clay), the loops should be reduced as noted in Table 16; if lower, the loops should be lengthened. Loop lengths also must be lengthened if the bore fill (or grout) conductivity is lower than 1.5 W/(m·K), as noted in Table 16.

Layout is dictated by drilling conditions. The total length of 196 m requires four bores, because the driller can only drill to 53 m. This can be accomplished with four 48 to 50 m holes. Table 16 suggests between three and five parallel circuits for the grid. Three and five circuits do not divide evenly into the four U-bends. Therefore, four circuits (one per U-bend) should be used in an arrangement similar to Figure 25.

Central Plant Systems

Central plant GCHP systems use central water-to-water equipment (e.g., a water-cooled chiller) to move thermal energy between a source loop (the ground coupled heat exchanger), a chilled-water loop, and a hot-water loop.Here, the term *central plant* implies the mechanical equipment is in one centralized location; it does not imply a campus is served, and single buildings are a common application. The central plant source loop is commonly a vertical closed-loop heat exchanger, but any combination of GCHP types may be used. The chilled- and hot-water loops may serve any HVAC distribution equipment (fan coils or radiant systems are efficient options) as long as design hot-water supply temperatures do not exceed heat pump temperature ranges (typically 54.4°C). Best practice in these applications is largely theoretical or anecdotal; research is needed on the efficacy of the various central plant GCHP applications and designers considering central plant GCHPs must be cautious.

Compared to traditional unitary (water-to-air) GCHP systems, central plant systems offer the potential advantages of (1) incorporating direct heat recovery from hot-water loads to chilled-water loads, (2) sometimes allowing waterside economizing, (3) centralizing equipment maintenance, and (4) expanding retrofit opportunities. However, when such plants are connected to conventional distribution such as variable air volume (VAV), the loss of zone level heating and cooling results in large fan and reheat energy penalties. Pumping power is often higher than equivalent unitary heat pump systems. Central plants also have significantly more complex design, controls, commissioning, operational training, and maintenance. Most existing tools and methods for sizing ground heat exchangers and evaluating energy performance do not accurately represent central plant GCHP operation.

As with unitary systems, central plant systems may take many forms. Figure 26 illustrates the basic building blocks of a central plant GCHP system. Any number of heat recovery chillers and heating or cooling heat pumps may be installed. Either or both of the load-side loops may be connected to the source loop to achieve direct heat transfer (water economizing). The loops may be separated by control valves or heat exchangers (as shown in Figure

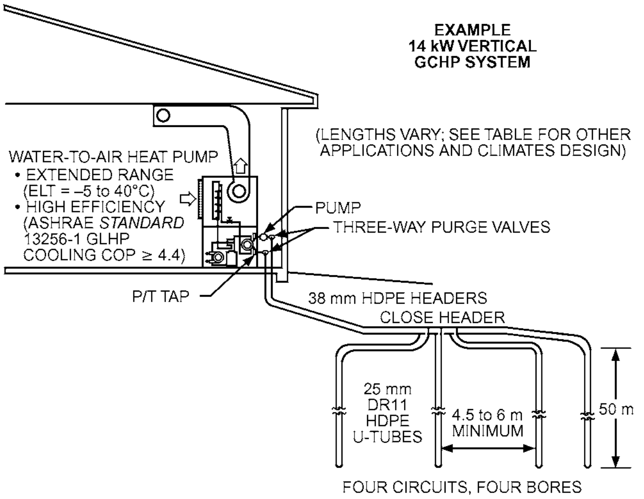

Fig. 25 Residential Design Example

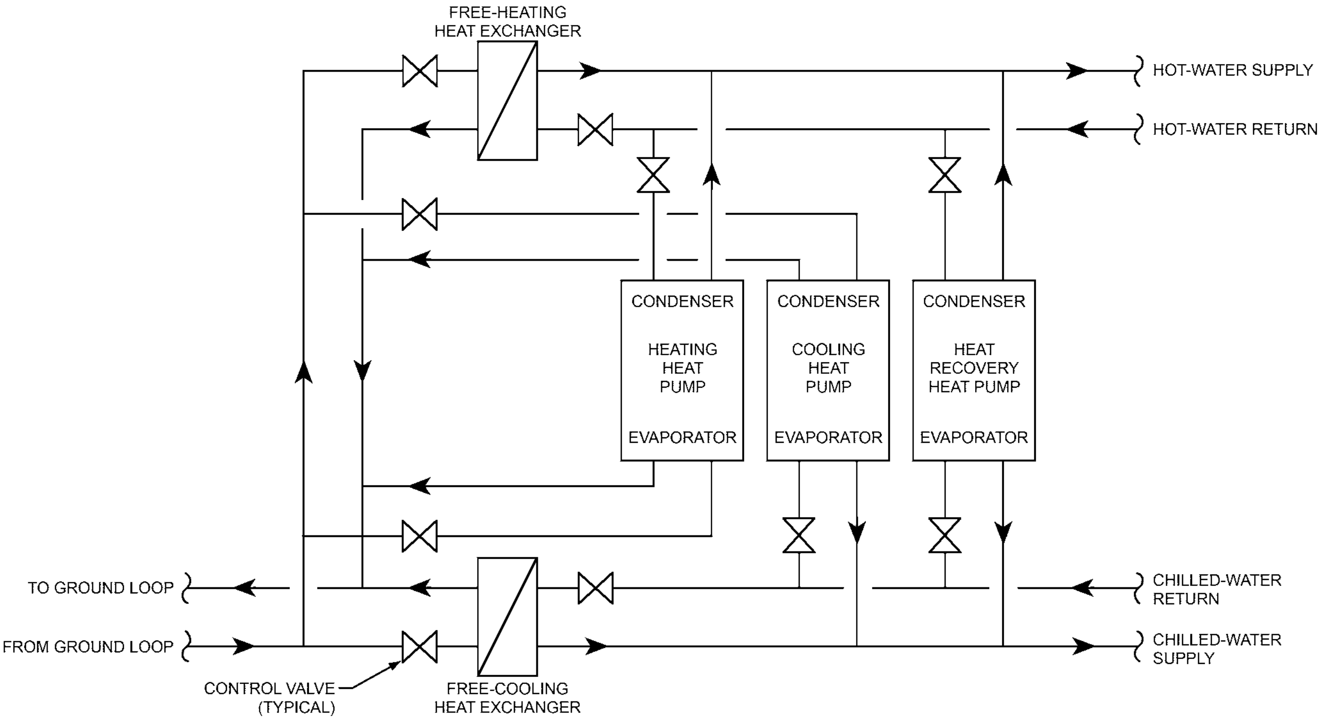

Fig. 26 Central Plant GCHP System

26), but loops should be linked only by control valves where fluid type and pressure are compatible.

Most central plant heat pump equipment is designed for use in one of three basic strategies:

- **Parallel water-to-water heat pumps:** dedicated heat pumps provide hot and/or chilled water in parallel. This type is often used in conjunction with unitary heat pumps or in simple applications where there is little opportunity for heat recovery or water economizing.
- **Packaged modular heat pumps:** multiple units are connected by control valves to any of the loops (source, hot water, or chilled water) such that each individual heat pump may serve for heating, cooling, or heat recovery.
- **Heat pump chiller:** one or more large heat recovery chillers, designed to operate with a large lift, operate to maintain both hot and chilled water at required temperatures. No dedicated cooling heat pump or heating heat pump is provided. The heat exchangers (or direct valve connections between loops) provide the means to achieve heat rejection or heat absorption with the ground heat exchanger.

To provide stable temperature control and part load operation, central plant GCHP systems can benefit from additional thermal capacitance (buffer tanks) on the load side loops. Any loop flow control methodology may be used; however, variable flow should be used to minimize pumping energy penalties where equipment allows. Consider using water as the working fluid wherever possible, because of the energy and capital cost associated with antifreeze solutions.

Central plant designers have the option to connect hybrid heating and cooling equipment to the load side of the heat pumps instead of the source/ground side, which adds redundancy and reduces pump and compressor energy at the expense of increased controls complexity. Hybrid air-cooled chillers may serve the chilled-water loop directly, whereas evaporative cooling equipment is best placed on the source loop in series or in parallel with the ground heat exchanger. Connecting a hybrid boiler to the hot-water loop reduces thermal stress for boilers designed to operate at higher temperatures and provides direct emergency heat; connecting a hybrid boiler to the source loop reduces control interconnection/complexity and reduces heat pump faults caused by low entering water temperatures.

Antifreeze Requirements

Closed-loop horizontal and surface water heat exchanger systems often require antifreeze in the circulating water in locations with significant heating seasons. Antifreeze may not be needed in a comparable vertical borehole heat exchanger, because the deep ground temperature is essentially constant. At a depth of 2 m, a typical value for horizontal heat exchangers, ground temperature varies by approximately ±5 K. Even if the mean ground temperature is 15°C in late winter, ground temperature at a 2 m depth drops to 10°C. The heat extraction process lowers the temperature even further around the heat exchanger pipes, probably by an additional 5 K or more. Even with good heat transfer to the circulating water, the entering water temperature (leaving the ground heat exchanger) is around 5°C. Lakes that freeze at the surface in the winter approach 4°C at the bottom, yielding nearly the same margin of safety against freezing of the circulating fluid. An additional 5 K temperature difference is usually needed in the heat pump's refrigerant-to-water heat exchanger to transfer heat to the refrigerant. Having a refrigerant-to-water coil surface temperature below the freezing point of water risks growing a layer of ice on the water side of the heat exchanger. In the best case, coil icing restricts and may eventually block the flow of water and cause a shutdown. In the worst case, ice could burst the tubing in the coil and require a major service expense.

Table 18 Suitability of Selected GCHP Antifreeze Solutions

Category	Methanol	Ethanol	Propylene Glycol	Potassium Acetate	CMA	Urea
Life-cycle cost	***	***	**1	**1	**1	***
Corrosion	**2	**3	***	**	**4	*5
Leakage	***	**6	**6	*7	*8	*9
Health risk	*10,11	**10,12	***10	***10	***10	***10
Fire risk	*13	*13	***14	***	***	***
Environment risk	**15	**15	***	**15	**15	***
Future-use risk	*16	**17	***	**18	**19	**19

Key: * Potential problems, caution in use required
** Minor potential for problems
*** Little or no potential for problems

Category	Notes
Life-cycle cost	1. Higher-than-average installation and energy costs.
Corrosion	2. High black iron and cast iron corrosion rates.
	3. High black iron, cast iron, copper, and copper alloy corrosion rates.
	4. Medium black iron, copper, and copper alloy corrosion rates.
	5. Medium black iron, high cast iron, and extremely high copper and copper alloy corrosion rates.
Leakage	6. Minor leakage observed.
	7. Moderate leakage observed. Extensive leakage reported in installed systems.
	8. Moderate leakage observed.
	9. Massive leakage observed.
Health risk	10. Protective measures required with use. See Material Safety Data Sheet (MSDS).
	11. Prolonged exposure can cause headaches, nausea, vomiting, dizziness, blindness, liver damage, and death. Use of proper equipment and procedures reduces risk significantly.
	12. Additives make ethanol poisonous for human consumption. See Material Safety Data Sheet (MSDS).
Fire risk	13. Pure fluid only. Little risk when diluted with water in antifreeze.
	14. Very minor potential for pure fluid fire at elevated temperatures.
Environment risk	15. Water pollution.
Future-use risk	16. Toxicity and fire concerns. Prohibited in some locations.
	17. Toxicity, fire, and environmental concerns.
	18. Potential leakage concerns.
	19. Not currently used as GSHP antifreeze solution. May be difficult to obtain approval for use.

Source: Heinonen and Tapscott (1996).

Several factors must be considered when selecting an antifreeze for a ground-loop heat exchanger; the most important are (1) effect on system life-cycle cost, (2) corrosivity, (3) leakage, (4) health risks, (5) fire risks, (6) environmental risks from spills or disposal, and (7) risk of future use (acceptability of the antifreeze over the life of the system). A study by Heinonen and Tapscott (1996) evaluating six antifreezes against these seven criteria is summarized in Table 18. No single material satisfies all criteria. Methanol and ethanol have good viscosity characteristics at low temperatures, yielding lower-than-average pumping power requirements. However, in concentrated forms they both pose a significant fire hazard. Methanol is also toxic, eliminating it from consideration in areas that require nontoxic antifreeze to be used. Propylene glycol had no major concerns, with only leakage and pumping-power requirements prompting minor concerns. Potassium acetate, calcium magnesium acetate (CMA), and urea have favorable environmental and safety

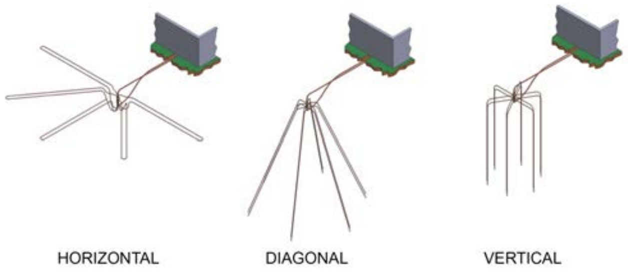

Fig. 27 DXGCHP Ground Heat Exchanger Configurations

performance, but are all subject to significant leakage problems, which has limited their use.

1.4 GROUND-COUPLED HEAT PUMP SYSTEMS USING REFRIGERANT-BASED HEAT TRANSFER FLUIDS (DIRECT EXCHANGE)

Direct-exchange ground-coupled heat pumps (DXGCHPs) circulate refrigerant from the heat pump in sealed copper tubing to directly exchange heat with the ground. In heating mode, the ground loop system functions as an evaporator, absorbing heat from the ground and causing the refrigerant to change phase from liquid to vapor. In cooling mode, the ground loop system functions as a condenser, discharging heat to the ground and changing the refrigerant from vapor to liquid. DXGCHP systems are applied primarily to residential and moderately sized commercial buildings, and are ideal for installation where space is limited because of the smaller ground loop footprint and drilling equipment required. Distribution systems for DXGCHPs use conditioned air delivered through a direct-expansion air handler or cased coil, hydronic heating and cooling, or both. Potable water heating is an option. DXGCHP systems can be applied to various geological formations and typically in locations with ground temperatures of 4.5 to 26.6°C. DXGCHPs are generally sized up to 21 kW. Multiple systems are specified for higher-capacity applications.

System Design

The DXGCHP system operation is very similar the GCHP shown in Figure 1, except that the refrigerant is piped directly through the ground loop, the buried polyethylene tubing is replaced with copper tubing, and the water circulating pump and refrigerant-to-water heat exchanger are eliminated.

DXGCHP ground heat exchanger systems can be horizontal, diagonal, or vertical (Figure 27). A typical DXGCHP distribution system illustrating the liquid and vapor manifold arrangement is shown in Figure 28. The ground heat exchangers are comprised of multiple individual ground loops, with the number of ground loops increasing with system capacity. Each loop is typically two copper tubes with a return bend connecting them at one end, and ranges in size from 6.4 to 12.7 mm OD, depending on the specific design. The tube diameter must be small to achieve high velocity, which ensures adequate oil return to the compressor, but large enough so the pressure drop does not significantly lower system performance. In addition, the selected lubricant must maintain a relatively low viscosity down to –15°C for proper oil return during the heating season.

The vertical and diagonal ground loop systems in Figure 27 require drilling 76 mm minimum diameter boreholes to accommodate a ground loop and thermal grout. The horizontal earth loop system in Figure 27 can be either a trench or pit configuration. All ground loop systems, including line sets and manifolds, must be at least 2.4 m below grade or 0.5 m below the local frost line, whichever is deeper, to ensure adequate year-round heat exchange with the surrounding ground.

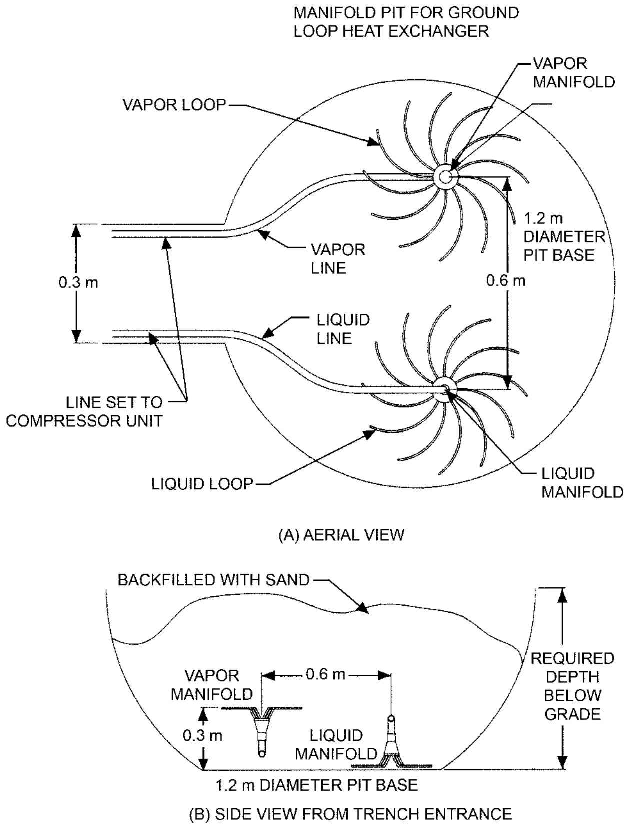

Fig. 28 Typical DXGCHP Ground Heat Exchanger Distribution System

DXGCHP heat exchanger lengths and configurations are currently selected using DXGCHP manufacturers' performance tables, which are based on empirical laboratory and field test data accrued over the last 40 years. Generalized analytical techniques for the design and application of DXGCHP ground heat exchanger systems are currently being developed. Using a manufacturer's performance tables requires knowledge of the soil temperature (e.g., from Figure 10), building loads (see ACCA [2008, 2016] and Chapters 17 and 18 of the 2017 *ASHRAE Handbook—Fundamentals*), and available land area and geology.

Available Land Area and Geology. The available land area, geology at the site, and knowledge and experience of local excavators and drillers influence the selected configuration of the ground heat exchanger. The specifier may make a preliminary selection of the ground loop configuration before sizing the system. In general, if the job site has relatively level land and enough space is available, excavating and installing a horizontal pit or trench ground loop system is economically attractive. There must be adequate space to put the excavated earth. Horizontal ground loops can also be installed by horizontally boring (see Figure 3).

If vertical ground loops are to be installed, the required drilling will disturb far less surface space than horizontal systems. Vertical systems for capacities up to 21 kW can be installed within a surface footprint of only 2.5 m diameter, which makes this configuration well suited for installation where ground surface area is limited. In addition, borehole diameters of 76 mm for each ground loop allow use of small, maneuverable drill rigs.

Site geology, including soil composition and associated thermal conductivity, is a major factor in selecting the appropriate ground loop configuration with sufficient ground loop surface area for effective heat transfer. DXGCHP manufacturers provide tables for selecting ground heat exchanger configurations and surface areas that accommodate various soil thermal conductivities. Sufficient soil samples should be taken from the ground loop field and analyzed for pH and potentially corrosive elements. If corrosive elements are present beyond the manufacturer's stated threshold levels, an alternative acceptable location for the ground heat exchanger system is required.

Ground Heat Exchanger Corrosion Protection System

DXGCHP ground heat exchangers are typically constructed of copper because of its high thermal conductivity and compatibility with refrigerant system pressures; annealed copper tubing is malleable, making it easy to install. Because it is a noble metal, it is almost impervious to corrosion from soils found worldwide. However, copper is still vulnerable to corrosion in aggressive soils, and must be protected. The simplest way to prevent corrosion is to apply cathodic protection by connecting the copper to another metal, typically zinc, which is more easily corroded. The sacrificial metal corrodes instead of the protected copper. Although this method of corrosion protection is low cost and easy to apply, a major drawback is that corrosion protection fades over time as the sacrificial metal deteriorates. The sacrificial metal must be replaced to maintain an adequate level of corrosion protection.

A more effective means of protecting copper in aggressive soils is the **impressed current cathodic protection (ICCP)** system (Figure 29). This system provides an electronically regulated continuous current from a titanium anode covered with a mixed-metal oxide, to the copper ground loops, resulting in superior long-term ground heat exchanger system durability and performance. DXGCHP manufacturers design ICCP systems as integral, matched components of specific DXGCHP systems to ensure superior corrosion protection for the ground heat exchanger, thus eliminating the need for the specifier to attempt designing the ICCP system separately. Part of the specification process includes contacting local utilities to learn whether there are existing underground impressed current protection systems, and the effective range of those systems, the proximity of which could potentially interfere with the DXGCHP ground heat exchanger protection system.

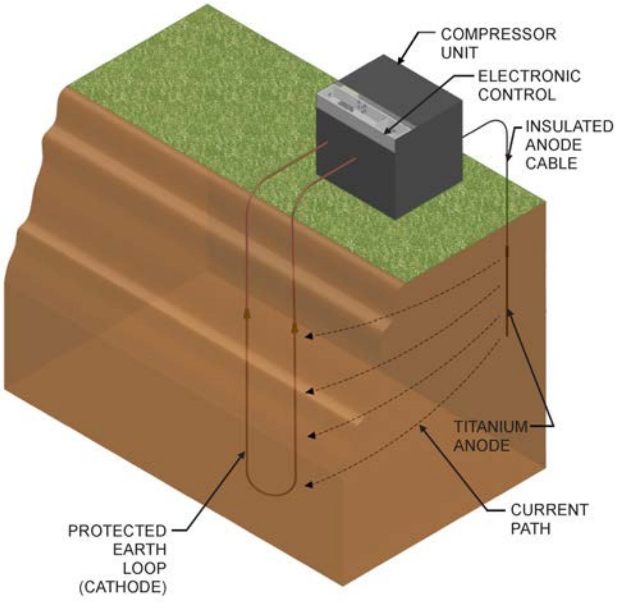

Fig. 29 Typical Impressed Current Protection System

1.5 OPEN-LOOP GROUNDWATER HEAT PUMP SYSTEM COMPONENTS

A groundwater heat pump system (GWHP) removes groundwater from a well and delivers it to a heat pump (or an intermediate heat exchanger) where heat is absorbed from or rejected to the water. Both unitary and central plant designs are used. In the unitary type, a large number of small water-to-air heat pumps are distributed throughout the building. The central plant design uses one or a small number of large-capacity chillers supplying hot and chilled water to a two- or four-pipe distribution system. The unitary approach is more common and tends to be more energy-efficient.

Direct systems (in which groundwater is pumped directly to the heat pump without an intermediate heat exchanger) are not recommended except on the very smallest installations. Although some systems of this design have been successful, many have had serious difficulty even with groundwater of apparently benign chemistry. Thus, prudent design for commercial/industrial-scale projects isolates groundwater from the building system with a heat exchanger. The increased capital cost of installing the heat exchanger is only a small percentage of the total cost and, in view of these systems' greatly reduced maintenance requirements, is quickly recovered.

Past GWHP systems sometimes used surface disposal (to rivers, lakes, drainage ditches, etc.) of the groundwater. Current standards use reinjection instead, because it eliminates the potential for negative effects on the aquifer water level over time and preserves the positive environmental character associated with GSHP systems.

Regardless of the type of equipment installed in the building, the specific components for handling groundwater are similar. Primary items include (1) wells (supply and injection), (2) well pump and controls, and (3) groundwater heat exchanger. Some specifics of these items are discussed in the Direct-Use Geothermal Energy section of this chapter. In addition to those comments, the following considerations apply specifically to unitary GWHP systems using a groundwater isolation heat exchanger.

Water Wells

This section includes information on water wells that is generally common to both direct-use and groundwater heat pump (GWHP) systems. Water well open-loop systems and standing column well best practices are covered in ANSI/CSA/IGSHPA *Standard* C448-16.

An **aquifer** is a geologic unit that can yield groundwater to a well in sufficient quantities to be of practical use (UOP 1975). Aquifers can exist in areas where water is present in conjunction with pore spaces in the subsurface materials sufficient to allow the water to move laterally.

In many projects, construction of the well (or wells) is handled through a separate contract between the owner and the driller or a hydrology/hydrogeology consultant. As a result, the engineer is not responsible for its design. However, because design of the building system depends on the wells' performance, it is critical that the engineer be familiar with water well terminology and test data. The most important consideration with regard to the wells is that they be completed and tested (for flow volume and water quality) before final system design, in much the same way that ground thermal properties testing precedes GCHP system design.

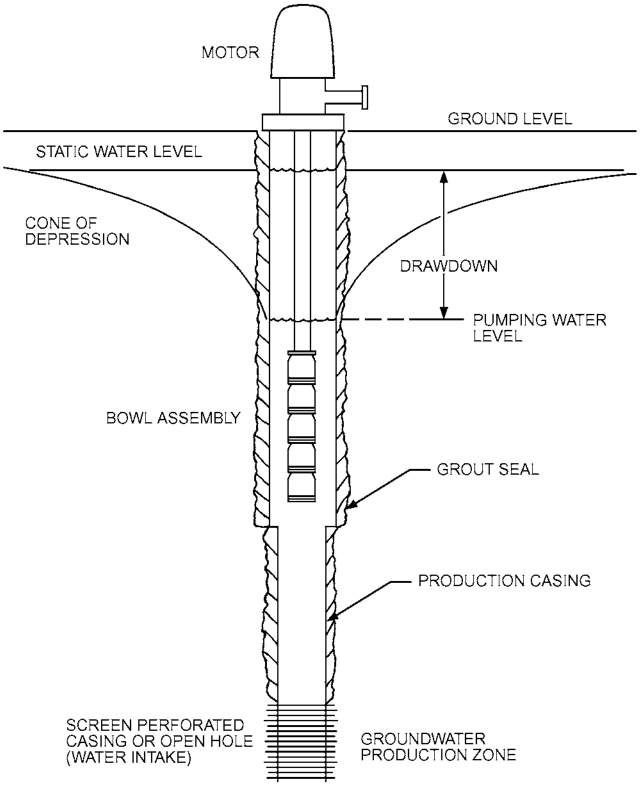

Fig. 30 Water Well Terminology

Figure 30 illustrates some important well terms. Several references (Anderson 1984; Campbell and Lehr 1973; EPA 1975; Roscoe Moss Company 1985) cover well drilling and well construction in detail.

Static water level (SWL) is the level that exists under static (nonpumping) conditions. In some cases, this level is much closer to the surface than that at which the driller encounters water during drilling. **Pumping water level (PWL)** is the level that exists under specific pumping conditions. Generally, this level is different for different pumping rates (higher pumping rates mean lower pumping levels). The difference between the SWL and the PWL is the **drawdown**. The well's **specific capacity** may be quoted in L/s per metre of drawdown. For example, for a well with a static level of 15 m that produces 30 L/s at a pumping level of 25 m, drawdown = 25 – 15 = 10 m; specific capacity = 30/10 = 3.0 L/s per metre.

Water entrance velocity (through the screen or perforated casing) can be an important design consideration. Velocity should be limited to a maximum of 0.03 m/s (0.015 m/s for injection wells) to avoid incrustation of the entrance openings. The **pump bowl assembly** (impeller housings and impellers) is always placed sufficiently below the expected pumping level to prevent cavitation at the peak production rate. For the previous example, this pump should be placed at least 30 m below the casing top (pump setting depth = 30 m) to allow for adequate submergence at peak flow. Along with any expected annual aquifer water level fluctuations, the specific **NPSH pressure** required for a pump varies with each application and should be carefully considered in selecting the setting depth along with any expected annual aquifer water level fluctuations.

For the well pump, **total pump pressure** is composed of four primary components: lift, column friction, surface requirements, and injection head (pressure). **Lift** is the vertical distance that

Table 19 Nominal Well Surface Casing Sizes

Pump Bowl Diameter, mm	Suggested Casing Size, mm	Minimum Casing Size, mm	Submersible Flow Range 3450 rpm, L/s	Lineshaft Flow Range, 1750 rpm, L/s
100	150	125	<5	<3
150	250	200	5 to 22	3 to 11
180	300	250	16 to 38	9 to 17
200	300	250	22 to 50	16 to 30
230	360	300	30 to 53	17 to 34
250	360	300	30 to 63	
300	400	360	57 to 82	

water must be pumped to reach the surface. In the example, lift is 25 m. The additional 5 m of submergence imposes no static pump head (pressure).

Column friction, the friction loss in the pump column between the bowl assembly and the surface, is calculated from pump manufacturer data in a similar manner to other pipe friction calculations (see Chapter 22 of the 2017 *ASHRAE Handbook—Fundamentals*). **Surface pressure requirements** account for friction losses through piping, heat exchangers, and controls, and in many applications are between 8 and 11 m. **Injection pressure requirements** are a function of well design, aquifer conditions, and water quality. In theory, an injection well penetrating the same aquifer as the production well experiences a water level rise (assuming equal flows) that mirrors the drawdown in the production well. Using the earlier example, an injection well with a 15 m static level would experience a water level rise of 10 m, resulting in a surface injection pressure of 10 – 15 = –5 m (i.e., a water level that remains 5 m below the ground surface). Thus, no additional pump head is required for injection in the example.

In practice, injection pressure requirements usually exceed the theoretical value. With good (non-scaling) water quality, careful drilling, and little sand production, injection pressure should be near the theoretical value. For poor water quality, high sand production, or poor well construction, injection pressure may be 10 to 40% higher.

The well casing diameter depends on the diameter of the pump (bowl assembly) necessary to produce the required flow rate. Table 19 presents nominal casing sizes for a range of water flow rates.

In addition to the production well, most systems should include an injection well to dispose of the fluid after it has passed through the system. Injection stabilizes the aquifer from which the fluid is withdrawn by reducing or eliminating long-term drawdowns, and helps to ensure long-term productivity. Construction of injection wells differs from production wells primarily in the recommended screen velocity (0.015 m/s, or 1/2 that of production wells) and well sealing design. Injection wells, particularly those likely to be subject to positive injection pressure, should be fully cased and sealed from the top of the injection zone to the surface.

It is commonly thought that wells, particularly injection wells, often fail, but failure is more often attributable to the designer than to the well itself. The most common factors in reduced water well (production and injection) performance are incrustation and biofouling of screens, formation plugging with fines, sand pumping, casing/screen collapse, and pump problems (Driscoll 1986). To a large extent, incrustation and biofouling can be reduced by minimizing drawdown through careful well design and the avoidance of excessive groundwater flows. Material selection appropriate for the water chemistry and avoidance of substandard casing and screen products can reduce or eliminate failures in these components. Sand production should be limited by screen, gravel pack, and development practices, or removed by strainers before injection. With such good practices, maintenance intervals can be reduced to approximately 10 to 15 years in favorable conditions, and 5 to 8 years in unfavorable settings. One key to successful water well operations is effective monitoring: regular testing of well yield, drawdown, specific capacity, and sand production, coupled with periodic review of trends in these parameters.

Flow Testing

When possible, well testing should be completed before mechanical design. Only with actual flow test data and water chemical analysis information can accurate design proceed.

Flow testing can be divided into three different types of tests: rig, short-term, and long-term (Stiger et al. 1989). Rig tests are generally very short and are accomplished while the drilling rig is on site. The primary purpose of this test is to purge the well of remaining drilling fluids and cuttings and to get a preliminary indication of yield. The length of the test is generally governed by the time required for the water to run clean. The rate is determined by the available pumping equipment. Frequently, the well is blown (pumped with the drilling rig's air compressor). As a result, limited information about the well's production characteristics is available from a rig test. If the well is air lifted, it may not be useful to collect water samples for chemical analysis because certain chemical constituents may be oxidized by the compressed air.

Properly conducted, short-term, single-well tests lasting 4 to 24 h yield information about well flow rate, temperature, drawdown, and recovery. These tests are used most frequently for direct-use and GWHP applications. The test is generally run with a temporary electric submersible pump or lineshaft turbine pump driven by an internal combustion engine and are often performed by a well pump contractor.

A step test (Table 20), the most common type, involves at least three production rates, the largest being equal to the design flow rate for the system served. The three points are the minimum required to determine a productivity curve for the well that relates production to drawdown (Stiger et al. 1989). The key parameters monitored during these tests are well water level and water flow. Water level and pumping rate should be stabilized at each point before flow is increased. In many cases, water level is monitored with a bubbler or an electric sounder, and flow is measured using an orifice meter. More sophisticated instrumentation (e.g., pressure transducers for water level, magnetic flow meters, data loggers) can also be used. Short-term testing is generally used for small projects and provides information on yield, drawdown, and specific capacity.

Test results should reflect stable flow rates, and individual flow steps are extended until water level readings stabilize. In many cases, brief intervals of turbidity may occur at flow changes, but extensive periods of turbidity indicate instability in the near-well formation.

Long-term tests of up to 30 days provide information on the reservoir. Normally, these tests involve monitoring nearby wells to evaluate interference effects. The data are useful in calculating transmissivity and storage coefficient, reservoir boundaries, and recharge areas (Stiger et al. 1989) but are rarely used for direct-use and GWHP systems.

It is also important to collect background information before the test, and water level recovery data after pumping has ceased. Recovery data in particular can be used to evaluate skin effect, which is a type of well flow resistance caused by residual drilling fluids, insufficient screen or slotted liner area, or improper filter pack.

Groundwater Quality

The importance of groundwater quality depends on the system design. Systems using isolation heat exchangers commonly encounter no water quality issues (other than iron bacteria) that would prevent a GWHP system from operating under reasonable maintenance levels.

Table 20 Example Well Flow Test Results SWL 21 m

For systems that use groundwater directly in heat pump units (e.g., standing-column systems and small residential GWHP systems), several issues are of concern. The primary water quality problem in the United States is scaling, usually of calcium carbonate (lime). Because this type of scaling is partially temperature driven, the temperature of surfaces that groundwater contacts determines the extent to which scaling will occur. In these systems, peak temperatures in the refrigerant-to-water exchanger in cooling mode are likely to be over 70°C. For the same system using an isolation plate heat exchanger, the groundwater is unlikely to encounter temperatures over 32°C. Using the plate heat exchanger reduces the propensity for scaling and limits any scale that does occur to a single heat exchanger. Rafferty (2000b) provides information on water scaling potential on a state-by-state basis.

Hydrogen sulfide can destroy the oxide layer on copper, copper-nickel alloys, and stainless steels, and make these metals vulnerable to acidic corrosion. Titanium heat exchangers are recommended for hydrogen-sulfide-bearing waters.

Excessive iron, particularly ferrous iron, in the water can result in coating of heat transfer surfaces if the water is exposed to air (allowing the iron to oxidize to the ferric state, a form with much lower solubility in water). Periodically removing this iron from the plates of a single heat exchanger is much less labor intensive than removing it from tens or hundreds of individual heat pump heat exchangers. Table 21 summarizes the minimum parameters that should be evaluated for a GWHP application.

Particulate matter (e.g., sand) in the groundwater stream, although usually not a problem in the mechanical system, can effectively plug injection wells. Sand production should be addressed in construction of the production well (screen/gravel pack/development). If it must be dealt with on the surface, a screen or strainer is preferable to a centrifugal separator, which can be ineffective at start-up and shutdown and can experience variable flow (Kavanaugh and Rafferty 2014). Perforation size selection is critical to a strainer's effectiveness, and should be based on 90 to

Table 21 Water Chemistry Constituents

Quality	Comment
pH	Typical range: 6.5 to 9.0. Lower values typically associated with higher rates of general corrosion in ferrous and copper alloys; higher values associated with scaling.
TDS	Total dissolved solids: gross indicator of quantity of dissolved constituents. Higher levels associated with increased corrosion and/or scaling; used in calculation of scale index.
Fe	Iron: use care to prevent exposure to air; problems possible at >0.5 ppm.
Total M alkalinity	Ability of water to buffer acid; strongly linked to scale and used to calculate scaling index. Usually expressed as ppm $CaCO_3$.
Ca	Calcium ion: linked to scaling of water and used to calculate scaling index. Expressed in ppm Ca × 0.5 = ppm as $CaCO_3$.
CO_3/HCO_3	Carbonate/bicarbonate: varies in concentration with pH.
Hardness	Linked to scaling and used to calculate scale index; at >100 ppm, scaling can occur. Expressed in ppm or g/m^3.
Cl	Chloride: accelerates corrosion of carbon and stainless steels; may be elevated in coastal areas.
Mn	Manganese: causes black scale; possible deposits at >0.2 ppm.
O_2	Oxygen: dissolved gas; accelerates corrosion; promotes other reactions; test in field.
H_2S	Hydrogen sulphide: dissolved gas; rotten egg odor >0.5 ppm; attacks copper alloys; test in field.
CO_2	Carbon dioxide: dissolved gas, often present at pH < 7.5, test in field. GW pressurization keeps CO_2 in solution.
Stability index	
(Ryznar index)	Originally developed to predict corrosion but used in GWHP for scaling prediction; calculated from temperature, Ca, TDS, alkalinity, and hardness. Must use temperature reflective of application: 29°C for systems with plate heat exchanger, 66°C for nonisolated systems.
Saturation index	
(Langlier index)	Similar to stability index. Originally developed to predict corrosion but used in GWHP for scaling prediction; calculated from temperature, Ca, TDS, alkalinity, and hardness. Must use temperature reflective of application: 29°C for systems with plate heat exchanger, 66°C for nonisolated systems
BART	Bacteriological activity reaction test: broad indicator of various bacteria. Most common tests are for iron-reducing (IRB), slime-forming (SLYM), and sulfate-reducing (SRB) bacteria.

100% removal of the particulate material. Particle size information can be based on the sieve analysis results of drill cuttings (used to size the well screen) or of a sample taken during well flow testing. In applications with very fine sand, multiple strainers in parallel may be necessary to control pressure drop (Rafferty 2008).

Well Pumps

Submersible pumps have not performed well in higher-temperature, direct-use projects. However, the submersible pump is a cost-effective option with normal groundwater temperatures, as encountered in heat pump applications. The low temperature eliminates the need to specify an industrial design for the motor/protector, thereby greatly reducing the first cost relative to direct use. Caution should still be used for wells that are expected to produce moderate amounts of sand. The high speed (nominal 60 Hz) of most submersible pumps makes them susceptible to erosion damage. Applications with sand/particles greater than 400 to 600 μm should specify sand fighter submersible pump configurations.

Small groundwater systems have frequently been identified with excessive well pump energy consumption. The reasons for excessive pump energy consumption (high water flow rate, coupling to the domestic pressure tank, and low efficiency of small

submersible pumps) are generally not present in large, commercial groundwater systems. In large systems, the groundwater flow per unit capacity is frequently less than half that of residential systems. Pressure at the wellhead is not the 200 to 350 kPa typical of domestic systems, but is rather a function only of pressure losses through the groundwater loop. Finally, large well pumps have efficiencies of up to 83% compared to the 35 to 40% range for small submersible pumps.

In GWHP system design, the control method for the well pump determines the extent to which the optimum relationship between well pump power and heat pump power is preserved at off-peak conditions. There are several ways the pump can be controlled. Multiple pumps can be staged to meet system loads, either with multiple wells or with multiple pumps installed in a single well. A dual set-point control similar to that used in boiler/tower systems energizes the well pump above a given temperature in cooling mode and below a given temperature in heating mode. Between those temperatures, the building loop floats without the addition of groundwater. To control well pump cycling, it is necessary to establish a temperature range (difference between pump-on and pump-off temperatures) over which the pump operates in both the heating and cooling modes. The size of this range is primarily a function of the building loop water volume in terms of litres per peak per kilowatt of peak block system load (Rafferty 2000c). Table 22 summarizes these data. In the example in Table 23, the optimum system building loop return temperature (at peak system EER) is 27.0°C. If this system had a water volume of 8.61 L/kW, from Table 22, a range of 4 K in cooling mode would be required. This range would result in a well pump start temperature of 27.0 + (4/2) = 29°C and a well pump stop temperature of 27.0 – (4/2) = 25°C. A similar calculation can be made for heating mode. From Table 22, for systems with very low thermal mass, the dual set-point method of control becomes impractical because of the very large temperature range required. For these applications, an alternative method of control (variable speed, staging, etc.) is required.

Well pumps may also be controlled using a variable-speed drive, which responds to building loop return temperature by varying groundwater flow to the exchanger to maintain the cooling or heating mode set point. Submersible-motor variable-speed applications are somewhat different than surface motor applications. Most manufacturers limit speed reduction to 50%, and other issues such as minimum water velocity for motor cooling, switching frequency, reactor requirement, and motor protection must be addressed. Additional information on VFD applications for submersible motors is available in Rafferty (2008).

Heat Exchangers

Design of a plate-and-frame heat exchanger is largely a trade-off between pressure drop, which influences pumping (operating cost), and overall heat transfer coefficient, which influences surface area (capital cost). In general, exchangers in GWHP systems can be economically selected for approach temperatures (between loop return and groundwater leaving temperatures) as low as 1.7 K. Most selections involve an approach of between 1.7

and 3.9 K and a pressure drop of less than 70 kPa on the building loop side. Excessive fouling factors (>3.5 × 10^{-5} [m^2·K]/W) should not be specified when selecting plate heat exchangers, which can be easily disassembled and cleaned.

Heat exchanger cost may be reduced for groundwater applications by using Type 304 stainless steel plates rather than the Type 316 or titanium plates common in direct-use projects. The low temperature and generally low chloride content of heat pump fluids frequently make the less expensive Type 304 material acceptable. Chloride content of the groundwater, particularly in coastal areas, should always be compared to values in Figure 40 to determine plate material acceptability. Exchanger performance should be checked at minimum system flow rates to ensure adequate heat transfer. In some cases, very low design pressure drop selections can encounter inadequate heat transfer at minimum flows.

1.6 OPEN-LOOP GROUNDWATER HEAT PUMP SYSTEM DESIGN

Extraction Well Commercial Systems

This section applies to systems with an extraction well and means to return the water elsewhere, such as reinjection wells or surface disposal. An open-loop system design must balance well pumping power with heat pump performance. As groundwater flow increases through a system, more favorable average temperatures are produced for the heat pumps. Higher groundwater flow rates, to a point, increase system EER or COP: increased well pump power is outweighed by decreased heat pump power requirements (because of the more favorable temperatures). At some point, additional increases in groundwater flow result in a greater increase in well pump power than the resulting decrease in heat pump power. The key strategy in open-loop system design is identifying the point of maximum system performance with respect to heat pump and well pump power requirements. Once this optimum relationship has been established for the design condition, the method of controlling the well pump determines the extent to which the relationship is preserved at off-peak conditions. This optimization process involves evaluating the performance of the heat pumps and well pump(s) over a range of groundwater flows. Key data necessary to make this calculation include well performance (flow and drawdown at various groundwater flows) and heat pump performance versus entering water temperatures at different flow rates. Well information is generally derived from well pump test results. Heat pump performance data are available from the manufacturer.

GWHP systems employ the same type of extended-range unitary heat pumps as GCHP systems. Building loop pumping guidelines (see Table 6) in the GCHP portion of this chapter also apply to GWHP systems. In large commercial applications, the head loss associated with the isolation heat exchanger in a GWHP system is typically lower than that of an equivalently sized ground heat exchanger in a GCHP system. A guideline for building loop head loss in a GWHP system can be described as follows:

$$\text{Building loop head loss (kPa)} = 84 + 0.01d$$

where d = pipeline distance m from plate heat exchanger outlet to most distant heat pump unit inlet.

This calculation assumes a maximum pressure loss of 4 kPa/10 m, fittings at 25% of total pressure loss, and a heat pump unit pressure loss of 36 kPa. Because of more extensive fittings, retrofits can sometimes exceed this value.

For moderate-efficiency heat pumps (COP of 4), efficient loop pump design (0.016 W/W), and a heat exchanger approach of 1.5°C, Figure 31 provides curves for two different groundwater temperatures (GWT = 10 and 18°C) and two well pump situations

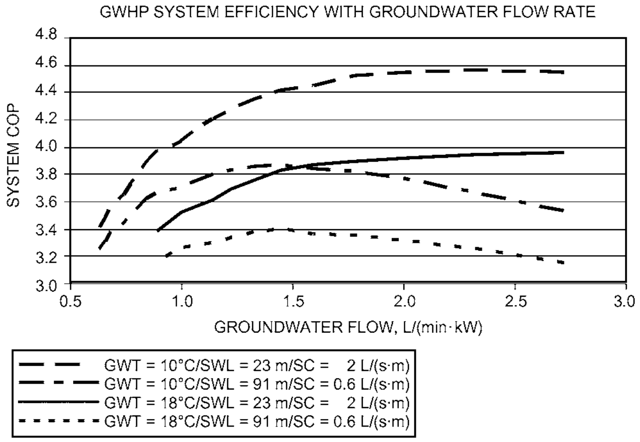

Fig. 31 Optimum Groundwater Flow for Maximum System COP

SWL is static water level in m, and
SC is specific capacity of well in L/(s·m).
(Kavanaugh and Rafferty 2014)

(static water level [SWL] 23 m/specific capacity 2 L/[s·m] and SWL 91 m/specific capacity 0.6 L/[s·m]). The curves are plotted for constant well pump head, a situation which does not occur in practice. In reality, well pump head rises with flow but at a rate typically less than that in friction head applications.

Although the four curves show a clear optimum flow, sometimes operating at a lower groundwater flow reduces well/pump capital cost and the problem of fluid disposal. These considerations are highly project specific, but do afford the designer some latitude in flow selection. Generally, an optimum design results in a groundwater flow rate that is less than the building loop flow rate.

The exception is when groundwater temperatures are less than 8.3°C or greater than 22.2°C. In these situations, the groundwater flow requirement is influenced more by avoiding excessive heat pump EWT in the cooling mode (groundwater temperatures above 22.2°C) and heat pump LWTs that could result in freezing conditions in the heating mode (groundwater temperatures less than 8.3°C). In the case of low water temperatures, some designers have found it advantageous to use antifreeze in the building loop to slightly broaden the allowable loop temperature range.

Table 23 provides design data for a specific example system.

Central Plant Systems

Central plant systems, in which a conventional or heat recovery central chiller is connected to a four-pipe system, are the oldest type of open-loop design, having first been installed in the late 1940s. Because of the cost and energy requirements of the central plant design, these systems typically do not result in the same level of energy efficiency as unitary GWHP systems.

For central plant groundwater systems, two heat exchangers are normally used: one in the chilled-water loop and one in the condenser water loop (Figure 32). The evaporator-loop exchanger provides a heat source for heating-dominated operation and the condenser-loop exchanger provides a heat sink for cooling-dominated operation.

Sizing the **condenser-loop exchanger** is based on providing sufficient capacity to reject the condenser load in the absence of any building heating requirement.

Sizing the **chilled-water-loop exchanger** must consider two loads. The primary criterion is the load required during heating-dominant operation. The exchanger must transfer sufficient heat

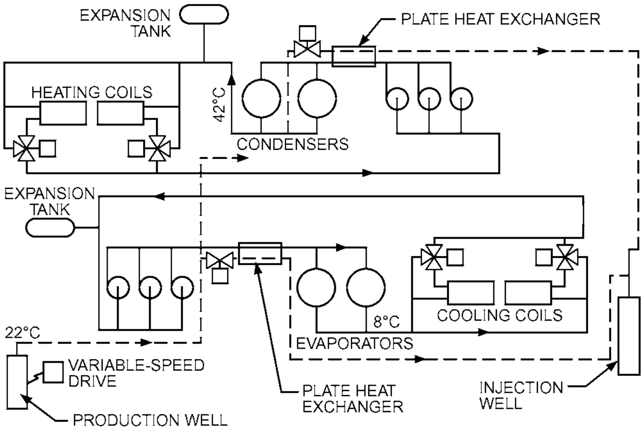

Fig. 32 Central Plant Groundwater System

*Block cooling load 300 kW, 15.5°C groundwater, 23 m well static water level, 0.41 L/(s·m) specific capacity, 11 m surface head losses, 2.2 K heat exchanger approach, 13 L/s building loop flow at 20 m pressure.

(when combined with compressor heat) from the groundwater to the chilled-water loop to meet the building's space heating requirement. Depending on the relative groundwater and chilled-water temperatures and on the design temperature rise, exchangers may also provide some free cooling during cooling-dominant operation. If groundwater temperature is lower than that of chilled water returning to the exchanger, some chilled-water load can be met by the exchanger. This mode is most likely available in regions with groundwater temperatures below 15°C.

Central plant chiller controls must also allow for the unique operation with a groundwater source. Controls can be similar to those on a heat recovery chiller with a tower, with one important difference. In a conventional heat recovery chiller, waste heat is available only when there is a building chilled-water (or conditioning) load. In a groundwater system, a heat source (the groundwater) is available year round. To take advantage of this source during the heating season, the chiller must be loaded in response to the heating load instead of the chilled-water load. That is, the control must include a heating-dominant mode and a cooling-dominant mode. Two general designs are available for this:

- Chiller capacity remains controlled by chilled-water (supply or return) temperature, and groundwater flow through the chilled-water exchanger is varied in response to the heating load

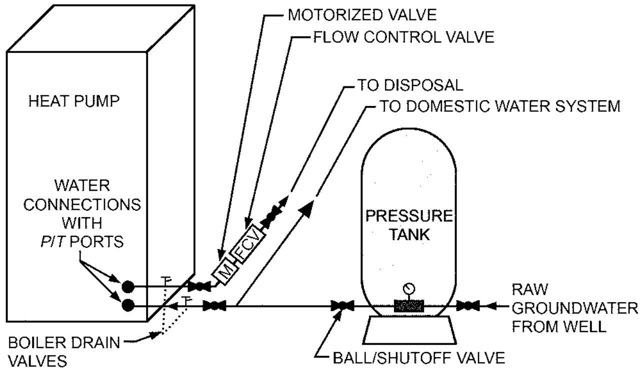

Fig. 33 Motorized Valve Placement

- Chiller capacity is controlled by the heating-water (condenser) loop temperature, and groundwater flow through the chilled-water exchanger is controlled by chilled-water temperature

For buildings with a significant heating load, the former may be more attractive, whereas the latter may be appropriate for conventional buildings in moderate to warm climates.

Extraction Well Residential Systems

This section applies to systems with an extraction well and means to return the water elsewhere, such as reinjection wells or surface disposal. Residential groundwater heat pump systems have the same design considerations as commercial groundwater heat pump systems, but differ on three main items: typically they (1) are integrated with a household domestic water system, (2) are single-zone systems, and (3) do not isolate the groundwater from the heat pump unit(s).

Groundwater heat pumps are a prudent choice in residential buildings on well water if the groundwater is of good quality. As such, the heat pump can be integrated into the domestic water system and considered another water-using appliance. Design care must be taken to ensure that the well and pressure tank have adequate capacity to handle the additional flow demand of the heat pump. Well pumps may be of the submersible or jet type, and the design groundwater flow rate should be chosen based on its temperature such that the system COP or EER is maximized. Flow control valves are recommended in the discharge line to ensure that the well is not over-pumped. Placement of a slow-closing motorized valve also on the discharge line ensures positive pressure on the heat pump water coil, and stops the flow of water when the heat pump is not operating (Figure 33). Flow control valves may be noisy as they meter flow. This noise can be mitigated by placing the motorized shutoff valve, with its associated pressure drop, after (downstream of) the flow control valve.

The pressure tank provides water at pressure on demand without short-cycling the well pump. A prepressurized bladder tank is preferred, and it should be large enough that filling it with the well pump takes at least 1 min.

Residential groundwater heat pump systems are small enough that the additional cost of an isolation heat exchanger is typically not economically justified. Raw groundwater is generally used as the heat transfer fluid, but provisions must be made (such as hose bibs or boiler drains) to allow for flushing and descaling of the heat pump water/refrigerant coil if necessary.

After exiting the heat pump, groundwater should be returned to a point of discharge in accordance with best practices and/or local codes. Surface discharge to a pond or wetland, or infiltration in to a dry well may be more of an option in these smaller systems than

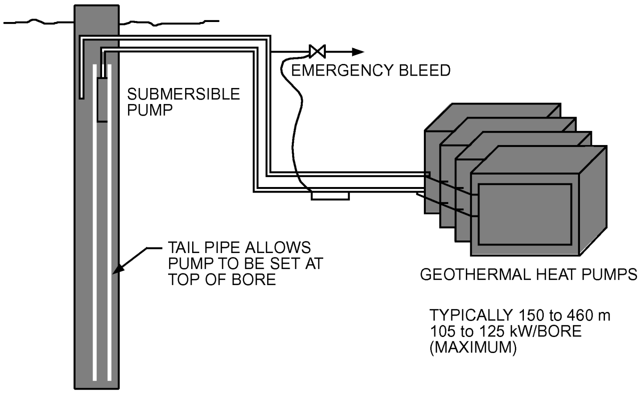

Fig. 34 Commercial Standing-Column Well

with larger commercial systems due to the correspondingly lower flow rates.

Standing-Column Systems

Standing-column systems use the same well to extract and re-inject the water (Figure 34), and consist of a borehole cased in steel or other material until competent bedrock is reached. The casing must be driven 7.5 to 15 m into, and sealed in, the competent bedrock. Bedrock sealing requirements vary by state. The remaining depth of the well is then self supporting through bedrock. Standing-column wells (SCWs) are most practical and cost effective when used in areas with near-surface (<60 m) consolidated bed rock; the long steel/PVC casing needed to reach deeper bedrock can make the systems very expensive. Though standing-column systems have been applied mostly in the northeastern United States, approximately 60% of the country is underlain by near-surface bedrock suitable for the systems.

The SCW combines supply and injection wells into one, and does not depend on the presence or flow of groundwater, beyond that of the typical bleed rate of 10 to 20% of total pumped flow (based on a 0.055 L/[s·kW] design flow rate). The bleed circuit effectively extracts water from the SCW by diverting part of the water returning from the heat pump into a reinjection well, storm drain, or roof drain, but generally not into sewer or septic systems. SCWs are always augmented with a bleed circuit to monitor the entering water temperature. Further, the bleed circuit can be used to promote advective flow (bleed circuit reduces water level in SCW and therefore increases flow of groundwater, which is near the undisturbed ground temperature, into the well) to regulate the entering water temperature (Figure 34). The additional advective flow can restabilize (i.e., bring back to far-field temperatures by overflowing smaller amounts of water on command) well water temperatures that are below or above design limits because of variations in rock conductivity, building anomalies, or nonstandard weather patterns. This advective flow is a powerful short-term method of warming and cooling well columns that are beyond design limits. Additional advective flow can be promoted by drawing water from the well for domestic or commercial use. Bleed operation is most critical during winter: entering water temperatures below 4.5 to 5.5°C can result in water leaving the heat pump(s) at less than 1°C, for systems designed for flows of 0.05 L/(s·kW). Adequate control to bleed the SCW or shut the heat pump off (and instead use backup heat) must be provided to avoid freezing the water in the heat exchangers.

Water being returned to the bore cannot be allowed to free fall. Free falling water entraps air, which reduces heat exchanger performance and promotes scaling and microbial corrosion. The water should be returned to the SCW using a solid drop pipe, typically 7.5 to 15 m below the level of the maximum static water depth. If the drop pipe contains more than 10 m of water, a perfect vacuum is formed. With a vacuum on the return line, the bleed circuit cannot release water, and air will be drawn in. Therefore, a back-pressure device should be installed in the return line between the bleed-circuit tee and the SCW, to maintain a positive gage pressure of 35 to 70 kPa at the bleed-circuit tee.

For residential application, a 75 to 150 m well provides a heating/cooling capacity of 7 to 28 kW. A relatively simple SCW is used where a submersible well pump is placed at the bottom of the bore. In many jurisdictions, a single well can function with the dual use of geothermal heat transfer and domestic water. In addition to saving construction costs, this technique enhances advective heat transfer by daily use of domestic water. Dual-use wells typically require (1) the submersible pump to be at a lower elevation than the return drop pipe and (2) installation of a back-flow preventer between the heat pump and the domestic water take-off line.

For commercial application, a heating capacity of 370 to 445 kW or cooling capacity of 105 to 125 kW can be expected from a single 460 m deep standing-column well. These estimated capacities assume a 10% (0.055 L/[s·kW]) on command and intermittent advective bleed flow. For deep commercial SCWs more than 152 m, a tail pipe (porter shroud assembly [PSA]) is inserted to form a conduit to draw up water, and an annulus to return water downward (ANSI/CSA/IGSHPA *Standard* C448-16). This tail pipe is perforated at the bottom to form a diffuser. Water is drawn into the diffuser and up the central riser pipe to the submersible pump. The well pump must be located below the water table in line with the central riser pipe. The tail pipe allows a shorter, reduced-power wire size as well as more accessible well pump service. SCW well bore configurations are based upon casing-to-bedrock size, bedrock bore size, and PSA size. The most common SCW is 400 m deep and uses an 200 mm casing into bedrock pocket, 150 mm rock bore and a 100 mm PSA. The designer can anticipate stable and slightly higher temperature from the well bottom; below 150 m ground water temperatures typically increase by 0.45 to 0.9 K per 100 m. Ideal spacing between SCWs is 15 to 28 m, to inhibit well-to-well thermal interference (Orio et al. 2005). Typically, spacing between SCWs is greater than vertical closed-loop (GCHP) boreholes. Closer spacing affects well field performance and can be evaluated with design software. Additional information on standing-column systems can be found in Spitler (2002).

In practice, SCWs are a trade-off between extraction well groundwater systems and GCHPs. Flow testing requirements for SCWs are less extensive than for extraction well groundwater systems. The capacity per bore length is less than extraction well systems because SCWs are recharged by advection of only 10 to 20% of total pumped flow, rather than 100% of flow with extraction wells. The SCW capacities are larger than for closed-loop GCHPs because SCWs promote partial advection; they have lower bore thermal resistance since there is no conduction resistance from grout or plastic pipe; and well depths can be deeper without application problems related to large pressure drop in long, narrow pipes.

The U.S. Environmental Protection Agency (EPA) Underground Injection Control program considers standing-column reinjection well water a Class V water use, type 5A7, noncontact cooling water for geothermal heating and cooling. The EPA and equivalent state agencies regard SCW reinjection as a beneficial use. Permitting or notice may be required, depending on average daily water flow rates. SCWs are serviced by qualified well contractors with minimal familiarization training.

1.7 SURFACE WATER HEAT PUMPS

Surface water bodies can be very good heat sources and sinks if properly used. In some cases, lakes can be the very best water supply for cooling. Various water circulation designs are possible; several of the more common are presented here. ANSI/CSA/IGSHPA *Standard* C448-16 contains guidance for both open- and closed-loop surface water heat exchangers.

In a **closed-loop system**, one or more water-to-water or water-to-air heat pumps are linked to one or more submerged coils or flat plate heat exchangers, referred to as **surface water heat exchangers (SWHEs)**. Heat is exchanged to (cooling mode) or from (heating mode) the lake by the fluid (usually a water/antifreeze mixture) circulating inside the SWHE. The heat pump transfers heat to or from the air in the building.

In an **open-loop system**, water is pumped from the lake through a heat exchanger and returned to the lake some distance from the point at which it was removed.

Thermal stratification of water often keeps large quantities of cold water undisturbed near the bottom of deep lakes. This water is cold enough to adequately cool buildings by simply being circulated through heat exchangers. A heat pump is not needed for cooling, and energy use is substantially reduced. Closed-loop coils may also be used in colder lakes. Heating can be provided by a separate source or with heat pumps in heating mode. As noted previously, precooling or supplemental total cooling are also allowed when water returning to the building is near or below 13°C.

Heat Transfer in Lakes

Heat is transferred to lakes by three primary modes: radiant energy from the sun, convective heat transfer from the surrounding air (when the air is warmer than the water), and conduction from the ground. Solar radiation, which can exceed 950 W/m^2 of lake area, is the dominant heating mechanism, but it occurs primarily in the upper portion of the lake unless the lake is very clear. About 40% of solar radiation is absorbed at the surface (Pezent and Kavanaugh 1990). Approximately 93% of the remaining energy is absorbed at depths visible to the human eye.

Convection transfers heat to the lake when the lake surface is cooler than the air. Wind speed increases the rate at which heat is transferred to the lake, but maximum heat gain by convection is usually only 10 to 20% of maximum solar heat gain. Conduction gain from the ground is even less than convection gain (Pezent and Kavanaugh 1990).

Lakes are cooled primarily by evaporative heat transfer at the surface. Convective cooling or heating in warmer months contributes only a small percentage of the total because of the relatively small temperature difference between the air and lake surface. At night when the sky is clear, longwave radiation can account for significant amount of cooling. The relatively warm water surface radiates heat to the cooler sky. For example, on a clear night, a cooling rate of up to 160 W/m^2 is possible from a lake 14°C warmer than the sky. The last mode of heat transfer, conduction to the ground, does not play a major role in lake cooling (Pezent and Kavanaugh 1990), though it does provide significant heating under winter conditions (Gu and Stefan 1990) when the surface of the lake is frozen.

To put these heat transfer rates in perspective, consider a 4000 m^2 lake used in connection with a 35 kW heat pump. In cooling mode, the unit rejects approximately 44 kW to the lake. This is 11 W/m^2, or approximately 1% of the maximum heat gain from solar radiation in the summer. In winter, a 35 kW heat pump absorbs only about 26 kW, or 6.5 W/m^2, from the lake.

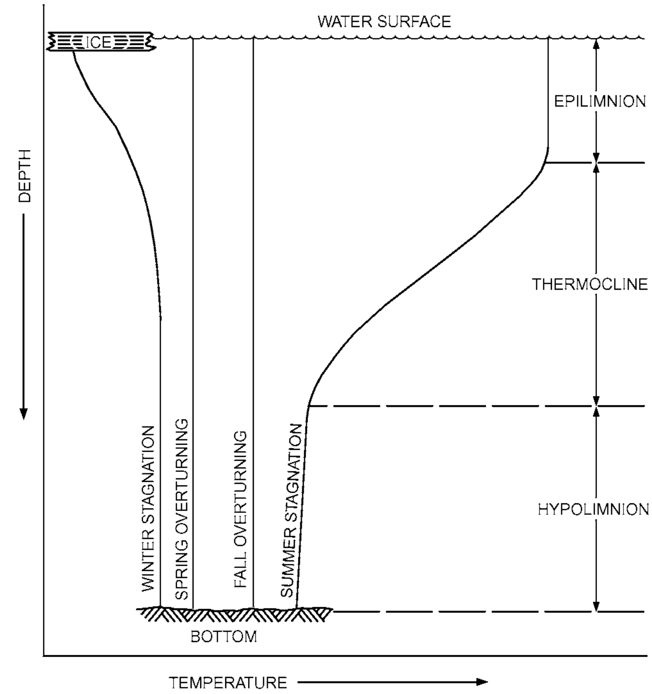

Fig. 35 Idealized Diagram of Annual Cycle of Thermal Stratification in Lakes

Thermal Patterns in Lakes

The maximum density of water occurs at 4.0°C, not at the freezing point of 0°C. This phenomenon, in combination with normal modes of heat transfer to and from lakes, produces temperature profiles advantageous to efficient heat pump operation. In the winter, the coldest water is at the surface. It tends to remain at the surface and freeze. The bottom of a deep lake stays 3 to 5 K warmer than the surface. This condition is referred to as **winter stagnation**. The warmer water is a better heat source than the colder water at the surface.

As spring approaches, the surface water warms until the temperature approaches the maximum density point of 4.0°C. The winter stratification becomes unstable, and circulation loops begin to develop from top to bottom. This condition of spring overturn (Peirce 1964) causes the lake temperature to become fairly uniform.

Later in the spring, as water temperatures rise above 7°C, the circulation loops are in the upper portion of the lake. This pattern continues throughout the summer. The upper portion of the lake remains relatively warm, with evaporation cooling the lake and solar radiation warming it. The lower portion (hypolimnion) of the lake remains cold because most radiation is absorbed in the upper zone. Circulation loops do not penetrate to the lower zone, and conduction to the ground is quite small. The result is that, in deeper lakes with small or medium inflows, the upper zone is 21 to 32°C, the lower zone is 4 to 13°C, and the intermediate zone (thermocline) has a sharp change in temperature in a small change in depth. This condition is referred to as **summer stagnation**.

As fall begins, the water surface begins to cool by radiation and evaporation. With the approach of winter, the upper portion begins to cool toward the freezing point and the lower levels approach the maximum density temperature of 4.0°C. An ideal temperature-versus-depth chart is shown in Figure 35 for each of the four seasons (Peirce 1964).

Many lakes do exhibit near-ideal temperature profiles. However, (1) high inflow/outflow rates, (2) insufficient depth for stratification, (3) level fluctuation, (4) wind, and (5) lack of enough cold weather to establish sufficient amounts of cold water necessary for summer stratification can disrupt the profile. Therefore, a thermal survey of the lake should be conducted or existing surveys of similar lakes in similar geographic locations should be consulted (Hattemer and Kavanaugh 2005). When interpreting survey data, be aware that there are annual variations in temperature profiles that will not be reflected in measurements for a single year. Shallow ponds and lakes often destratify completely. This does not preclude their use for SWHP systems, but does reduce performance in cooling mode and may require larger heat exchangers compared to lakes that remain stratified.

The thermal and environmental effects of heat rejection and absorption on larger lakes and streams have been studied (Bashyum et al. 2017; Hattemer et al. 2006; Spitler and Mitchell 2016). However, the effect of SWHPs on thermal stratification profiles is not well characterized, and there is a lack of experimental data. The relative importance of heat transfer modes is not well known, especially during heating mode. There are no publicly available design tools that consider the many heat and mass flow modes of lakes, streams, and oceans. The model of unstratified ponds developed by Chiasson et al. (2000b) has been implemented in publicly available energy calculation programs, but its lack of accounting for stratification, freezing on the coil, or freezing at the surface limits its usefulness for analysis of deeper lakes and operation in heating mode. The model developed by Spitler et al. (2012) accounts for stratification and for freezing both on the coil and at the surface, but makes several approximations such as neglecting inflows, outflows, and water level variations. Furthermore, validation of all such models is necessarily limited to a small number of lakes for which experimental data are available. Therefore, some caution in using such tools is warranted.

It would be ideal to have a set of statistically characterized temperature profiles (e.g., 1% and 99% design temperature profiles), but the data simply do not exist. With few exceptions, lake temperature profiles are measured infrequently, if at all. Available sources with significant quantities of data include the Consortium of Universities for the Advancement of Hydrologic Science's Hydrologic Information System (CUAHSI HIS 2017), the U.S. EPA's STORET database (EPA 2017), and the U.S. Geological Survey (USGS 2017).

Closed-Loop Lake Water Heat Pump Systems

The closed-loop SWHEs shown in Figure 36 have several advantages over the open loop:

- Fouling is reduced because clean water (or water/antifreeze solution) circulates through the heat pump
- Pumping-power requirement is lower because there is no elevation head from the lake surface to the heat pumps
- It is the only type recommended with unitary heat pumps if a lake temperature below 4°C is possible: fluid outlet temperature is about 3 K below that of the inlet at a flow of 54 mL/s per kilowatt, and icing occurs on heat exchanger surfaces when the lake water temperature is in the 1 to 3°C range

Disadvantages of closed-loop systems include the following:

- Heat pump performance decreases slightly because circulation fluid temperature drops 2 to 7 K below lake temperature
- Coils may be damaged in public lakes; thermally fused polyethylene loops are much more resistant to damage than copper, glued plastic (PVC), or tubing with band-clamped joints
- Fouling can occur on the outside of the lake coil, particularly in murky lakes or where coils are located on or near the lake bottom.

High-density polyethylene (HDPE 3408) is recommended for in-lake piping. All connections must be either thermally socket-fused or butt-fused. These plastic pipes should also have protection from UV radiation, especially when near the surface. Polyvinyl chloride (PVC) pipe and plastic pipe with band-clamped joints are not recommended.

Plate heat exchangers are also available, and manufacturers typically provide estimated capacities for specified conditions. However, use care in applying metal heat exchangers in cold climates. For an equal temperature difference between the reservoir and fluid inside the coil, the surface temperature of metal heat exchangers is closer to the freezing point of water. The higher thermal resistance of HDPE results in a larger required surface area and a much lower heat transfer per unit of surface area. Thus, the surface temperature of an adequately designed HDPE coil tends to be higher than that of a metal tube or plate and less likely to develop ice on the coil exterior. In certain circumstances, ice build-up may occur on the closed-loop SWHE nonetheless. Use proper methods for anchoring the SWHE to resist the upward buoyant force caused by ice build-up.

The piping networks of closed-loop systems resemble those used in ground-coupled heat pump systems. Both a large-diameter header between the heat pump and lake coil and several parallel loops of piping in the lake are required. Loops are spread out to limit thermal interference, hot spots, and cold pockets. Although this layout is preferred in terms of performance, installation is more time consuming. Many contractors simply unbind plastic pipe coils and submerge them in a loose bundle. Some compensation for thermal interference is obtained by making bundled coils longer than the spread coils. A diagram of this type of installation is shown in Figure 36A.

Copper coils have also been used successfully. Copper tubes have a very high thermal conductivity, so coils only one-fourth to one-third the length of plastic coils are required. However, copper pipe does not have the durability of HDPE 3408, and if fouling is possible, coils must be significantly longer.

Open-Loop Lake Water Heat Pump and Direct Surface Cooling Systems

Open-loop surface water heat pump systems use heat pumps or chillers to provide heating and/or cooling, with surface water

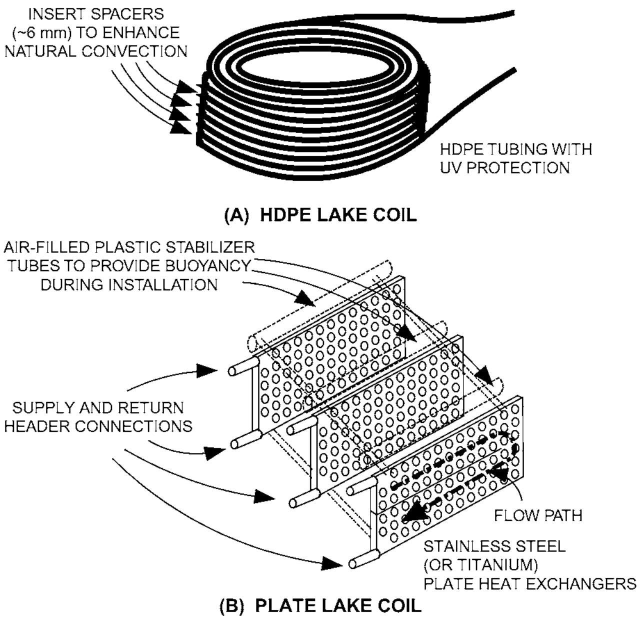

Fig. 36 SWHEs: (A) HDPE Coil Type and (B) Plate Type

circulating through a heat exchanger to provide the heat source and/or sink. The heat pumps may be unitary or custom built.

Direct surface water cooling (DSWC) systems use cold lake or sea water to provide cooling without heat pumps. Because the total (horizontal + vertical) distance between the building(s) being cooled and the actual location of the cold water is often significant, the scale of the system that is economically feasible tends to be quite large.

In cases where the lake or sea water may not be cool enough to meet all demands, hybrid systems that can provide cooling with or without heat pumps or chillers have also been used. Published descriptions of all three types of systems have been reviewed by Mitchell and Spitler (2013).

As noted previously, open-loop systems with unitary heat pumps are not suitable for lake temperatures below 4.4°C because of the risk of freezing in the evaporator. However, larger installations that use custom-designed heat pumps are successfully operated in Scandinavia under even colder conditions. Their capacities can be as large as 30 MW. One such system takes water from the Baltic Sea at 3°C and returns it at 0.5°C using falling film evaporators (i.e., plate evaporators with the sea water sprayed on to the outside of the evaporator) (Mitchell and Spitler 2013).

Open-loop systems are generally designed with either a submersible pump in a wet sump pit connected to the water body or with a conventional centrifugal pump in a dry sump pit. It is also possible in some applications to place the pump just above the water level. Small (e.g., residential) systems are sometimes installed with a submersible pump in the water body.

Design guidelines for open-loop systems may be summarized as follows:

- HDPE is recommended for pipelines because of its flexibility, durability, and high thermal resistance. HDPE is also fusible and floats in water, which makes it possible to connect large sections of pipe together for surface installation.
- Design intakes to avoid entrainment and impingement of sediment and fish. A radial wedge wire intake screen with 2 to 10 mm openings placed 2 to 3 m above the lake or seabed is recommended. Limit screened face velocity to 0.15 m/s.
- For direct surface water cooling applications, intake water temperature should be no higher than 13°C for space air dehumidification. Water with higher temperatures may also be used for sensible only cooling or precooling.
- Pumps may be configured in a wet-sump or dry-sump configuration. For wet-sump pumping designs, a large-diameter intake pipeline or a deep sump pit may be necessary to achieve the required flow rate. For dry-sump pumping configurations, available net positive suction head should be calculated carefully to check against the pump specifications. Pump material should be chosen to resist corrosion and erosion.
- Heat exchangers operating in salt water should be constructed from titanium; those operating in freshwater may use stainless steel. Water quality should be tested and verified.
- Heat exchanger fouling may be a problem in warmer climates. Methods for addressing this concern include chlorine dosing, permanently installed brush systems, or disassembly and cleaning.
- Heat pumps for larger systems are typically custom designed units. If used for heating, multistage compression is common.
- Outfall structures should discharge at a depth that will not promote nutrient enhancement of the outfall area. They should also discharge near the lake or seabed and cover a large enough area so as to prevent a high thermal gradient in the source water body.

2. DIRECT-USE GEOTHERMAL ENERGY

2.1 RESOURCES

Geothermal energy is the thermal energy in the earth's crust: thermal energy in rock and fluid (water, steam, or water containing large amounts of dissolved solids) that fills the pores and fractures in the rock, sand, and gravel. Calculations show that the earth, originating from a completely molten state, would have cooled and become completely solid many thousands of years ago without an energy input beyond that of the sun. It is believed that the ultimate source of geothermal energy is radioactive decay within the earth (Bullard 1973).

Through plate motion and vulcanism, some of this energy is concentrated at high temperature near the surface of the earth. Energy is also transferred from deeper parts of the crust to the earth's surface by conduction and by convection in regions where geological conditions and the presence of water allow.

Because of variation in volcanic activity, radioactive decay, rock conductivities, and fluid circulation, different regions have different heat flows (through the crust to the surface), as well as different temperatures at a particular depth. The normal increase of temperature with depth (i.e., the normal geothermal gradient) is about 24 K/km of depth, with gradients of 9 to 48 K/km being common. Areas that have higher temperature gradients and/or higher-than-average heat flow rates constitute the most interesting and viable economic resources. However, areas with normal gradients may be valuable resources if certain geological features are present.

Geothermal resources of the United States are categorized into the following types:

Igneous point resources are associated with magma bodies, which result from volcanic activity. These bodies heat the surrounding and overlying rock by conduction and convection, as allowed by the rock permeability and fluid content in the rock pores.

Hydrothermal convection systems are hot fluids near the earth's surface that result from deep circulation of water in areas of high regional heat flow. A widely used resource, these fluids rise from natural convection between hotter, deeper formations and cooler formations near the surface. The passageway that provides for this deep convection must consist of adequately permeable fractures and faults.

Geopressured resources, present widely in the Gulf Coast of the United States, consist of regional occurrences of confined hot water in deep sedimentary strata, where pressures of greater than 75 MPa are common. This resource also contains methane, which is dissolved in the geothermal fluid.

Radiogenic heat sources exist in various regions as granitic plutonic rocks that are relatively rich in uranium and thorium. These plutons have a higher heat flow than the surrounding rock; if the plutons are blanketed by sediments of low thermal conductivity, an elevated temperature at the base of the sedimentary section can result. This resource has been identified in the eastern United States.

Deep regional aquifers of commercial value can occur in deep sedimentary basins, even in areas of only normal temperature gradient. For deep aquifers to be of commercial value, (1) basins must be deep enough to provide usable temperature levels at the prevailing gradient, and (2) permeability in the aquifer must be adequate for flow.

Thermal energy in geothermal resources exists primarily in the rocks and only secondarily in the fluids that fill the pores and fractures. Thermal energy is usually extracted by bringing to the surface

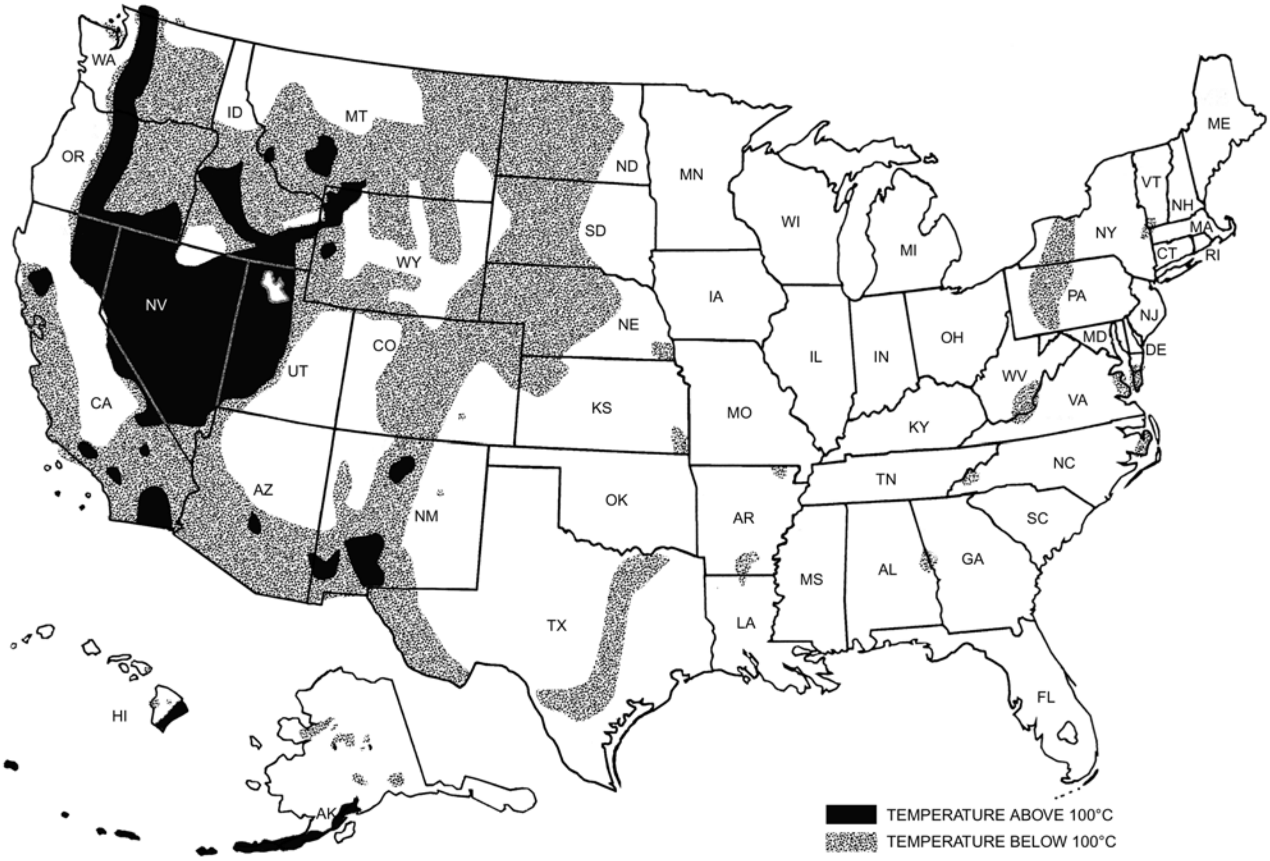

Fig. 37 U.S. Hydrothermal Resource Areas
(Lienau et al. 1995)

the hot water or steam that occurs naturally in the open spaces in the rock. Where rock permeability is low, the energy extraction rate is low. In permeable aquifers, fluid produced may be injected back into the aquifer at some distance from the production well to pass through the aquifer again and recover some of the energy in the rock. Figure 37 indicates geothermal resource areas in the United States.

Temperature

The temperature of fluids produced in the earth's crust and used for their thermal energy content varies from below 5 to 360°C. As shown in Figure 37, local gradients also vary with geologic conditions. The lower value represents fluids used as the low-temperature energy source for heat pumps, and the higher temperature represents an approximate value for the HGP-A well at Hilo, Hawaii.

The following classification by temperature is used in the geothermal industry:

High temperature	$t > 150°C$
Intermediate temperature	$90°C < t < 150°C$
Low temperature	$t < 90°C$

Electric generation is generally not economical for resources with temperatures below about 150°C, which is the reason for the division between high- and intermediate-temperature. However, binary (organic Rankine cycle) power plants, with the proper set of circumstances, have demonstrated that it is possible to generate electricity economically above 110°C. In 1988, there were 86 binary plants worldwide, generating a total of 126.3 MW (Di Pippo 1988).

Geothermal resources at lower temperatures are more common. The frequency by reservoir temperature of identified convective systems above 90°C is shown in Figure 38.

2.2 FLUIDS

Geothermal energy is extracted from the earth through naturally occurring fluids in rock pores and fractures. Fluids produced are steam, hot water, or a two-phase mixture of both. These may contain various amounts of impurities, notably dissolved gases and dissolved solids.

Geothermal resources that produce essentially dry steam are **vapor-dominated**. Although these are valuable resources, they are rare. Hot-water (**fluid-dominated**) resources are much more common and can be produced either as hot water or as a two-phase mixture of steam and hot water, depending on the pressure maintained on the production well. If pressure in the production casing or in the formation around the casing is reduced below the saturation pressure at that temperature, some of the fluid will flash, and a two-phase fluid will result. If pressure is maintained above the saturation pressure, the fluid remains single-phase. In fluid-dominated resources, both dissolved gases and dissolved solids are significant.

Geothermal fluid chemistry varies over a wide range. In the Imperial valley of California, some high-temperature geothermal fluids may contain up to 300 000 mg/kg of **total dissolved solids (TDS)**. Fluids of this character are extremely difficult to accommodate in systems design and materials selection. In fact, most low-temperature fluids contain less than 3000 mg/kg and many meet drinking water standards. Despite this, even

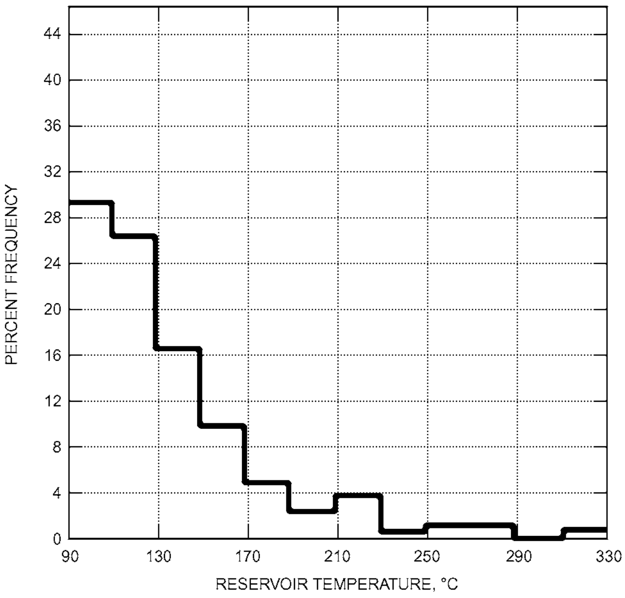

Fig. 38 Frequency of Identified Hydrothermal Convection Resources Versus Reservoir Temperature
(Muffler 1979)

geothermal fluids of a few hundred mg/kg TDS can cause substantial problems with standard construction materials.

2.3 PRESENT USE

Discoveries of concentrated radiogenic heat sources and deep regional aquifers in areas of near-normal temperature gradient indicate that 37 states in the United States have economically exploitable direct-use geothermal resources (Interagency Geothermal Coordinating Council 1980). The Geysers, in northern California, is the largest single geothermal development in the world. The U.S. Department of Energy created a database of geothermal system data (including ground resource data) for practitioners to share data about installations (NGDS 2014).

The total electricity generated by geothermal development in the world was 7974 MW in 2000 (Lund et al. 2001). Direct application of geothermal energy for space heating and cooling, water heating, agricultural growth-related heating, and industrial processing represented about 15 000 MW worldwide in 2000. In the United States in 2000, direct-use installed capacity amounted to 6400 MW, providing 5.65×10^6 MWh.

The major uses of geothermal energy in the United States are for heating greenhouse and aquaculture facilities. The principal industrial use is for food processing.

2.4 DESIGN

A major goal in designing direct-use systems is capturing the most possible heat from each litre of fluid pumped. System owning and operating costs are composed primarily of well pumping and well capitalization components; maximizing system Δt (i.e., minimizing flow requirements) minimizes well capital cost and pump operating cost. In many cases, system design can benefit from connecting loads in series according to temperature requirements. Direct-use system design is covered in detail in Anderson and Lund (1980) and Rafferty (1989a).

Direct-use systems can be divided into four subsystems: (1) production, including the producing wellbore and associated wellhead equipment; (2) transmission and distribution to transport geothermal energy from the resource site to the user site and then distribute it to the individual user loads; (3) user system; and (4) disposal, which can be either surface disposal or injection back into a formation.

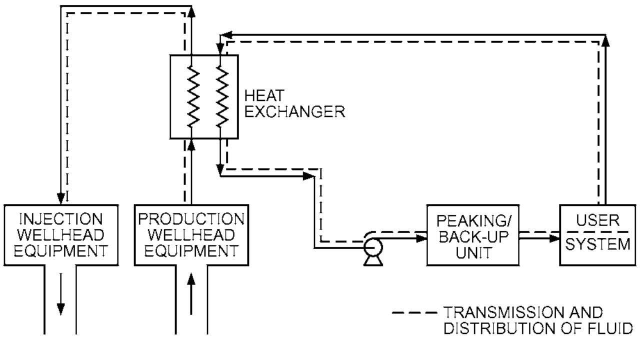

Fig. 39 Geothermal Direct-Use System with Wellhead Heat Exchanger and Injection Disposal

In a typical direct-use system, geothermal fluid is produced from the production borehole by a lineshaft multistage centrifugal pump. When the geothermal fluid reaches the surface, it is delivered to the application site through the transmission and distribution system.

In Figure 39, geothermal fluid is separated from the heating system by a heat exchanger. This secondary loop is especially desirable when the geothermal fluid is particularly corrosive and/or causes scaling. The geothermal fluid is pumped directly back into the ground without loss to the surrounding surface.

2.5 COST FACTORS

The following characteristics influence the cost of energy delivered from geothermal resources:

- Well depth
- Distance between resource location and application site
- Well flow rate
- Resource temperature
- Temperature drop
- Load factor
- Composition of fluid
- Ease of disposal

Many of these characteristics have a major influence because the cost of geothermal systems is primarily front-end capital cost; annual operating cost is relatively low.

Well Depth

The cost of the wells is usually one of the larger items in the overall cost of a geothermal system, and increases with resource depth. Compared to many geothermal areas worldwide, well depth requirements in the western United States are relatively shallow; most larger geothermal systems there operate with production wells of less than 600 m, and many at less than 300 m.

Distance Between Resource Location and Application Site

Direct use of geothermal energy must occur near the resource. The reason is primarily economic; although geothermal (or secondary) fluid could be transmitted over moderately long distances (greater than 100 km) without great temperature loss, such transmission is generally not economically feasible. Most existing geothermal projects have transmission distances of less than 1500 m.

Well Flow Rate

Energy output from a production well varies directly with the fluid flow rate. The energy cost at the wellhead varies inversely with the well flow rate. A typical good resource has a production rate of 25 to 50 L/s per production well; however, geothermal direct-use wells have been designed to produce up to 130 L/s.

Resource Temperature

The available temperature is fixed by the prevailing resource. The temperature can restrict applications. It often requires a reevaluation of accepted application temperatures, which were developed for uses served by conventional fuels for which the application temperature could be selected at any value in a relatively broad range. Most existing direct-use projects use fluids in the 55 to 110°C range.

Temperature Drop

Because well flow is limited, power output from a geothermal well is directly proportional to the temperature drop of the geothermal fluid connected to the system. Consequently, a larger temperature drop reduces operating (pumping) and capital (well and production pump) costs.

Cascading geothermal fluid to uses with lower temperature requirements can help achieve a large temperature difference (Δt). Most geothermal systems are designed for a Δt between 17 and 28 K, although one system was designed for a Δt of 56 K with an 88°C resource temperature.

Load Factor

Defined as the ratio of the average load to the design capacity of the system, the load factor effectively reflects the fraction of time that the initial investment in the system is working. Again, because geothermal cost is primarily initial rather than operating cost, this factor significantly affects a geothermal system's viability. As the load factor increases, so does the economy of using geothermal energy. The two main ways of increasing the load factor are (1) to select applications where it is naturally high, and (2) to use peaking equipment so that the geothermal design load is not the application peak load, but rather a reduced load that occurs over a longer period.

Composition of Fluid

The quality of the produced fluid is site specific and may vary from less than 1000 mg/kg TDS to heavily brined. Fluid quality influences two aspects of the design: (1) material selection to avoid corrosion and scaling effects, and (2) disposal or ultimate end use of the fluid.

Ease of Disposal

The costs associated with disposal, particularly when injection is involved, can substantially affect development costs. Historically, most geothermal effluent was disposed of on the surface, including discharge to irrigation, rivers, and lakes. This method of disposal is considerably less expensive than constructing injection wells.

Geothermal fluids sometimes contain chemical constituents that make surface disposal problematic. Some of these constituents are listed in Table 24.

Most new, large geothermal systems use injection for disposal to minimize environmental concerns and ensure long-term resource reliability. If injection is chosen, the depth at which the fluid can be injected affects well cost substantially. Many jurisdictions require the fluid be returned to the same or similar aquifers; thus, it may be necessary to bore the injection well to the same depth as the production well. Direct-use injection wells are considered Class V wells under the U.S. Environmental Protection Agency's Underground Injection Control (UIC) program. Water wells, along with terminology relating to the technology, are discussed in the section on Ground-Source Heat Pumps.

Table 24 Selected Chemical Species Affecting Fluid Disposal

Species	Reason for Control
Hydrogen sulfide (H_2S)	Odor
Boron (B^{3+})	Damage to agricultural crops
Fluoride (F^-)	Level limited in drinking water sources
Radioactive species	Levels limited in air, water, and soil

Source: Lunis (1989).

Direct-Use Water Quality Testing

Low-temperature geothermal fluids commonly contain seven key chemical species that can significantly corrode standard materials of construction (Ellis 1989). These include

- Oxygen (generally from aeration)
- Hydrogen ion (pH)
- Chloride ion
- Sulfide species
- Carbon dioxide species
- Ammonia species
- Sulfate ion

The principal effects of these species are summarized in Table 25. Except as noted, the described effects are for carbon steel. Kindle and Woodruff (1981) present recommended procedures for complete chemical analysis of geothermal well water.

Two of these species are not reliably detected by standard water chemistry tests and deserve special mention. Dissolved oxygen does not occur naturally in low-temperature (50 to 100°C) geothermal fluids that contain traces of hydrogen sulfide. However, because of slow-reaction kinetics, oxygen from air inleakage may persist for some minutes. Once the geothermal fluid is produced, it is extremely difficult to prevent contamination, especially if pumps used to move the fluid are not downhole-submersible or lineshaft turbine pumps. Even if fluid systems are maintained at positive pressure, air inleakage at pump seals is likely, particularly with the low level of maintenance in many installations.

Hydrogen sulfide is ubiquitous in extremely low concentrations in geothermal fluids above 50°C. This corrosive species also occurs naturally in many cooler groundwaters. For strongly affected alloys, such as cupronickel, hydrogen sulfide concentrations in the low micrograms per kilogram range may have a serious detrimental effect, especially if oxygen is also present. At these levels, the characteristic rotten egg odor of hydrogen sulfide may be absent, so field testing may be required for detection. Hydrogen sulfide levels down to 50 μg/kg can be detected using a simple field kit; however, absence of hydrogen sulfide at this low level may not preclude damage by this species.

Two other key species that should be measured in the field are pH and carbon dioxide concentrations. This is necessary because most geothermal fluids release carbon dioxide rapidly, causing a rise in pH.

Production of suspended solids (sand) from a well should be addressed during well construction with gravel pack, screen, or both. Proper selection of the screen/gravel pack is based on sieve analysis of cutting samples from drilling. Surface separation is less desirable because it requires sand to pass first through the pump, reducing its useful life.

Biological fouling is largely a phenomenon of low-temperature (<32°C) wells. The most prominent organisms are various strains (*Galionella*, *Crenothrix*) of what are commonly referred to as **iron bacteria**. These organisms typically inhabit water with a pH

Table 25 Principal Effects of Key Corrosive Species

Species	Principal Effects
Oxygen	• Extremely corrosive to carbon and low-alloy steels; 0.03 mg/kg shown to cause fourfold increase in carbon steel corrosion rate. • Concentrations above 0.05 mg/kg cause serious pitting. • In conjunction with chloride and high temperature, <0.1 mg/kg dissolved oxygen can cause chloride-stress corrosion cracking (chloride-SCC) of some austenitic stainless steels.
Hydrogen ion (pH)	• Primary cathodic reaction of steel corrosion in air-free brine is hydrogen ion reduction. Corrosion rate decreases sharply above pH 8. • Low pH (5) promotes sulfide stress cracking (SSC) of high-strength low-alloy (HSLA) steels and some other alloys coupled to steel. • Acid attack on cements.
Carbon dioxide species (dissolved carbon dioxide, bicarbonate ion, carbonate ion)	• Dissolved carbon dioxide lowers pH, increasing carbon and HSLA steel corrosion. • Dissolved carbon dioxide provides alternative proton reduction pathway, further exacerbating carbon and HSLA steel corrosion. • May exacerbate SSC. • Strong link between total alkalinity and corrosion of steel in low-temperature geothermal wells.
Hydrogen sulfide species (hydrogen sulfide, bisulfide ion, sulfide ion)	• Potent cathodic poison, promoting SSC of HSLA steels and some other alloys coupled to steel. • Highly corrosive to alloys containing both copper and nickel or silver in any proportions.
Ammonia species (ammonia, ammonium ion)	• Causes stress corrosion cracking (SCC) of some copper-based alloys.
Chloride ion	• Strong promoter of localized corrosion of carbon, HSLA, and stainless steel, as well as of other alloys. • Chloride-dependent threshold temperature for pitting and SCC. Different for each alloy. • Little if any effect on SSC. • Steel passivates at high temperature in pH 5, 6070 mg/kg chloride solution with carbon dioxide. 133 500 mg/kg chloride destroys passivity above 150°C.
Sulfate ion	• Primary effect is corrosion of cements.

Source: Ellis (1989).
Note: Except as indicated, described effects are for carbon steel.

range of 6.0 to 8.0, dissolved oxygen content of less than 5 mg/kg, ferrous iron content of less than 0.2 mg/kg, and a temperature of 8 to 16°C (Hackett and Lehr 1985). Iron bacteria can be identified microscopically. The most common treatment for iron bacteria infestation is chlorination, surging, and flushing; success depends on maintaining proper pH (less than 8.5), dosage, free residual chlorine content (13 to 32 mg/kg), contact time (24 h minimum), and agitation or surging. Precleaning (wire brushing) of the screen and redevelopment of the well after treatment are key to effectiveness. Hackett and Lehr (1985) provide additional detail on treatment.

2.6 MATERIALS AND EQUIPMENT

For system parts exposed to the fluid, materials selection is an important part of the design process. Chemical treatment of the geothermal fluid is not an effective strategy in most cases, because of economics and environmental (disposal) considerations. Corrosion and scaling in direct-use systems are generally addressed by isolating the fluid from the majority of the system using a plate heat exchanger.

Performance of Materials

Carbon Steel. The Ryznar index has traditionally been used to estimate the corrosivity and scaling tendencies of potable water supplies. However, one study found no significant correlation (at the 95% confidence level) between carbon steel corrosion and the Ryznar index (Ellis and Smith 1983). Therefore, the Ryznar and other indices based on calcium carbonate saturation should not be used to predict corrosion in geothermal systems, though they remain valid for scaling prediction.

In Class Va geothermal fluids [as described by Ellis (1989); <5000 mg/kg total key species (TKS), total alkalinity 207 to 1329 mg/kg as $CaCO_3$, pH 6.7 to 7.6], corrosion rates of about 100 to 500 μm per year can be expected, often with severe pitting.

In Class Vb geothermal fluids [as described by Ellis (1989); <5000 mg/kg TKS, total alkalinity <210 mg/kg as $CaCO_3$, pH 7.8 to 9.85], carbon steel piping has given good service in a number of systems, as long as system design rigorously excluded oxygen. However, introduction of 0.03 mg/kg oxygen under turbulent flow conditions causes a fourfold increase in uniform corrosion. Saturation with air often increases the corrosion rate by at least 15 times. Oxygen contamination at the 0.05 mg/kg level often causes severe pitting. Chronic oxygen contamination causes rapid failure.

External surfaces of buried steel pipe must be protected from contact with groundwater. Groundwater is aerated and has caused pipe failures by external corrosion. Required external protection can be obtained by coatings, pipe-wrap, or preinsulated piping, provided the selected material resists the system operating temperature and thermal stress.

At temperatures above 57°C, galvanizing (zinc coating) does not reliably protect steel from either geothermal fluid or groundwater. Hydrogen blistering can be prevented by using void-free (killed) steels.

Low-alloy steels (steels containing not more than 4% alloying elements) have corrosion resistance similar, in most respects, to carbon steels. As with carbon steels, sulfide promotes entry of atomic hydrogen into the metal lattice. If the steel exceeds a hardness of Rockwell C22, sulfide stress cracking may occur.

Copper and Copper Alloys. Copper-tubed fan-coil units and heat exchangers have consistently poor performance because of traces of sulfide species found in geothermal fluids in the United States. Copper tubing rapidly becomes fouled with cuprous sulfide films more than 1 mm thick. Serious crevice corrosion occurs at cracks in the film, and uniform corrosion rates of 50 to 150 μm per year appear typical, based on failure analyses.

Experience in Iceland also indicates that copper is unsatisfactory for heat exchange service and that most brasses (Cu-Zn) and bronzes (Cu-Sn) are even less suitable. Cupronickel often performs more poorly than copper in low-temperature geothermal service because of trace sulfide.

Much less information is available regarding copper and copper alloys in non-heat-transfer service. Copper pipe shows corrosion behavior similar to copper heat exchange tubes under conditions of moderate turbulence (Reynolds numbers of 40 000 to 70 000). An internal inspection of yellow brass valves showed no significant corrosion. However, silicon bronze CA 875 (12-16Cr, 3-5Si, <0.05Pb, <0.05P), an alloy normally resistant to dealloying, failed in less than three years when used as a pump impeller. Leaded red brass (CA 836 or 838) and leaded red bronze (SAE 67) appear viable as pump internal parts. Based on a few tests at Class Va sites, aluminum bronzes have shown potential for corrosion in heavy-walled components (Ellis 1989).

Solder is yet another problem area for copper equipment. Lead-tin solder (50Pb, 50Sn) was observed to fail by dealloying after a few years' exposure. Silver solder (1Ag, 7P, Cu) was completely removed from joints in under two years. If the designer elects to accept this risk, solders containing at least 70% tin should be used.

Stainless Steel. Unlike copper and cupronickel, stainless steels are not affected by traces of hydrogen sulfide. Their most likely application is heat exchange surfaces. For economic reasons, most heat exchangers are probably of the plate-and-frame type, most of which are fabricated with one of two standard alloys, Type 304 and Type 316 stainless steel. Some pump and valve trim also are fabricated from these or other stainless steels.

These alloys are subject to pitting and crevice corrosion above a threshold chloride level, which depends on the chromium and molybdenum content of the alloy and on the temperature of the geothermal fluid. Above this temperature, the passivation film, which gives the stainless steel its corrosion resistance, is ruptured, and local pitting and crevice corrosion occur. Figure 40 shows the relationship between temperature, chloride level, and occurrence of localized corrosion of Type 304 and Type 316 stainless steel. This figure indicates, for example, that localized corrosion of Type 304 may occur in 27°C geothermal fluid if the chloride level exceeds approximately 210 mg/kg; Type 316 is resistant at that temperature until the chloride level reaches approximately 510 mg/kg. Because of its 2 to 3% molybdenum content, Type 316 is always more resistant to chlorides than is Type 304.

Aluminum. Aluminum alloys are not acceptable in most cases because of catastrophic pitting.

Titanium. This material has extremely good corrosion resistance and could be used for heat exchanger plates in any low-temperature geothermal fluid, regardless of dissolved oxygen content. Great care is required if acid cleaning is to be performed. The vendor's instructions must be followed. The titanium should not be scratched with iron or steel tools; this can cause pitting.

Chlorinated Polyvinyl Chloride (CPVC) and Fiber-Reinforced Plastic (FRP). These materials are easily fabricated and are not adversely affected by oxygen intrusion. External protection against groundwater is not required. The mechanical properties of these materials at higher temperatures may vary greatly from those at ambient temperature, and the materials' mechanical limits should not be exceeded. The usual mode of failure is creep rupture: strength decays with time. Follow manufacturer's directions for joining to avoid premature failure of joints.

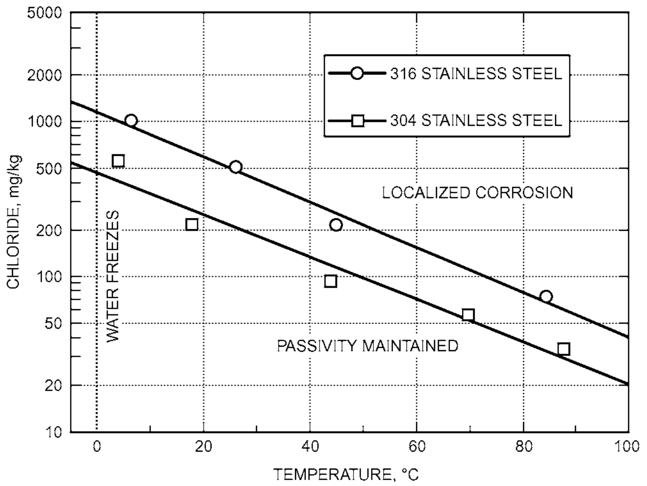

Fig. 40 Chloride Concentration Required to Produce Localized Corrosion of Stainless Steel as Function of Temperature
(Efrid and Moeller 1978)

Elastomeric Seals. Tests on O-ring materials in a low-temperature system in Texas indicated that a fluoroelastomer is the best material for piping of this nature; Buna-N is also acceptable (Ellis 1989). Neoprene, which developed extreme compression set, was a failure. Natural rubber and Buna-S should also be avoided. Ethylene-propylene terpolymer (EPDM) has been used successfully in gasket, O-ring, and valve seats in many systems. EPDM materials have swollen in some systems using oil-lubricated turbine pumps.

Pumps

Production well pumps are among the most critical components in a geothermal system and have been the source of much system downtime. Therefore, proper selection and design of the production well pump is extremely important. Well pumps are available for larger systems in two general configurations: lineshaft and submersible. The lineshaft type is most often used for direct-use systems (Rafferty 1989b).

Lineshaft Pumps. Lineshaft pumps are similar to those typically used in irrigation applications. An aboveground driver, typically an electric motor, rotates a vertical shaft extending down the well to the pump. The shaft rotates pump impellers in the pump bowl assembly, which is positioned at such a depth in the wellbore that adequate net positive suction pressure is available when the unit is operating. Two designs for the shaft/bearing portion of the pump are available: open and enclosed.

In the **open lineshaft pump**, the shaft bearings are supported in "spiders," which are anchored to the pump column pipe at 1.5 to 3 m intervals. The shaft and bearings are lubricated by the fluid flowing up the pump column. In geothermal applications, bearing materials for open lineshaft designs are typically elastomer compounds. The shaft material is typically stainless steel. Experience with this design in geothermal applications has been mixed. It appears that the open lineshaft design is most successful in applications with high (<15 m) static water levels or flowing artesian conditions. Open lineshaft pumps are generally less expensive than enclosed lineshaft pumps for the same application.

In an **enclosed lineshaft pump**, an enclosing tube protects the shaft and bearings from exposure to the pumped fluid. A lubricating fluid is admitted to the enclosed tube at the wellhead. It flows down the tube, lubricates the bearings, and exits where the column attaches to the bowl assembly. The bowl shaft and bearings are lubricated by the pumped fluid. Oil-lubricated, enclosed lineshaft pumps have the longest service life in low-temperature, direct-use applications.

These pumps typically include carbon or stainless steel shafts and bronze bearings in the lineshaft assembly, and stainless steel shafts and leaded red bronze bearings in the bowl assembly. Keyed-type impeller connections (to the pump shaft) are superior to collet-type connections (Rafferty 1989b).

Because of the lineshaft bearings, lineshaft pump reliability decreases as pump-setting depth increases. Nichols (1978) indicates that, below about 240 m, reliability is questionable, even under good pumping conditions.

Submersible Pumps. The electrical submersible pump consists of three primary components located downhole: the pump, the drive motor, and the motor protector. The pump is a vertical multistage centrifugal type. The motor is usually a three-phase induction type that is filled with oil for cooling and lubrication; it is cooled by heat transfer to the pumped fluid moving up the well. The motor protector is located between the pump and the motor and isolates the motor from the well fluid while allowing pressure equalization between the pump intake and the motor cavity.

The electrical submersible pump has several advantages over lineshaft pumps, particularly for wells requiring greater pump bowl setting depths. The deeper the well, the greater the economic advantage of the submersible pump. Moreover, it is more versatile, adapting more easily to different depths.

Submersible pumps have not demonstrated acceptable lifetimes in most geothermal applications. Although they are commonly used in high-temperature, downhole applications in the oil and gas industry, the acceptable overhaul interval in that industry is much shorter than in a geothermal application. In addition, most submersibles operate at 3600 rpm, resulting in greater susceptibility to erosion in aquifers that produce moderate amounts of sand. They have, however, been applied in geothermal projects where an existing well of relatively small diameter must be used. At 3600 rpm, they provide greater flow capacity for a given bowl size than an equivalent 1750 rpm lineshaft pump.

Standard cold-water submersible motors can be used at temperatures up to approximately 50°C with adequate precautions. These consist primarily of ensuring adequate water velocity past the motor (minimum 0.9 m/s), which may require the use of a sleeve, and a small degree of motor oversizing (Franklin Electric 2001).

Well Pump Control. Well pumps serving variable loads are often controlled using variable-speed drives (VSDs). Submersible pumps can also be controlled using VSDs, but special precautions are required. Drive-rated motors are not commonly available for these applications, so external electronic protection should be used to prevent premature motor failure. In addition, the motor manufacturer must be aware that the motor will applied in a variable-speed application. Finally, because of the large static head in many well pump applications, controls should be configured to prevent the pump from operating at no-flow conditions.

Heat Exchangers

Geothermal fluids can be isolated with large central heat exchangers, as in the case of a district heating system, or with exchangers at individual buildings or loads. In both cases, the principle is to isolate the geothermal fluid from complicated systems or those that cannot readily be designed to be compatible with the geothermal fluid. The main types of heat exchangers used in transferring energy from the geothermal fluid are plate and downhole.

Plate Heat Exchangers. For all but the very smallest applications, plate-and-frame heat exchangers are the most commonly used design. Available in corrosion-resistant materials, easily cleanable, and able to accommodate increased loads by adding plates, these exchangers are well suited to geothermal applications. Their high performance is also an asset in many system designs. Because geothermal resource temperatures are often less than those used in conventional hot-water heating system design, minimizing temperature loss at the heat exchanger is frequently a design issue. Approach temperatures of 2 K and less are common.

Materials for plate heat exchangers in direct-use applications normally include Buna-N or EPDM gaskets and 316 or titanium plates. Plate selection is often a function of temperature and chloride content of the water. For applications characterized by chloride contents of >50 mg/kg at 93°C, titanium would be used. At lower temperatures, much higher chloride exposure can be tolerated (see Figure 40).

Downhole Heat Exchangers. The downhole heat exchanger (DHE) is an arrangement of pipes or tubes suspended in a wellbore (Culver and Reistad 1978). A secondary fluid circulates from the load through the exchanger and back to the load in a closed loop. The primary advantage of a DHE is that only heat is extracted from the earth, which eliminates the need to dispose of spent fluids. Other advantages are the elimination of (1) well pumps with their initial operating and maintenance costs, (2) the potential for depletion of groundwater, and (3) environmental and institutional restrictions on surface disposal. One disadvantage of a DHE is the limited amount of heat that can be extracted from or rejected to the well. The amount of heat extracted depends on the hydraulic conductivity of the aquifer and well design. Because of the limitations of natural convection, only about 10% of the heat output of the well is available from a DHE in comparison to pumping and using surface heat exchange (Reistad et al. 1979). With wells of approximately 95°C and depths of 150 m, output under favorable conditions is sufficient to serve the needs of up to five homes.

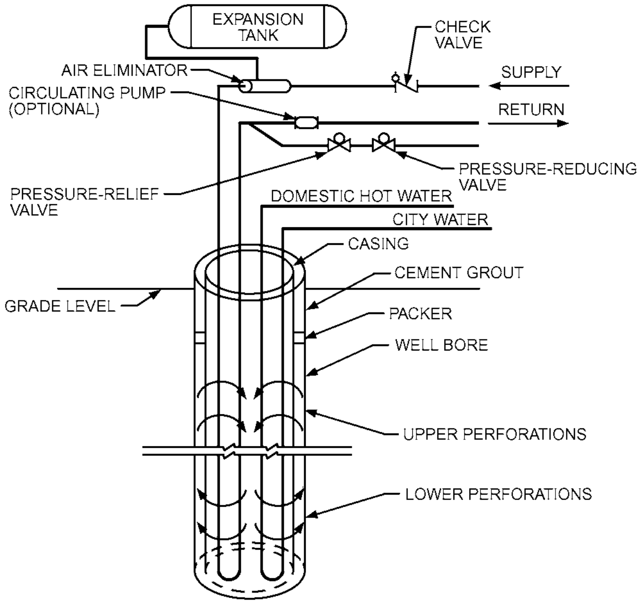

Fig. 41 Typical Connection of Downhole Heat Exchanger for Space and Domestic Hot-Water Heating
(Reistad et al. 1979)

The DHE in low- to moderate-temperature geothermal wells is installed in a casing, as shown in Figure 41.

Downhole heat exchangers with higher outputs rely on water circulation within the well, whereas lower-output DHEs rely on earth conduction. Circulation in the well can be accomplished by two methods: (1) undersized casing and (2) convection tube. Both methods rely on the difference in density between the water surrounding the DHE and that in the aquifer.

Circulation provides the following advantages:

- Water circulates around the DHE at velocities that, in optimum conditions, can approach those in the shell of a shell-and-tube exchanger.
- Hot water moving up the annulus heats the upper rocks and the well becomes nearly isothermal.
- Some of the cool water, being denser than the water in the aquifer, sinks into the aquifer and is replaced by hotter water, which flows up the annulus.

Figure 41 shows well construction in competent formation (i.e., where the wellbore will stand open without a casing). An undersized casing with perforations at the lowest producing zone (usually near the bottom) and just below the static water level is installed. A packer near the top of the competent formation allows installation of an annular seal between it and the surface. When the DHE is installed and heat extracted, thermosiphoning causes cooler water inside the casing to move to the bottom, and hotter water moves up the annulus outside the casing.

Because most DHEs are used for space heating (an intermittent operation), heated rocks in the upper portion of the well store heat for the next cycle.

Where the well will not stand open without casing, a convection tube can be used. This is a pipe one-half the diameter of the casing either hung with its lower end above the well bottom and its upper end below the surface or set on the bottom with perforations at the bottom and below the static water level. If a U-bend DHE is used, it can be either inside or outside the convection tube. DHEs operate best in aquifers with a high hydraulic conductivity and that provide water movement for heat and mass transfer.

Valves

In large (>65 mm) pipe sizes, resilient-lined butterfly valves are preferred for geothermal applications. The lining material protects the valve body from exposure to the geothermal fluid. The rotary rather than reciprocating motion of the stem makes the valve less susceptible to leakage and build-up of scale deposits. For many direct-use applications, these valves are composed of Buna-N or EPDM seats, stainless steel shafts, and bronze or stainless steel disks. Where oil-lubricated well pumps are used, a seat material of oil-resistant material is recommended. Gate valves have been used in some larger geothermal systems but have been subject to stem leakage and seizure. After several years of use, they are no longer capable of 100% shutoff.

Piping

Piping in geothermal systems can be divided into two broad groups: pipes used inside buildings and those used outside, typically buried. Indoor piping carrying geothermal water is usually limited to the mechanical room. Carbon steel with grooved end joining is the most common material.

For buried piping, many existing systems use some form of nonmetallic piping, particularly asbestos cement (which is no longer available) and glass fiber. With the cost of glass fiber for larger sizes (>150 mm) sometimes prohibitive, ductile iron is frequently used. Available in sizes >50 mm, ductile iron offers several positive characteristics: low cost, familiarity to installation crews, and wide availability. It requires no allowances for thermal expansion if push-on fittings are used.

Most larger-diameter buried piping is preinsulated. The basic ductile iron pipe is surrounded by a layer of insulation (typically polyurethane), which is protected by an outer jacket of PVC or high-density polyethylene (HDPE).

Standard ductile iron used for municipal water systems is sometimes modified for geothermal use. The seal coat used to protect the cement lining of the pipe is not suitable for the temperature of most geothermal applications; in applications where the geothermal water is especially soft or low in pH, the cement lining should be omitted, as well. Special high-temperature gaskets (usually EPDM) are used in geothermal applications. Few problems have been encountered in using ferrous piping with low-temperature geothermal fluids unless high chloride concentration, low (<7.0) pH, or oxygen is present in the fluid. Most cases of corrosion failure have resulted from external attack by soil moisture in buried applications. For more information on piping systems for these applications, see Chapter 12 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and ASHRAE (2013a, 2013b).

2.7 RESIDENTIAL AND COMMERCIAL BUILDING APPLICATIONS

The primary applications for direct use of geothermal energy in the residential and commercial area are space and domestic water heating. Space cooling using the absorption process is possible but rarely applied.

Space Heating

Figure 42 illustrates a system that uses geothermal fluid at 75°C (Austin 1978). The geothermal fluid is used in two main equipment components for heating the buildings: (1) a plate heat exchanger that supplies energy to a closed heating loop previously heated by a natural gas boiler (the boiler remains as a standby unit) and (2) a water-to-air coil used for preheating ventilation air. In this system, proper control is crucial for economical operation.

The average temperature of discharged fluid is 49 to 54°C. Geothermal fluid is used directly in the preheat coils in the buildings, which would probably not be the case if the system were designed today (Lienau 1979).

Figure 43 shows a geothermal district heating system that has a unique feature: its design is based on a peak load Δt of 38 K using an 88°C resource. It is of closed-loop design with central heat exchangers. The production well has an artesian shut-in pressure of 170 kPa, so the system operates with no production pump for most of the year. During colder weather, a surface centrifugal pump located at the wellhead boosts the pressure.

Geothermal flow from the production well is initially controlled by a throttling valve on the supply line to the main heat exchanger, which responds to a temperature signal from the supply water on the closed-loop side of the heat exchanger. When the throttling valve reaches the full-open position, the production booster pump is enabled. The pump is controlled through a variable-speed drive that responds to the same supply-water signal as the throttling valve. The booster pump is designed for a peak flow rate of 19 L/s of 88°C water.

A few district heating systems have also been installed using an open distribution system. In this design, central heat exchangers (as in Figure 43) are eliminated and the geothermal water is delivered to individual building heat exchangers. When more than a few buildings are connected to the system, using central heat exchangers is normally more cost effective.

Terminal equipment used in geothermal systems is the same as that used in nongeothermal heating systems. However, certain types of equipment are better suited to geothermal design than others.

In many cases, buildings heated by low-temperature geothermal sources operate at lower supply water temperatures than conventional hydronic designs. Because many geothermal sources are designed to take advantage of a large Δt, proper

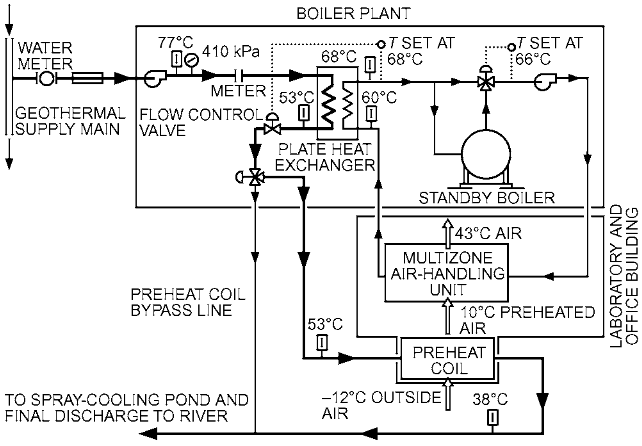

Fig. 42 Heating System Schematic

selection of equipment for low flow and low temperature is important.

Finned-coil, forced-air systems generally function best in this low-temperature/high-Δt situation. One or two additional rows of coil depth compensate for the lower supply water temperature. Although an increased Δt affects coil circuiting, it improves controllability. This type of system should be able to use a supply water temperature as low as 60°C.

Radiant floor panels are well suited to very low water temperatures, particularly in industrial applications with little or no floor covering. In industrial settings, with a bare floor and a relatively low space-temperature requirement, the average water temperature could be as low as 35°C. For a higher space temperature and/or thick floor coverings, a higher water temperature may be required.

Baseboard convectors and similar equipment are the least capable of operating at low supply-water temperature. At 65°C average water temperatures, derating factors for this design load may be affected. This type of equipment can be operated at low temperatures from the geothermal source to provide base-load heating, with peak load supplied by a conventional boiler. Ensure the boiler does not supply a higher fraction of the load than intended by the designer.

Domestic Water Heating

Domestic water heating in a district space-heating system is beneficial because it increases the overall size of the energy load, energy demand density, and load factor. For those resources that cannot heat water to the required temperature, preheating is usually possible. Whenever possible, the domestic hot-water load should be placed in series with the space-heating load to reduce system flow rates and increase Δt.

Space Cooling

Geothermal energy has seldom been used for cooling, although emphasis on solar energy and waste heat has created interest in cooling with thermal energy. The absorption cycle is most often used, and lithium bromide/water absorption machines are available in a wide range of capacities. Temperature and flow requirements for absorption chillers run counter to the general design philosophy for geothermal systems: they require high supply water temperatures and a small Δt on the hot-water side. Figure 44 shows the effect of reduced supply water temperature on machine performance. The machine is rated at a 115°C input temperature, so derating factors must be applied if the machine is operated below this temperature. For example, operation at a 93°C supply water temperature results in a 50% decrease in capacity, which seriously affects the economics of absorption cooling at a low resource temperature.

Coefficient of performance (COP) is less seriously affected by reduced supply water temperature. The nominal COP of a single-stage machine at 115°C is 0.65 to 0.70; that is, for each kilowatt of cooling output, a heat input of 1 kW divided by 0.65, or 1.54 kW, is required.

Most absorption equipment is designed for steam input (an isothermal process) to the generator section. When this equipment is operated from a hot-water source, a relatively small Δt must be used. This creates a mismatch between building flow requirements for space heating and cooling. For example, assume a 20 000 m^2 building is to use a geothermal resource for heating and cooling.

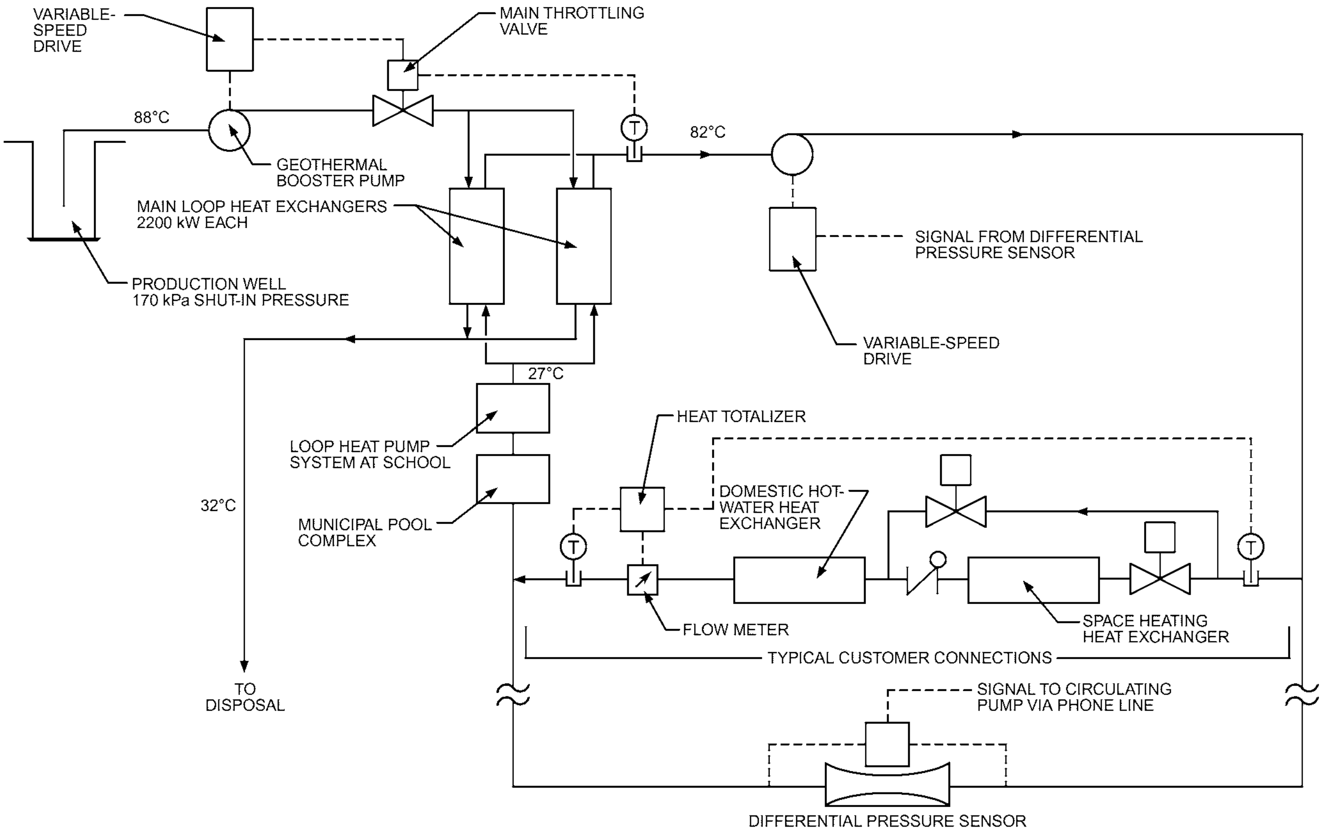

Fig. 43 Closed Geothermal District Heating System
(Rafferty 1989a)

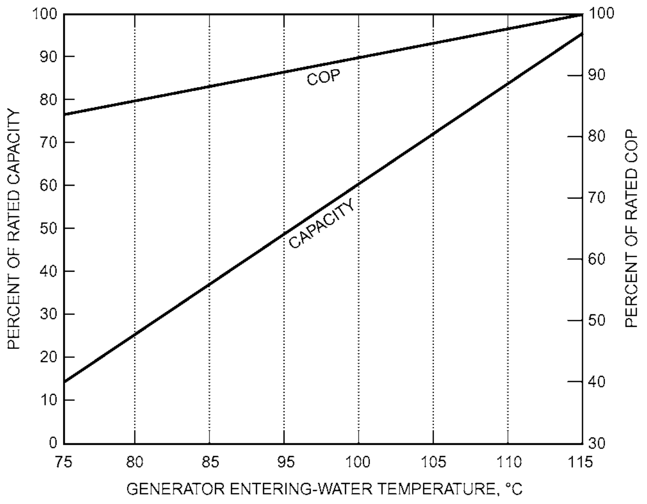

Fig. 44 Typical Lithium Bromide Absorption Chiller Performance Versus Temperature
(Christen 1977)

At 80 W/m^2 and a design Δt of 22 K, the flow requirement for heating is 16 L/s. At 95 W/m^2, a Δt of 8 K, and a COP of 0.65, the flow requirement for cooling is 78 L/s.

Some small-capacity (10 to 90 kW) absorption equipment has been optimized for low-temperature operation in conjunction with solar heat. Although this equipment could be applied to geothermal resources, the prospects are questionable. Small absorption equipment generally competes with packaged direct-expansion units in this range; absorption equipment requires a great deal more mechanical auxiliary equipment for a given capacity. The cost of the chilled-water piping, pump, and coil; cooling-water piping, pump, and tower; and hot-water piping raises the capital cost of the absorption equipment substantially. Only in large sizes (>35 kW) and in areas with high electric rates and high cooling requirements (>2000 full-load hours) would this type of equipment offer an attractive investment to the owner (Rafferty 1989a).

Cascading Systems

Cascading geothermal systems have been used for centuries all over the world (Lund 2010). These systems typically use intermediate- ($90 < t < 150$°C) and low-temperature (90°C) resources, depending on the first step of the cascade. As shown in Figure 38, low-temperature resources are most frequently identified but are underused. Resources typically include hot/warm fluid well production, springs, ponds, shallow groundwater flows, and geologic features such as hot pots.

The nature of the resource, temperature, volume, and chemical composition determine the heat collection method and use. In ideal cases, the thermal fluid may be used directly to heat or cool, but indirect collection methods are more common. Open water systems may use a heat exchanger immersed in the fluid. Other sources need to be pumped and a plate-and-frame heat exchanger used. The goal is to use as much heat from the fluid as possible. The designer should carefully examine fluid quality to determine the best harvesting method, system material composition, and disposal of the geothermal fluid.

An example of a cascading system is a hot-water well producing 22 L/s of 68°C, low TDS, and approximately neutral pH water used for the following heat cascading temperature loads: domestic hot water at 60°C, a large spa at 40°C, a pool at 29°C, warm-water irrigation storage and a water feature to a pond at about 27 to 22°C, and finally through a lake plate heat exchanger in the pond serving GSHPs to heat and cool selected campus buildings. Another common application is to use a low-temperature cascading system for hydroponic and aquaculture in both remote and urban environments.

2.8 INDUSTRIAL APPLICATIONS

Design philosophy for the use of geothermal energy in industrial applications, including agricultural facilities, is similar to that for space conditioning. However, these applications have the potential for much more economical use of the geothermal resource, primarily because they (1) operate year-round, which gives them greater load factors than possible with space-conditioning applications; (2) do not require extensive (and expensive) distribution to dispersed energy consumers, as is common in district heating; and (3) often require various temperatures and, consequently, may be able to make greater use of a particular resource than space conditioning, which is restricted to a specific temperature. In the United States, the primary non-space-heating applications of direct-use geothermal resources are dehydration (primarily vegetables), gold mining, and aquaculture.

3. RENEWABILITY

Geothermal energy is a renewable resource (see the section on Nonrenewable and Renewable Energy Sources in Chapter 34 of the 2017 *ASHRAE Handbook—Fundamentals* for discussion). Quantification of the source may be required for renewable portfolio standards, utility programs, etc.; to do this, measure or calculate the electric or thermal energy that is either generated from, or avoided by, use of the geothermal resource.

Geothermal energy ultimately comes from a variety of sources, including earth heat and solar energy. Direct-use and higher-temperature geothermal resources may be considered renewable, because the heat removed is replaced by natural processes: heat is generated deep in the earth and transferred to more shallow depths. The geothermal resource must be carefully managed, however, and can eventually be depleted if used at too high of a rate.

Geothermal heat pumps (GHPs) also use these sources (albeit in a more complex, indirect fashion) for building heating, cooling, and domestic hot water. Because this method of using geothermal energy does require electricity input, quantification of the renewable portion of GHP operation is to be based on the amount of electric and thermal energy that is avoided by use of GHPs. Attempts at quantifying this avoidance have been made (European Union 2013), but more work is needed before a more specific methodology can be published here.

THE sun radiates considerable energy onto the earth. Desire to put that relatively low-intensity (rarely over 950 W/m^2) energy to work has led to the creation of many types of devices to convert that energy into useful forms, mainly heat and electricity. Economic valuing of that energy drives the ebb and flow of the global solar industry. This chapter discusses several different types of solar equipment and system designs for various HVAC applications, as well as methods to determine availability of the solar resource.

Worldwide, solar energy use varies in application and degree. In China and, to a lesser extent, Australasia, solar energy is widely used, particularly for water heating. In the Middle East, solar power is used for desalination and absorption air conditioning. Solar energy use in the United States is relatively modest, driven by tax policy and utility programs that generally react to energy shortages or the price of oil. In Europe, government incentives have fostered use of photovoltaic and thermal systems for both domestic hot-water and space heating (**solar combi systems**), which have a well-established market in several countries, and solar cooling is an emerging market with a significant growth potential. Combined solar space heating/cooling and domestic hot-water production (**solar combi-plus systems**) may lead to both high solar fractions and economical systems because of the continuous (annual) exploitation of the solar collector field and other system components.

Recent interest in sustainability and green buildings has led to an increased focus on solar energy devices for their nonpolluting and renewable qualities; replacing fossil fuel with domestic, renewable energy sources can also enhance national security by reducing dependence on imported energy.

For more information on the use of solar and other energy sources, see the Energy Information Administration (EIA) of the U.S. Department of Energy (www.eia.gov) and the International Energy Agency (www.iea.org).

1. QUALITY AND QUANTITY OF SOLAR ENERGY

Solar Constant

Solar energy approaches the earth as electromagnetic radiation, with wavelengths ranging from 0.1 μm (x-rays) to 100 m (radio waves). The earth maintains a thermal equilibrium between the annual input of shortwave radiation (0.3 to 2.0 μm) from the sun and the outward flux of longwave radiation (3.0 to 30 μm). Only a limited band is considered in terrestrial applications, because 99% of the sun's radiant energy has wavelengths between 0.28 and 4.96 μm. The current value of the solar constant (which is defined as the intensity of solar radiation on a surface normal to the sun's rays, just beyond the earth's atmosphere at the average earth-sun distance) is 1366.1 W/m^2 (ASTM *Standard* E490). Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* has further information on the available extraterrestrial solar radiation.

The preparation of this chapter is assigned to TC 6.7, Solar Energy Utilization.

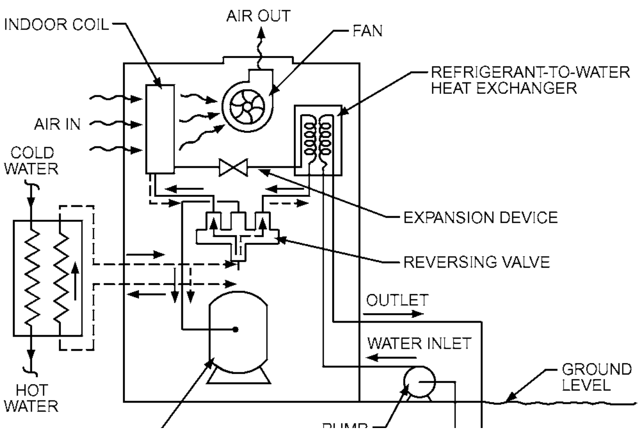

Fig. 1 Variation of Declination δ (degrees) and Equation of Time ET as Function of Day of Year

Solar Angles

The axis about which the earth rotates is tilted at an angle of 23.45° to the earth's orbital plane and the sun's equator. The earth's tilted axis results in a day-by-day variation of the angle between the earth-sun line and the earth's equatorial plane, called the **solar declination** δ. This angle varies with the date, as shown in Figure 1, and may be estimated by the following equation:

$$\delta = 23.45 \sin\left[360° \times \frac{284 + N}{365}\right] \quad (1)$$

where N = day of year, with January 1 = 1.

The relationship between δ and the date from year to year varies to an insignificant degree. The daily change in the declination is the primary reason for the changing seasons, with their variation in distribution of solar radiation over the earth's surface and the varying number of hours of daylight and darkness. Note that the following sections are based in the northern hemisphere; sites in the southern hemisphere will be 180° from the examples (e.g., a solar panel should face north).

The earth's rotation causes the sun's apparent motion (Figure 2). The position of the sun can be defined in terms of its altitude β above

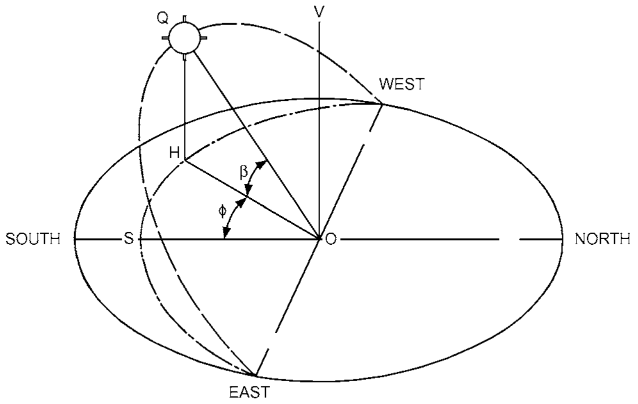

Fig. 2 Apparent Daily Path of the Sun Showing Solar Altitude β and Solar Azimuth ϕ

the horizon (angle HOQ) and its azimuth ϕ, measured as angle HOS in the horizontal plane.

At solar noon, the sun is exactly on the meridian, which contains the south-north line. Consequently, the solar azimuth ϕ is 0°. The noon altitude β_N is given by the following equation as

$$\beta_N = 90° - \text{LAT} + \delta \tag{2}$$

where LAT = latitude.

Because the earth's daily rotation and its annual orbit around the sun are regular and predictable, the solar altitude and azimuth may be readily calculated for any desired time of day when the latitude, longitude, and date (declination) are specified. Apparent solar time (AST) must be used, expressed in terms of the hour angle H, where

$$H = (\text{Number of hours from solar noon}) \times 15° = \frac{\text{Number of minutes from solar noon}}{4} \tag{3}$$

Solar Time

Apparent solar time (AST) generally differs from local standard time (LST) or daylight saving time (DST), and the difference can be significant, particularly when DST is in effect. Because the sun appears to move at the rate of 360° in 24 h, its apparent rate of motion is 4 min per degree of longitude. The AST can be determined from the following equation:

$$\text{AST} = \text{LST} + \text{ET} + (4 \text{ min})(\text{LST meridian} - \text{Local longitude}) \tag{4}$$

All standard meridians are multiples of 15° east or west of the prime meridian, which is at the Royal Observatory in Greenwich, U.K. The longitude correction is a positive value for the western hemisphere and negative for the eastern hemisphere. The longitudes of the seven standard time meridians that affect North America are Atlantic ST, 60°W; Eastern ST, 75°W; Central ST, 90°W; Mountain ST, 105°W; Pacific ST, 120°W; Alaska ST, 135°W; and Hawaii-Aleutian ST, 150°W. Starting with the prime meridian through Greenwich, many European countries define their standard meridians based on legal, political, and economic, as well as purely physical or geographical, criteria. The longitudes of the three standard time meridians that affect Europe are western European ST (U.K., Ireland, and Portugal), 0°; central European ST, 15°E [e.g., Spain (except for Canary Islands) to the south, Serbia to the east, and Sweden to the north]; and eastern European ST, 30°E (e.g., Greece and Cyprus to the south, Turkey to the east, Finland to the north).

The equation of time (ET) is the measure, in minutes, of the extent by which solar time, as determined by a sundial, runs faster or slower than local standard time (LST), as determined by a clock that runs at a uniform rate. The equation of time may be estimated by the following equation:

$$\text{ET} = 9.87 \sin 2B - 7.53 \cos B - 1.5 \sin B \tag{5}$$

where $B = 0.989(N - 81)$.

Example 1. Find AST at noon DST on July 21 for Washington, D.C., longitude = 77°W; for Chicago, longitude = 87.6°W; and for Athens, Greece, longitude = 23.75°E.

Solution: Noon DST is 11:00 AM LST. Washington is in the eastern time zone, and the LST meridian is 75°W. From Equation (5), the equation of time for July 21 (N = 202) is –6.07 min. Thus, from Equation (4), noon DST for Washington is

$$\text{AST} = 11{:}00 - 6.07 + 4(75 - 77) = 10{:}45.93 \text{ AST} = 10.77 \text{ h}$$

Chicago is in the central time zone, and the LST meridian is 90°W. Thus, from Equation (4), noon central DST is

$$\text{AST} = 11{:}00 - 6.07 + 4(90 - 87.6) = 11{:}03.53 \text{ AST} = 11.06 \text{ h}$$

Athens is in the eastern European time zone, and the LST meridian is 30°E. Thus, from Equation (4), noon DST is

$$\text{AST} = 11{:}00 - 6.07 - 4(30 - 23.75) = 10{:}28.93 \text{ AST} = 10.48 \text{ h}$$

The hour angles H (see Figure 3) for these three examples are

for Washington, $H = (12.00 - 10.77)15° = 18.6°$ east
for Chicago, $H = (12.00 - 11.06)15° = 14.1°$ east
for Athens, $H = (12.00 - 10.48)\ 15° = 22.8°$ east

To find the solar altitude β and the azimuth ϕ when the hour angle H, latitude LAT, and declination δ are known, the following equations may be used:

$$\sin \beta = \cos(\text{LAT}) \cos \delta \cos H + \sin(\text{LAT}) \sin \delta \tag{6}$$

$$\sin \phi = \cos \delta \sin H / \cos \beta \tag{7}$$

or

$$\cos \phi = (\cos H \cos \delta \sin \text{LAT} - \sin \delta \cos \text{LAT}) / \cos \beta \tag{8}$$

Incident Angle

The angle between the line normal to the irradiated surface (OP′ in Figure 3) and the earth-sun line OQ is called the incident angle θ. It is important in solar technology because it affects the intensity of the direct component of solar radiation striking the surface and the surface's ability to absorb, transmit, or reflect the sun's rays.

To determine θ, the surface azimuth ψ and the surface-solar azimuth γ must be known. The surface azimuth (angle POS in Figure 3) is the angle between the south-north line SO and the normal PO to the intersection of the irradiated surface with the horizontal plane, shown as line OM. The surface-solar azimuth, angle HOP, is designated by γ and is the angular difference between the solar azimuth ϕ and the surface azimuth ψ. For surfaces facing east of south, $\gamma = \phi - \psi$ in the morning and $\gamma = \phi + \psi$ in the afternoon. For surfaces facing west of south, $\gamma = \phi + \psi$ in the morning and $\gamma = \phi - \psi$ in the afternoon. For south-facing surfaces, $\psi = 0°$, so $\gamma = \phi$ for all conditions. The angles δ, β, and ϕ are always positive.

For a surface with a tilt angle Σ (measured from the horizontal), the angle of incidence θ between the direct solar beam and the normal to the surface (angle QOP′ in Figure 3) is given by

$$\cos \theta = \cos \beta \cos \gamma \sin \Sigma + \sin \beta \cos \Sigma \tag{9}$$

For vertical surfaces, $\Sigma = 90°$, $\cos \Sigma = 0$, and $\sin \Sigma = 1.0$, so Equation (9) becomes

$$\cos \theta = \cos \beta \cos \gamma \tag{10}$$

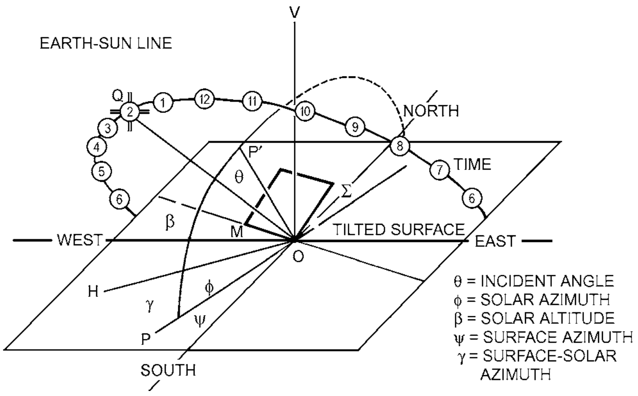

Fig. 3 Solar Angles with Respect to a Tilted Surface

For horizontal surfaces, $\Sigma = 0°$, $\sin \Sigma = 0$, and $\cos \Sigma = 1.0$, so Equation (9) leads to

$$\theta_H = 90° - \beta \tag{11}$$

Example 2. Find θ for a south-facing surface tilted upward 30° from the horizontal at 40° north latitude at 4:00 PM, AST, on August 21.

Solution: From Equation (3), at 4:00 PM on August 21,

$$H = 4 \times 15° = 60°$$

From Equation (1) for August 21 ($N = 233$),

$$\delta = 11.8°$$

From Equation (6),

$$\sin \beta = \cos 40° \cos 11.8° \cos 60° + \sin 40° \sin 11.8°$$
$$\beta = 30.4°$$

From Equation (7),

$$\sin \phi = \cos 11.8° \sin 60°/\cos 30.4°$$
$$\phi = 79.4°$$

The surface faces south, so $\phi = \gamma$. From Equation (9),

$$\cos \theta = \cos 30.4° \cos 79.4° \sin 30° + \sin 30.4° \cos 30°$$
$$\theta = 58.8°$$

Solar Spectrum

Beyond the earth's atmosphere, the effective blackbody temperature of the sun is 5760 K. The maximum spectral intensity occurs at 0.48 µm in the green portion of the visible spectrum. Thekaekara (1973) presents tables and charts of the sun's extraterrestrial spectral irradiance from 0.120 to 100 µm, the range in which most of the sun's radiant energy is contained. The ultraviolet portion of the spectrum below 0.40 µm contains 8.73% of the total, another 38.15% is contained in the visible region between 0.40 and 0.70 µm, and the infrared region contains the remaining 53.12%.

Solar Radiation at the Earth's Surface

In passing through the earth's atmosphere, some of the sun's direct radiation is scattered by nitrogen, oxygen, and other molecules, which are small compared to the wavelengths of the radiation; and by aerosols, water droplets, dust, and other particles with diameters comparable to the wavelengths (Gates 1966). This scattered radiation causes the sky to appear blue on clear days, and some of it reaches the earth as diffuse radiation.

Attenuation of the solar rays is also caused by absorption, first by the ozone in the outer atmosphere, which causes a sharp cutoff at 0.29 µm of the ultraviolet radiation reaching the earth's surface (Figure 4). In the longer wavelengths, there are series of absorption bands caused by water vapor, carbon dioxide, and ozone. The total amount of attenuation at any given location is determined by (1) the length of the atmospheric path through which the rays travel and (2) the composition of the atmosphere. The path length is expressed in terms of the air mass *m*, which is the ratio of the mass of atmosphere in the actual earth-sun path to the mass that would exist if the sun were directly overhead at sea level ($m = 1.0$). For all practical purposes, at sea level, $m = 1.0/\sin \beta$. Beyond the earth's atmosphere, $m = 0$.

Before 1967, solar radiation data were based on an assumed solar constant of 1324 W/m^2 and on a standard sea-level atmosphere containing the equivalent depth of 2.8 mm of ozone, 20 mm of precipitable moisture, and 300 dust particles per cm^3. Threlkeld and Jordan (1958) considered the wide variation of water vapor in the atmosphere above the United States at any given time, and particularly the seasonal variation, which finds three times as much moisture in the atmosphere in midsummer as in December, January, and February. The basic atmosphere was assumed to be at sea-level barometric pressure, with 2.5 mm of ozone, 200 dust particles per cm^3, and an actual precipitable moisture content that varied throughout the year from 8 mm in midwinter to 28 mm in mid-July. Figure 5 shows the variation of the direct normal irradiation I_{DN} with solar altitude, as estimated for clear atmospheres and for an atmosphere with variable moisture content.

The ASHRAE clear-sky model described in previous editions of this chapter operated under several well-known limitations. For example, the clearness number was not universally available; its value varied between 0.85 and 1.20 according to location and season in the United States, and was often taken as unity for lack of better data in other countries. The model also lacked universal applicability and the values of its coefficients had to be altered according to location. In addition, the model was derived from a very limited number of measurements, and its applicability outside the United States had never been demonstrated. Finally, clear-sky diffuse irradiance was proportional to beam irradiance, a fact that runs contrary to intuition (i.e., hazier skies should lead to less direct but more diffuse solar irradiation). To overcome these limitations, ASHRAE research projects RP-1363 and RP-1453 developed a significant update of the model (Thevenard and Gueymard 2010). The objectives were to obtain a more accurate model that could enable calculation of clear-sky radiation for any location in the world for all 12 months of the year, while retaining a relatively simple formulation. The resulting model (Gueymard and Thevenard 2013) can be found in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*, along with the tabulated parameters required at different locations.

Design Values of Total Solar Irradiation

The total solar irradiation $I_{t\theta}$ of a terrestrial surface of any orientation and tilt with an incident angle θ is the sum of the direct component $I_{DN} \cos \theta$ plus the diffuse component $I_{d\theta}$ coming from the sky plus whatever amount of reflected shortwave radiation I_r may reach the surface from the earth or from adjacent surfaces:

$$I_{t\theta} = I_{DN} \cos \theta + I_{d\theta} + I_r \tag{12}$$

The diffuse component is difficult to estimate because of its wide variations and nondirectional nature. Figure 5 shows typical values of diffuse irradiation of horizontal and vertical surfaces. For additional information on calculating clear-sky solar radiation, see Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals.*

The maximum daily amount of solar irradiation that can be received at any given location is that which falls on a flat plate with its surface kept normal to the sun's rays so it receives both direct and diffuse radiation. For fixed flat-plate collectors, the total amount of clear-day irradiation depends on the orientation and slope. As shown by Figure 6 for 40° north latitude, the total irradiation of horizontal surfaces reaches its maximum in midsummer, whereas vertical south-facing surfaces experience their maximum irradiation

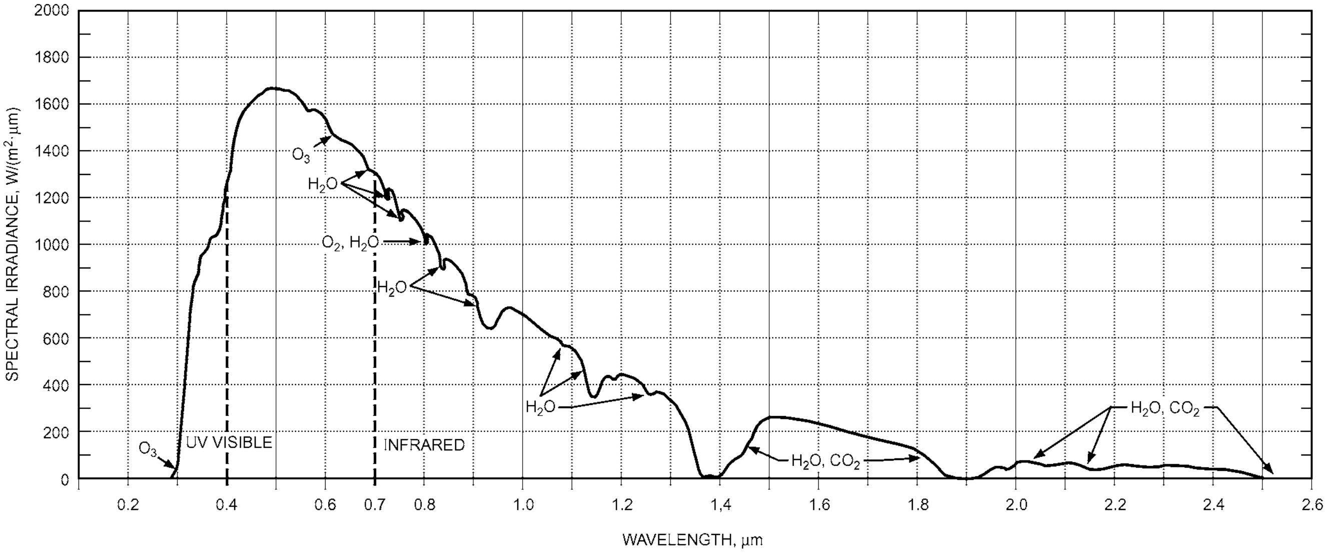

Fig. 4 Spectral Solar Irradiation at Sea Level for Air Mass = 1.0

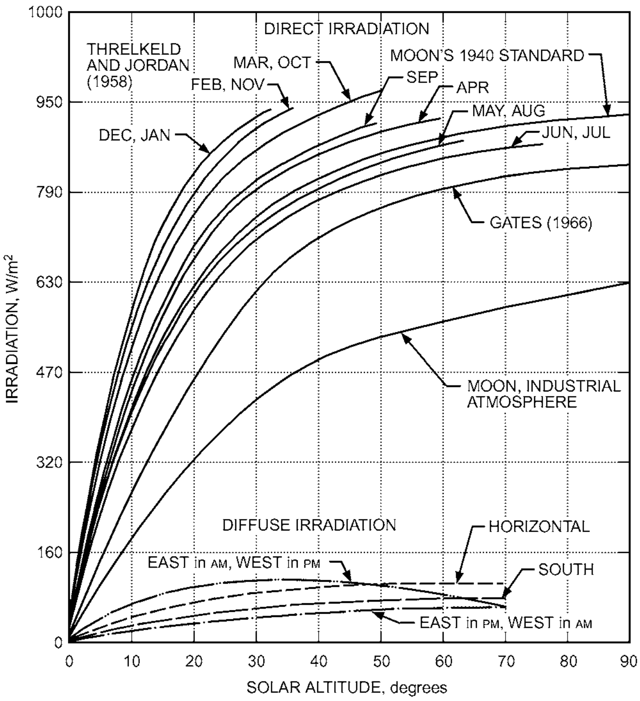

Fig. 5 Variation with Solar Altitude and Time of Year for Direct Normal Irradiation

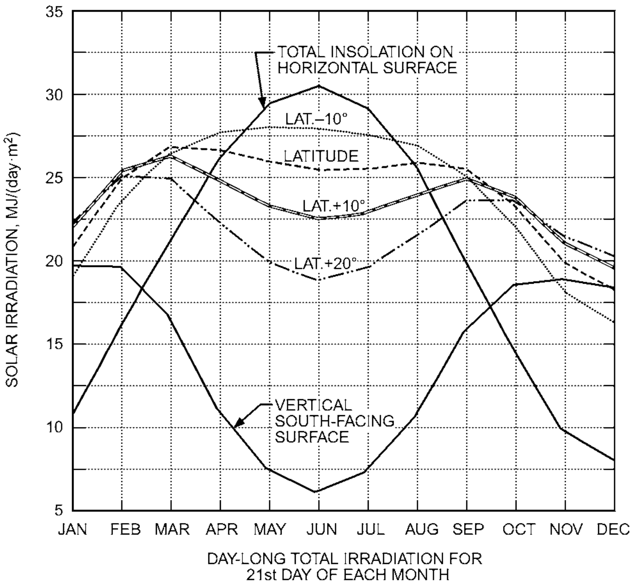

Fig. 6 Total Daily Irradiation for Horizontal, Tilted, and Vertical Surfaces at 40° North Latitude

during the winter. These curves show the combined effects of the varying length of days and changing solar altitudes.

In general, flat-plate collectors are mounted at a fixed tilt angle Σ (above the horizontal) to give the optimum amount of irradiation for each purpose. Collectors intended for winter heating benefit from higher tilt angles than those used to operate cooling systems in summer. Solar water heaters, which should operate satisfactorily throughout the year, require an angle that is a compromise between the optimal values for summer and winter. Figure 6 shows the monthly variation of total day-long irradiation on the 21st day of each month at 40° north latitude for flat surfaces with various tilt angles.

NREL tables (rredc.nrel.gov/solar/pubs/redbook/) give the average solar irradiation of each month, at latitudes 24 to 64° north, on surfaces with the following orientations: normal to the sun's rays (direct normal data do not include diffuse irradiation); horizontal; south-facing, tilted at (LAT–15), LAT, (LAT+15), and 90° from the horizontal. The day-long total irradiation for fixed surfaces is highest for those that face south, but a deviation in azimuth of 15 to 20° causes only a small reduction.

Solar Energy for Flat-Plate Collectors

The preceding data apply to clear days. Irradiation for average days may be estimated for any specific location by referring to publications of the U.S. Weather Service. The *Climatic Atlas of the*

United States website (NOA 2010; www.ncdc.noaa.gov/climate atlas/) gives maps of monthly and annual values of percentage of possible sunshine, total hours of sunshine, mean solar radiation, mean sky cover, wind speed, and wind direction. The European Solar Radiation Atlas (Scharmer and Grief 2000) is a database that provides spatial and temporal climatic information for different time scales, including irradiation (global and its components), sunshine duration, air temperature, precipitation, water vapor pressure, and air pressure for a number of stations. Chapter 14 in the 2017 *ASHRAE Handbook—Fundamentals* also provides several sources for obtaining solar data.

The total daily horizontal irradiation data reported by the U.S. Weather Bureau for approximately 100 stations before 1964 show that the percentage of total clear-day irradiation is approximately a linear function of the percentage of possible sunshine. The irradiation is not zero for days when the percentage of possible sunshine is reported as zero, because substantial amounts of energy reach the earth in the form of diffuse radiation. Instead, the following relationship exists for the percentage of possible sunshine (ratio of day-long horizon irradiation to clear-day total horizon irradiation):

$$\frac{\text{Day-long actual } I_{tH}}{\text{Clear day } I_{tH}} 100 = a + b \tag{13}$$

where a and b are empirical constants for any specified month at any given location. See also Duffie and Beckman (2006) and Jordan and Liu (1977).

Longwave Atmospheric Radiation

In addition to the shortwave (0.3 to 2.0 µm) radiation it receives from the sun, the earth receives longwave radiation (4 to 100 µm, with maximum intensity near 10 µm) from the atmosphere. In turn, a surface on the earth emits longwave radiation q_{Rs} in accordance with the Stefan-Boltzmann law:

$$q_{Rs} = e_s \sigma T_s^4 \tag{14}$$

where

e_s = surface emittance
σ = Stefan-Boltzmann constant, 5.67×10^{-8} W/(m²·K⁴)
T_s = absolute temperature of surface, K

For most nonmetallic surfaces, the longwave hemispheric emittance is high, ranging from 0.84 for glass and dry sand to 0.95 for black built-up roofing. For highly polished metals and certain selective surfaces, e_s may be as low as 0.05 to 0.20.

Atmospheric radiation comes primarily from water vapor, carbon dioxide, and ozone (Bliss 1961); very little comes from oxygen and nitrogen, although they make up 99% of the air.

Approximately 90% of the incoming atmospheric radiation comes from the lowest 90 m. Thus, air conditions at ground level T_{at} largely determine the magnitude of the incoming radiation. Downward radiation from the atmosphere q_{Rat} may be expressed as

$$q_{Rat} = e_{at} \sigma T_{at}^4 \tag{15}$$

The sky emittance e_{at} is a complex function of air temperature and moisture content. The dew point of the atmosphere near the ground determines the total amount of moisture in the atmosphere above the place where the dry-bulb (db) and dew-point (dp) temperatures of the atmosphere are determined (Reitan 1963). Bliss (1961) found that the sky emittance is related to the dew-point temperature, as shown by Table 1.

The apparent sky temperature T_{sky} is defined as the temperature at which the sky (as a blackbody) emits radiation at the rate actually emitted by the atmosphere at ground level temperature with its actual emittance e_{at}. Then,

Table 1 Sky Emittance and Amount of Precipitable Moisture Versus Dew-Point Temperature

Dew Point, °C	Sky Emittance, e_{at}	Precipitable Water, mm
–30	0.68	3.3
–25	0.70	3.7
–20	0.72	4.3
–15	0.74	5.0
–10	0.76	6.2
–5	0.78	8.2
0	0.80	11.2
5	0.82	15.0
10	0.84	20.3
15	0.86	28.0
20	0.88	38.6

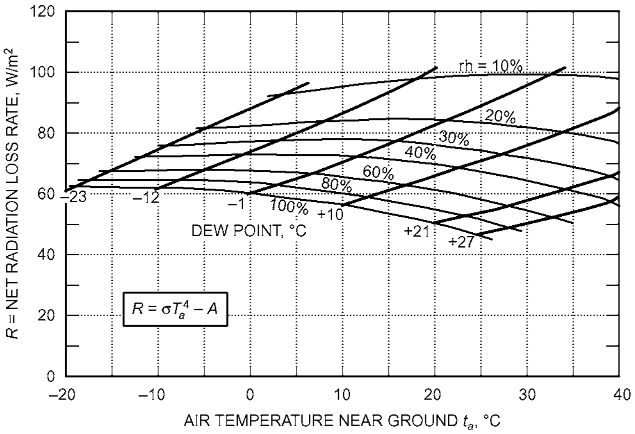

Fig. 7 Radiation Heat Loss to Sky from Horizontal Blackbody

$$\sigma T_{sky}^4 = e_{at} \sigma T_{at}^4 \tag{16}$$

or

$$T_{sky}^4 = e_{at} T_{at}^4 \tag{17}$$

Example 3. Consider a summer night condition when ground-level temperatures are 17.5°C dew point and 30°C dry bulb. From Table 1, e_{at} at 17.5°C dew point is 0.87, and the apparent sky temperature is

$$T_{sky} = 0.87^{0.25}(30 + 273.15) = 292.8 \text{ K}$$

Thus, T_{sky} = 292.8 – 273.15 = 19.6°C, which is 10.4 K below the ground-level dry-bulb temperature.

For a winter night in Arizona, when temperatures at ground level are 15°C db and –5°C dp, from Table 1, the sky emittance is 0.78, and the apparent sky temperature is 270.8 K or –2.4°C.

A simple relationship, which ignores vapor pressure of the atmosphere, may also be used to estimate the apparent sky temperature:

$$T_{sky} = 0.0552\, T_{at}^{1.5} \tag{18}$$

where T is in kelvins.

If the temperature of the radiating surface is assumed to equal the atmospheric temperature, the heat loss from a black surface (e_s = 1.0) may be found from Figure 7.

Example 4. For the conditions in the previous example for summer, 30°C db and 17.5°C dp, the rate of radiative heat loss is about 72 W/m². For winter, 15°C db and –5°C dp, the heat loss is about 85 W/m².

Where a rough, unpainted roof is used as a heat dissipater, the rate of heat loss rises rapidly as the surface temperature goes up. For the summer example, a painted metallic roof, e_s = 0.96, at 38°C (311 K) will have a heat loss rate of

$$q_{Rs} = 0.96 \times 5.67 \times 10^{-8}[311^4 - 292.8^4]$$
$$= 109 \text{ W/m}^2$$

This analysis shows that radiation alone is not an effective means of dissipating heat under summer conditions of high dew-point and ambient temperatures. In spring and fall, when both the dew-point and dry-bulb temperatures are relatively low, radiation becomes much more effective.

On overcast nights, when cloud cover is low, the clouds act much like blackbodies at ground-level temperature, and virtually no heat can be lost by radiation. Exchange of longwave radiation between the sky and terrestrial surfaces occurs in the daytime as well as at night, but the much greater magnitude of the solar irradiation masks the longwave effects.

2. SOLAR ENERGY COLLECTION

Solar energy can be converted by (1) chemical, (2) electrical, and (3) thermal processes. Photosynthesis is a chemical process that plants and other organisms use to convert CO_2 to O_2 and carbohydrates. Photovoltaic cells convert solar energy to electricity. The section on Photovoltaic Applications discusses some applications for these devices. The thermal conversion process provides thermal energy for space heating and cooling, domestic water heating, power generation, distillation, and process heating.

Solar Heat Collection by Flat-Plate Solar Thermal Collectors

The solar irradiation calculation methods presented in the previous sections may be used to estimate how much energy is likely to be available at any specific location, date, and time of day for collection by either a concentrating device, which uses only the direct rays of the sun, or by a flat-plate solar thermal collector (hereinafter called a **flat-plate collector**), which can use both direct and diffuse irradiation. Temperatures needed for space heating and cooling do not exceed 90°C, even for absorption refrigeration, and they can be attained with carefully designed flat-plate collectors.

A flat-plate collector generally consists of the following components (see Figure 8):

- **Glazing.** One or more sheets of glass or other radiation-transmitting material.
- **Tubes, fins, or passages.** To conduct or direct the heat transfer fluid from the inlet to the outlet.
- **Absorber plates.** Flat, corrugated, or grooved plates, to which the tubes, fins, or passages are attached. The plate may be integral with the tubes.
- **Headers or manifolds.** To admit and discharge the heat transfer fluid.
- **Insulation.** To minimize heat loss from the back and sides of the collector.
- **Container or casing.** To surround the other components and protect them from dust, moisture, etc.

Collectors have been built in a wide variety of designs from many different materials (Figure 9). They have been used to heat fluids such as water, water plus an antifreeze additive, or air. Their major purpose is to collect as much solar energy as possible at the lowest possible total cost. The collector should also have a long effective life, despite the adverse effects of the sun's ultraviolet radiation; corrosion or clogging because of acidity, alkalinity, or hardness of the heat transfer fluid; freezing or air binding in the case of water, or deposition of dust or moisture in the case of air; and broken glazing because of thermal expansion, hail, vandalism, or other causes. These problems can be minimized by using tempered glass.

Glazing Materials

Glass has been widely used to cover flat-plate solar collectors because it can transmit as much as 90% of the incoming shortwave solar irradiation while transmitting very little of the longwave radiation emitted outward from the absorber plate. Glass with low iron content has a relatively high transmittance for solar radiation (approximately 0.85 to 0.90 at normal incidence), but its transmittance is essentially zero for the longwave thermal radiation (5.0 to 50 μm) emitted by sun-heated surfaces. Note that commercially available grades of window and greenhouse glass have normal incidence transmittances of about 0.87 and 0.85, respectively. For direct radiation, the transmittance varies markedly with the angle of incidence, as shown in Table 2, which gives transmittances for single and double glazing using double-strength clear window glass.

Plastic films and sheets also have high shortwave transmittance, but because most usable varieties also have transmission bands in the middle of the thermal radiation spectrum, their longwave transmittances may be as high as 0.40.

Plastics are also generally limited in the temperatures they can sustain without deteriorating or undergoing dimensional changes. Only a few kinds of plastics can withstand the sun's ultraviolet radiation for long periods. However, they are not broken by hail and other stones and, in the form of thin films, they are completely flexible and have low mass.

The glass generally used in solar collectors may be either single-strength (2.2 to 2.5 mm thick) or double-strength (2.92 to 3.38 mm thick).

The 4% reflectance from each glass/air interface is the most important factor in reducing transmission, although a gain of about 3% in transmittance can be obtained by using water-white glass. Antireflective coatings and surface texture can also improve transmission significantly. The effect of dirt and dust on collector glazing may be quite small, and the cleansing effect of an occasional rainfall is usually adequate to maintain the transmittance within 2 to 4% of its maximum.

The glazing should admit as much solar irradiation as possible and reduce upward loss of heat as much as possible. Although glass

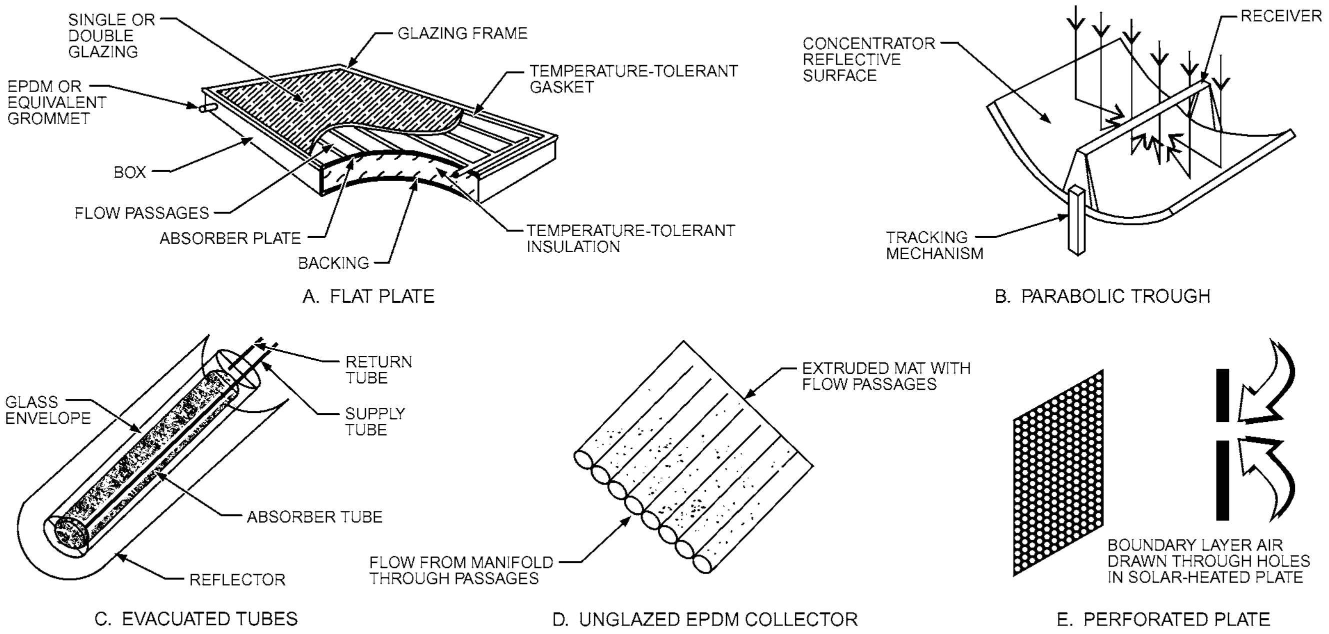

Fig. 9 Various Types of Solar Collectors

Table 2 Variation with Incident Angle of Transmittance for Single and Double Glazing and Absorptance for Flat-Black Paint

Incident Angle, Deg	Transmittance: Single Glazing	Transmittance: Double Glazing	Absorptance for Flat-Black Paint
0	0.87	0.77	0.96
10	0.87	0.77	0.96
20	0.87	0.77	0.96
30	0.87	0.76	0.95
40	0.86	0.75	0.94
50	0.84	0.73	0.92
60	0.79	0.67	0.88
70	0.68	0.53	0.82
80	0.42	0.25	0.67
90	0.00	0.00	0.00

is virtually opaque to the longwave radiation emitted by absorber plates, absorption of that radiation causes an increase in the glass temperature and a loss of heat to the surrounding atmosphere by radiation and convection. This type of heat loss can be reduced by using an infrared-reflective coating on the underside of the glass; however, such coatings are expensive and reduce the effective solar transmittance of the glass by as much as 10%.

In addition to serving as a heat trap by admitting shortwave solar radiation and retaining longwave thermal radiation, the glazing also reduces heat loss by convection. The insulating effect of the glazing is enhanced by using several sheets of glass, or glass plus plastic. Loss from the back of the plate rarely exceeds 10% of the upward loss.

Absorber Plates

The absorber plate absorbs as much of the irradiation as possible through the glazing, while losing as little heat as possible up to the atmosphere and down through the back of the casing. The absorber plates transfer retained heat to the transport fluid. The absorptance of the collector surface for shortwave solar radiation depends on the nature and color of the coating and on the incident angle, as shown in Table 2 for a typical flat-black paint.

By suitable electrolytic or chemical treatments, selective surfaces can be produced with high values of solar radiation absorptance α and low values of longwave emittance e. Essentially, typical selective surfaces consist of a thin upper layer, which is highly absorbent to shortwave solar radiation but relatively transparent to longwave thermal radiation, deposited on a substrate that has a high reflectance and a low emittance for longwave radiation. Selective surfaces are particularly important when the collector surface temperature is much higher than the ambient air temperature.

For fluid-heating collectors, passages must be integral with, or firmly bonded to, the absorber plate. A major problem is obtaining a good thermal bond between tubes and absorber plates without incurring excessive costs for labor or materials. Materials most frequently used for absorber plates are copper, aluminum, and steel. UV-resistant plastic extrusions are used for low-temperature application. If the entire absorber area is in contact with the heat transfer fluid, the material's thermal conductance is not important.

Whillier (1964) concluded that steel tubes are as effective as copper if the bond conductance between tube and plate is good. Potential corrosion problems should be considered with the use of any metal. Bond conductance can range from 5700 W/(m^2·K) for a securely soldered or brazed tube, to 17 W/(m^2·K) for a poorly clamped or badly soldered tube. Plates of copper, aluminum, or stainless steel with integral tubes are among the most effective types available. Figure 9 shows a few of the solar water and air heaters that have been used with varying degrees of success.

Concentrating Collectors

Temperatures far above those attainable by flat-plate collectors can be reached if a large amount of solar radiation is concentrated on a relatively small collection area. Simple **reflectors** can markedly increase the amount of direct radiation reaching a collector, as shown in Figure 10A.

Because of the apparent movement of the sun across the sky, conventional concentrating collectors must follow the sun's daily motion. There are two methods by which the sun's motion can be

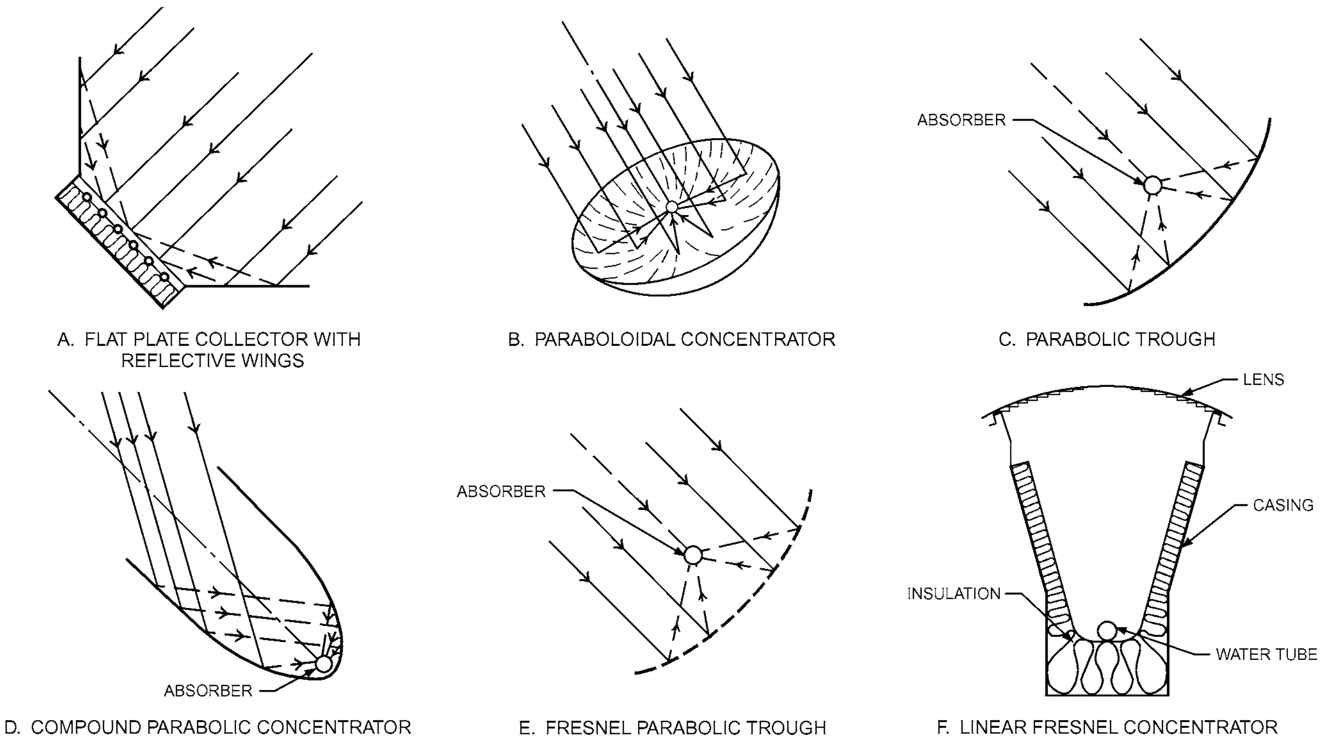

Fig. 10 Types of Concentrating Collectors

readily tracked. The altazimuth method requires the tracking device to turn in both altitude and azimuth; when performed properly, this method enables the concentrator to track the sun exactly. **Paraboloidal solar furnaces** (Figure 10B) generally use this system. The polar, or equatorial, mounting points the axis of rotation at the North Star, tilted upward at the angle of the local latitude. By rotating the collector 15° per hour, it tracks the sun almost perfectly (perfectly on March 21 and September 21). If the collector surface or aperture must be kept normal to the solar rays, a second motion is needed to correct for the change in the solar declination. This motion is not essential for most solar collectors.

The maximum variation in the angle of incidence for a collector on a polar mount is ±23.5° on June 21 and December 21; the incident angle correction then is cos 23.5° = 0.917.

Horizontal reflective parabolic troughs, oriented east and west (Figure 10C), require continuous adjustment to compensate for changes in the sun's declination. There is inevitably some morning and afternoon shading of the reflecting surface if the concentrator has opaque end panels. The necessity of moving the concentrator to accommodate the changing solar declination can be reduced by moving the absorber or by using a trough with two sections of a parabola facing each other, as shown in Figure 10D. Known as a **compound parabolic concentrator (CPC)**, this design can accept incoming radiation over a relatively wide range of angles. By using multiple internal reflections, any radiation that is accepted finds its way to the absorber surface located at the bottom of the apparatus. By filling the collector shape with a highly transparent material having an index of refraction greater than 1.4, the acceptance angle can be increased. By shaping the surfaces of the array properly, total internal reflection occurs at the medium/air interfaces, which results in a high concentration efficiency. Known as a **dielectric compound parabolic concentrator (DCPC)**, this device has been applied to the photovoltaic generation of electricity (Cole et al. 1977).

The parabolic trough of Figure 10E can be simulated by many flat strips, each adjusted at the proper angle so that all reflect onto a common target. By supporting the strips on ribs with parabolic contours, a relatively efficient concentrator can be produced with less tooling than the complete reflective trough.

Another concept applies this segmental idea to flat and cylindrical lenses. A modification is shown in Figure 10F, in which a linear **Fresnel lens**, curved to shorten its focal distance, can concentrate a relatively large area of radiation onto an elongated receiver. Using the equatorial sun-tracking mounting, this type of concentrator has been used to attain temperatures well above those that can be reached with flat-plate collectors.

One disadvantage of concentrating collectors is that, except at low concentration ratios, they can use only the direct component of solar radiation, because the diffuse component cannot be concentrated by most types. However, an advantage of concentrating collectors is that, in summer, when the sun rises and sets well to the north of the east-west line, the sun tracker, with its axis oriented north-south, can begin to accept radiation directly from the sun long before a fixed, south-facing flat plate can receive anything other than diffuse radiation from the portion of the sky that it faces. At 40° north latitude, for example, the cumulative direct radiation available to a sun tracker (on a clear day) is 36.1 MJ/m^2, whereas the total radiation falling on the flat plate tilted upward at an angle equal to the latitude is only 25.2 MJ/m^2 each day. Thus, in relatively cloudless areas, the concentrating collector may capture more radiation per unit of aperture area than a flat-plate collector.

To get extremely high inputs of radiant energy, many flat mirrors or heliostats using altazimuth mounts can be used to reflect their incident direct solar radiation onto a common target. Using slightly concave mirror segments on the heliostats, large amounts of thermal energy can be directed into the cavity of a steam generator to produce steam at high temperature and pressure.

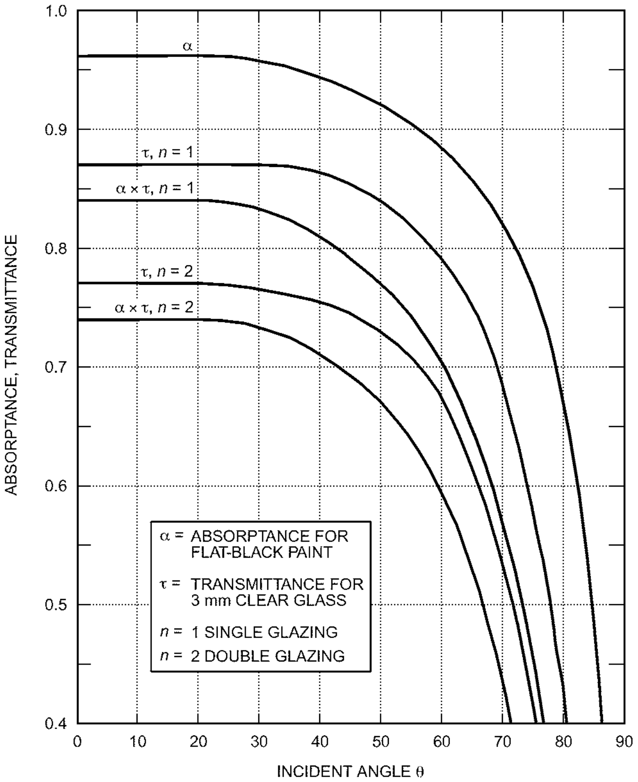

Fig. 11 Variation of Absorptance and Transmittance with Incident Angle

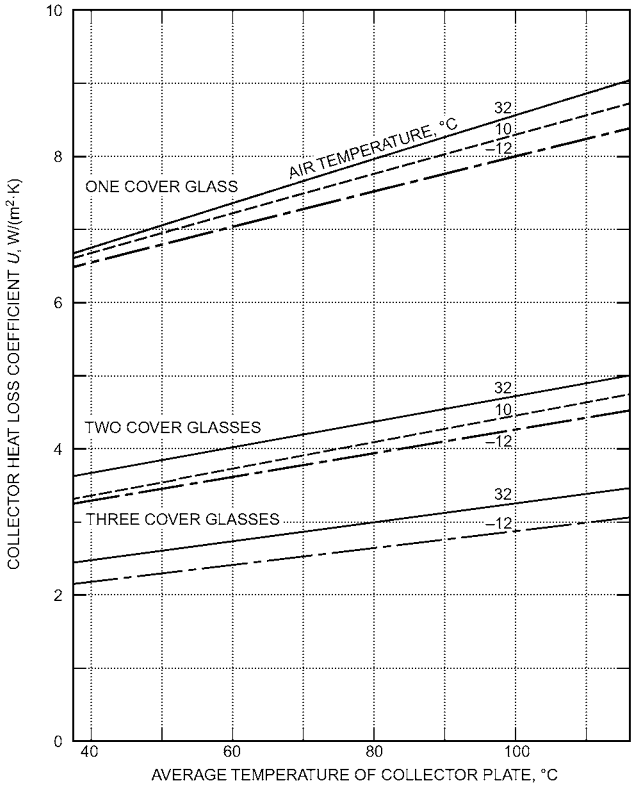

Note: Absorber plate is coated with nonselective flat-black paint.

Fig. 12 Variation of Overall Heat Loss Coefficient U_L with Absorber Plate Temperature and Ambient Air Temperatures for Single-, Double-, and Triple-Glazed Collectors

Flat-Plate Collector Performance

The performance of collectors may be analyzed using a procedure originated by Hottel and Woertz (1942) and extended by Whillier (in Jordan and Liu 1977). The basic equation is

$$q_u = I_{t\theta}(\tau\alpha)_\theta - U_L(t_p - t^{at}) = \dot{m}\, c_p(t_{fe} - t_{fi})/A_{ap} \qquad (19)$$

Equation (19) also may be adapted for use with concentrating collectors:

$$q_u = I_{DN}(\tau\alpha)_\theta(\rho\Gamma) - U_L(A_{abs}/A_{ap})(t_{abs} - t_a) \qquad (20)$$

where

q_u = useful heat gained by collector per unit of aperture area, W/m²
$I_{t\theta}$ = total irradiation of collector, W/m²
I_{DN} = direct normal irradiation, W/m²
$(\tau\alpha)_\theta$ = transmittance τ of cover times absorptance α of plate at prevailing incident angle θ
U_L = overall heat loss coefficient, W/(m²·K)
t_p = temperature of absorber plate, °C
t_a = temperature of atmosphere, °C
t_{abs} = temperature of absorber, °C
$\dot{m}$ = fluid flow rate, kg/s
c_p = specific heat of fluid, kJ/(kg·K)
t_{fe}, t_{fi} = temperatures of fluid leaving and entering collector, °C
$\rho\Gamma$ = reflectance of concentrator surface times fraction of reflected or refracted radiation that reaches absorber
A_{abs}, A_{ap} = areas of absorber surface and of aperture that admit or receive radiation, m²

The transmittance for single and double glazing and the absorptance for flat-black paint may be found in Table 2 for incident angles from 0 to 90°. These values, and the products of τ and α, are also shown in Figure 11. The solar-optical properties of the glazing and absorber plate change little for θ between 0° and 30°, but, because all values reach zero when θ = 90°, they drop off rapidly for values of θ beyond 40°.

For nonselective absorber plates, U_L varies with the temperature of the plate and the ambient air, as shown in Figure 12. For selective surfaces, which strongly reduce the emittance of the absorber plate, U_L is much lower than the values shown in Figure 12. Ask manufacturers of such surfaces for values applicable to their products, or consult test results that give the necessary information.

Example 5. A flat-plate collector is operating in Denver, latitude = 40° north, on July 21 at noon solar time, and the total solar irradiation incident on the plane of the collector $I_{t\theta}$ is 967 W/m². The atmospheric temperature is 30°C, and the average temperature of the absorber plate is 60°C. The collector is single-glazed with flat-black paint on the absorber. The collector faces south, and the tilt angle is 30° from the horizontal. Find the rate of heat collection and collector efficiency. Neglect losses from the back and sides of the collector.

Solution: From Equation (1) for July 21 (N = 202), δ = 20.4°.

From Equation (2),

$$\beta_N = 90° - 40° + 20.4° = 70.4°$$

From Equation (3), H = 0; therefore from Equation (7), sin φ = 0 and thus, φ = 0°. Because the collector faces south, ψ = 0°, and γ = φ. Thus γ = 0°. Then Equation (9) gives

$$\cos\theta = \cos 70.4° \cos 0° \sin 30° + \sin 70.4° \cos 30°$$
$$= (0.335)(1)(0.5) + (0.942)(0.866)$$
$$= 0.983$$
$$\theta = 10.6°$$

From Figure 11, for n = 1, τ = 0.87 and α = 0.96.

From Figure 12, for an absorber plate temperature of 60°C and an air temperature of 30°C, U_L = 7.3 W/(m²·K).

Then from Equation (19),

$$q_u = 967(0.87 \times 0.96) - 7.3(60 - 30) = 589\ \text{W/m}^2$$

Collector efficiency η is

$$589/967 = 0.60$$

The general expression for collector efficiency is

$$\eta = (\tau\alpha)_\theta - U_L(t_p - t_a)/I_{t\theta} \qquad (21)$$

For incident angles below about 35°, the product τα is essentially constant and Equation (21) is linear with respect to the parameter $(t_p - t_a)/I_{t\theta}$, as long as U_L remains constant.

ASHRAE (in Jordan and Liu 1977) suggested introducing an additional term, the **collector heat removal factor F_R**, to allow use of the fluid inlet temperature in Equations (19) and (21):

$$q_u = F_R\,[I_{t\theta}(\tau\alpha)_\theta - U_L(t_{fi} - t_a)] \qquad (22)$$

$$\eta = F_R\,(\tau\alpha)_\theta - F_R\,U_L(t_{fi} - t_a)/I_{t\theta} \qquad (23)$$

where F_R equals the ratio of the heat actually delivered by the collector to the heat that would be delivered if the absorber were at t_{fi}. F_R is found from the results of a test performed in accordance with ISO *Standard* 9806-2017. The Solar Rating and Certification Corporation (SRCC) conducts this test in the United States and publishes the results, along with day-long performance outputs. Similar organizations around the world (e.g., the International Organization for Standardization [ISO], the European Committee for Standardization [CEN], Commonwealth Scientific and Industrial Research Organization [CISRO]) provide similar test results. For additional information on SRCC ratings, see Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

The results of such a test are plotted in Figure 13. When the parameter is zero, because there is no temperature difference between fluid entering the collector and the atmosphere, the value of the *y*-intercept equals $F_R(\tau\alpha)$. The slope of the efficiency line equals the overall heat loss factor U_L multiplied by F_R. For the single-glazed, nonselective collector with the test results shown in Figure 13, the *y*-intercept is 0.82, and the *x*-intercept is 0.12 (m²·K)/W. This collector used high-transmittance single glazing, τ = 0.91, and black paint with an absorptance of 0.97, thus $F_R = 0.82/(0.91 \times 0.97) = 0.93$.

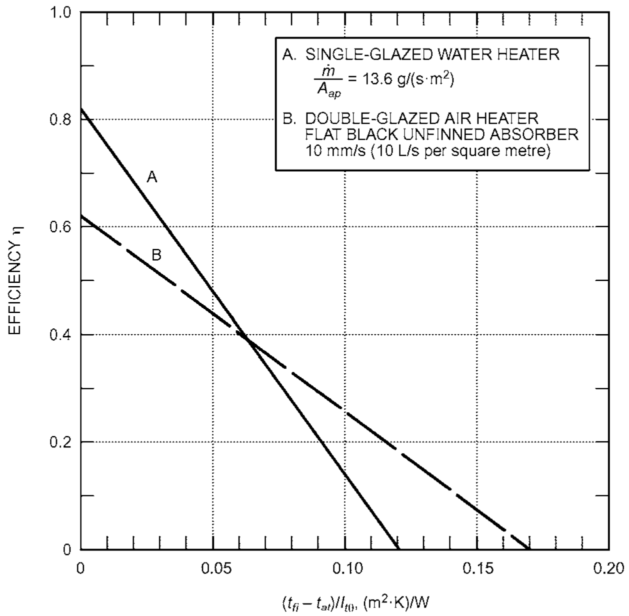

Fig. 13 Efficiency Versus $(t_{fi} - t_{at})/I_{t\theta}$ for Single-Glazed Solar Water Heater and Double-

Assuming that the relationship between η and the parameter is actually linear, as shown, then the slope is –0.82/0.12 = –6.78; thus $U_L = 6.78/F_R = 6.78/0.93 = 7.29$ W/(m²·K). The tests on which Figure 13 is based were run indoors. Wind speed and fluid velocity can affect measured efficiency.

Figure 13 also shows the efficiency of a double-glazed air heater with an unfinned absorber coated with flat-black paint. The *y*-intercept for the air heater B is considerably less than it is for water heater A because (1) transmittance of the double glazing used in B is lower than the transmittance of the single glazing used in A and (2) F_R is lower for B than for A because of the lower heat transfer coefficient between air and the unfinned metal absorber.

The *x*-intercept for air heater B is greater than it is for the water heater A because the upward loss coefficient U_L is much lower for the double-glazed air heater than for the single-glazed water heater. The data for both A and B were taken at near-normal incidence with high values of $I_{t\theta}$. For Example 5, using a single-glazed water heater, the value of the parameter would be close to (60 – 30)/967 = 0.031 (m²·K)/W, and the estimated efficiency, 0.60, agrees closely with the test results.

When irradiation is below about 315 W/m², losses from the collector may exceed the heat that can be absorbed. This situation varies with the temperature difference between the collector inlet temperature and the ambient air, as suggested by Equation (22).

When the incident angle rises above 30°, the product of the glazing's transmittance and the absorber plate's absorptance τα begins to diminish; thus, heat absorbed also drops. Losses from the collector are generally higher as time moves farther from solar noon, and consequently efficiency also drops. Thus, daylong efficiency is lower than near-noon performance. During early afternoon, efficiency is slightly higher than at the comparable morning time, because the ambient air temperature is lower in the morning than in the afternoon.

ISO *Standard* 9806-2017 describes the **incident angle modifier**, which may be found by tests run when the incident angle is set at 30, 45, and 60°. The incident angle modifier is the ratio of the actual $(\tau\alpha)_\theta$ factor at some incidence angle θ to the normal $(\tau\alpha)_n$ factor at normal incident radiation; for normal angles of incidence, the modifier is unity. Simon (1976) showed that for many flat-plate collectors, the incident angle modifier is a linear function of the quantity (1/cos θ – 1). For evacuated tubular collectors, the incident angle modifier may grow with rising values of θ. For additional information on the incident angle modifier, see ISO *Standard* 9806-2017 and Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

The efficiency should be reported in terms of the gross collector area A_g rather than the aperture area A_{ap}. The reported efficiency is lower than that given by Equation (23), but the total energy collected is not changed by this simplification:

$$\eta_g = \frac{\eta_{ap} A_{ap}}{A_g} \qquad (24)$$

3. WATER HEATING SYSTEMS

A solar water heater includes a solar collector that absorbs solar radiation and converts it to heat, which is then absorbed by a heat transfer fluid (water, a nonfreezing liquid, or air) that passes through the collector. The heat transfer fluid's heat is stored or used directly.

Portions of the solar energy system are exposed to the weather, so they must be protected from freezing. The system must also be protected from overheating caused by high insolation levels during periods of low energy demand.

In solar water heating, water is heated directly in the collector or indirectly by a heat transfer fluid that is heated in the collector, passes through a heat exchanger, and transfers its heat to domestic or service water. The heat transfer fluid is transported by either natural or forced circulation. Natural circulation occurs by natural convection (thermosiphoning), whereas forced circulation uses pumps or fans. Except for thermosiphon systems, which need no control, solar domestic and service water heaters are controlled by differential thermostats.

Five types of solar energy systems are used to heat domestic and service hot water: thermosiphon, direct circulation, indirect, integral collector storage, and site built. Recirculation and draindown are used to protect direct solar water heaters from freezing.

Hot-Water System Components

This section describes the major components involved in the collection, storage, transportation, control, and distribution of solar heat for a domestic hot-water (DHW) system.

Collectors. Flat-plate collectors are most commonly used for water heating because of the year-round load requiring temperatures of 30 to 80°C. For discussions of other collectors and applications, see Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, and previous sections of this chapter. Collectors must withstand extreme weather (e.g., freezing, stagnation, high winds), as well as system pressures.

Heat Transfer Fluids. Heat transfer fluids transport heat from the solar collectors to the domestic water. There are potential chemical and mechanical problems with this transfer, primarily in systems in which a heat exchanger interface exists with the potable water supply. Both the chemical compositions of the heat transfer fluids (pH, toxicity, and chemical durability) and their mechanical properties (specific heat and viscosity) must be considered.

Except in unusual cases, or when potable water is being circulated, the energy transport fluid is nonpotable and could contaminate potable water. Even potable or nontoxic fluids in closed circuits are likely to become nonpotable because of contamination from metal piping, solder joints, and packing, or by the inadvertent installation of a toxic fluid at a later date.

Thermal Energy Storage. Heat collected by solar domestic and service water heaters is virtually always stored in a liquid in tanks. Storage tanks and bins should be well insulated. In domestic hot-water systems, heat is usually stored in one or two tanks. The hot-water outlet is at the top of the tank, and cold (makeup) water enters the tank through a dip tube that extends down to within 100 to 150 mm of the tank bottom. The outlet on the tank to the collector loop should be approximately 100 mm above the tank bottom to prevent scale deposits from being drawn into the collectors. Water from the collector array returns to the top of the storage tank. A plumbing arrangement connecting the collector array to the middle to lower portion of the tank may take advantage of thermal stratification, depending on the delivery temperature from the collectors and the flow rate through the storage tank.

Single-tank electric auxiliary systems often incorporate storage and auxiliary heating in the same vessel. Conventional electric water heaters commonly have two heating elements: one near the top and one near the bottom. If a dual-element tank is used in a solar energy system, the bottom element should be disconnected and the top left functional to take advantage of fluid stratification. Standard gas- and oil-fired water heaters should not be used in single-tank arrangements. In gas and oil water heaters, heat is added to the bottom of the tanks, which reduces both stratification and collection efficiency in single-tank systems.

Dual-tank systems often use the solar domestic hot-water storage tank as a preheat tank. The second tank is normally a conventional domestic hot-water tank containing the auxiliary heat source. Multiple tanks are sometimes used in large institutions, where they operate similarly to dual-tank heaters. Although using two tanks may increase collector efficiency and the solar fraction, it increases tank heat losses. The makeup water inlet is usually a dip tube that extends near the bottom of the tank.

Estimates for sizing storage tanks usually range from 40 to 100 L per square metre of solar collector area. The estimate used most often is 75 L per square metre of collector area, which usually provides enough heat for a sunless period of about a day. Storage volume should be analyzed and sized according to the project water requirements and draw schedule; however, solar applications typically require larger-than-normal tanks, usually the equivalent of the average daily load.

For details on thermal energy storage, see Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Heat Exchangers. Indirect solar water heaters require one or more heat exchangers. Heat transfer from solar collectors to potable hot water has the potential for contaminating the water. Heat exchangers influence the effectiveness of energy collected to heat domestic water. They also separate and protect the potable water supply from contamination when nonpotable heat transfer fluids are used in the collector loop. For this reason, various codes regulate the need for and design of heat exchangers.

Heat exchanger selection should consider the following:

- Heat exchange effectiveness
- Pressure drop, operating power, and flow rate
- Design pressure, configuration, size, materials, and location
- Cost and availability
- Reliable protection of potable water supply from contamination by heat transfer fluid
- Leak detection, inspection, and maintainability
- Material compatibility with other elements (e.g., metals and fluids)
- Thermal compatibility with design parameters such as operating temperature, and fluid thermal properties

Heat exchanger selection depends on characteristics of fluids that pass through the heat exchanger and properties of the exchanger itself. Fluid characteristics to consider are fluid type, specific heat, mass flow rate, and hot- and cold-fluid inlet and outlet temperatures. Physical properties of the heat exchanger to consider are the overall heat transfer coefficient of the heat exchanger and the heat transfer surface area.

For most solar domestic hot-water designs, only the hot and cold inlet temperatures are known; the other temperatures must be calculated using the heat exchanger's physical properties. Two quantities that are useful in determining a heat exchanger's heat transfer and a collector's performance characteristics when it is combined with a given heat exchanger are the (1) fluid capacitance rate, which is the product of the mass flow rate and specific heat of fluid passing through the heat exchanger, and (2) heat exchanger effectiveness, which relates the capacitance rate of the two fluids to the fluid inlet and outlet temperatures. Effectiveness is equal to the ratio of the actual heat transfer rate to the maximum heat transfer rate theoretically possible. Generally, a heat exchanger effectiveness of 0.4 or greater is desired.

Expansion Tanks. An indirect solar water heater operating in a closed collector loop requires an expansion tank to prevent excessive pressure. Fluid in solar collectors under stagnation conditions can boil, causing excessive pressure to develop in the collector loop, and expansion tanks must be sized for this condition. Expansion tank sizing formulas for closed-loop hydronic systems, found in Chapter 13 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, may be used for solar heater expansion tank sizing, with the volume of water in the system defined as the total volume of fluid in the solar collectors and of any piping located above the collectors, if significant. This sizing method provides a passive means for eliminating fluid loss through overtemperature or stagnation, common problems in closed-loop solar systems. It results in a larger expansion tank than typically found in hydronic systems, but the increase in cost is small compared to the savings in fluid replacement and maintenance costs (Lister and Newell 1989).

Pumps. Pumps circulate heat transfer liquid through collectors and heat exchangers. In solar domestic hot-water heaters, the pump is usually a centrifugal circulator driven by a motor of less than 300 W. The flow rate for collectors generally ranges from 0.010 to 0.027 $L/(s \cdot m^2)$. Pumps used in drainback systems must provide pressure to overcome friction and to lift the fluid to the collectors.

Piping. Piping can be plastic, copper, galvanized steel, or stainless steel. The most widely used is nonlead, sweat-soldered L-type copper tubing. M-type copper is also acceptable if allowed by local building codes. If water/glycol is the heat transfer fluid, galvanized pipes or tanks must not be used because unfavorable chemical reactions will occur; copper piping is recommended instead. Also, if glycol solutions or silicone fluids are used, they may leak through joints where water would not. Piping should be compatible with the collector fluid passage material; for example, copper or plastic piping should be used with collectors having copper fluid passages.

Piping that carries potable water can be plastic, copper, galvanized steel, or stainless steel. In indirect systems, corrosion inhibitors must be checked and adjusted no less than annually, preferably every three months. Inhibitors should also be checked if the system overheats during stagnation. If dissimilar metals are joined, dielectric or nonmetallic couplings should be used. The best protection is sacrificial anodes or getters in the fluid stream. Their location depends on the material to be protected, anode material, and electrical conductivity of the heat transfer fluid. Sacrificial anodes of magnesium, zinc, or aluminum are often used to reduce corrosion in storage tanks. Because many possibilities exist, each combination must be evaluated. A copper-aluminum or copper-galvanized steel joint is unacceptable because of severe galvanic corrosion. Aluminum, copper, and iron have a greater potential for corrosion.

Elimination of air, accommodating thermal pipe expansion/contraction, and proper piping slope must be considered to avoid possible failures. Collector pipes (particularly manifolds) should be designed to allow expansion from stagnation temperature to extreme cold weather temperature. Expansion can be controlled with offset elbows in piping, hoses, or expansion couplings. Expansion loops should be avoided unless they are installed horizontally, particularly in systems that must drain for freeze protection. The collector array piping should slope 5 mm per metre for drainage (DOE 1978a).

Air can be eliminated by placing air vents at all piping high points and by air purging during filling. Flow control, isolation, and other valves in the collector piping must be chosen carefully so that these components do not restrict drainage significantly or back up water behind them. In systems without antifreeze, the collectors must drain completely.

Valves and Gages. Valves in solar domestic hot-water systems must be located to ensure system efficiency, satisfactory performance, and safety of equipment and personnel. Drain valves must be ball type; gate valves may be used if the stem is installed horizontally. Check valves or other valves used for freeze protection or for reverse thermosiphoning must be reliable to avoid significant damage.

Auxiliary Heat Sources. On sunny days, a typical solar energy system should supply water at a predetermined temperature, and the solar storage tank should be large enough to hold sufficient water for a day or two. Because of the intermittent nature of solar radiation, an auxiliary heater must be installed to handle hot-water requirements. If a utility is the source of auxiliary energy, auxiliary heater operation can be timed to take advantage of off-peak utility rates. The auxiliary heater should be carefully integrated with the solar energy heater to obtain maximum solar energy use. For example, the auxiliary heater should not destroy any stratification that may exist in the solar-heated storage tank, which would reduce collector efficiency.

Ductwork, particularly in systems with air-type collectors, must be sealed carefully to avoid leakage in duct seams, damper shafts, collectors, and heat exchangers. Ducts should be sized using conventional air duct design methods.

Control. Controls regulate solar energy collection by controlling fluid circulation, activate system protection against freezing and overheating, and initiate auxiliary heating when it is required. The three major control components are sensors, controllers, and actuators. Sensors detect conditions or measure quantities, such as temperature. Controllers receive output from the sensors, select a course of action, and signal a component to adjust the condition. Actuators, such as pumps, valves, dampers, and fans, execute controller commands and regulate the system. The trend is to maintain a near-constant temperature difference between the collector outlet and inlet, to maximize daily heat collection. Currently, controls operate in a user-adjustable temperature difference range.

Temperature sensors measure the temperature of the absorber plate near the collector outlet and near the bottom of the storage tank. The sensors send signals to a controller, such as a differential temperature thermostat, for interpretation.

The differential thermostat compares signals from the sensors with adjustable set points for high and low temperature differentials. The controller performs different functions, depending on which set points are met. In liquid systems, when the temperature difference between the collector and storage reaches a high set point, usually 7 to 8 K, the pump starts, automatic valves are activated, and circulation begins. When the temperature difference reaches a low set point, usually 2 K, the pump is shut off and the valves are deenergized and returned to their normal positions. To restart the system, the differential temperature set point must again be met. If the system has either freeze or overheat protection, the controller opens or closes valves or dampers and starts or stops pumps or fans to protect the system when its sensors detect conditions indicating that either freezing or overheating is about to occur.

Sensors must be selected to withstand high temperature, such as may occur during collector stagnation. Collector loop sensors should be located as close as possible to the outlet of the collectors, either in or on a pipe above or near the collector, or in the collector outlet passage.

The storage temperature sensor should be near the bottom of the storage tank to detect the temperature of fluid before it is pumped to the collector or heat exchanger. Storage fluid is usually coldest at that location because of thermal stratification and the location of the makeup water supply. The sensor should be either securely attached to the tank and well insulated, or immersed inside the tank near the collector supply.

The freeze protection sensor, if required, should be located so that it detects the coldest liquid temperature when the collector is shut down. Common locations are the back of the absorber plate at the bottom of the collector, the collector intake or return manifolds, or the center of the absorber plate. The center absorber plate location is recommended because reradiation to the night sky freezes the collector heat transfer fluid, even though the ambient temperature is above freezing. Some system types, such as the recirculation system, have two sensors for freeze protection; others, such as the draindown, use only one.

Control of on/off temperature differentials affects system efficiency. If the differential is too high, the collector starts later than it should; if it is too low, the collector starts too soon. The turn-on differential for liquid systems usually ranges from 5.5 to 17 K and is commonly lower in warmer climates and higher in cold climates. For air systems, the range is usually 14 to 25 K.

The turn-off temperature differential is more difficult to estimate. Selection depends on a comparison between the value of the energy collected and the cost of collecting it. It varies with individual systems, but a value of 2 K is typical and generally the fixed default value in the control.

Water temperature in the collector loop depends on ambient temperature, solar radiation, radiation from the collector to the night sky, and collector loop insulation. Freeze protection sensors should be set to detect 4°C.

Sensors are important but often overlooked control components. They must be selected and installed properly because no control can produce accurate outputs from unreliable sensor inputs. Sensors are used in conjunction with a differential temperature controller and are usually supplied by the controller manufacturer. Sensors must survive the anticipated operating conditions without physical damage or loss of accuracy. Low-voltage sensor circuits must be located away from high-voltage lines to avoid electromagnetic interference. Sensors attached to collectors should be able to withstand the stagnation temperature.

Sensor calibration, which is often overlooked by installers and maintenance personnel, is critical to system performance; a routine calibration maintenance schedule is essential.

Another control option is to use a photovoltaic (PV) panel that powers a DC pump. A properly sized and oriented PV panel converts sunlight into electricity to run a small circulating pump. No additional sensing is required because the PV panel and pump output increase with sunlight intensity and stop when no sunlight (collector energy) is available. However, to prevent operation when the collector outlet temperature is lower than the storage tank, a DC-powered differential controller may be used. Cromer (1984) showed that, with proper matching of pump and PV electrical characteristics, PV panel sizes as low as 1.35 W/m^2 of thermal panel may be used successfully. Difficulty with late starting and running too long in the afternoon can be alleviated by tilting the PV panel slightly to the east during commissioning of the installed system. Electronic devices such as a maximum power point tracker and linear current booster can also improve pump performance at start-up (Bai et al. 2011).

Thermosiphon Systems

Thermosiphon systems (Figure 14) heat potable water or a heat transfer fluid and rely on natural convection to transport it from the collector to storage. For direct systems, pressure-reducing valves are required when the city water pressure is greater than the working pressure of the collectors. In a thermosiphon system, the storage tank must be elevated above the collectors, which sometimes requires designing the upper level floor and ceiling joists to bear this additional load. Extremely hard or acidic water can cause scale deposits that clog or corrode the absorber fluid passages. Thermosiphon flow is induced whenever there is sufficient sunshine, so these systems do not need pumps.

Direct-Circulation Systems

A direct-circulation system (Figure 15) pumps potable water from storage to the collectors when there is enough solar energy available to warm it. It then returns the heated water to the storage tank until it is needed. Collectors can be mounted either above or below the storage tank. Direct-circulation systems are only feasible in areas where freezing is infrequent. Freeze protection is provided either by recirculating warm water from the storage tank or by flushing the collectors with cold water. Direct water-heating systems should not be used in areas where the water is extremely hard or acidic because scale deposits may clog or corrode the absorber fluid passages, rendering the system inoperable.

Direct-circulation systems are exposed to city water line pressures and must withstand pressures as required by local codes. Pressure-reducing valves and pressure-relief valves are required when city water pressure is greater than the working pressure of the collectors. Direct-circulation systems often use a single storage tank

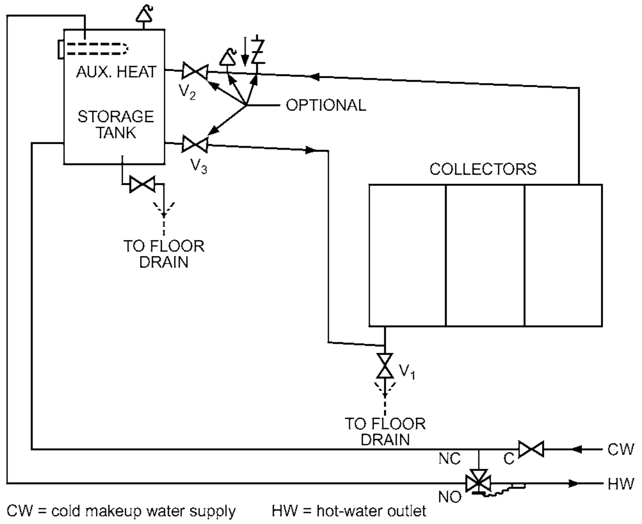

Fig. 14 Thermosiphon System

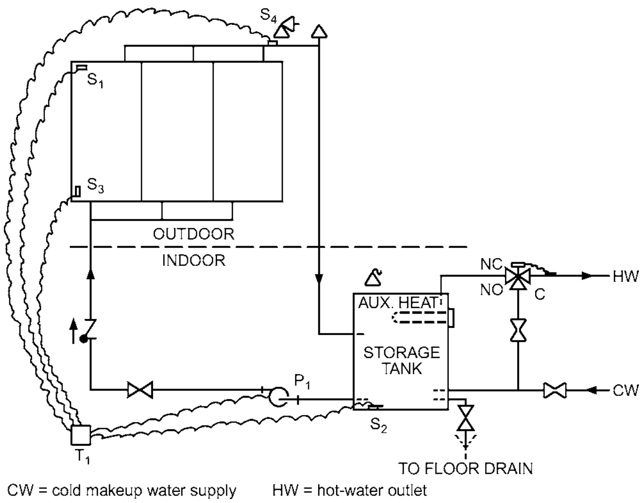

Fig. 15 Direct Circulation System

for both solar energy storage and the auxiliary water heater, but two-tank storage systems can be used.

Draindown Systems. Draindown systems (Figure 16) are direct-circulation water-heating systems in which potable water is pumped from storage to the collector array, where it is heated. Circulation continues until usable solar heat is no longer available. When a freezing condition is anticipated or a power outage occurs, the system drains automatically by isolating the collector array and exterior piping from the city water pressure and using one or more valves for draining. Solar collectors and associated piping must be carefully sloped to drain the collector's exterior piping.

Indirect Water-Heating Systems

Indirect water-heating systems (Figure 17) circulate a freeze-protected heat transfer fluid through the closed collector loop to a heat exchanger, where its heat is transferred to the potable water. The most commonly used heat transfer fluids are water/ethylene glycol and water/propylene glycol solutions, although other heat transfer fluids such as silicone oils, hydrocarbons, and refrigerants can also be used (ASHRAE 1983). These fluids are nonpotable, sometimes toxic, and normally require double-wall heat exchangers. The

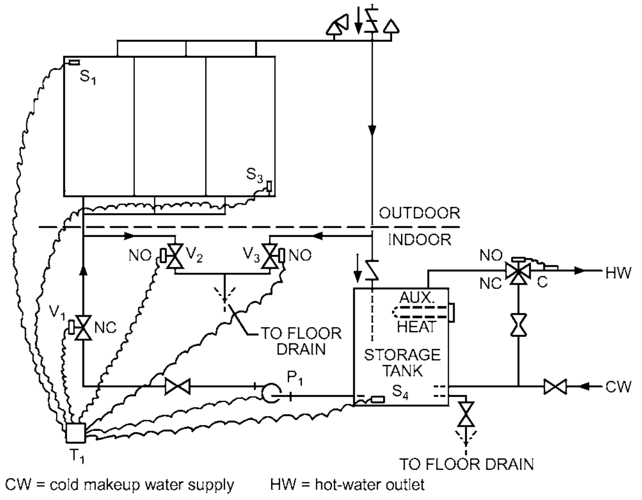

Fig. 16 Draindown System

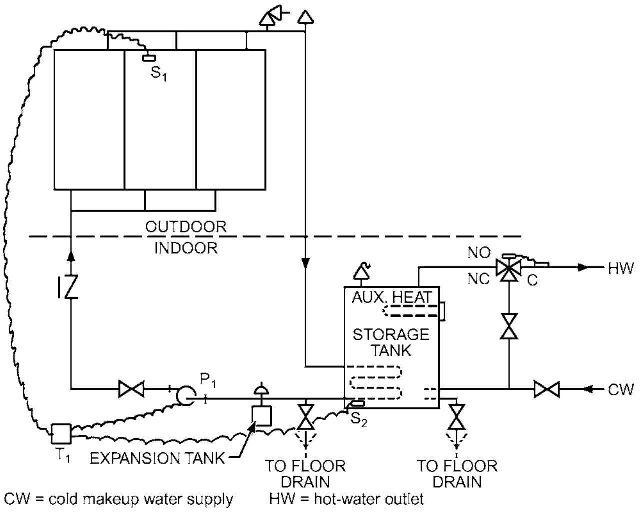

Fig. 17 Indirect Water Heating

double-wall heat exchanger can be located inside the storage tank, or an external heat exchanger can be used. The collector loop is closed and therefore requires an expansion tank and a pressure-relief valve. A one- or two-tank storage can be used. Additional overtemperature protection may be needed to prevent the collector fluid from decomposing or becoming corrosive.

Designers should avoid automatic water makeup in systems using water/antifreeze solutions because a significant leak may raise the freezing temperature of the solution above the ambient temperature, causing the collector array and exterior piping to freeze. Also, antifreeze systems with large collector arrays and long pipe runs may need a time-delayed bypass loop around the heat exchanger to avoid freezing the heat exchanger on start-up.

Drainback Systems. Drainback systems are generally indirect water-heating systems that circulate treated (typically demineralized water or 50% glycol/water) or untreated water through the closed collector loop to a heat exchanger, where its heat is transferred to the potable water. Circulation continues until usable energy is no longer available. When the pump stops, the collector fluid drains by gravity to a storage or tank. In a pressurized system, the tank also serves as an expansion tank, so it must have a temperature- and pressure-relief valve to protect against excessive

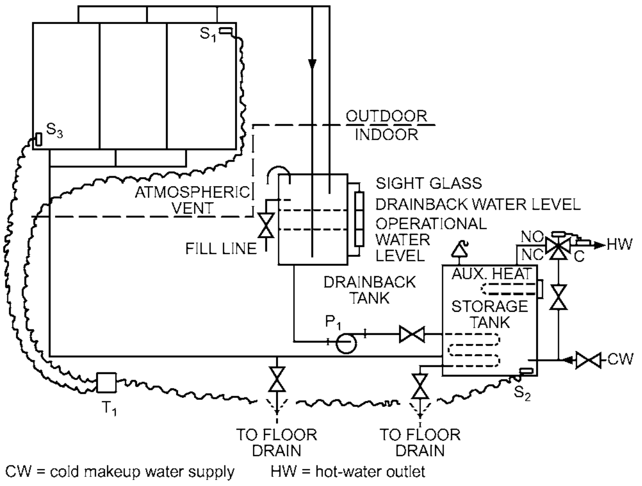

Fig. 18 Drainback System

pressure. In an unpressurized system (Figure 18), the tank is open and vented to the atmosphere.

The collector loop is isolated from the potable water, so valves are not needed to actuate draining, and scaling is not a problem. The collector array and exterior piping must be sloped to drain completely, and the pumping pressure must be sufficient to lift water to the top of the collector array.

Integral Collector Storage Systems

Integral collector storage (ICS) systems use hot-water storage as part of the collector. Some types use the surface of a single tank as the absorber, and others use multiple long, thin tanks placed side by side horizontally to form the absorber surface. In this latter type of ICS, hot water is drawn from the top tank, and cold replacement water enters the bottom tank. Because of the greater nighttime heat loss from ICS systems, they are typically less efficient than pumped systems, and using selective surfaces (see Chapter 37 of the 2016 *ASHRAE Handbook—Systems and Equipment*) is strongly recommended. ICS systems are normally installed as a solar preheater without pumps or controllers. Flow through the ICS system occurs on demand, as hot water flows from the collector to a hot-water auxiliary tank in the structure.

SRCC provides annual performance results for these various types of systems at www.solar-rating.org.

Site-Built Systems

Site-built, large-volume solar air- or water-heating equipment is used in commercial and industrial applications. These site-built systems are based on a transpired solar collector for air heating and shallow solar pond technologies.

Transpired Solar Collector. This collector preheats outdoor air by drawing it through small holes in a metal panel. It is typically installed on south-facing walls and is designed to heat outdoor air for building ventilation or process applications (Kutscher 1996). The prefabricated panel, made of dark metal with thousands of small holes, efficiently heats and captures fresh air by drawing it through a perforated adsorber, eliminating the cost and reflection losses associated with a glazing. The sun heats the metal panel, which in turn heats a boundary layer of air on its surface. Air is heated as it is drawn through the small holes into a ventilation system for delivery as ventilation air, for crop drying, or other process applications (Shukla et al. 2012).

Shallow Solar Pond. The shallow solar pond (SSP) is a large-scale ICS solar water heater (Figure 19) capable of providing more than 19 m^3 of hot water per day for commercial and industrial use.

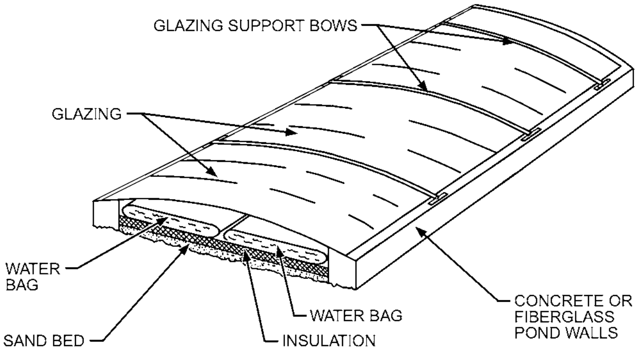

Fig. 19 Shallow Solar Pond

These ponds are built in standard modules and tied together to supply the required load. The SSP module can be ground mounted or installed on a roof. It is typically 5 m wide and up to 60 m long. The module contains one or two flat water bags similar to a water bed. The bags rest on a layer of insulation inside concrete or fiberglass curbs. The bag is protected against damage and heat loss by greenhouse glazing. A typical pond filled to a 100 mm depth holds approximately 23 m^3 of water.

Pool Heaters

Solar pool heaters do not require a separate storage tank, because the pool itself serves as storage. In most cases, the pool's filtration pump forces the water through the solar panels or plastic pipes. In some retrofit applications, a larger pump may be required to handle the solar heater's needs, or a small pump may be added to boost pool water to the solar collectors.

Automatic control may be used to direct the flow of filtered water to the collectors when solar heat is available; this may also be accomplished manually. Normally, solar heaters are designed to drain down into the pool when the pump is turned off; this provides the collectors with freeze protection.

Four primary types of collector designs are used for swimming pool heat: (1) rigid black plastic panels (polypropylene), usually 1.2 by 3 m or 1.2 by 2.4 m; (2) tube-on-sheet panels, which typically have a metal deck (copper or aluminum) with copper water tubes; (3) an ethylene-propylene diene monomer (or ethylene-propylene terpolymer) (EPDM) rubber mat, extruded with water passages running its length; and (4) arrays of black plastic pipe, usually 28 mm diameter acrylonitrile butadiene styrene (ABS) plastic (Root et al. 1985).

Hot-Water Recirculation

Domestic hot-water (DHW) recirculation systems (Figures 20 and 21), which continuously circulate domestic hot water throughout a building, are found in motels, hotels, hospitals, dormitories, office buildings, and other commercial buildings. Recirculation heat losses in these systems are usually a significant part of the total water-heating load. In Figures 20 and 21, the three-way valve prevents heated water from returning to the solar storage tank when the return temperature is greater than the solar tank temperature. This ensures that heated water is used only when it is hot enough and prevents heating of the solar tank by the conventional heater. Using a cycle timer to control the DHW circulating pump that is synchronized with the building hot-water consumption profile can also help reduce circulation losses. The return line on the makeup preheat system can go directly to the conventional water heater to eliminate the three-way valve and prevent the solar tank from being heated by auxiliary energy.

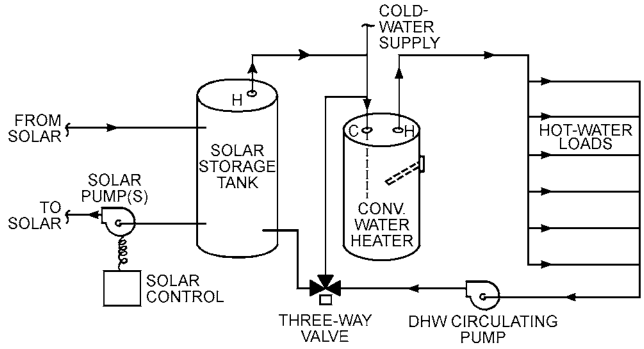

Fig. 20 DHW Recirculation System

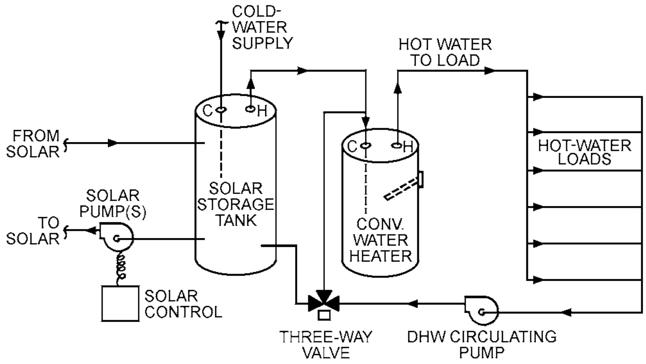

Fig. 21 DHW Recirculation System with Makeup Preheat

4. ACTIVE AND PASSIVE SYSTEMS FOR SOLAR HEATING AND COOLING SYSTEMS

The components and subsystems discussed previously may be combined to create a wide variety of solar heating and cooling systems. These systems fall into two principal categories: passive and active.

Passive solar systems require little, if any, nonrenewable energy to make them function (Yellott 1977; Yellott et al. 1976). Every building is passive in the sense that the sun tends to warm it by day, and it loses heat at night. Passive systems incorporate solar collection, storage, and distribution into the architectural design of the building and make minimal or no use of fans to deliver the collected energy to the conditioned spaces. Passive solar heating, cooling, and lighting design must consider the building envelope and its orientation, the thermal storage mass, and window configuration and design. Athienitis and Santamouris (2002), Balcomb et al. (1984), DOE (1980/1982), LBL (1981), and Mazria (1979) give estimates of energy savings resulting from the application of passive solar design concepts.

Active solar systems use either liquid or air as the collector fluid. Active systems must have a continuous availability of electricity to operate pumps and fans. A complete system includes solar collectors, energy storage devices, and pumps or fans for transferring energy to storage or to the load. The load can be space cooling, heating, or hot water. Although it is technically possible to construct a solar heating and cooling system to supply 100% of the design load, such a system would be uneconomical and oversized. The size of the solar system, and thus its ability to meet the load, is determined by life-cycle cost analysis that weighs the cost of energy saved against the amortized solar cost.

Active solar energy systems have been combined with heat pumps for water and/or space heating. The most economical arrangement in residential heating is a solar system in parallel with a heat pump, which supplies auxiliary energy when the solar source is not available. For domestic water systems requiring high water temperatures, a heat pump placed in series with the solar storage tank may be advantageous. Freeman et al. (1979) and Morehouse and Hughes (1979) present information on performance and estimated energy savings for solar-heat pumps.

Hybrid systems combine elements of both active and passive systems. They require some nonrenewable energy, but the amount is so small that they can maintain a coefficient of performance (COP) of about 50. An example is a floor slab thermal storage system that reradiates heat to a load (e.g., a building conditioned space) from a thermal mass surface after having been charged using an air collection system where insulated ducts feed warm air into cavities created within the heat storage slab (Howard 1986). Combining passive with active solar systems and other renewable energy sources is often the most satisfactory way to achieve very high annual solar savings (Swift and Lawrence 2010).

Passive Systems

A well-designed passive solar building needs (1) an appropriate thermal load (i.e., minimize heating loads first); (2) aperture, such as clear, glazed windows; (3) thermal storage (e.g., massive floors or walls, containers of water) to minimize overheating and to allow use of heat at night; (4) control, either manual or automatic, to address overheating; and (5) night insulation of the aperture so that there is not a net heat loss (Swift and Lawrence 2010). Passive systems may be divided into several categories. The first residence to which the name **solar house** was applied used a large expanse of south-facing glass to admit solar radiation; this is known as a **direct-gain** passive system. The solar collector (windows) and storage (e.g., floors, walls) are part of the occupied space and typically have the highest percent of heating load met by solar. The optimal amount of thermal mass is often around 20 cm thick high-density concrete for direct-gain floors over conditioned basements. Optimization requires a design concept that captures and stores the highest amount of solar energy without unnecessarily increasing cost or complexity. Direct-gain surfaces should have high absorptivity (dark color) and should not be covered by carpet, tile, much furniture, or other obstacles that prevent absorption of available solar radiation. To reduce heat losses, thermal mass should be well insulated from the outdoor environment or ground.

Indirect-gain passive systems use the south-facing wall surface or the roof to absorb solar radiation, which causes a rise in temperature that, in turn, conveys heat into the building in several ways. Pueblos and cliff dwellings built by indigenous peoples in what is now the southwestern United States used this principle. Glass has led to modern adaptations of the indirect-gain principle (Balcomb et al. 1977; Trombe et al. 1977; Wilson 1979).

By glazing a large south-facing, massive masonry wall, solar energy can be absorbed during the day, and heat conduction to the inner surface provides radiant heating at night. The wall's mass and its relatively low thermal diffusivity delay the heat's arrival at the indoor surface until it is needed. The glazing reduces heat loss from the wall back to the atmosphere and increases the system's collection efficiency.

Openings in the wall near the floor and ceiling allow convection to transfer heat to the room. Air in the space between the glass and the wall warms as soon as the sun heats the outer surface of the wall. The heated air rises and enters the building through the upper openings. Cool air flows through the lower openings, and convective heat gain can be established as long as the sun is shining.

In another indirect-gain passive system, a metal roof/ceiling supports transparent plastic bags filled with water (Hay and Yellott 1969). Movable insulation above these water-filled bags is rolled away during the winter day to allow the sun to warm the stored water. The water then transmits heat indoors by convection and radiation. The insulation remains over the water bags at night or during overcast days. During the summer, the water bags are exposed at night for cooling by (1) convection, (2) radiation, and (3) evaporation of water on the bags. The insulation covers the water bags during the day to protect them from unwanted irradiation. Pittenger et al. (1978) tested a building for which water rather than insulation was moved to provide summer cooling and winter heating.

Attached greenhouses (sunspaces) can be used as solar attachments when the orientation and other local conditions are suitable. The greenhouse can provide a buffer between the exterior wall of the building and the outdoors. During daylight, warm air from the greenhouse can be introduced into the house by natural convection or a small fan.

In most passive systems, control is accomplished by moving a component that regulates the amount of solar radiation admitted into the structure. Manually operated window shades or venetian blinds are the most widely used and simplest controls, but they may also be operated automatically.

Passive heating and cooling systems have been effective in field demonstrations A well-designed passive-solar-heated building may provide 45 to nearly 100% of daily heat requirements. Architectural design features can dramatically reduce air-conditioning loads through heat gain avoidance techniques and natural cooling, where climatically appropriate (Howard and Pollock 1982; Howard and Saunders 1989).

Passive solar daylighting has been shown to be cost effective, providing dual benefits: it both reduces electric power demand and lowers cooling costs in properly designed interiors and atrium spaces.

5. COOLING BY NOCTURNAL RADIATION AND EVAPORATION

Radiative cooling is a natural heat loss that causes formation of dew, frost, and ground fog. Because its effects are the most obvious at night, it is sometimes termed **nocturnal radiation**, although the process continues throughout the day. Thermal infrared radiation, which affects the surface temperature of a building wall or roof, may be estimated by using the **sol-air temperature** concept. Radiative cooling of window and skylight surfaces can be significant, especially under winter conditions when the dew-point temperature is low.

The most useful parameter for characterizing the radiative heat transfer between horizontal nonspectral emitting surfaces and the sky is the **sky temperature T_{sky}**. If S designates the total downward radiant heat flux emitted by the atmosphere, then T_{sky} is defined as

$$T_{sky}^4 = S/\sigma \tag{25}$$

where $\sigma = 5.67 \times 10^{-8}$ W/(m²·K⁴).

The sky radiance is treated as if it originates from a blackbody emitter of temperature T_{sky}. The **net radiative cooling rate R_{net}** of a horizontal surface with absolute temperature T_{rad} and a nonspectral emittance ε is then

$$R_{net} = \varepsilon\sigma(T_{rad}^4 - T_{sky}^4) \tag{26}$$

Values of ε for most nonmetallic construction materials are about 0.9.

Radiative building cooling has not been fully developed. Design methods and performance data compiled by Hay and Yellott (1969) and Marlatt et al. (1984) are available for residential roof ponds that use a sealed volume of water covered by sliding insulation panels as the combined rooftop radiator and thermal storage. Other conceptual radiative cooling designs have been proposed, but more developmental work is required (Erell and Etzion 2000; Givoni 1981; Mitchell and Biggs 1979).

The sky temperature is a function of atmospheric water vapor, amount of cloud cover, and air temperature; the lowest sky temperatures occur under an arid, cloudless sky. The monthly average sky temperature depression, which is the average of the difference between the ambient air temperature and the sky temperature, typically is between 5 and 24 K throughout the continental United States. Martin and Berdahl (1984) calculated this quantity using hourly weather data from 193 sites, as shown in the contour map for the month of July (Figure 22).

The sky temperature may be too high at night to effectively cool the structure. Martin and Berdahl (1984) suggest that the sky temperature should be less than 16°C to achieve reasonable cooling in July (Figure 23). In regions where sky temperatures fall below 16°C 40% or more of the month, all nighttime hours are effectively available for radiative cooling.

Clark (1981) modeled a horizontal radiator at various surface temperatures in convective contact with outdoor air for 77 U.S. locations. The average monthly cooling rates for a surface temperature of 25°C are plotted in Figure 24. If effective steps are taken to reduce the surface convection coefficient by modifying the radiator geometry or using an infrared-transparent glazing, it may be possible to improve performance beyond these values.

Argiriou et al. (1993) calculated the sky temperature depression and useful cooling energy of a typical flat-plate radiative air cooler for 28 southern European and four southeastern U.S. cities, to

Fig. 22 Average Monthly Sky Temperature Depression ($T_{air} - T_{sky}$) for July, °C
(Adapted from Martin and Berdahl 1984)

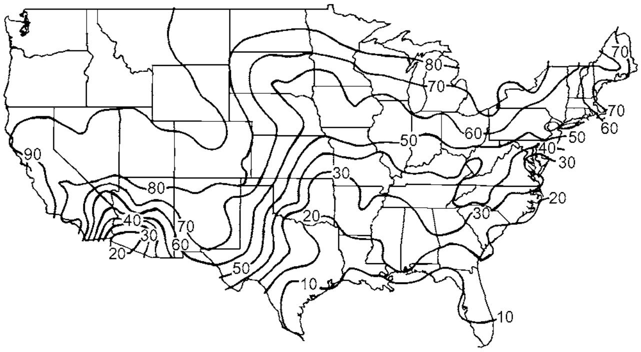

Fig. 23 Percentage of Monthly Hours when Sky Temperature Falls below 16°C
(Adapted from Martin and Berdahl 1984)

estimate the effectiveness and feasibility of radiative cooling applications. The mean daily useful cooling energy delivered ranges between 193 and 749 kJ/m² for average sky conditions and 250 and 795 kJ/m² for clear-sky conditions. For areas with high humidity levels, such as the southeastern United States, the potential effectiveness is limited to 148 to 488 kJ/m² for average sky conditions and 250 to 659 kJ/m² for clear-sky conditions. Using a wind screen can improve performance at locations that are dominated by high wind speeds.

Active Systems

Active systems absorb solar radiation with collectors and convey it to storage using a suitable fluid. As heat is needed, it is obtained from storage via heated air or water. Control is exercised by several types of thermostats, the first being a differential device that starts the flow of fluid through the collectors when they have been sufficiently warmed by the sun. It also stops fluid flow when the collectors no longer gain heat. In locations where freezing occurs only rarely, a low-temperature sensor on the collector controls a circulating pump when freezing is impending. This process wastes some stored heat, but it prevents costly damage to the collector panels. This system is not suitable for regions where freezing temperatures persist for long periods.

The space-heating thermostat is generally the conventional double-contact type that calls for heat when the temperature in the controlled space falls to a predetermined level. If the temperature in storage is adequate to meet the heating requirement, a pump or fan starts to circulate the warm fluid. If the temperature in the storage subsystem is inadequate, the thermostat calls on the auxiliary or standby heat source.

Space Heating and Service Hot Water

Solar combi systems are solar heating installations providing space heating as well as domestic hot water for the building occupants (IEA Task 26). The primary energy sources are solar and an auxiliary source such as biomass, gas, oil, or electricity, either direct or with a heat pump. The solar contribution (the part of the heating demand met by solar energy) varies from 10% to 100%, depending on the size of the solar collector surface, storage volume, heat load, and climate. Europe has the most well-developed market for different solar thermal applications (Balaras et al. 2010). In 2016, around 2% of the global installed capacity supplied heat for both domestic hot water and space heating (solar combi systems). In Europe, the share of combi systems was about 19% of the total solar thermal market. The total capacity of glazed and evacuated tube solar

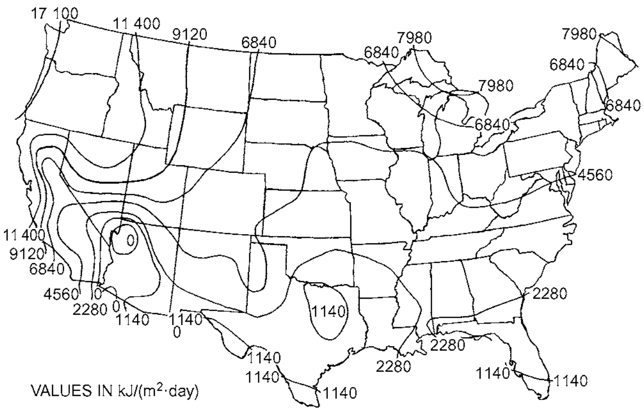

Fig. 24 July Nocturnal Net Radiative Cooling Rate from Horizontal Dry Surface at 25°C
(Adapted from Clark 1981)

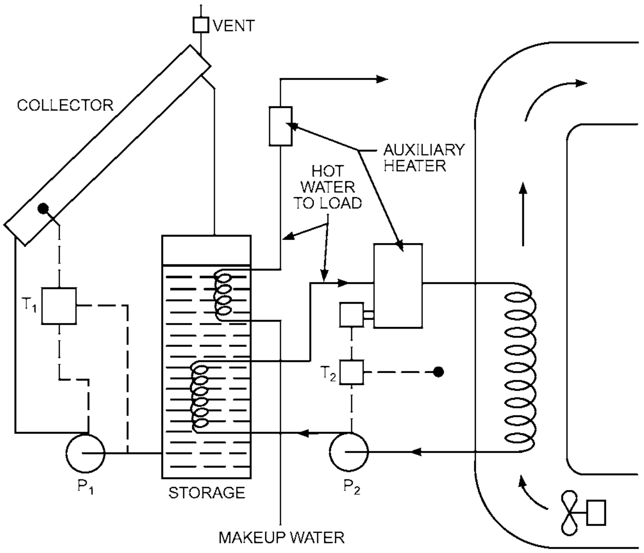

Fig. 25 Solar Collection, Storage, and Distribution System for Domestic Hot Water and Space Heating

collectors for solar combi systems already have a market share of 41% in Germany, 39% in Austria, and 21% in Switzerland (Weiss and Spork-Dur 2017).

Figure 25 shows one of the many systems for service hot water and space heating. In this case, a large, atmospheric-pressure storage tank is used, from which water is pumped to the collectors by pump P_1 in response to the differential thermostat T_1. Drainback is used to prevent freezing, because the amount of antifreeze required would be prohibitively expensive. Service hot water is obtained by placing a heat exchanger coil in the tank near the top, where, even if stratification occurs, the hottest water will be found.

An auxiliary water heater boosts the temperature of the sun-heated water when required. Thermostat T_2 senses the indoor temperature and starts pump P_2 when heat is needed. If water in the storage tank becomes too cool to provide enough heat, the second contact on the thermostat calls for heat from the auxiliary heater.

Standby heat becomes increasingly important as heating requirements increase. The heating load, winter availability of solar radiation, and cost and availability of the auxiliary energy must be determined. It is rarely cost effective to do the entire heating job for either space or service hot water by using the solar heat collection and storage system alone.

Electric resistance heaters have the lowest first cost, but often have high operating costs. Water-to-air heat pumps, which use sun-heated water from the storage tank as the evaporator energy source, are an alternative auxiliary heat source. The heat pump's COP is about 3 to 4. When both summer cooling and winter heating are needed, the heat pump is a logical solution, particularly in large systems where a cooling tower is used to dissipate the heat withdrawn from the system.

The system shown in Figure 25 may be retrofitted into a warm-air furnace. In such systems, the primary heater is deleted from the space heating circuit, and the coil is located in the return duct of the existing furnace. Full back-up is thus obtained, and the auxiliary heater provides only the heat not available at the storage temperature.

6. COOLING BY SOLAR ENERGY

Peak cooling demand in summer coincides with high solar radiation availability; this creates an excellent opportunity to exploit solar energy with heat-driven cooling machines. The main obstacle for large-scale applications, beside the currently high first cost, is the lack of practical experience with the design, control, operation, installation, and maintenance of these systems. For low-power cooling systems, there are limited commercially available technologies, but strong ongoing research. Photovoltaic-operated refrigeration cycles and solar mechanical refrigeration also have applications of practical interest (Klein and Reindl 2005).

Swartman et al. (1974) emphasize various absorption systems. Newton (in Jordan and Liu 1977) discusses commercially available water vapor/lithium bromide absorption refrigeration systems. Standard absorption chillers are generally designed to give rated capacity for activating fluid temperatures well above 90°C at full load and design condenser water temperature. Few flat-plate collectors can operate efficiently in this range; therefore, a lower hot-fluid temperature is used when solar energy provides the heat. Both condenser water temperature and percentage of design load are determinants of the optimum energizing temperature, which can be quite low, sometimes below 50°C. Proper control can raise the COP at these part-load conditions.

Many large commercial or institutional cooling installations must operate year round, and Newton (in Jordon and Liu 1977) showed that the low-temperature cooling water available in winter enables the LiBr/H_2O to function well with a hot-fluid inlet temperature below 88°C. Residential chillers in sizes as low as 5.3 kW, with an inlet temperature in the range of 80°C, have been developed. An overview of various European installations is presented in Balaras et al. (2010). Ongoing international efforts are also reviewed in IEA Task 38.

Solar Cooling with Absorption Refrigeration

When solar energy is used for cooling as well as for heating, the absorption system shown in Figure 26 or one of its many modifications may be used. The collector and storage must operate at a temperature approaching 90°C on hot summer days when the water from the cooling tower exceeds 27°C, but considerably lower operating water temperatures may be used when cooler water is available from the tower. Controls for collection, cooling, and distribution are generally separated, with the circulating pump P_1 operating in response to the collector thermostat T_1. Thermostat T_2 senses the indoor air-conditioned space temperature. When T_2 calls for heating, valves V_1 and V_2 direct water flow from the storage tank through the unactivated auxiliary heater to the fan-coil in the air distribution system. The fan F_2 in this unit may respond to the thermostat also, or it may have its own control circuit so that it can bring in outdoor air when the temperature is suitable.

When thermostat T_2 calls for cooling, the valves direct hot water into the absorption unit's generator, and pumps P_3 and P_4 are activated to pump cooling tower water through the absorber and condenser circuits and chilled water through the cooling coil in the air distribution system. A relatively large hot-water storage tank allows the unit to operate when no sunshine is available. A chilled-water storage tank (not shown) may be added so that the absorption unit can operate during the day whenever water is available at a sufficiently high temperature to make the unit function properly. The COP of a typical lithium bromide/water absorption unit may be as high as 0.75 under favorable conditions, but frequent on/off cycling of the unit to meet a high variable cooling load may cause significant loss in performance because the unit must be heated to operating temperature after each shutdown. Modulating systems are analyzed differently than on/off systems.

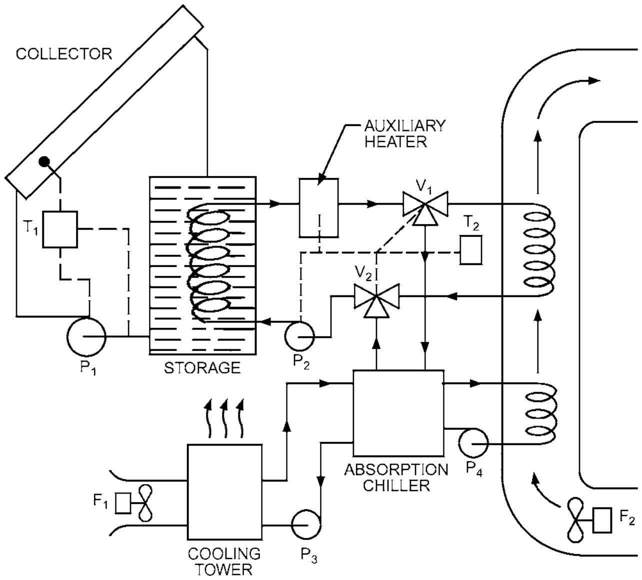

Fig. 26 Space Heating and Cooling System Using Lithium Bromide/Water Absorption Chiller

Water-cooled condensers are required with the absorption cycles, because the lithium bromide/water cycle operates with a relatively delicate balance among the temperatures of the three fluid circuits (cooling tower water, chilled water, and activating water). Steam-operated absorption systems, from which solar cooling systems are derived, customarily operate at energizing temperatures of 110 to 116°C, but these are above the capability of most flat-plate collectors. The solar cooling units are designed to operate at considerably lower temperature, but unit ratings are also lowered.

Smaller domestic units may operate with natural circulation, or **percolation**, which carries the lithium bromide/water solution from the generator (to which the activating heat is supplied) to the separator and condenser; there, the reconcentrated LiBr is returned to the absorber while the water vapor goes to the condenser before being returned to the evaporator, where cooling occurs. Larger units use a centrifugal pump to transfer the fluid.

Design, Control, and Operation Guidelines

Absorption is the most popular heat-driven cooling technology, although different sorption technologies are also available (e.g. adsorption, see Chapter 32 of the 2017 *ASHRAE Handbook—Fundamentals*). Each technology has specific characteristics that match the building's HVAC design, loads, and local climatic conditions. A good design must first exploit all available solar radiation and then cover the remaining loads from conventional sources (Henning 2007).

Proper calculations for collector and storage size depend on the solar cooling technology used. A hot-water storage may be integrated between the solar collectors and the heat-driven chiller to dampen fluctuations in the return temperature of the hot water from the chiller. Storage size depends on the application: when cooling loads mainly occur during the day, a smaller storage is necessary than when the loads peak in the evening. Strictly avoid heating the hot-water storage by the back-up heat source. The storage only exists to store excess heat of the solar system and to make it available when sufficient solar heat is not available.

The single-effect absorption machine gives best results with a heat supply temperature of 80 to 100°C. Double- and triple-effect machines require higher supply temperatures. Therefore, these machines require a higher-temperature collector. However, with a double-effect system, if the solar-supplied temperature drops below 100ºC, the performance drops sharply, below that of a single-effect.

Most large-scale applications (300 kW and up) use LiBr/H_2O and produce chilled water at about 6 to 7°C; the COP is relatively higher than for H_2O/ammonia (NH_3). However, LiBr systems must be water cooled and thus usually require a cooling tower, whereas NH_3 systems can have an air-cooled condenser. Because of the large vapor volume of the water refrigerant, LiBr/H_2O chillers usually have large physical dimensions. For small cooling loads and for applications where it is not possible to use water cooling, an H_2O/NH_3 system is preferred.

In hot and sunny climates, the required solar collector area is approximately 3 to 4 m^2 per kW cooling. Higher heat supply temperature for multieffect chillers require higher-cost evacuated tube or concentrating collectors, and may need a high-temperature (i.e., thermochemical) storage.

In LiBr/H_2O systems, the refrigerant freezes at 0°C, so care is necessary while the machine is idle, especially in winter. Another potential problem is crystallization of the LiBr solution at high concentrations, which may result from high generator temperatures or from inadequate temperature control at other parts of the machine. Thus, the heat supply temperature from the solar collectors or heat storage must be adequately controlled. The cooling water temperature, particularly to the absorber, must also be monitored. Chiller capacity may be controlled by increasing the heat supply temperature or decreasing the cooling water temperature; both techniques increase capacity as well as the COP.

A fuel-fired boiler usually covers the need for a back-up system to heat the desorber of the heat-driven chiller. However, use caution because, during periods of low solar radiation availability, collectors connected in series with a back-up boiler can turn into a heat sink instead of a heat source. Alternatively, one may use a back-up conventional chiller alongside the solar-assisted machine, but this requires an additional full-sized chiller, which would be idle for long periods. A viable design solution for a single-effect absorption cycle is to incorporate an auxiliary desorber powered by the back-up, whereas the original desorber is powered by solar heat. The weak solution goes first to the solar-powered desorber, where it is concentrated as much as possible with the available solar heat, and then proceeds to the auxiliary desorber, where it is concentrated further using heat from the back-up source. Vapor from both desorbers is then supplied to the condenser.

7. SIZING SOLAR HEATING AND COOLING SYSTEMS: ENERGY REQUIREMENTS

Methods used to determine solar heating and/or cooling energy requirements for both active and passive/hybrid systems are described by Feldman and Merriam (1979) and Hunn et al. (1987). Descriptions of public- and private-domain methods are included. The following simulation techniques are suitable for active heating and cooling systems analysis, and for passive/hybrid heating, cooling, and lighting analysis.

Performance Evaluation Methods

The performance of any solar energy system is directly related to the (1) heating load, (2) amount of solar radiation available, and (3) solar energy system characteristics. Various calculation methods use different procedures and data when considering the available solar radiation. Some simplified methods consider only average annual incident solar radiation; complex methods may use hourly data.

Solar energy system characteristics, as well as individual component characteristics, are required to evaluate performance. The degree of complexity with which these systems and components are described varies from system to system.

The cost effectiveness of a solar domestic and service hot-water heating system depends on the initial cost and energy cost savings. A major task is to determine how much energy is saved. The **annual solar fraction** (the annual solar contribution to the water-heating load divided by the total water-heating load) can be used to estimate these savings. It is expressed as a decimal or percentage and generally ranges from 0.3 to 0.8 (30 to 80%), although more extreme values are possible.

Simplified Analysis Methods

A very simplified way to initially estimate the size of a solar heating system is to divide the average daily load by the daily output of a particular collector based on its SRCC rating for the application and solar conditions. This requires knowledge of the average daily incident solar radiation for the site and the type of collector best suited to the application. See Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information.

Simplified analysis methods have the advantages of computational speed, low cost, rapid turnaround (especially important during iterative design phases), and ease of use by persons with little technical experience. Disadvantages include limited flexibility for design optimization, lack of control over assumptions, and a limited selection of systems that can be analyzed. Thus, if the application, configuration, or load characteristics under consideration are significantly nonstandard, a detailed computer simulation may be required to achieve accurate results. This section describes the *f*-Chart method for active solar heating and the solar load ratio method for passive solar heating (Dickinson and Cheremisinoff 1980; Klein and Beckman 1979; Lunde 1980).

Water-Heating Load

The amount of hot water required must be estimated accurately because it affects component selection. Oversized storage may result in low-temperature water that requires auxiliary heating to reach the desired supply temperature. Undersizing can prevent the collection and use of available solar energy. Chapter 50 gives methods to determine the load.

Active Heating/Cooling

Beckman et al. (1977) developed the *f*-Chart method using an hourly simulation program (Klein et al. 1976) to evaluate space heating and service water heating in many climates and conditions. The results of these analyses correlate the fraction *f* of the heat load met by solar energy. The correlations give the fraction *f* of the monthly heating load (for space heating and hot water) supplied by solar energy as a function of collector characteristics, heating loads, and weather. The standard error of the differences between detailed simulations in 14 locations in the United States and the *f*-Chart predictions was about 2.5%. Correlations also agree within the accuracy of measurements of long-term performance data. Beckman et al. (1977, 1981) and Duffie and Beckman (2006) discuss the method in detail.

The *f*-Chart method requires the following data:

- Monthly average daily radiation on a horizontal surface
- Monthly average ambient temperatures
- Collector thermal performance curve slope and intercept from standard collector tests; that is, $F_R U_L$ and $F_R(\tau\alpha)_n$ (see ISO *Standard* 9806-2017 and Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)
- Monthly space- and water-heating loads

Standard Systems

The *f*-Chart assumes several standard systems and applies only to these liquid configurations. The standard **liquid heater** uses water, an antifreeze solution, or air as the heat transfer fluid in the collector loop and water as the storage medium (Figure 27). Energy is stored in the form of sensible heat in a water tank. A water-to-air heat exchanger transfers heat from the storage tank to the building. A liquid-to-liquid heat exchanger transfers energy from the main storage tank to a domestic hot-water preheat tank, which in turn supplies solar-heated water to a conventional water heater. A conventional furnace or heat pump is used to meet the space heating load when energy in the storage tank is depleted.

Figure 28 shows the assumed configuration for a **solar air heater** with a pebble-bed storage unit. Energy for domestic hot water is provided by heat exchange from air leaving the collector to a domestic water preheat tank, as in the liquid system. The hot water is further heated, if necessary, by a conventional water heater. During summer operation, a seasonal, manually operated storage bypass damper is used to avoid heat loss from the hot bed into the building.

The standard **solar domestic water heater** collector heats either air or liquid. Collected energy is transferred by a heat exchanger to a domestic water preheat tank that supplies solar-heated water to a conventional water heater. The water is further heated to the desired temperature by conventional fuel if necessary.

f-Chart Method

Computer simulations correlate dimensionless variables and the long-term performance of the systems. The fraction *f* of the monthly space- and water-heating loads supplied by solar energy is empirically related to two dimensionless groups. The first dimensionless group *X* is collector loss; the second *Y* is collector gain:

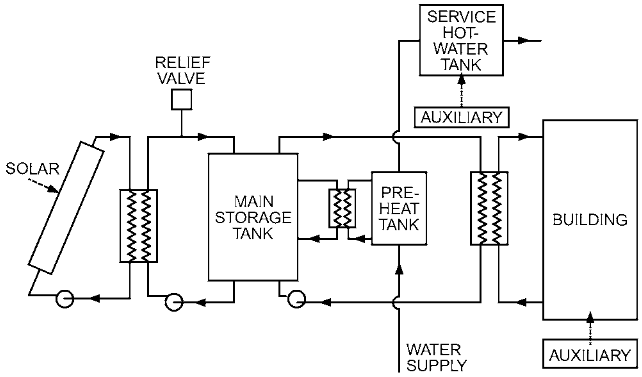

Fig. 27 Liquid-Based Solar Heating System
(Adapted from Beckman et al. 1977)

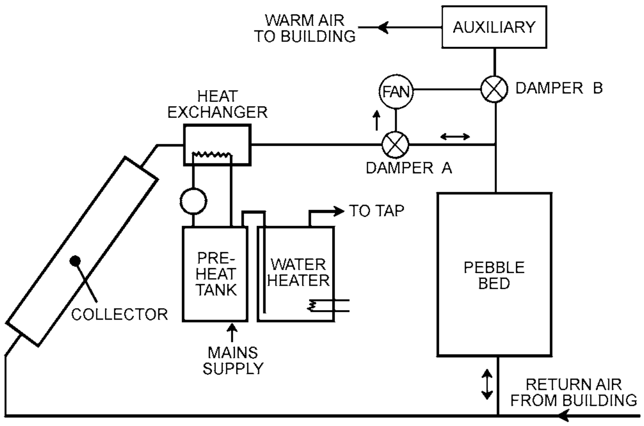

Fig. 28 Solar Air Heating System
(Adapted from Beckman et al. 1977)

$$X = \frac{F_R U_L A_c \Delta\theta}{L}\left(\frac{F_r}{F_R}\right)(t_{ref} - \bar{t}_a) \quad (27)$$

$$Y = \frac{F_R(\tau\alpha)_n \bar{H}_T N A_c}{L}\left(\frac{F_r}{F_R}\right)\left[\frac{(\overline{\tau\alpha})}{(\tau\alpha)_n}\right] \quad (28)$$

where

A_c = area of solar collector, m^2
F_r = collector heat exchanger efficiency factor
F_R = collector efficiency factor
U_L = collector overall energy loss coefficient, $W/(m^2 \cdot K)$
$\Delta\theta$ = total number of seconds in month
$\bar{t}_a$ = monthly average ambient temperature, °C
L = monthly total heating load for space heating and hot water, J
$\bar{H}_T$ = monthly averaged daily radiation incident on collector surface per unit area, $J/(d \cdot m^3)$
N = number of days in month
$(\overline{\tau\alpha})$ = monthly average transmittance-absorptance product
$(\tau\alpha)_n$ = normal transmittance-absorptance product
t_{ref} = reference temperature, 100°C

$F_R U_L$ and $F_R(\tau\alpha)_n$ are obtained from collector test results. The ratios F_r/F_R and $(\overline{\tau\alpha})/(\tau\alpha)_n$ are calculated using methods given by Beckman et al. (1977). The value of $\bar{t}_a$ is obtained from meteorological records for the month and location desired. $\bar{H}_T$ is calculated from the monthly averaged daily radiation on a horizontal surface by the methods previously discussed in this chapter or in Duffie and Beckman (2006). The monthly load L can be determined by any appropriate load-estimating method, including analytical techniques or measurements. Values of the collector area A_c are selected for the calculations. Thus, all the terms in these equations can be determined from available information.

Transmittance τ of the transparent collector cover and the absorptance α of the absorber plate depend on the angle of incidence of solar radiation on the collector surface. Collector tests are usually run with the radiation nearly perpendicularly incident on the collector. Thus, the value of $F_R(\tau\alpha)_n$ determined from these tests ordinarily corresponds to the transmittance and absorptance values for radiation at normal incidence. Depending on collector orientation and time of year, the monthly average values of transmittance and absorptance can be significantly lower. The *f*-Chart method requires knowledge of the ratio of the monthly average to normal incidence transmittance-absorptance.

The *f*-Chart method for liquid systems is similar to that for air systems. The fraction of the monthly total heating load supplied by the solar air heating system is correlated with the dimensionless groups X and Y, as shown in Figure 29. To determine the fraction of the heating load supplied by solar energy for a month, values of X and Y are calculated for the collector and heating load in question. The value of f is determined at the intersection of X and Y on the *f*-Chart, or from the following equivalent equations.

Air system:

$$f = 1.04Y - 0.065X - 0.159Y^2 + 0.00187X^2 - 0.0095Y^3 \quad (29)$$

Liquid system:

$$f = 1.029Y - 0.065X - 0.245Y^2 + 0.0018X^2 - 0.025Y^3 \quad (30)$$

This is done for each month of the year. The solar energy contribution for the month is the product of f and the total heating load L for the month. Finally, the fraction F of the annual heating load supplied by solar energy is the sum of the monthly solar energy contributions divided by the annual load:

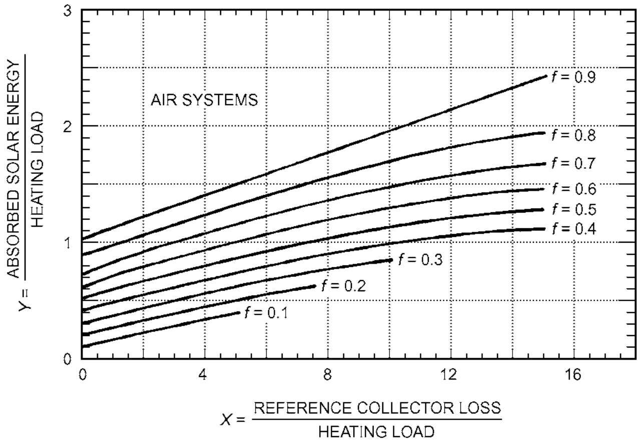

Fig. 29 Chart for Air System
(Adapted from Beckman et al. 1977)

$$F = \sum fL / \sum L \quad (31)$$

Example 6. Calculating the heating performance of a residence, assume that a solar heating system is to be designed for use in Madison, WI, with two-cover collectors facing south, inclined 58° with respect to the horizontal. The air heating collectors have the characteristics $F_R U_L$ = 2.84 $W/(m^2 \cdot K)$ and $F_R(\tau\alpha)_n$ = 0.49. The $\bar{t}_a$ is –7°C, the total space and water-heating load for January is 36 GJ), and the solar radiation incident on the plane of the collector is 13 $MJ/(d \cdot m^2)$. Determine the fraction of the load supplied by solar energy with a system having a collector area of 50 m^2.

Solution: For air systems, there is no heat exchanger penalty factor and F_r/F_R = 1. The value of $(\overline{\tau\alpha})/(\tau\alpha)_n$ is 0.94 for a two-cover collector in January. Therefore, the values of X and Y are

$$X = 2.84[100 - (-7)](31)(86\,400)(50/36) = 1.13$$

$$Y = (0.49)(1)(0.49)(13)(31)(50/36) = 0.26$$

Then the fraction f of the energy supplied for January is 0.19. The total solar energy supplied by this system in January is

$$fL = 0.19 \times 36 = 6.84 \text{ GJ}$$

The annual system performance is obtained by summing the energy quantities for all months. The result is that 37% of the annual load is supplied by solar energy.

The collector heat removal factor F_R that appears in X and Y is a function of the collector fluid flow rate. Because of the higher cost of power for moving fluid through air collectors rather than through liquid collectors, the capacitance rate used in air heaters is ordinarily much lower than that in liquid heaters. As a result, air heaters generally have a lower F_R. Values of F_R corresponding to the expected airflow in the collector must be used to calculate X and Y.

Increased airflow rate tends to improve collector performance by increasing F_R, but it tends to decrease performance by reducing the degree of thermal stratification in the pebble bed (or water storage tank). The *f*-Chart for air systems is based on a collector airflow rate of 10 L/s per square metre of collector area. The performance with different collector airflow rates can be estimated by using the appropriate values of F_R in both X and Y. A further modification to the value of X is required to account for the change in degree of stratification in the pebble bed.

Air system performance is less sensitive to storage capacity than that of liquid systems for two reasons: (1) air systems can operate with air delivered directly to the building in which storage is not used, and (2) pebble beds are highly stratified and additional capacity is effectively added to the cold end of the bed, which is seldom heated and cooled to the same extent as the hot end. The *f*-Chart for air systems is for a nominal storage capacity. Performance of systems with other storage capacities can be determined by modifying the dimensionless group *X* as described in Beckman et al. (1977).

With modification, *f*-Charts can be used to estimate performance of solar water heating operating in the range of 50 to 70°C. The main water supply temperature and minimum acceptable hot-water temperature (i.e., desired delivery temperature) both affect the performance of solar water heating. The dimensionless group *X*, which is related to collector energy loss, can be redefined to include these effects. If monthly values of *X* are multiplied by a correction factor, the *f*-Chart for liquid-based solar space- and water-heating systems can be used to estimate monthly values of *f* for water heating. Experiments and analysis show that the load profile for a well-designed heater has little effect on long-term performance. Although the *f*-Chart was originally developed for two-tank systems, it may be applied to single- and double-tank domestic hot-water systems with and without collector tank heat exchangers. The standard *f*-Chart method is not designed to provide performance estimates of thermosiphon and ICS systems.

For industrial process heating, absorption air conditioning, or other processes for which the delivery temperature is outside the normal *f*-Chart range, modified *f*-Charts are applicable (Klein et al. 1976). The concept underlying these charts is that of solar usability: the fraction of the total solar energy that is useful in the given process. This fraction depends on the required delivery temperature as well as collector characteristics and solar radiation. The procedure allows the energy delivered to be calculated in a manner similar to that for *f*-Charts. An example of applying this method to solar-assisted heat pumps is presented in Svard et al. (1981).

Other Active Collector Methods

The **relative areas method**, based on correlations of the *f*-Chart method, predicts annual rather than monthly active heating performance (Barley and Winn 1978). An hourly simulation program was used to develop the **monthly solar-load ratio (SLR) method**, another simplified procedure for residential systems (Dickinson and Cheremisinoff 1980). Based on hour-by-hour simulations, a method was devised to estimate performance based on monthly values of horizontal solar radiation and heating kelvin-days. This SLR method has also been extended to nonresidential buildings for a range of design water temperatures (Dickinson and Cheremisinoff 1980; Schnurr et al. 1981).

Passive Heating

A widely accepted simplified passive space heating design tool is the solar-load ratio (SLR) method (Balcomb et al. 1984; DOE 1980/1982). It can be applied manually, although, like the *f*-Chart, software is also available. The SLR method for passive systems is based on correlating results of multiple hour-by-hour computer simulations, the algorithms of which have been validated against test cell data for the following generic passive heating types: direct gain, thermal storage wall, and attached sunspace. Monthly and annual performance, as expressed by the auxiliary heating requirement, is predicted by this method. The method applies to single-zone, envelope-dominated buildings. A simplified, annual-basis distillation of SLR results, the **load collector ratio (LCR) method**, and several simple-to-use rules have grown out of the SLR method. Several hand-held calculator and microcomputer programs have been written using the method (Nordham 1981).

The SLR method uses a single dimensionless correlating parameter (SLR), which Balcomb et al. (1982) define as a particular ratio of solar energy gains to building heating load:

$$\text{SLR} = \frac{\text{Solar energy absorbed}}{\text{Building heating load}} \tag{32}$$

A correlation period of 1 month is used; thus the quantities in the SLR are calculated for a 1 month period.

The parameter that is correlated to the SLR, the **solar savings fraction (SSF),** is defined as

$$\text{SSF} = 1 - \frac{\text{Auxiliary heat}}{\text{Net reference load}} \tag{33}$$

The SSF measures the energy saving expected from the passive solar building, relative to a reference nonpassive solar building.

In Equation (33), the net reference load is equal to the kelvin-day load KD of the nonsolar elements of the building:

$$\text{Net reference load} = (\text{NLC})(\text{KD}) \tag{34}$$

where NLC is the net load coefficient, which is a modified *UA* coefficient computed by leaving out the solar elements of the building. The nominal units are kJ/(K·day). The term KD is the temperature departure in kelvin-days computed for an appropriate base temperature. A building energy analysis based on the SLR correlations begins with a calculation of the monthly SSF values. The monthly auxiliary heating requirement is then calculated by

$$\text{Auxiliary heat} = (\text{NLC})(\text{KD})(1 - \text{SSF}) \tag{35}$$

Annual auxiliary heat is calculated by summing the monthly values.

By definition, SSF is the fraction of the heat load of the nonsolar portions of the building met by the solar element. If the solar elements of the building (south-facing walls and window in the northern hemisphere) were replaced by other elements so that the net annual flow of heat through these elements was zero, the building's annual heat consumption would be the net reference load. The savings achieved by the solar elements would therefore be the net reference load in Equation (34) minus the auxiliary heat in Equation (35), which gives

$$\text{Solar savings} = (\text{NLC})(\text{KD})(\text{SSF}) \tag{36}$$

Although simple, in many situations and climates, Equation (36) is only approximately true because a normal solar-facing wall with a normal complement of opaque walls and windows has a near-zero effect over the entire heating season. In any case, the auxiliary heat estimate is the primary result and does not depend on this assumption.

The hour-by-hour simulations used as the basis for the SLR correlations are done with a detailed model of the building in which all the design parameters are specified. The only parameter that remains a variable is the solar collector area, which can be expressed in terms of the load collector ratio (LCR):

$$\text{LCR} = \frac{\text{NLC}}{A_p} = \frac{\text{Net load coefficient}}{\text{Projected collector area}} \tag{37}$$

Performance variations are estimated from the correlations, which allow the user to account directly for thermostat set point, internal heat generation, glazing orientation, and configuration, shading, and other solar radiation modifiers. Major solar system characteristics are accounted for by selecting one of 94 reference designs. Other design parameters, such as thermal storage thickness and conductivity, and the spacing between glazings, are included in a series of sensitivity calculations obtained using hour-by-hour simulations. The results are generally presented in graphic form so that the designer can see the effect of changing a particular parameter.

Solar radiation correlations for the collector area have been determined using hour-by-hour simulation and typical

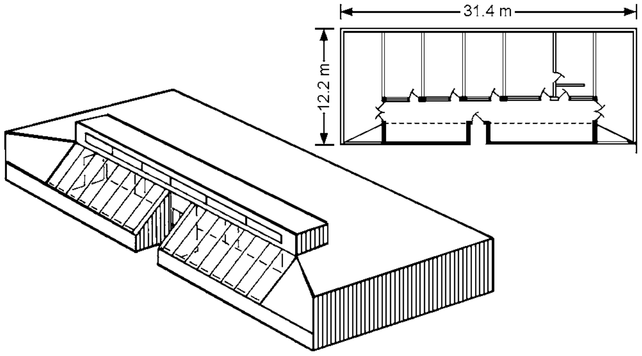

Fig. 30 Commercial Building in Example 7

Table 3 Calculations for Example 7

	Area A, m^2	U-Factor, W/(m^2·K)	UA, W/K
Opaque wall	186	0.23	42.8
Ceiling	279	0.17	47.4
Floor (over crawl space)	279	0.23	64.2
Windows (E, W, N)	9	3.12	28.1
		Subtotal	18.25
Infiltration			95.0
		Subtotal	277.5
Sunspace (treated as unheated space)			79.5
		Total	357

ASHRAE procedures are approximated with V = volume, m^3; c = heat capacity of Denver air, kJ/(m^3·K); ACH = air changes/h; equivalent UA for infiltration = $V$$c$ACH. In this case, V = 680 m^3, c = 1.006 kJ/(m^3·K), and ACH = 0.5.

meteorological year (TMY) weather data. These correlations are expressed as ratios of incident-to-horizontal radiation, transmitted-to-incident radiation, and absorbed-to-transmitted radiation as a function of the latitude minus mid-month solar declination and the atmospheric clearness index (i.e., ratio between the actual clear-day direct irradiation intensity at a specific location and the intensity calculated for the standard atmosphere for the same location and date).

Performance predictions of the SLR method have been compared to predictions made by the detailed hour-by-hour simulations for a variety of climates in the United States. The standard error in the prediction of the annual SSF, compared to the hour-by-hour simulation, is typically 2 to 4%.

The annual solar savings fraction calculation involves summing the results of 12 monthly calculations. For a particular city, the resulting SSF depends only on the LCR of Equation (37), system type, and the temperature base used in calculating the temperature departure. Thus, tables that relate SSF to LCR for various systems and for various kelvin-day base temperatures may be generated for a particular city. Such tables are easier for hand analysis than are the SLR correlations.

Annual SSF versus LCR tables have been developed for 209 locations in the United States and 14 cities in southern Canada for 94 reference designs and 12 base temperatures (Balcomb et al. 1984). Fernandez-Gonzalez (2007) evaluates the thermal performance of five passive solar strategies (direct gain, Trombe wall, water wall, sunspace, and roof pond) under severe winter climates with predominant overcast sky conditions.

Example 7. (Abstracted from the detailed version in Balcomb et al. [1982].) Consider a small office building located in Denver, Colorado, with 279 m^2 of usable space and a sunspace entry foyer that faces due south; the vertically projected collector area A_p is 39 m^2. A sketch and preliminary plan are shown in Figure 30. Distribution of solar heat to the offices is primarily by convection through the doorways from the sunspace. The principal thermal mass is in the common wall that separates the sunspace from the offices and in the sunspace floor. Even though lighting and cooling are likely to have the greatest energy costs for this building, heating is a significant energy item and should be addressed by a design that integrates passive solar heating, cooling, and lighting.

Solution: Table 3 shows calculations of the net load coefficient. Then,

$$\text{NLC} = 86\,400 \times 277.5 = 24.0 \text{ MJ/(K·d)}$$

and the total load coefficient includes the solar aperture

$$\text{TLC} = 86\,400 \times 357 = 30.8 \text{ MJ/(K·d)}$$

From Equation (37), the load collector ratio is

$$\text{LCR} = 24.0/39 = 0.615 \text{ MJ/(m}^2\text{·K·d)}$$

If the daily internal heat is 135 MJ/day, and the average thermostat setting is 20°C, then

$$T_{base} = 20 - 135/30.8 = 15.6°\text{C}$$

(Note that solar gains to the space are not included in the internal gain term as they customarily are for nonsolar buildings.)

In this example, the solar system is type SSD1, defined in Balcomb et al. (1982, 1984). It is a semiclosed sunspace with a 300 mm masonry common wall between it and the heated space (offices). The aperture is double-glazed, with a 50° tilt and no night insulation. To achieve a vertically projected area of 39 m^2, a sloped glazed area of 39/sin 50° = 51 m^2 is required.

The SLR correlation for solar system type SSD1 is shown in Figure 31. Values of the absorbed solar energy S and heating kelvin-days KD to base temperature 15.6°C are determined monthly. For S, the solar radiation correlation presented in Balcomb et al. (1984) for tabulated Denver, CO, weather data is used. For January, the horizontal surface incident radiation is 9.54 MJ/(m^2·K). The 15.6°C base kelvin-days are 518. Using the tabulated incident-to-absorbed coefficients found in Balcomb et al. (1984), S = 495.4 MJ/m^2. Thus S/KD = 0.9564 MJ/(m^2·K·d). From Figure 31, at an LCR = 0.615 MJ/(m^2·K·d), the SSF = 0.51. Therefore, for January,

$$\begin{aligned} \text{Net reference load} &= 518(24.0) = 12.43 \text{ GJ} \\ \text{Solar savings} &= 12.43(0.51) = 6.34 \text{ GJ} \\ \text{Auxiliary heat} &= 12.43 - 6.34 - 6.09 \text{ GJ} \end{aligned}$$

Repeating this calculation for each month and adding the results for the year yields an annual auxiliary heat of 21.0 GJ.

Other Passive Heating Methods

The concept of usability has been applied to passive buildings. In this approach, the energy requirements of zero- and infinite-capacity buildings are calculated. The amount of solar energy that enters the building and exceeds the instantaneous load of the zero-capacity building is then calculated. This excess energy must be dumped in the zero-capacity building, but it can be stored to offset heating loads in a finite-capacity building. Methods are provided to interpolate between the zero- and infinite-capacity limits for finite-capacity buildings. Equations and graphs for direct gain and collector-storage wall systems are given in Monsen et al. (1981, 1982).

8. INSTALLATION GUIDELINES OF SOLAR THERMAL COLLECTORS

Most solar components are the same as those in HVAC and hot-water systems (pumps, piping, valves, and controls), and their installation is not much different from a conventional installation. Solar collectors are the most unfamiliar component in a solar heater. They are located outdoors, which requires penetration of the building envelope. They also require a structural element to support them at the proper tilt and orientation toward the sun.

The site must be taken into account. Collectors should be (1) located so that shading is minimized and (2) installed so that they

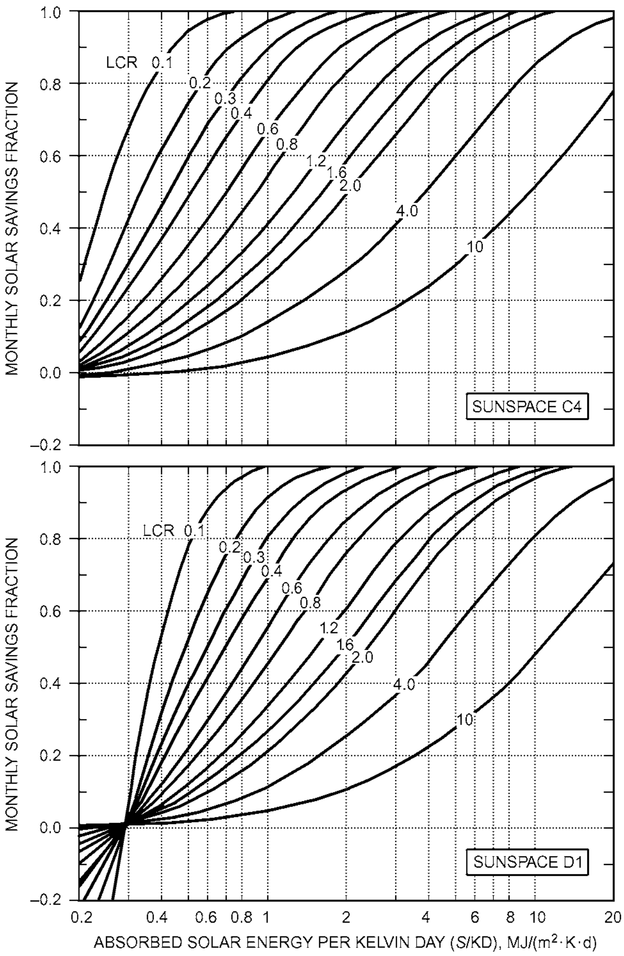

Fig. 31 Monthly SSF Versus Monthly *S*/KD for Various LCR Values

are attractive both on and off site. They should also be located to minimize vandalism and to avoid a safety hazard.

Collectors should be placed near the storage tank to reduce piping cost and heat loss. The collector and piping must be installed so that they can be drained without trapping fluid in the system.

For best annual performance, collectors should be installed at a tilt angle above the horizontal that is appropriate for the local latitude. In the northern hemisphere they should be oriented toward true south, not magnetic south. Small variations in tilt (±10°) and orientation (±20°) do not reduce performance significantly.

Collector Mounting

Solar thermal collectors are usually mounted on the ground or on flat or pitched roofs. A roof location necessitates penetration of the building envelope by mounting hardware, piping, and control wiring. Ground or flat-roof-mounted collectors are generally rack mounted.

Pitched-roof mounting can be done several ways. Collectors can be mounted on structural **standoffs**, which support them at an angle other than that of the roof to optimize solar tilt. In another pitched-roof-mounting technique known as **direct mounting**, collectors are placed on a waterproof membrane on top of the roof sheeting. The finished roof surface, together with the necessary collector structural attachments and flashing, is then built up around the collector. A weatherproof seal between the collector and the roof must be maintained to prevent leakage, mildew, and rotting.

Integral mounting can be done for new pitched-roof or curtain-wall construction. The collector is attached to and supported by the structural framing members. The top of the collector then serves as the finished roof surface. Weathertightness is crucial to avoid damage and mildew. This building-integrated approach is often incorporated in green building design and generally is used for photovoltaic modules, rather than thermal collectors.

Collectors should support snow loads that occur on the roof area they cover. The collector tilt usually expedites snow sliding with only a small loss in efficiency. The roof structure should be free of objects that could impede snow sliding, and the collectors should be raised high enough to prevent snow buildup over them.

The mounting structure should be built to withstand winds of at least 160 km/h, which impose a wind load of 1.9 kPa on a vertical surface or an average of 1.2 kPa on a tilted roof (HUD 1977). Wind load requirements may be higher, depending on local building codes, especially in coastal areas exposed to hurricanes. Flat-plate collectors mounted flush with the roof surface should be constructed to withstand the same wind loads. See Chapter 55 for additional information.

The collector array becomes more vulnerable to wind gusts as the angle of the mount increases. This wind load, in addition to the equivalent roof area wind loads, should be determined according to accepted engineering procedures (ASCE *Standards* 7, 8, and 9).

Expansion and contraction of system components, material compatibility, and use of dissimilar metals must be considered. Collector arrays and mounting hardware (bolts, screws, washers, and angles) must be well protected from corrosion. Steel mounting hardware in contact with aluminum and copper piping in contact with aluminum hardware are both examples of metal combinations that have a high potential for corrosion. Dissimilar metals can be separated by washers made of fluorocarbon polymer, phenolic, or neoprene rubber.

Freeze Protection

Freeze protection is extremely important and is often the determining factor when selecting a system in the United States. Freezing can occur at ambient temperatures as high as 6°C because of radiation to the night sky. Manual freeze protection should not be used for commercial installations.

One simple way of protecting against freezing is to drain fluid from the collector array and interior piping when potential freezing conditions exist. Drainage may be automatic, as in draindown and drainback systems, or manual, as in direct thermosiphon systems. Automatic systems should be capable of fail-safe drainage operation, even in the event of pump failure or power outage. In some cases water may be designed to drain back through the pump, so the design must allow refilling without causing cavitation.

In areas where freezing is infrequent, recirculating water from storage to the collector array can be used as freeze protection. Freeze protection can also be provided by using fluids that resist freezing. Fluids such as water/glycol solutions, silicone oils, and hydrocarbon oils are circulated by pumps through the collector array and double-wall heat exchanger. Draining the collector fluid is not required, because these fluids have freezing points well below the coldest anticipated outdoor temperature.

In mild climates where recirculation freeze protection is used, a second level of freeze protection should be provided by flushing the collector with cold supply water when the collector approaches near-freezing temperatures. This can be accomplished with a temperature-controlled valve that will automatically open a small port at a near-freezing temperature of about 4.5°C and then close at a slightly higher temperature.

Overheat Protection

During periods of high insolation and low hot-water demand, overheating can occur in the collectors or storage tanks. Protection against overheating must be considered for all portions of the solar hot-water system. Liquid expansion or excessive pressure can burst piping or storage tanks. Steam or other gases within a system can restrict liquid flow, making the system inoperable.

The most common methods of overheat protection stop circulation in the collection loop until the storage temperature decreases, discharge the overheated water and replace it with cold makeup water, or use a heat exchanger as a means of heat rejection. Some freeze protection methods can also provide overheat protection by circulating the collector fluid at night to radiate excess heat.

For nonfreezing fluids such as glycol antifreezes, overheat protection is needed to limit fluid degradation at high temperatures during collector stagnation.

Safety

Safety precautions required for installing, operating, and servicing a solar domestic hot-water heater are essentially the same as those for a conventional domestic hot-water heater. One major exception is that some solar systems use nonpotable heat transfer fluids. Local codes may require a double-wall heat exchanger for potable water installations.

Pressure relief must be provided by valves in all parts of the collector array that can be isolated. The outlet of these relief valves should be piped to a container or drain, and not where people could be affected.

Start-Up Commissioning Procedure

After completing installation, tests must be performed before charging or filling the system. The system must be checked for leakage, and pumps, fans, valves, and sensors must be checked to see that they function. Testing procedures vary with system type.

Closed-loop systems should be hydrostatically tested. The system is filled and pressurized to 1.5 times the operating pressure for one hour and inspected for leaks and any appreciable pressure drop.

Draindown systems should be tested to be sure that all water drains from the collectors and piping located outdoors. All lines should be checked for proper pitch so that gravity drains them completely. All valves should be verified to be in working order.

Drainback systems should be tested to ensure that collector fluid drains back to the reservoir tank when circulation stops and that the system refills properly.

Air systems should be tested for leaks before insulation is applied by starting the fans and checking the ductwork for leaks.

Pumps and sensors should be inspected to verify that they are in proper working order. Proper cycling of the pumps can be checked by a running time meter. A sensor that is suspected of being faulty can be dipped in hot and cold water alternately to see if the pump starts or stops.

After system testing and before filling or charging it with heat transfer fluid, the system should be flushed to remove debris.

Maintenance

All systems should be checked at least once a year in addition to any periodic maintenance that may be required for specific components. A log of all maintenance performed should be kept. System designers and installers should provide building owners with operating manuals that describe maintenance procedures and operating modes in sufficient detail to support ongoing performance.

The collectors' outer glazing should be hosed down periodically. Leaves, seeds, dirt, and other debris should be carefully swept from the collectors. Take care not to damage plastic covers.

Without opening a sealed collector panel, check the absorber plate for surface coating damage caused by peeling, crazing, or scratching. Also, inspect the collector tubing to ensure that it contacts the absorber. If the tubing is loose, consult the manufacturer for repair instructions.

Heat transfer fluids should be tested and replaced at intervals suggested by the manufacturer. Also, the solar energy storage tank should be drained about every six months to remove sediment.

Performance Monitoring/Minimum Instrumentation

Temperature sensors and temperature differential controllers are required to operate most solar systems. However, additional instruments should be installed for monitoring, checking, and troubleshooting.

Thermometers should be located on the collector supply and return lines so that the temperature difference in the lines can be determined visually.

A pressure gage should be inserted on the discharge side of the pump. The gage can be used to monitor the pressure that the pump must work against and to indicate if the flow passages are blocked.

Running time meters on pumps and fans may be installed to determine if the system is cycling properly.

9. DESIGN, INSTALLATION, AND OPERATION CHECKLIST OF SOLAR HEATING AND COOLING SYSTEMS

The following checklist is for designers of solar heating and cooling systems. Specific values have not been included because these vary for each application. The designer must decide whether design figures are within acceptable limits for any particular project (see DOE [1978b] for further information). The review order listed does not reflect their precedence or importance during design.

Collectors

- Check flow rate for compliance with manufacturer's recommendation.
- Check that collector area matches the application and claimed solar fraction of the load.
- Review collector instantaneous efficiency curve and check match between collector and system requirements.
- Relate collector construction to end use; two cover plates are not required for low-temperature collection in warm climates and may, in fact, be detrimental. Two cover plates are more efficient when the temperature difference between the absorber plate and outdoor air is high, such as in severe winter climates or when collecting at high temperatures for cooling. Radiation loss only becomes significant at relatively high absorber plate temperatures. Selective surfaces should be used in these cases. Flat-black surfaces are acceptable and sometimes more desirable for low collection temperatures.
- Check match between collector tilt angle, latitude, and collector end use.
- Check collector azimuth.
- Check collector location for potential shading and exposure to vandalism or accidental damage.
- Review provisions for high stagnation temperature. If not used, are liquid collectors drained or left filled in summer?
- Check for snow hang-up and ice formation. Will casing vents become blocked?
- Review precautions, if any, against outgassing.
- Check access for cleaning covers.
- Check mounting for stability in high winds.
- Check for architectural integration. Do collectors on roof present rainwater drainage or condensation problems? Do roof penetrations present potential leak problems?
- Check collector construction for structural integrity and durability. Will materials deteriorate under operating conditions? Will any pieces fall off?

- Are liquid collector passages organized in such a way as to allow natural fill and drain? Does mounting configuration affect this?
- Does air collector duct connection promote balanced airflow and uniform heat transfer? Are connections potentially leaky?

Heat Transfer Fluid

- Check that flow rate through the collector array matches system parameters.
- If antifreeze is used, check that flow rate has been modified to allow for the viscosity and specific heat.
- Review properties of proposed antifreeze. Some fluids are highly flammable. Check toxicity, vapor pressure, flash point, and boiling and freezing temperatures at atmospheric pressure.
- Check means of makeup into antifreeze system. An automatic water makeup system can result in freezing.
- Check that provisions are made for draining and filling the system (air vents at high points, drains at low points, pipes correctly graded in-between, drainback vented to storage or expansion tank).
- If system uses drainback freeze protection, check that
  - Provision is made for drainback volume and back venting
  - Pipes are graded for drainback
  - Solar primary pump is sized for lift head
  - Pump is self-priming if tank is below pump
- Check that collector pressure drop for drainback is slightly higher than static pressure between supply and return headers.
- Optimum pipe arrangement is reverse-return with collectors in parallel. Series collectors reduce flow rate and increase head. A combination of parallel/series can sometimes be beneficial, but check that equipment has been sized and selected properly.
- Cross-connections under different operating modes sometimes result in pumps operating in opposition or tandem, causing severe hydraulic problems.
- If heat exchangers are used, check that approach temperature differential has been recognized in the calculations.
- Check that adequate provisions are made for water expansion and contraction. Use specific volume/temperature tables for calculation. Each unique circuit must have its own provision for expansion and contraction.
- Three-port valves tend to leak through the closed port. This, together with reversed flows in some modes, can cause potential hydraulic problems. As a general rule, simple circuits and controls are better.

Airflow

- Check that flow rate through the collector array matches system design values.
- Check temperature rise across collectors using air mass flow and specific heat.
- Check that duct velocities are within design limits.
- Check that cold air or water cannot flow from collectors by gravity under “no-sun” conditions.
- Verify duct material and construction methods. Ductwork must be sealed to reduce loss.
- Check duct configuration for balanced flow through collector array.
- Check number of collectors in series. More than two collectors in series can reduce collection efficiency.

Thermal Storage

- Check that thermal storage capacity matches values of collector area, collection temperature, use temperature, and load.
- Verify that thermal inertia does not impede effective operation.
- Check provisions for promoting temperature stratification during both collection and use.
- Check that pipe and duct connections to storage are compatible with the control, ensuring that only the coolest air goes to the collectors and connections.
- If liquid storage is used for high-temperature (above 90°C) applications, check that tank material and construction can withstand the temperature and pressure.
- Check that storage location does not promote unwanted heat loss or gain and that adequate insulation is provided.
- Verify that liquid storage tanks are treated to resist corrosion. This is particularly important in tanks that are partially filled.
- Check that provision is made to protect liquid tanks from exposure to either overpressure or vacuum.

Uses

Domestic Hot Water

- Characteristics of domestic hot-water loads include short periods of high draw interspersed with long dormant periods. Check that domestic hot-water storage matches solar heat input.
- Check that provisions have been made to prevent reverse heating of the solar thermal storage by the domestic hot-water back-up heater.
- Check that the design allows cold makeup water preheating on days of low solar input.
- Verify that the antiscald valve limits domestic hot-water supply to a safe temperature during periods of high solar input.
- Depending on total dissolved solids, city water heated above 65°C may precipitate a calcium carbonate scale. If collectors are used to heat water directly, check provisions for preventing scale formation in absorber plate waterways.
- Check whether the heater is required to have a double-wall heat exchanger and that it conforms to appropriate codes if the collector uses nonpotable fluids.

Heating

- Warm-air heating systems can use solar energy directly at moderate temperatures. Check that air volume is sufficient to meet the heating load at low supply temperatures and that the limit thermostat has been reset.
- At times of low solar input, solar heat can still be used to meet part of the load by preheating return air. Check location of solar heating coil in system.
- Baseboard heaters require relatively high supply temperatures for satisfactory operation. Their output varies as the 1.5 power of the log mean temperature difference and falls off drastically at low temperatures. If solar is combined with baseboard heating, check that supply temperature is compatible with heating load.
- Heat exchangers imply an approach temperature difference that must be added to the system operating temperature to derive the minimum collection temperature. Verify calculations.
- Water-to-air heat pumps rely on a constant solar water heat source for operation. When the heat source is depleted, the back-up system must be used. Check that storage is adequate.

Cooling

- Solar-activated absorption cooling with fossil fuel back-up is currently the only commercially available active cooling. Be assured of all design criteria and a large amount of solar participation. Verify calculations.
- Storing both hot and chilled water may make better use of available storage capacity.

Controls

- Check that control design matches desired modes of operation.
- Verify that collector loop controls recognize solar input, collector temperature, and storage temperature.

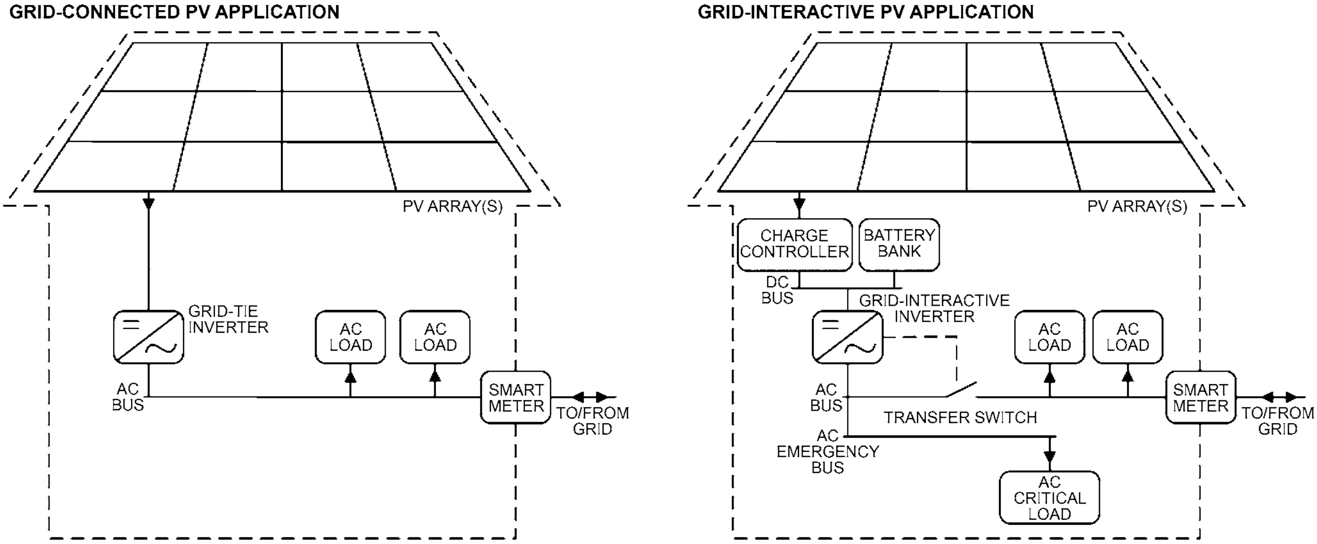

Fig. 32 Grid-Connected (Left) and Grid-Interactive (Right) Photovoltaic Applications for Buildings
(Natural Resources Canada 2018)

- Verify that controls allow both the collector and usage loops to operate independently.
- Check that control sequences are reversible and always revert to the most economical mode.
- Check that controls are as simple as possible within the system requirements. Complex controls increase the frequency and possibility of breakdowns.
- Check that all controls are fail-safe.

Performance

- Check building heating, cooling, and domestic hot-water loads as applicable. Verify that building thermal characteristics are acceptable.
- Check solar energy collected on a monthly basis. Compare with loads and verify solar participation.

10. PHOTOVOLTAIC APPLICATIONS

Solar photovoltaic (PV) systems, unlike solar thermal systems, convert solar radiation into electricity, rather than heat. Therefore, instead of pumps, piping, and valves, a PV system's energy transmission elements are comprised of wires, switches, fuses, power conversion equipment (e.g., inverters, charge controllers), and other electrical equipment. Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* discusses the fundamentals of PV operation and key system components.

Photovoltaics are used for electricity generation to power remotely located communication equipment, remote monitoring, lighting, water pumping, battery charging, and cathodic protection. In the built environment, PV systems are designed to reduce nonrenewable energy consumption, reduce peak power demand, and/or enhance energy resiliency. The first step before designing a PV application is to analyze electric loads and minimize them wherever possible. The size of a PV array can be reduced substantially with an energy-conserving building design and by implementing energy efficiency measures such as high-efficiency HVAC equipment, appliances, motors, and plug loads.

Grid-Connected Systems

This section describes PV system applications that are connected to the electric utility and allow for bidirectional flow of electricity between the client (e.g., a building with on-grid PV system) and the power grid (Figure 32).

Grid-Connected Systems. Grid-connected (also known as **grid-tied**) PV systems use string inverters or microinverters that convert DC power from the PV array to AC. The AC output power is then fed to the AC load circuit. The inverters are designed to synchronize their AC output (phase, frequency, and voltage) with the electric utility.

A typical grid-connected PV system uses no battery storage. Excess power generated during the day is fed back to the utility grid. Grid power is used when the PV system does not generate enough energy to fulfill the building's electricity requirements. During a power outage, a grid-tie inverter automatically disconnects, so no solar power is fed to the AC load circuit or to the grid until grid power is restored.

The main objective is to reduce energy consumption from the grid. However, this system could also include a small battery storage system to reduce peak power demand.

Grid-Interactive Systems. These are advanced configurations of a grid-connected system that can also function in an isolated mode (when the grid is down) or in a parallel-to-the-grid mode by using **grid-interactive inverters** (Figure 32). A grid-interactive inverter can regulate or form its own local grid, thus allowing the PV system to feed the AC load circuit with power for emergency loads even when the grid is down. It may also be able to perform advanced inverter functions at the request of the utility, such as improving voltage or reactive power characteristics. In areas where energy resiliency and emergency operation are of importance (e.g., areas vulnerable to earthquakes, hurricanes, heat waves, ice storms, etc.), the use of grid-interactive inverters is recommended. A typical grid-interactive system incorporates battery storage and aims to reduce end-use utility energy consumption, reduce peak power demand, and enhance energy resiliency.

PV for Buildings

Photovoltaic modules can be installed on flat roofs, sloped roofs, facades, and shading elements. In all cases, the PV system should be designed and installed without compromising any requirements or functions of the building envelope.

Building-Applied PV. In building-applied PV (BAPV) applications, the PV modules are mounted on the building to generate solar

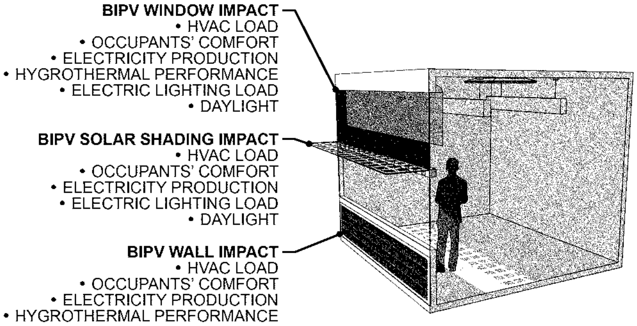

Fig. 33 Representation of Major Interactions Between BIPV Application, Building Systems, and Occupants
(Natural Resources Canada 2018)

electricity. If the BAPV system is removed, the building envelope will still perform as designed. Rack-mounted photovoltaic systems on roofs or facades are typical examples. In these applications, the PV modules are mounted either parallel to the building surface or at optimal tilt and azimuth angles to maximize energy yield.

Building-Integrated PV. In building-integrated PV (BIPV) applications, the PV modules act as a building envelope product or system in addition to generating solar electricity. If a BIPV system is removed, the building envelope performance is compromised and the BIPV will need to be replaced by an appropriate envelope product or system. Typical applications include flat or inclined BIPV roofing and skylights, opaque and transparent BIPV curtain walls, double-skin BIPV facades, and exterior BIPV shading elements. Depending on the application, a BIPV system might influence daylighting, passive solar gains, and visual as well as thermal and acoustic comfort. As a result, the building heating, cooling, and electric lighting loads are also affected (Figure 33). Ideally, design of a BIPV system should take place in conjunction with the design of the HVAC system and the building envelope.

PV with Thermal Energy Recovery. PV modules typically convert 5 to 22% of the incident solar radiation into electricity; a small fraction is reflected while the rest is absorbed and converted into thermal energy (in some cases where the PV module is transparent, a portion of the incident solar radiation is also transmitted). In a **photovoltaic module with thermal energy recovery (PVT)**, a fraction of this thermal energy is recovered either actively or passively by a heat recovery fluid (air, a liquid, or a refrigerant). As a result, PVT collectors produce both thermal and electrical energy using the same surface area.

Thermal energy can also be recovered from BIPV systems. Such systems are called **building-integrated photovoltaics with thermal energy recovery (BIPVT).** Air-based PVT or BIPVT systems have an open-loop configuration and use air as the heat recovery fluid. A ventilation cavity is created by installing the photovoltaic modules at a certain distance from the facade or roof on which they are mounted. A fan located downstream of the ventilation cavity draws ambient air through the cavity from one or multiple inlets. The air circulates behind the photovoltaic array to recover some of the heat generated by the modules before entering the building through one or multiple ducts in a plenum. In most PVT or BIPVT systems, air flows from bottom to top to avoid going against natural buoyancy and increasing the system pressure drop. Other airflow patterns are possible, however, such as double-pass flow.

The thermal energy collected can be used directly, as preheated fresh air, or for space or domestic hot-water heating through an air-to-water heat exchanger or heat pump (Figure 34). For all applications, however, the thermal energy generated is not useable at all times. Thus, a well-designed BIPVT roof or facade should have a

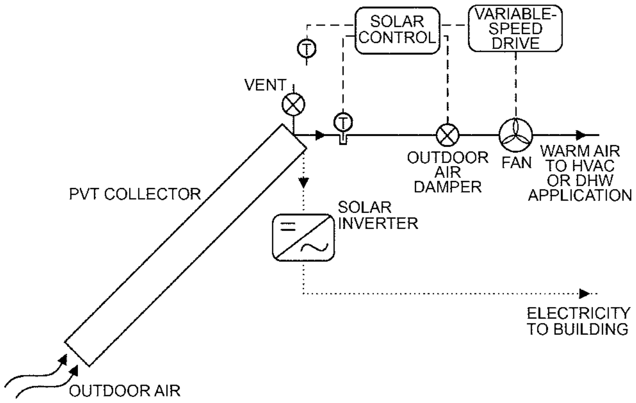

Fig. 34 Air-Based PVT System
(Natural Resources Canada 2018)

venting system for the air to escape the cavity naturally when thermal energy is not required and the BIPVT mechanical ventilation system is off. The same design approach also applies on PVT systems. This natural ventilation prevents the cells from overheating. Both forced and natural ventilation operating modes should be considered when selecting the ventilation cavity thickness. Under natural convection, the Nusselt number inside the cavity increases with cavity thickness, enhancing the cooling of the modules. Under mechanical ventilation conditions, however, the convective heat transfer coefficient between the air and the back surface of the module decreases as the cavity thickness increases due to reduced air velocity.

Note that, by operating a PVT or BIPVT roof system during the night, the outdoor air can be precooled by nocturnal radiation and introduced into the building for night cooling.

Other Photovoltaic Applications

Photovoltaic and photovoltaic-battery systems can be implemented in virtually any application where a supply of AC or DC power is required. A list of other popular PV applications, many of which are off-grid (not connected to the larger utility grid), follows. In off-grid systems, the accurate estimate of electrical load consumption and PV system losses is critical.

Remote Site Electrification. Photovoltaics are used to provide power to rural residences, visitor centers in parks, vacation cabins, island and villages, remote research facilities, and military test areas that are not connected to an electric utility (off-grid). The loads include lighting, small appliances, water pumps (including circulators on solar water-heating systems), and communications equipment. Load demand varies from a few watts to tens of kilowatts. Deep-cycle battery is most often used in these applications for nighttime power, and is typically sized to meet the load for two to three days' autonomy (without PV input). Hybrid systems are also common, using wind, small hydro, or diesel/propane generation equipment. Systems may be DC only, or include an **off-grid inverter** for AC-loads.

Communications. Photovoltaics can provide reliable power with little maintenance for communications systems, especially those in remote areas (away from the power grid) with extreme weather conditions (e.g., high winds, heavy snows, ice). Examples include communication relay towers, travelers' information transmitters, cellular phones, mobile radio systems, emergency call boxes, and military test equipment. These systems range in size from a few watts for call boxes to several kilowatts for microwave repeater stations. For larger systems at remote sites, an engine generator is often combined with the photovoltaic-battery system. These hybrid systems with two or more generators can achieve nearly 100% availability.

Remote Monitoring. Photovoltaics provide power at remote sites to sensors, data loggers, and associated transmitters for meteorological monitoring, structural condition measurement, seismic recording, irrigation control, highway/traffic monitoring, security monitoring, and scientific research. Most of these applications require less than 200 W, and many can be powered by a single photovoltaic module. Vandalism may be a problem in some areas, so non-glass-covered modules are sometimes used. Mounting the modules on a tall pole or in an inaccessible manner may also help avoid damage or theft. The batteries are often located in the same weather-resistant enclosure as the data acquisition/monitoring equipment. This enclosure is sometimes camouflaged or buried for protection. Some data loggers come with their own battery and charge regulator.

Signs and Signals. A popular application for photovoltaics is warning signs. Typical devices include navigational beacons, audible signals such as sirens, highway warning signs, railroad signals, and aircraft warning beacons. Because these signals are critical to public safety, they must be operative at all times, and thus the reliability of the photovoltaic system is extremely important. High reliability can be achieved by using large-capacity batteries. Many of these systems operate in harsh environments. Maritime applications use special PV modules that are resistant to corrosion from salt water.

Water Pumping and Control. Photovoltaics are typically used for intermediate-sized water pumping applications (those larger than hand pumps and smaller than large engine-powered pumps). The range of sizes for photovoltaic-powered pumps is a few hundred watts to a few kilowatts. Applications include domestic use, water for campgrounds, irrigation, village water supplies, and livestock watering. Photovoltaics for livestock watering can be more economical than maintaining a distribution line to a remote pump on a ranch. Most pumping systems do not use batteries but instead pump water into holding tanks for storage. For this application, photovoltaic modules may be mounted on tracking frames that maximize energy production by tracking sun position on a continuous basis.

Rest Room Facilities. Highway rest stops, public beach facilities, outdoor recreation parks, and public campgrounds may have photovoltaics to operate air circulation and ventilation fans, interior and exterior lights, and auxiliary water pumps for sinks and showers. For most of these applications, the initial cost for photovoltaic power is the least expensive option.

Charging Auto, Boat, and RV Batteries. Batteries self discharge over time if they are not used. This is a problem for organizations that maintain a fleet of vehicles such as fire-fighting or snow removal equipment, some of which are infrequently used. Photovoltaic battery chargers can solve this problem by providing a trickle charging current that keeps the battery highly charged. A small PV module, not rated for prolonged outdoor exposure, can be placed inside the windshield and plugged into the vehicle's power socket, thus using existing wiring and protection circuits and providing a quick disconnect for the module. Modules are installed on the roof or engine hood of larger vehicles. Another application is using PV modules to charge the batteries in electric vehicles, although large PV arrays are typically needed in this case.

11. DESIGN AND PERFORMANCE OF PHOTOVOLTAIC SYSTEMS

General design considerations are similar to solar thermal collectors, with orientation in the northern hemisphere generally facing south at a similar tilt to the latitude (LAT ± 15°), for latitudes below 65°. PV systems with other orientations and tilt angles will still generate solar electricity, but with lower energy yield. This is due to reduced irradiance (e.g., an east- or west-facing BIPV facade receives significantly less solar radiation than an equatorial-facing one, on an annual basis), soiling, or snow accumulation. However, nonoptimal angles may be desired for aesthetic, economic, or generation profile tuning reasons.

PV Design Considerations

An on-site visit and site survey are essential for the proper design, installation and performance of a PV system. The final system design should be performed by a certified professional. The design must comply with local electrical codes. Local building codes may also apply, as well as fire safety regulation and other legislation.

Shading. During the design of any PV system, attention should be given to routine shading (e.g., self-shading, shading due to surrounding buildings, vegetation, topography) or temporary shading (e.g., shading due to vegetation, snow, soiling). A shadow cast on a PV system has higher impact on its energy yield than it would for a solar thermal system because PV is reliant on direct photon energy. Ideally, a PV array should be installed in a shadow-free environment to avoid impact on yield and damage to the PV modules. In reality, shading losses are hard to avoid in an urban or suburban environment. A shading analysis should be carried out to minimize these losses. In the case of a building, a shading analysis also indicates the surfaces with the highest solar potential. Several tools and techniques are available to assist with a shading analysis, including existing building or PV performance simulation tools. For BIPV curtain wall applications, the mounting hardware (mullions) might introduce some shading. Thus, low-profile (or flushed) mullions are recommended.

For crystalline silicon (c-Si) PV systems, mounting in landscape orientation helps to minimize shading losses due to the location of the bypass diodes on the module circuit. The diodes protect the PV cells from damaging reverse-current flow when a PV cell is shaded. However the diodes are prone to failure, and attempts should be made to minimize routine shading. PV-module level inverters or maximum power point trackers can help reducing power losses by optimizing the power output of each PV module individually, so that a low-performing PV module does not impact others in the system.

Soiling and Snow. The amount, type, and characteristics of soiling depend on location. Soiling can cause a reduction in power output between 2% and, in extreme cases, 25%. In most locations, losses due to soiling represent less than 5%, because most soiling is removed by rainfall. Tilt angles of 12º or higher also allow for more self cleaning with rain. Uniform shading reduces power output. It does not typically damage the PV modules, however, because all cells are uniformly affected. Sometimes, a "dirt dam," which can shade a row of PV cells, may form at the lower edge of a framed PV module. Bird droppings and leaves are frequent causes of localized shading. Localized shading can damage a PV module, especially if the protective bypass diode is malfunctioning. In areas where snow accumulation might be a concern, tilt angles of 45º and higher are recommended. In this case, precautions should be taken to ensure pedestrian safety in case of sliding snow.

PV Mounting. General mounting considerations are similar to solar thermal collectors (see the section on Collector Mounting). Mounting tilt, azimuth angle, and module layout influence the maximum electricity production potential. The layout should avoid routine inter-row racking shading and other known shading obstacles. The building and racking system must be able to handle increased loads from the PV system as well as resulting wind and snow loading. Seismic calculations may be needed for earthquake-prone areas. The roof/building condition should have an estimated lifetime at least as long as the PV system (20 years or more).

Care must be taken to ensure that any roof penetration for BAPV and BIPV installations is sealed to prevent water ingress. For ballasted systems, the roofing membrane must be protected from damage due to the mass and possible movement of the system. In addition, adequate rear ventilation is required for most PV modules to ensure product safety and performance. This is typically 100 mm minimum clearance at the rear side of the PV module. An exception is PV modules rated for building integrated installations. Care should be taken when racking and/or module-level electronics may impede ventilation. In all cases, refer to the temperature rating and installation recommendations given by the equipment manufacturer. Clearance should also be given to allow for water drainage and leaf/debris clearing.

Seasonal and daily expansion and contraction of metal components, PV modules, and cabling should be accounted for. Direct contact between dissimilar metals (e.g., steel and aluminum) should be avoided due to galvanic corrosion; stainless steel is often used as an intermediary, especially between aluminum PV module frames and copper grounding/bonding wires.

Ideally, there are access paths to allow servicing of equipment. In some jurisdictions, fire codes require certain setbacks. For sloped-roof installations and carport/canopy applications, sliding snow may present a hazard to pedestrians.

PV equipment staging before installation and structural calculations should also be considered at the design stage.

Wiring Management. PV systems are often comprised of both AC and DC wiring. In AC circuits, electron flow changes direction multiple times every second at a given frequency. However, with DC electricity, electrons flow in one direction only, similar to air moving from higher to lower pressure. Therefore, because the current never crosses zero in a DC circuit, electrical arcing from DC faults can last longer than AC arcs. For this reason, AC switchgear and protection devices cannot be substituted for DC purpose. Special care must also be provided to avoid degraded contact resistance in wiring components due to mechanical stress or corrosion. Ratings for outdoor cables are different than for indoor applications. Cable selection must account for their exposure to the elements, service and installation temperature, and exposure to sunlight. Means must be provided to secure the wiring, avoid abrasion from sharp corners and movement due to wind or other vibrations, and withstand load from snow or freezing rain. Similarly, connectors should be supported and provided with drip loops to avoid water ingress. In some locations, mechanical screening methods are used to protect the DC wiring from rodents.

For BIPV. Depending on the BIPV application, performance and design considerations extend beyond solar electricity generation. Design considerations related to common envelope assemblies (Chapter 45) also apply to BIPV systems.

For BIPV roof applications (the use of typical PV modules), PV shingles or lightweight flexible PV modules can serve as a waterproofing membrane. The design should consider thermal expansion of both modules and cabling.

For BIPV curtain wall applications, BIPV arrays can serve as a face-sealed or rain screen system. A drained/vented air cavity behind the BIPV module should be designed to (1) minimize rain entry in the wall and outward drainage of the cavity and (2) prevent module overheating by allowing natural ventilation in the cavity.

For BIPV fenestration applications, BIPV modules should always be the outermost layer of the glazing unit to maximize solar electricity generation and minimize overheating. The selection of optical, thermal, and electrical properties of the BIPV fenestration product should be the result of an integrated design approach where solar gains, solar electricity generation, visual and thermal comfort, and acoustic and thermal insulation are assessed through building performance simulations. Chapter 60 discusses the integrated design approach that should be followed in the design and realization of BIPV system applications.

For BIPV shading applications, BIPV modules should be oriented to provide the building or building facade with the desired shading while limiting routine or temporary shading on the modules.

When BIPV systems are located in areas prone to hurricanes, cyclones, or earthquakes or the application requires blast or impact live load protection, they should be designed to satisfy the relevant safety and performance standards.

Depending on building size, “blanks” are sometimes used to mimic the visual aesthetics of PV modules to fill gaps in the PV system and achieve the electrical wiring configuration required. Because these are typically not exact replicas, they should be symmetrically positioned to maintain aesthetics.

For BIPVT. In PVT or BIPVT systems, the thermal yield influences the electrical yield and vice versa. Most PV technologies operate with higher efficiency at lower temperature. Therefore, a more efficient thermal system removing more heat allows the PV to generate more electricity. In a BIPVT air system, performance is affected not only by the cavity thickness, but also by its configuration and the solar cell technology used. In addition, the thermal and electrical yield of BIPVT air systems depends on the weather and operating conditions that typically affect both air solar thermal collectors and photovoltaic modules. These variables include incident solar radiation, ambient air temperature, wind speed, air flowrate, and second-order effects, such as solar angle of incidence and air mass. Generally, useful performance metrics for BIPVT air systems consist of thermal efficiency, air temperature rise, and electrical efficiency. The effects of irradiance and wind speed on the thermal efficiency, air temperature rise, and PV modules back-surface temperature of a nearly 4.5 m long BIPVT system with a 4 cm cavity thickness are shown in Figures 35 and 36.

Heat recovery in BIPVT systems can be improved with heat enhancement strategies such as fins and roughness elements. Fins create a larger surface area for heat transfer, but usually increase pressure drop inside the cavity and, as a result, the fan power requirements. The purpose of roughness elements is to generate local turbulence to increase the heat transfer coefficient locally, limiting the impact on the pressure losses. The design of such roughness elements is challenging, however, because the operating flowrate strongly affects their efficiency. The addition of **thermal boosters** is also an option to achieve higher temperatures in a BIPVT system. These boosters are similar to glazed air solar thermal collectors and are generally added at the top section of a BIPVT roof or facade to increase the air temperature prior to entering the building.

Fan Power Requirements. To estimate the total pressure drop in a BIPVT system, consider the pressure losses associated with the following components of the system: (1) the actual BIPVT roof or facade, (2) the dampers, (3) the plenum, and (4) the ducts and fittings required to bring the preheated air to its final end usage.

Pressure losses associated with the BIPVT roof or facade are generally much less than those of the other components, especially the ducts and fittings bringing the preheated air in the plenum. However, this depends on the BIPVT configuration. For example, a small cavity thickness or the presence of heat transfer enhancement strategies such as fins can significantly increase the pressure drop of the actual BIPVT roof or facade. Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals* examines this subject in greater detail.

Batteries. Off-grid and grid-connected systems may contain batteries. The design, size, and ratings depend on the application. Deep-cycle batteries can be discharged to a higher capacity, and the number of cycles indicates how often this can occur. Racking must be robust and appropriate for the battery type. Ventilation or insulation requirements and temperature ratings depend on the battery technology and installation location. Hazardous DC voltages and significant short-circuit capacity may be present. Initial charging may be necessary before first use, and routine maintenance for some technologies may be impractical for certain applications.

PV, BAPV, and BIPV Electrical Performance

A number of methods can predict the performance of PV and BIPV systems. Though distinct in complexity and accuracy of prediction offered, all have something in common: all require the incident solar radiation and the PV cell operating temperature as minimum inputs. For additional information on calculating incident solar radiation from first principles, see Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*.

PV Modules. The simplified model presented provides an estimate of the electrical yield of PV modules (excluding inverter and balance of system), based on typical meteorological data. Note that PV specifications are typically given in international SI units; care should be taken when using I-P conversions. The solar power generation is calculated based on Evan's model (reported in watts):

$$P_{mod} = c\eta_{ref}[1 + \mu_{P,mp}(t_{cell} - t_{ref})]IA_g \qquad (38)$$

Table 4 Typical Values and Range of Module Electrical Efficiency (η_{ref}) and Temperature Coefficient at Maximum Power Point ($\mu_{P,mp}$), for Various Photovoltaic Technologies

Photovoltaic Technology	η_{ref} Typical	η_{ref} Range	$\mu_{P,mp}$ (%/°C^{-1}) Typical	$\mu_{P,mp}$ (%/°C^{-1}) Range
Monocrystalline silicon	0.157	0.084 to 0.221	–0.453	–0.898 to –0.227
Polycrystalline silicon	0.149	0.062 to 0.204	–0.456	–0.679 to –0.343
Silicon heterostructures (HIT)	0.173	0.126 to 0.197	–0.333	–0.470 to +0.002
Amorphous silicon (a-Si)	0.064	0.053 to 0.088	–0.261	–0.351 to –0.215
Micromorphous silicon (a-Si/μc-Si)	0.082	0.063 to 0.104	–0.320	–0.394 to –0.181
Cadmium telluride (CdTe)	0.139	0.094 to 0.170	–0.287	–0.422 to –0.166
Copper indium (gallium) selenide (CI[G]S)	0.117	0.055 to 0.167	–0.357	–0.518 to –0.216

where

c = unit correction coefficient, 1
I = incident total irradiance, W/m²
P_{mod} = electrical output of PV modules, W
t_{cell} = operating cell temperature, °C
t_{ref} = reference temperature, usually at 25°C
η_{ref} = electrical efficiency under reference conditions (typically to 1000 W/m², PV module temperature of 25°C and solar spectrum of air mass 1.5), available through manufacturer's data sheet of solar module
$\mu_{P,mp}$ = temperature coefficient at maximum power point, available through manufacturer's data sheet of solar module, °C^{-1}

Module reference efficiency and power temperature coefficient are usually provided in the PV manufacturer's data sheet. Table 4 provides typical values for various photovoltaic module technologies available on the market. These values may vary depending on solar cell technology, module assembly, and manufacturer.

The calculation of the PV power generation also requires the PV operating cell temperature $t_{t,cell}$ as an input. King's model (King et al. 2004) uses an implicit correlation between the measured back-surface temperature $t_{t,back}$ and operating cell temperature:

$$t_{t,cell} = t_{t,back} + (I/I_{ref})\Delta t \tag{39}$$

In a typical PV module, the back-surface temperature refers to the rear side of the module. In a BIPV window, the back-surface temperature refers to the rear side of the BIPV window, which is the surface of the insulated glazing unit facing the indoor environment (e.g., surface 4 on a double glazing window). When the back-surface temperature is unknown or cannot be measured directly, the following empirical model can be used:

$$t_{t,back} = c_1 I e^{(a + bU_{met})} + t_a \tag{40}$$

where

a = empirically determined coefficient indicating upper temperature limit under low wind speeds and high solar irradiance
b = empirically determined coefficient indicating rate at which back-surface temperature drops with wind speed, (m/s)$^{-1}$
c_1 = unit correction coefficient, 1 (m²·K)/W
I_{ref} = reference solar irradiance, typically 1000 W/m²
$t_{t,back}$ = back-surface PV module temperature, °C
t_a = ambient air temperature, °C
U_{met} = wind speed measured at standard 10 m height, m/s
Δt = $t_{cell} - t_{back}$, temperature difference between cell and module back surface at irradiance level of 1000 W/m²

Table 5 provides representative coefficient values for PV and BIPV systems, using crystalline silicon PV cells. The empirically determined coefficients may vary depending on PV module assembly, mounting arrangement, and location.

Table 5 Typical Values for Coefficients *a*, *b*, and Δ*t* in Prediction of PV or BIPV Electrical Yield

Type of PV Application	*a*	*b*, (m/s)$^{-1}$	Δ*t*, K
Open rack PV, BAPV or BIPV with good rear ventilation	–3.47	–0.0594	3
BAPV or BIPV with medium rear ventilation	–2.98	–0.0471	1
BAPV or BIPV with poor rear ventilation	–2.81	–0.0455	0
Double glazing BIPV window with low emissivity coating (surface 2 or 3)	–2.85	–0.0351	9
Triple glazing BIPV window with low emissivity coatings (surfaces 2 and 4 or 3 and 5)	–2.88	–0.0319	11

Example 8. Estimate (1) the average operating cell temperature and (2) the PV modules' power generation for a 10 m² micromorphous double glazing BIPV curtain wall system under I = 700 W/m², t_a = 21°C, and U_{met} = 1.5 m/s.

Solution. Using Tables 4 and 5, the average back-surface temperature of a micromorphous double glazing BIPV window system can be calculated with Equation (40):

$$t_{back} = 1 \times 700e^{(-2.85 - 0.0351 \times 1.5)} + 21 = 59.4°\text{C}$$

(1) From Equation (39) and Table 5, the average operating cell temperature of the BIPV window system is:

$$t_{cell} = 59.4 + (700/1000)9 = 65.7°\text{C}$$

(2) From Equation (38) and Table 4, the estimated solar power generation is:

$$P_{mod} = 1 \times 0.082[1 - 0.320\%(65.7 - 25.0)]700 \times 10 = 499 \text{ W}$$

PV Systems. Besides PV modules, photovoltaic systems are comprised of a number of supporting equipment, which serves to make them operational. Depending on the system configuration, the **Balance of system (BoS)** may include inverters, DC and AC wiring, relays, transformers, charge/load controllers, and a battery bank. When compared to the PV module power output, the total output of a PV system is reduced due to losses related to BoS components, mismatch, wiring, and more. Table 6 provides a range of PV system losses for AC power rating due to various factors. Nevertheless, the losses are specific to each installation and location. Loss factors influenced by meteorological conditions also vary daily, seasonally, and annually. Taking into account the various losses, the PV system solar power generation is estimated as follows (reported in watts):

$$P_{el} = EL_{total}\, P_{mod} \quad (41)$$

where

EL_{total} = $(1 - EL_1)(1 - EL_2)\ldots(1 - EL_i)$, total electric loss factor
P_{el} = electrical output of PV system, W
EL_i = electric losses due to factor i

Example 9. Considering the PV installation from Example 8, calculate the PV system's power generation assuming total wiring losses of 3%, inverter losses of 4%, mismatch losses of 2%, losses due to soiling of 5%, and losses due to shading of 5%.

Solution. Considering the above loss factors, the PV system's power generation is calculated using Equation (41):

$$P_{el} = (1 - 0.03)(1 - 0.04)(1 - 0.02)(1 - 0.05)\,(1 - 0.05)499 = 411 \text{ W}$$

Preliminary PV Sizing and Design. The simplified approach presented here can be used to inform the preliminary design stages of a PV system, which consist of the following steps:

- Estimating the annual electrical load to be offset by the PV system (E_{annual}).
- Calculating the average daily electricity E_{daily} to be generated by the PV system.

$$E_{daily} = E_{annual}/365 \quad (42)$$

- Estimating the **sun hours** (i.e., equivalent number of hours which a particular location would be exposed to, if the sun was shining at I_{STC} = 1000 W/m^2) per day available for the location of interest. For the United States, this information is available through NREL's website at rredc.nrel.gov/solar/pubs/redbook/, and for Canada, through NRCan's website at www.nrcan.gc.ca/18366.

$$SHD = E_{sun}/I_{STC} \quad (43)$$

- Calculating the PV array installed capacity required.

$$P_{mod} = E_{daily}/SHD/EL_{total} \quad (44)$$

- Calculating the number of PV modules required.

$$N_{mod} = P_{mod}/P_{STC} \quad (45)$$

where

E_{annual} = annual electrical load to be offset by PV system, kWh
E_{daily} = daily average electricity to be generated by PV system, kWh
E_{sun} = daily average solar energy that strikes surface per unit area, for given location, kWh/(m^2·day)
I_{STC} = solar irradiance under standard testing conditions, 1000 W/m^2
N_{mod} = number of PV panels required
P_{STC} = power rating of module under standard testing conditions, W
SHD = sun hours per day, h

Example 10. A two-story apartment building (8 apartments) in Phoenix, AZ, has an annual energy consumption of 112,000 kWh. The building owner would like to have 40% of the annual energy requirement delivered by a flat roof-mounted solar PV system. Calculate the number of PV panels required to generate 40% of the building's annual energy requirement.

Site Specifications:

- Array orientation (solar azimuth ϕ): south (180°)
- Array tilt angle (Σ): 18°
- Site latitude (LAT): 33.43°N

Selected PV System Characteristics:

- Rated power of PV module under standard testing conditions: 310 W
- Module length: 1559.0 mm
- Module width: 1046.0 mm
- Module depth: 46.0 mm
- PV electric loss factor: 0.86

Solution

Step 1: Calculate the annual electrical load that needs to be offset by the PV system:

$$E_{annual} = 112{,}000 \times 40\% = 44{,}800 \text{ kWh}$$

Step 2: Estimate daily average energy usage:

$$E_{daily} = 44{,}800/365 = 123 \text{ kWh/day}$$

Step 3: For Phoenix, AZ, the SHD ≈ 6.4 h. The SHD is approximated by using the value for LAT-15° (rredc.nrel.gov/solar/pubs/redbook/). The PV array installed capacity required is

$$P_{mod} = (123/6.4)/0.86 \approx 22 \text{ kW}$$

Step 4: Calculate number of PV panels required:

$$N_{mod} = 22{,}000/310 \approx 75 \text{ modules of 310 W rated power each}$$

Example 11. Based on PV module characteristics listed in Example 10, calculate the minimum spacing required between rows to avoid inter-row shading on December 21 (during the winter season).

Solution. Assuming six hours of sunlight on December 21 (from 9:00 AM to 3:00 PM), the solar altitude and solar azimuth at 9:00 AM on December 21 are β = 19° and ψ = 139° respectively, as calculated using Equations (6) and (7). From Figure 37, the PV array height h can be calculated by simple trigonometry as follows:

$$h = \sin(\Sigma)w = 0.32 \text{ m}$$

Similarly, the PV shadow SH is calculated as follows:

$$\text{SH} = h/\tan(\beta) \approx 0.93 \text{ m}$$

Thus, the minimum inter-row spacing IS is

$$\text{IS} = \text{SH} \times \cos(180° - \psi) \approx 0.69 \text{ m}$$

Note that the last calculation takes into account the correction of the solar azimuth.

12. INSTALLATION AND OPERATION GUIDELINES FOR PHOTOVOLTAIC SYSTEMS

PV modules are generally smaller and lighter than solar thermal collectors. Nevertheless, they should be handled carefully due to their thin rear-insulating layer. Damage to the delicate PV cells may not be visible, but can reduce system performance significantly.

Proper installation is critical to the long-term reliability and performance of a PV system. Even with an appropriate design, a system's safety and power production can be negatively impacted by inadequate installation procedures. The crew performing the installation should, at minimum, be led by someone trained, qualified, and experienced in PV installation and system design. Depending on the jurisdiction, a certified electrician may be required for all or portions of the installation. A proper installation should not compromise any building envelope warranties.

Safety

The installation must comply with local electrical, fire, and building codes. Other legislation, as well as local zoning and urbanism restrictions, may also impact installation activities. Site-specific permitting or environmental studies may also be required. For grid-connected systems, the interconnection is subject to the local utility technical and administrative requirements. Interconnection permission should be obtained before project initiation, because in some cases electrical feeders may not be capable of hosting additional generation.

PV systems also pose unique hazards that must be understood, and mitigation procedures should be in place before undertaking an installation. These include hazardous DC voltages and currents whenever the sun is out (even if the system not on), AC voltages,

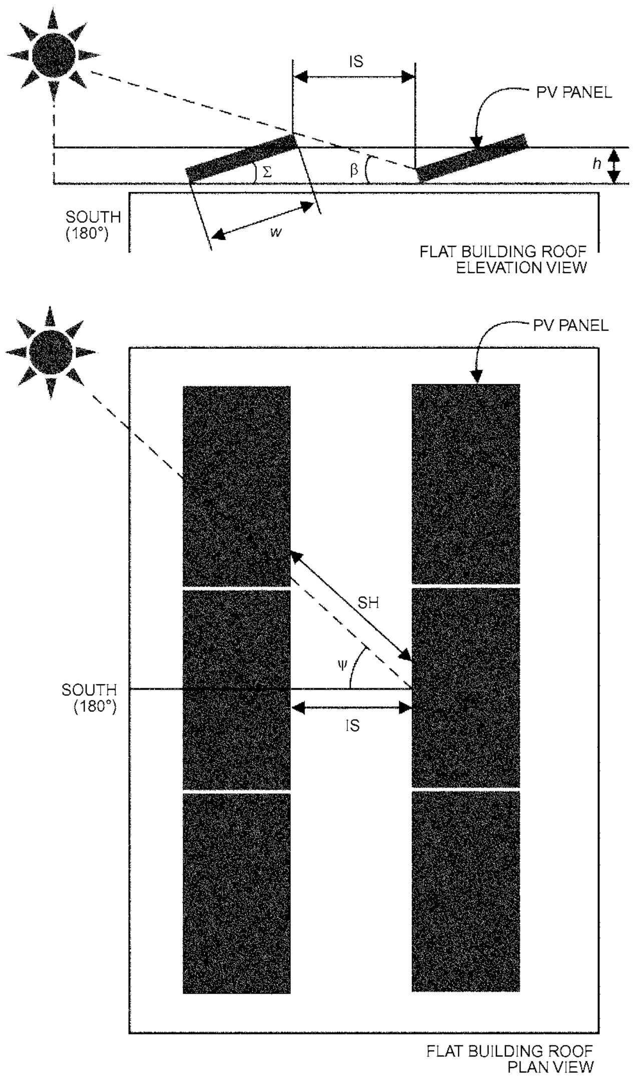

Fig. 37 Side View and Top View of Tilted PV Array Mounted on Flat Building Roof

cut/drop hazards, exposure to environmental elements, and fall hazards, especially if working at heights.

Documentation

All site and project documentation should be provided by the installer. This includes general system information, such as project identification and location, designer and installer contact information, DC ratings, and major equipment ratings, as well as detailed system information (i.e., single-line wiring diagrams, array layouts and string information, electrical equipment ratings, PV module and inverter datasheets, racking documentation, and installation manuals, warranty information). Photos of major pieces of equipment are useful, and any important information for O&M (e.g., location of emergency equipment and access/egress routes) should be included. All commissioning measurements, findings, and results, including weather conditions, should be in the documentation package provided to the customer.

On-site documentation should indicate presence of the PV system at the utility's entrance to the home and/or other visible place for emergency responders, and the equipment should be labeled and identified on a nearby single line diagram.

Start-Up Commissioning

During commissioning, the proper implementation of PV system design is confirmed, and any changes or site-specific conditions/concerns are noted and approved. Commissioning is done through a combination of visual inspections and performance verification. It is therefore important that the PV system documentation is complete and accurate.

Visual inspections examine all aspects of the PV array, mounting, wiring, electrical equipment, connections, and general site conditions. The PV system should be installed in a safe manner, following best practices and code requirements. Separate roof/building/electrical inspections may be necessary to maintain warranties and meet local requirements.

Damage to PV modules and system components can result if modules or strings are improperly wired. DC string polarity is therefore confirmed both visually and with an appropriately rated voltmeter, taking extreme care with the + or – sign. String voltages should be equal to the number of modules in a string times the open circuit voltage (V_{oc}), adjusted by the temperature coefficient. Deviations from this, especially when compared to adjacent and similarly configured strings, can indicate a problem with the string, an individual module, or the wiring.

Example 12: String Voltage Calculation. A module having V_{oc} = 36 V DC at STC (standard test conditions of 1000 W/m^2, 25°C cell temperature) and a voltage temperature coefficient of –0.6%/K will have a voltage of 41.4 V DC at 0°C. A string of 12 modules is therefore expected to have an open circuit voltage of 497 V DC at 0°C.

Ideally, current and power measurements are taken under clear blue sky, bright sunlight, low wind, and uniform conditions. This allows for more accurate measurements that can be compared between strings or used as an important baseline for future measurements. After confirming correct polarity and voltages at the DC side, and performing any verification of DC current, system grounding, and racking bonding, activating the inverter allows validation of the PV array power output. Many jurisdictions require the local electrical authority to conduct their safety inspection before allowing the inverter's operation /connection to the grid. Performance validation can be a simple confirmation of operation, a side-by-side comparison of output with another similarly configured array, or a detailed performance validation using simultaneous environmental monitoring under bright, blue sky and calm conditions.

Optionally, *I-V* curve measurements of each DC string can provide useful diagnostic and reference information. These are ideally taken above 600 W/m^2 under clear-sky conditions. Also, IR imaging of electronics and switches to identify hotspots is possible when the system is active (generating AC power). These are ideally taken above 600 W/m^2 but even a minimum irradiance of 300 W/m^2 (which will generate 30% of rated closed-circuit current [I_{sc}] in the components) may assist in identifying extreme equipment malfunctions.

Off-Grid Systems. Due to the variability in design parameters for off-grid systems, commissioning includes verification of software settings within the inverter, battery charge controller (if applicable), and any other critical piece of equipment. The initial battery stabilization procedure should have already been performed (if applicable), the batteries should be housed in a suitable location for the technology type, and the battery monitor's voltage readings should be confirmed using an independent meter.

Maintenance

With no moving parts, PV systems are low maintenance (but not no-maintenance), with tasks typically limited to visual inspection, monitoring, and occasional maintenance. Recommended tasks and frequency depend on the location, mounting type, and performance requirements. A standard frequency for small systems with no performance guarantee is annually. Many systems are monitored remotely, with on-site inspections limited to important stages of the project cycle, such as commissioning, warranty expiration, and asset transfer, or when remote monitoring indicates a concern. Many issues with PV systems can be remotely detected via careful system performance monitoring. A complete system documentation package is extremely useful for performing maintenance, and detailed maintenance records should be kept. This is especially important, because owners and maintenance personnel may change, and PV system typically have expected lifetimes in excess of 20 years.

Visual inspection typically starts with verification that all electronic equipment is operational and that no faults are indicated. An arc-fault alarm or a ground-fault trip can indicate hazardous conditions. In this case, the cause should be carefully investigated and addressed by a trained professional to avoid shock and fire hazards. All personnel on site typically wear personal protective equipment, are specially trained, and are aware of the hazards.

The PV array can be visually inspected for any PV module breakage or misaligned parts. To facilitate inspection and maintenance, the area should be designed for accessibility. Confirm that original design assumptions have not changed. Evidence of any fire hazards, (e.g., presence of leaves, debris, birds, rodents) should be immediately addressed. In some cases, mechanical barriers between PV modules and the roof are used to deter build-up of debris and chewing of cables by animals. A cleaning schedule may be desired. Wiring and connectors should remain securely fastened and have no indications of water ingress, abrasion, or arcing.

PV module racking structures often recommend checking bolt torques, particularly after the first year of operation, to ensure no movement due to seasonal effects or improper initial tightening. To confirm no water leakage into the building, roof/building penetration should be examined. Likewise, ballasted systems should be examined to ensure absence of movement and damage to roofing surface. Depending on the location, cleaning of the PV modules or snow removal may be cost effective.

Inverters and other electronic equipment may require annual filter cleaning. Electrical and mechanical connections should remain secure, with no signs of arcing or loosening. If outdoors, water damage can cause corrosion, resulting in fire or underperformance. Spare parts may be required in case of equipment malfunction. Infrared cameras may help to identify faulty components. To maintain accuracy, monitoring equipment should be cleaned and calibrated as required.

Performance Monitoring/Minimum Instrumentation

PV electronic equipment, such as inverters and solar battery charge controllers, often contain integrated displays for real-time and cumulative performance of the PV system. Typical parameters include instantaneous DC voltages, DC current, AC power, AC frequency, and year-to-date cumulative kilowatt-hour energy generation. Note that accuracy of the integrated monitoring displays varies. Many inverter manufacturers offer remote monitoring capabilities, either free or on a paid subscription basis. The web-based information availability and format depend on the manufacturer. External third-party meters may be attached to both the DC and AC side of the system to ensure correct operation, and these may also be remotely monitored. They typically offer better accuracy and can be configured based on the user's requirements.

To determine whether the system is performing optimally, environmental information is also required. Key pieces of environmental monitoring equipment are an in-plane irradiance sensor (spectrally matched reference cell or calibrated pyranometer), ambient temperature sensor (shielded), several PV module back-sheet temperature sensors (carefully affixed), and optional wind speed and direction sensors and snow/rain gages. Larger systems in dusty environments may use soiling sensors. These are connected to a data logger, and ideally take instantaneous measurements synchronized with the PV system monitoring equipment. This allows calculation of ideal versus actual power output, and visualization of any seasonal or annual performance losses. An alternative to an on-site environmental station is using satellite data or data from local meteorological stations (often near local airports), although care needs to be taken that the local topography, microclimate, and time interval are appropriate. It is best to corroborate satellite or meteorological station data with on-site data.

For systems with remote monitoring enabled, more frequent performance monitoring and fault detection is possible with little time required (often less than 5 minutes to log in and verify operation). This allows issues to be detected quickly and addressed as needed. Often, a third-party solar expert is engaged to perform these checks, sometimes using automated alert generation.

13. SYMBOLS

a = empirically determined coefficient indicating the upper temperature limit under low wind speeds and high solar irradiance
A = surface area, m^2
A_{abs}, A_{ap} = areas of absorber surface and of aperture that admit or receive radiation, m^2
A_c = area of solar collector, m^2
ACH = air changes per hour, ach
A_g = gross collector area, m^2
A_p = projected collector area, m^2
AST = apparent solar time, decimal h
b = empirically determined coefficient indicating rate at which back-surface temperature drops with wind speed $(m/s)^{-1}$
c = unit correction coefficient, 1
c_1 = unit correction coefficient, 1 $(m^2 \cdot K)/W$
c_p = specific heat of fluid, $kJ/(kg \cdot K)$
DST = daylight saving time, decimal h
e_{at} = sky emittance
E_{annual} = annual electrical load to be offset by PV system, kWh
E_{daily} = daily average electricity to be generated by PV system, kWh
EL = electric loss factor
e_s = surface emittance
E_{sun} = daily average solar energy that strikes a surface per unit area, for a given location, $kWh/(m^2 \cdot day)$
ET = equation of time, min
f = fraction of monthly space- and water-heating loads supplied by solar energy
F = fraction of the annual heating load supplied by solar energy
F_r = collector heat exchanger efficiency factor
F_R = collector heat removal factor; ratio of heat actually delivered by collector to heat that would be delivered if absorber were at t_{fi}
h = PV array height, m
H = hour angle, degrees
H_T = monthly averaged daily radiation incident on collector surface per unit area, $J/(d \cdot m^3)$
I = incident total irradiance, W/m^2
I_{DN} = direct normal irradiation, W/m^2
$I_{d\theta}$ = diffuse component of solar radiation from sky, W/m^2
I_r = reflected shortwave radiation, W/m^2
I_{ref} = reference solar irradiance, typically 1000 W/m^2
IS = minimum inter-row spacing, m
I_{STC} = solar irradiance under standard testing conditions, 1000 W/m^2
$I_{t\theta}$ = total solar irradiation of terrestrial surface or collector, W/m^2
KD = temperature departure in kelvin-days computed for an appropriate base temperature
L = monthly total heating load for space heating and hot water, J
LCR = load collector ratio; net load coefficient divided by projected collector area, $kJ/(m^2 \cdot K \cdot d)$
LST = local standard time, decimal h
m = air mass; = 1.0/sin β at sea level and 0 outside earth's atmosphere; also fluid flow rate, kg/s
$\dot{m}$ = fluid flow rate, kg/s

N = day of year, with January 1 = 1; also number of days in month
NLC = net load coefficient, kJ/(K·d)
N_{mod} = number of PV panels required
P_{el} = electrical output of the PV system, W
P_{mod} = electrical output of the PV modules, W
P_{STC} = power rating of module under standard testing conditions, W
q_{Rat} = downward radiation from atmosphere, W/m^2
q_{Rs} = longwave radiation emitted by surface on earth, W/m^2
q_u = useful heat gained by collector per unit of aperture area, W/m^2
R_{net} = net radiative cooling rate of horizontal surface, W/m^2
S = total downward radiant heat flux from atmosphere, W/m^2
SH = PV shadow length, m
SHD = sun hours per day, h
SLR = solar energy absorbed divided by building heating load
SSF = solar savings fraction
t_a = temperature of atmosphere, dry-bulb temperature, or average ambient temperature, °C
$\bar{t}_a$ = monthly average ambient temperature, °C
t_{abs} = temperature of absorber, °C
T_{at} = ground-level dry-bulb temperature, K
T_{back} = back-surface PV module temperature, °C
T_{base} = base temperature, °C
T_{cell} = operating cell temperature, °C
t_{fe}, t_{fi} = temperatures of fluid leaving and entering collector, respectively, °C
TLC = total load coefficient, kJ/(K·d)
t_p = temperature of absorber plate, °C
T_{rad} = absolute temperature of horizontal surface, K
t_{ref} = reference temperature, °C
T_s = absolute temperature of surface, K
T_{sky} = apparent sky temperature, K
U_L = overall heat loss coefficient, W/(m^2·K)
U_{met} = wind speed measured at standard 10 m height, m/s
U_{wind} = wind speed measured near collector's surface, m/s
X = reference collector loss divided by heating load
Y = absorbed solar energy divided by heating load

Greek

α = absorptance
β = sun's altitude above horizon, degrees
γ = surface-solar azimuth, degrees
δ = solar declination, degrees
$\Delta\theta$ = total number of hours in month
ΔT = temperature difference between the cell and the module back-surface at an irradiance level of 1000 W/m^2
ε = nonspectral emittance of horizontal surface; about 0.9 for most nonmetallic construction materials
η = collector's electrical or thermal efficiency as specified
η_{ref} = electrical efficiency under reference conditions, available through manufacturer's data sheet for solar module
θ = solar incident angle, degrees
$\mu_{P,mp}$ = temperature coefficient at maximum power point, °C^{-1}
$\rho\Gamma$ = reflectance of concentrator surface times fraction of reflected or refracted radiation that reaches absorber
σ = Stefan-Boltzmann constant, 5.67×10^{-8} W/(m^2·K^4)
Σ = tilt angle of surface, measured from horizontal, degrees
τ = transmittance
$\overline{(\tau\alpha)}$ = monthly average transmittance-absorptance product
$(\tau\alpha)_n$ = normal transmittance-absorptance product
$(\tau\alpha)_\theta$ = transmittance τ of cover times absorptance α of plate at prevailing incident angle θ
ϕ = solar azimuth, degrees
ψ = surface azimuth, degrees

CHAPTER 37

ENERGY AND WATER USE AND MANAGEMENT

Energy and Water Management 37.1
Communications 37.3
Energy and Water Accounting Systems 37.3
Analyzing Energy and Water Data 37.3
Surveys and Audits 37.10
Improving Discretionary Operations 37.11
Energy- and Water-Efficiency Measures 37.12
Implementing Energy-Efficiency Measures 37.13
Monitoring Results 37.14
Evaluating Success and Establishing New Goals 37.14
Building Emergency Energy Use Reduction 37.16

ENERGY and water management in buildings is the control of energy and water use and cost while maintaining indoor environmental conditions that provide comfort and meet functional needs. Water costs may include, but are not limited to, sewer, potable water, and reclaimed water. This chapter provides guidance on establishing an effective, ongoing energy and water management program, as well as information on planning and implementing energy and water management projects. The energy manager, or other similarly tasked advocate, should understand how energy and water are used in the building to manage these resources effectively by reducing waste and improving efficiency in energy- and water-consuming systems, optimizing energy and water supply, and reducing the unit price of the purchased utility.

1. ENERGY AND WATER MANAGEMENT

The specific processes by which building owners and operators control energy and water consumption and costs are as variable as building types. Small buildings, such as residences and small commercial businesses, can usually be managed by one person. Energy and water management procedures should be as simple, specific, and direct as possible. General energy and water management advice (e.g., from utility surveys; state, provincial, or local offices) can provide ideas, but these must be evaluated to determine whether they are applicable to the target building. Owners and operators of smaller buildings may only need advice on specific energy and water projects (e.g., boiler replacement, lighting retrofit). On the other hand, large or complex facilities, such as hospital or university campuses, industrial complexes, or large office buildings, usually require a team effort and process, as represented in Figure 1.

In general, energy and water management for existing buildings is comprised of these basic steps:

1. With support from senior management, appoint an energy or resource manager to oversee energy and water management system and ensure that someone is dedicated to the initiatives and accountable to the company.
2. Initiate early communication to solicit feedback for other steps of the process.
3. Establish an accounting system that records energy and water consumption and associated costs (should include comparisons with similar buildings, to benchmark and set performance goals).
4. Validate and analyze current and historical energy and water use data to help identify energy- and water-efficiency measures
5. Carry out energy and water surveys and walk-through audits to identify low/no-cost operations, maintenance, and efficiency measures. Having qualified professionals, such as energy engineers and energy and water auditors, do this is recommended.
6. Using the survey and audit results, optimize building operating procedures to eliminate waste.
7. Evaluate efficiency measures for expected savings, estimated implementation costs, risks, and nonenergy and water benefits. Recommend prioritized efficiency projects for implementation.
8. Implement approved energy-efficiency measures (EEMs) and water use reduction measures. Tender projects that must be outsourced.
9. Track results using the energy accounting system for overall performance, supplemented as needed by monitoring related to specific projects.
10. Compare results to past goals, revise as necessary, and develop new goals. Report to management and tenants. Return to step 7 and continue the process to maintain and continually improve building performance.

Each of these energy and water management program components is discussed in detail in the following sections.

ASHRAE *Standard* 100 provides useful details for energy management planning in existing buildings. Information on energy

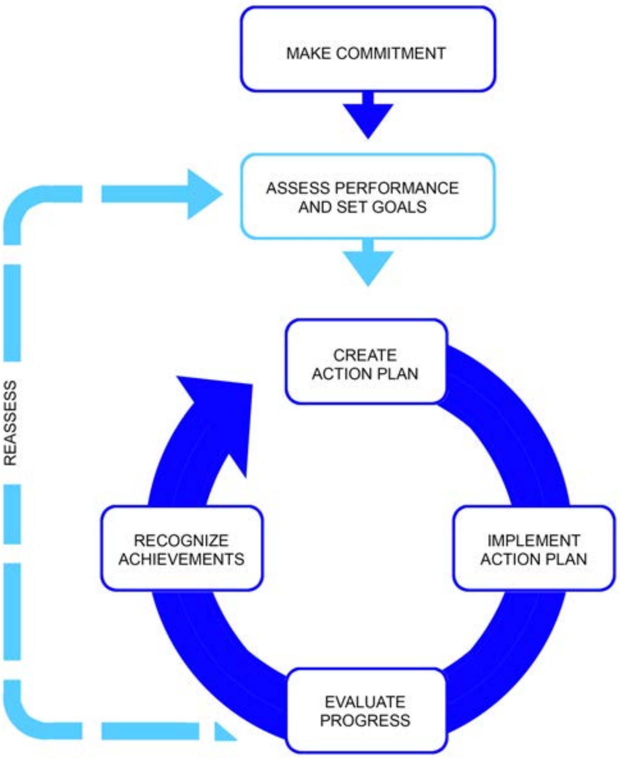

Fig. 1 An Energy and Water Management Process
(Adapted from www.energystar.gov)

The preparation of this chapter is assigned to TC 7.6, Building Energy Performance.

efficiency in new design can be found in all volumes of the *ASHRAE Handbook* and in ASHRAE *Standards* 90.1 and 90.2. Protocols for energy and indoor environmental quality performance and best practices are presented in ASHRAE (2010, 2012). The area most likely to be overlooked in new design is the ability to measure and monitor energy and water consumption and trends for each energy and water use category given in Chapter 42. Additional guidelines for this area can be found in Chapter 34 of the 2017 *ASHRAE Handbook—Fundamentals*.

Organizing for Energy and Water Management

To be effective, energy and water management must be given the same emphasis as management of any other cost/profit center. Top management should

- Establish the energy and water cost/profit center
- Assign management responsibility for the program
- Assign an energy and water manager and provide training
- Allocate resources
- Clearly communicate the energy and water management program to all departments and personnel
- Set clear program goals
- Encourage ownership of the program by all levels of the organization
- Set up an ongoing reporting and analysis procedure to monitor results
- Develop a feedback mechanism to allow timely revisions

It is common for a facility to allocate 3 to 10% of the annual energy and water cost for administration of an energy and water management program. The budget should include funds for continuing education of the energy manager and staff.

Energy Managers

The functions of an energy manager fall into four broad categories: technical, policy-related, planning and purchasing, and public relations. A list of specific tasks and a plan for their implementation must be clearly documented and communicated to building occupants. An energy manager in a large commercial complex may perform most of the following functions; one in a smaller facility may have only a few from each category to consider.

Technical functions.

- Conduct, or arrange for a qualified consultant to conduct, energy audits and recommissioning studies to identify energy- and water-efficiency measures
- Act as in-house technical consultant on new energy and water conservation technologies, alternative fuel sources, and energy- and water-efficient practices
- Evaluate energy and water efficiency of proposed new construction, building expansion, remodeling, and new equipment purchases
- Set performance standards for efficient operation and maintenance of equipment and facilities
- Review state-of-the-art energy and water management hardware
- Review building operation and maintenance procedures for optimal energy and water management
- Implement energy-efficiency measures (EEMs) and water use reduction measures
- Establish an energy and water accounting system
- Establish a baseline from which energy- and water-saving improvements can be measured
- Measure and maintain effectiveness of EEMs and water use reduction measures
- Measure energy and water use in the field to verify design and operating conditions

Policy-related functions.

- Fulfill energy policy established by top management
- Monitor federal and state (provincial) legislation and regulatory activities, and recommend policy/response
- Adhere to energy management building codes and water use restrictions established by local or state (provincial) authorities
- Represent the organization in energy associations
- Administer government-mandated reporting programs

Planning and purchasing functions.

- Take advantage of fuel-switching and load management opportunities
- Purchase equipment based on life-cycle cost
- Take advantage of energy- and water-efficiency programs offered by utilities and agencies
- Negotiate or advise on major utility contracts
- Develop contingency plans for supply interruptions or shortages
- Forecast and budget for short- and long-term energy and water requirements and costs
- Report regularly to top management and other stakeholders

Public relations functions.

- Make occupants aware of the benefits of efficient energy and water use
- Establish a mechanism to elicit and evaluate suggestions
- Recognize and communicate successful energy projects
- Establish an energy and water communications network
- Increase community awareness with press releases and appearances at civic group meetings

General qualifications.

- A technical background, preferably in engineering
- Experience in energy- and water-efficient design of building systems and processes
- Practical, hands-on experience with systems and equipment
- Goal-oriented management style
- Ability to work with people at all levels
- Technical report-writing and verbal communication skills

Desirable educational and professional qualifications.

- Bachelor of science degree, preferably in mechanical, electrical, architectural, industrial, or chemical engineering
- Thorough knowledge of energy resource planning and conservation
- Ability to analyze and compile technical and statistical information and reports, and interpret plans and specifications for building facilities
- Knowledge of
  - Utility rates, energy efficiency, and planning
  - Automatic controls and systems instrumentation
  - Energy-related metering equipment and practices
  - Project management

If it is not possible to add a full-time manager, an existing employee with a technical background should be considered and trained. Energy and water management should not be a collateral duty of an employee who is already fully occupied. Another option is to hire a professional energy management consultant. Energy services companies (ESCOs) provide energy and water services as part of a contract, with payments based on realized savings. Other companies charge a fee to perform a variety of energy and water management functions.

2. COMMUNICATIONS

Energy and water management requires careful planning and help from all personnel that operate and use the facility. A communication plan should be regularly reviewed by both the energy manager and senior management. The initial communiqué should introduce the plan and express the support of top management for high-level goals. Providing early information to tenants and staff is important, because it takes time to change behaviors. Once the communication plan is launched, the energy manager should be prepared to answer a variety of questions from different areas of the company.

An effective communication strategy may include

- A regular newsletter
- Posting energy- and water-saving tips or reminders
- Annual seminars with maintenance and cleaning staff
- Meeting with operations staff for training and feedback
- Reporting regularly to management and operations staff

Message content should be tailored to the specific audience. The more successful and accessible the communication is, the more quickly the energy and water management activities will become second nature. Diligent reporting promotes accountability and persistence of performance.

3. ENERGY AND WATER ACCOUNTING SYSTEMS

An accounting system that tracks consumption and costs on a continuing basis is essential. It provides usage data needed to identify areas of concern, allows for focused efforts, and confirms savings from energy- and water-efficiency projects. An effective accounting system can be used in ongoing energy and building performance measurement.

Energy and Water Accounting

Energy and water accounting is the tracking of energy and water usage and demand on a consistent basis to provide a current picture of building energy performance and to identify instances and trends of excess use. The energy manager should establish which metrics to measure and what units each metric should have. Typically, energy is tracked in units of kilowatt hours and water is tracked in litres or cubic metres (m^3). Peak electricity demand is often also tracked in kilowatts. A good manager tracks these metrics consistently. How these metrics are recorded can vary greatly depending on the technical expertise of the manager, the level of technology in the facility, and the number of buildings for which the manager is responsible. In many instances, a simple spreadsheet will suffice. In other cases, software with dashboard and graphics features is available. There are also web-based accounting systems and subscriptions. For example, Portfolio Manager, available through ENERGY STAR, is a free web-based portal that allows users to enter monthly energy data. The Portfolio Manager can calculate the facility's energy usage intensity (EUI) and provide a normalized ENERGY STAR score (www.energystar.gov/benchmark). Portfolio Manager normalizes by building type for weather, facilitates setting goals, helps compare multiple buildings in a portfolio, and is useful for numerous building types.

Energy and Water Accounting Process

The energy manager establishes procedures for meter reading, monitoring, and tabulating facility energy and water use and profiles. The manager also periodically reviews utility rates, rate structures, and trends, and monitors changes to the rate tariffs for the facility. This individual also provides periodic reports to top management, summarizing the work accomplished and its cost effectiveness, plans for future work, and projections of utility costs. Utility bill analysis software or a spreadsheet system can be used to track avoided costs. If efficiency measures are to be economical, continued monitoring and periodic re-auditing are necessary. The procedures in ASHRAE *Guideline* 14 can be used to measure and verify energy and water savings.

Utility Rates

Because most energy and water management activities are dictated by economics, the energy manager must understand the utility rates that apply to each facility. Electricity rates are more complex than gas or water rates, and some rate structures make cost calculations difficult. In addition to general commercial or institutional electricity rates, special rates may exist, influenced by factors such as time of day, interruptible service, on peak/off peak, summer/winter, and peak demand. Electricity rate schedules vary widely in North America; Chapters 38 and 57 discuss these in detail. Energy managers should work with local utility companies to identify the most favorable rates for their buildings and must understand how demand is computed as well as the distinction between marginal and average costs (see the section on Improving Discretionary Operations). The utility representative can help develop the most cost-effective methods of metering and billing.

4. ANALYZING ENERGY AND WATER DATA

Preparing for Cost and Efficiency Improvements

Reducing the cost per unit of energy as well as energy and water consumption provides opportunities for savings. Historically, energy users had little choice in selecting energy suppliers, and regulated tariffs applied. In recent years, there has been a move in North America and other parts of the world to deregulate energy markets, and there is more flexibility in supply and pricing. Electricity rate structures vary widely in North America; Chapter 38 discusses these in detail.

Electricity and water utilities commonly meter both consumption and demand. **Demand** is the peak rate of consumption, typically averaged over a 15 or 30 min period. Electricity and water utilities may also use a ratchet billing procedure based on demand. Contact the local utility to fully understand the demand component.

Some utilities use **real-time pricing (RTP)**, in which the utility calculates the marginal cost of power per hour for the next day, determines the price, and sends this hourly price to customers. The customer can then determine the power consumption at different times of the day. A variation on RTP was introduced in some areas: **demand exchange and active load management** pays customers to shed loads during periods of high utility demand. Also called **demand reduction** or **demand response**, the utilities ask participating customers to reduce their consumption for a period of time on as little as a few hours' notice.

Caution is advised in designing or installing systems that take advantage of utility rate provisions, because the structure or provisions of utility rates cannot be guaranteed for the life of the system. Provisions that change include on-peak times, declining block rates, and demand ratchets. Chapter 57 has additional information on billing rates,

Analyzing Energy and Water Use Data

Any reliable utility data should be examined. The primary data source is utility bills, but other sources include

- Time-of-use meter data and submeter energy and water usage data
- Combustion efficiency
- Water quality test results
- Recordings of indoor temperature and relative humidity
- Weather data (e.g., hourly temperature and relative humidity, wind, percent cloud cover)
- Power failure event recordings
- Occupancy data (e.g., schedules, people counts, occupant activity levels, special events and holidays)
- Water and energy benchmarking data from similar buildings in similar climates
- Equipment service and shutdown logs

- Facility drawing plans and specifications
- Benchmarking data (e.g., building location, size, monthly energy use, EUI, ECI)
- Computer modeling results

Utilities often provide metered data with measurement intervals as short as 15 min. Data from shorter time intervals make anomalies more apparent. High consumption at certain periods may reveal opportunities for cost reduction (Haberl and Komor 1990a, 1990b). If monthly data are used, they should be analyzed over several years.

A base year should be established as a reference point. Record the dates of meter readings so that energy use can be normalized for the number of days in a billing period. Any periods in which consumption was estimated (rather than measured) should be noted.

If energy data are available for more than one building or department, each should be tabulated separately. Initial tabulations should include both energy and cost per unit area (in an industrial facility, this may be energy and cost per unit of goods produced). Document variables such as heating or cooling degree-days, percent occupancy, quantity of goods produced, building occupancy, hours of operation, and daily weather conditions (see Chapter 14 in the 2017 *ASHRAE Handbook—Fundamentals*). Because these variables may not be directly proportional to energy use, it is best to plot information separately or to superimpose one plot over another. Examples of ways to normalize energy consumption for temperature and other variations are provided in ASHRAE *Guideline* 14.

Potential savings areas can be identified by separating base energy consumption from weather-dependent energy consumption. **Base-load energy use** is the amount of energy consumed independent of weather, such as for lighting, motors, domestic hot water, and miscellaneous office equipment. When a building has electric cooling and no electric heating, the base-load electric energy use is normally the energy consumed during the winter. The annual base-load energy use may also be estimated by taking the average monthly use during nonheating or noncooling months and multiplying by 12. For many buildings, subtracting the base-load energy use from total annual energy use yields a good estimate of heating or cooling energy consumption. This approach is not valid when building operation differs from summer to winter, when cooling operates year-round, or when space heating is used during summer (e.g., for reheat). Base-load analysis can be improved by using hourly load data. **Electric load factors (ELFs)** and occupancy factors can also be used instead of hourly energy profiles (Haberl and Komor 1990a, 1990b).

Although it can be difficult to relate heating and cooling energy directly to weather, several authors, including Fels (1986) and Spielvogel (1984), suggest that this is possible using a curve-fitting method to calculate the balance point of a building (discussed in Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals*). For this method, building use must be regular, and actual rather than estimated data must be used, along with accurate dates and weather data.

More detailed breakdown of energy use requires that some metered data be collected daily (winter versus summer days, weekdays versus weekends) and that some hourly information be collected to develop profiles for night (unoccupied), morning warm-up, day (occupied), and shutdown. Submetering of energy end uses is recommended for optimal energy management. For more information, see Chapter 42.

An example spreadsheet using three years of electricity bill data for a two-story office building in Atlanta, Georgia, is presented in Table 1. (See Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals* for floor plans and elevations of the building.)

Electrical Use Profile

The **electrical use profile (EUP)** report, shown in Figure 2, divides electrical consumption into base and weather-dependent consumption. The average daily consumption for each month appears in the daily use column in Table 1, and is plotted in the EUP graph. The average daily consumption is calculated by dividing the consumption for a particular month by its billing days.

The lowest value in the daily-use column of Table 1 is used to plot the facility's base electrical consumption (shown as the base use line in Figure 2). Where a facility uses electricity only for cooling or heating, or in an all-electric facility where there is no overlap between cooling and heating, the difference between these two lines represents the weather-dependent electrical consumption.

Weather-dependent energy consumption (either electricity or other fuels) may then be compared to the **cooling degree-days (CDD)** or **heating degree-days (HDD)** totals for the same time period (see Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*). This comparison shows how the building performs from month to month or year to year. The HDDs stop and CDDs start at the balance point, defined as the outdoor temperature at which, for a specified interior temperature, the total heat loss is equal to the heat gain from the sun, occupants, lights, etc. Note that all-electric buildings may have periods of overlap between heating and cooling, causing the base load to be overestimated and the heating and cooling estimates to be conservative.

Examine the average daily use line to see whether it follows the expected seasonal curve. For example, the shoulders of the curve for an electrically cooled, gas-heated hospital should closely follow the base electrical use line in the winter. As summer approaches, this curve should rise steadily to reflect the increased cooling load. Errors in meter readings, reading dates, or consumption variances appear as unusual peaks or valleys. Reexamine the data and correct errors as necessary.

If an unusual profile remains after correcting any errors, an area of potential energy savings may exist. For example, if the average daily use line for the facility is running near summer levels during March, April, May, October, and November, simultaneous heating and cooling may be occurring. This situation is shown in Figure 2 and often occurs with dual-duct systems.

Simultaneous heating and cooling is also indicated in the percent excess use column of Table 1. The values show the percent difference between the value appearing in the monthly base use column and the billed consumption for the month. In Figure 2, note how the excess consumption for spring and fall months runs close to the summer percentages. The monthly base use is the lowest value from the daily use column multiplied by the number of billing days for each month.

For electrically cooled, gas-heated facilities, weather-dependent consumption is the difference between the totals of the monthly base use column and the billed use column.

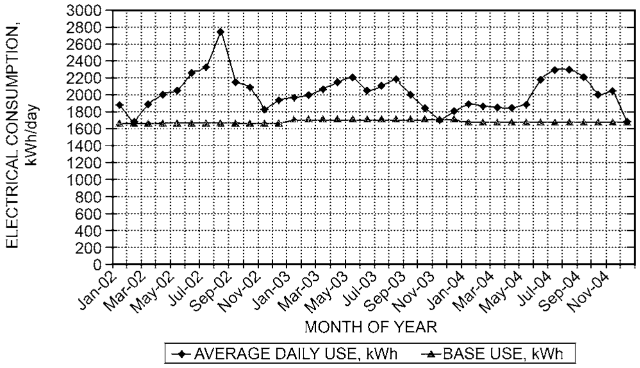

Fig. 2 Electrical Use Profile for Atlanta Example Building

[a]Maximum or minimum value for year. [b]Peak demand for year. [c]Minimum demand used in seasonal ELF calculation.

For an all-electric facility, subtract the total monthly consumption from total billed use for the cooling months, then do the same calculations for heating months to determine the electric cooling and heating loads, respectively.

Calculating Electrical Load and Occupancy Factors

Another method for detecting potential energy savings is to compare the facility's electrical load factor to its occupancy factor. An ELF exceeding its occupancy factor indicates a higher-than-expected electric use occurring outside normal occupancy (e.g., lights or fans are left on or air conditioning is not shut off as early in the day as possible in summer). Setback thermostats, direct digital control (DDC) strategies, time-of-day scheduling, and lighting controls can address this.

The ELF is the ratio of the average daily use and the maximum possible use if peak demand operated for a 24 h period. The occupancy factor is the ratio of the hours a building actually is occupied and 24 h/day occupancy.

To calculate the ELF, find the month with the lowest demand on the utility data analysis spreadsheet. This value represents the base monthly peak demand, and is usually found in the same or adjacent month as the month with the lowest consumption. From the EUP report, find the lowest value in the daily use column. For example, the lowest average daily use for the office building in Table 1 is 1704 kWh (in November 2003), and the lowest monthly demand from the spreadsheet is 122 kW (in October 2003). The ELF is calculated as follows:

$$\text{ELF} = \frac{\text{Lowest average daily use}}{\text{Lowest monthly demand} \times 24} = \frac{1704}{122 \times 24} = 58\%$$

The office is normally occupied from 7:30 AM to 6:30 PM, Monday to Friday. Therefore, the occupancy factor is calculated as

$$\text{Occupancy factor} = \frac{\text{Actual weekly occupied hours}}{24 \text{ h} \times 7 \text{ days}} = \frac{55}{168} = 33\%$$

Calculating Seasonal ELFs

ELFs can also be calculated for cooling and heating seasons. Typical defaults are May to August as cooling months, and the rest of the year as heating months, but these change based on climate.

The steps for calculating a seasonal ELF are as follows:

1. The daily base consumption is determined from the daily use column of the EUP report. Subtract the lowest value of the year from the highest value of the season.
2. The base demand is determined by subtracting the lowest monthly demand of the year from the demand recorded for the month with the highest daily use. These calculations can be refined further if on- and off-peak data are available.

For example, because the electrically cooled Atlanta example building operates year-round, the summer ELF must also be calculated. The daily base consumption (1089) is determined by subtracting the lowest value (1665) from the highest cooling-season value (2754) in the daily use column of the EUP report.

From the spreadsheet, take the demand from September 2002 (the month with the peak cooling-season actual demand) and subtract the lowest monthly demand (195 – 140) to determine the cooling-season base demand (55). Thus, the summer ELF is

$$\text{Summer ELF} = \frac{1089}{55 \times 24} = 82\% \text{ (for 2002)}$$

These calculations show that the cooling equipment is operating beyond building occupancy (82% versus 33%) Therefore, excessive equipment run times should be investigated. Note that comparing the ELF to the occupancy factor is meaningless for buildings occupied 24 h a day, such as hospitals.

Similar tables and charts may be created for natural gas, water, and other utilities.

Electricity Demand Billing

The Atlanta example building has a ratchet-type demand rate (see Chapter 57), and billed demand is determined as a percentage of actual demand in the summer months. The ratchet is illustrated in Figure 3, where billed demand is the greater of the measured demand or 95% of the highest measured demand within the past 12 months. The billed demand for January of the third year was 171 kW (171 = 0.95 × 180), or 95% of the actual demand from July of year 2.

In Table 1, the actual demand in the first six months of 2003 had no effect on the billed demand, and therefore no effect on the dollar amount of the bill; the same is true for the last three months of the year. Because of the demand ratchet, the billed demand in January 2004 (171 kW) was set in July 2003. This means that any conservation measures that reduce peak demand will not affect billed demand until the following summer (e.g., June to September 2004); however, consumption savings begin at the next billing cycle. The effect of demand ratchet rates is that any conservation measures implemented have a longer initial payback period simply because of the utility rate structure. The energy manager should investigate other rate structures, such as a time-of-use (TOU) or seasonal rates. Rate structures for smaller buildings may not include demand charges.

Benchmarking Energy Use

Benchmarking (comparing a building's normalized energy consumption to that of similar buildings) can be a useful first measure of energy efficiency. Relative energy use is commonly expressed in **energy utilization index (EUI**; energy use per unit area per year) and **cost utilization index (CUI**; energy cost per unit area per year). The Atlanta example building is 2852 m^2 in size, so its 2004 EUI is 866 MJ/m^2 and its CUI is $15.82/$m^2$.

Two sources of benchmarking data for U.S. buildings are ENERGY STAR (www.energystar.gov) and performance metrics developed using data from the U.S. Department of Energy's Energy Information Administration (DOE/EIA; www.eia.gov). Tables 2 to 4 present building performance metrics (benchmarks) developed from the 2012 DOE/EIA CBECS using a methodology similar to that described by Sharp (2014) and used in the development of building energy performance targets for ASHRAE *Standard* 100. Table 2 lists population metrics and total EUI distributional values derived for each building type (in both SI and I-P units). Table 3 lists distributional values derived for building electricity use, and Table 4 shows similar values for building energy costs. As an example of how to interpret and use these percentiles using Table 2, an administrative office with a total EUI of 62 is a typical performer (in the middle or 50th percentile of the distribution of office buildings). It is in the top-performing quartile (25th percentile) if it has an EUI of 41 or less, and it is in the worst-performing

Source: Calculated based on DOE/EIA preliminary 2012 CBECS microdata.

10% of office buildings if it has an EUI of 138 (90th percentile) or higher. When referring to these tables, keep in mind a facility's operating or occupied hours (which affect energy intensity) and current utility rates. Additional information on CBECS data and surveys is available at www.eia.doe.gov/emeu/cbecs.

Databases. Compiling a database of past energy use and cost is important. All reliable utility data should be examined. ASHRAE *Standard* 105 contains information that allows for uniform, consistent expressions of energy consumption in new and existing buildings.

The energy use database for a new building may consist solely of typical data for similar buildings, as in Table 2. This may be supplemented by energy simulation data developed during design. A new building should be commissioned to ensure proper operation of all systems, including any energy-efficiency features (see ASHRAE *Guideline* 1.1 and Chapter 43).

Source: Calculated based on DOE/EIA preliminary 2012 CBECS microdata.

All the data presented in these tables come from detailed reports of consumption patterns, and it is important to understand how they were derived. When using the data, verify correct use with the original EIA documents.

Mazzucchi (1992) lists data elements useful for normalizing and comparing utility billing information. Metered energy consumption and cost data are also published by trade associations, such as the Building Owners and Managers Association International (BOMA), the National Restaurant Association (NRA), and the American Hotel and Lodging Association (AH&LA). In some cases, local energy consumption data may be available from local utility companies or state or provincial energy offices.

Additional energy use information for homes and commercial buildings in Canada can be found at the Office of Energy Efficiency at www.oee.nrcan.gc.ca/corporate/statistics/neud/dpa/data_e/publications.cfm. In Europe, benchmarking data are defined on a national basis in the frame of the European Directive on the Energy Performance of Buildings (EPBD) (EC 2010). Balaras et al. (2007) provide an overview of relevant data for residential buildings, although detailed data for commercial buildings are rather limited (Gaglia et al 2007).

Benchmarking Water Use

As with energy, benchmarking a building's water use to established norms can be a quick, first indicator of an opportunity for

improving water efficiency. Building water performance metrics are just beginning to emerge because very limited data are available compared to those for energy. The DOE/EIA collected building water use data as part of its national 2012 CBECS survey. In 2017, the EIA used these data to generate national average water consumption metrics for 10 building types (not counting the "other" category). Their results can be found at www.eia.gov/consumption/commercial/reports/2012/water/. This is informed by a statistically based national sampling. The EPA WaterSense and ENERGY STAR programs collaborated to generate national median water consumptions for 14 building types based on the data collected through the ENERGY STAR program. The EPA's sample is based on users submitting data through their ENERGY STAR Portfolio Manager application, so it is not entirely random.

Table 5 presents distributional building water use intensity metrics for 25 building types (24 commercial and 1 multifamily building residential type). These metrics were developed by analyzing some available state-level data and combining the results with the EPA WaterSense/ENERGY STAR values to produce this more robust table. Metrics are presented on a water use intensity basis. The sensitivity of building energy performance metrics to regional differences within the United States has been analyzed, and national-level building energy metrics must be used with many cautions when comparing to a local building. Water metrics are not expected to be as

Source: U.S. Department of Energy, Oak Ridge National Laboratory
[a]Building use types with 10th to 90th percentile metrics account for over 60% of the water use in U.S. buildings.
[b]Confidence in percentile values typically decreases as number of observations (# Obs) decreases. Thus, percentile values where # Obs <20, and especially when very low, should be considered as indicators of values and not necessarily reliable values for benchmarking.
[c]NA: Data were not available to enable a determination of this value.

sensitive to regional variances, which may make national metrics more reliable for local comparisons, but that is yet to be proven. As more data become available, it will be possible to expand on the metrics in Table 5 and better evaluate their ability to be reliable comparators for indicating water efficiency performance of individual buildings. Note the metrics in Table 5 are developed from rather small samples in all cases, reflecting the limited amount of current publicly available water use data from which such metrics can be developed.

5. SURVEYS AND AUDITS

This section provides guidance on conducting building surveys and describes the levels of intensity of investigation.

Energy and Water Audits

The objective of an energy and water audit is to identify opportunities to reduce energy and water use and/or cost. The results should provide the information needed by an owner/operator to decide which recommendations to implement. Energy and water audits may include the following:

1. Collection and analysis of historical energy and water use
   - Review of more than one year of utility bills (preferably three years)
   - Review of billing rate class options with utility
   - Review of monthly patterns for irregularities
   - Development of target goals for energy, water, demand, and cost indices
2. Study of the building and its operational characteristics
   - Acquiring a basic understanding of the mechanical and electrical systems
   - A walk-through survey to become familiar with construction, equipment, operation, and maintenance
   - Meeting with the owner/operator and occupants to learn of special problems or needs
   - Identifying any required repairs to existing systems and equipment
3. Identifying potential modifications to reduce energy and water use or cost
   - Identifying low-/no-cost changes to the facility or to operating and maintenance procedures
   - Identifying potential equipment retrofit opportunities
   - Identifying training required for operating staff
   - A rough estimate of the breakdown of energy and water consumption for significant end-use categories
4. An engineering and economic analysis of potential modifications
   - For each practical measure, determine resultant savings
   - Estimate of effects on building operations and maintenance costs
   - Financial evaluation of estimated total potential investment
5. A rank-ordered list of all possible energy and water savings modifications
   - Selection of those that may be considered practical by the building owner
   - Assume that modifications with highest operational priority and/or best return on investment will be implemented first
   - Preliminary implementation costs and savings estimates
6. Results report
   - Description of building, operating requirements, and major energy- and water-using systems
   - Clear statement of savings from each modification and assumptions on which each is based
   - Review of list of practical modifications with the owner
   - Prioritizing modifications in recommended order of implementation
   - Recommend measurement and verification methods

ASHRAE (2011) identifies the following four levels of effort in the energy audit process, which can also be applied to water audits.

Preliminary Energy Use Analysis. This involves analysis of historic utility use and cost and development of the energy utilization index (EUI) of the building. Compare the building's EUI to similar buildings to determine whether further engineering study and analysis are likely to produce significant energy savings.

Level I: Walk-Through Analysis. This assesses a building's current energy cost and efficiency by analyzing energy bills and briefly surveying the building. The auditor should be accompanied by the building operator. Level I analysis identifies low-/no-cost measures and capital improvements that merit further consideration, along with an initial estimate of costs and savings. The level of detail depends on the experience of the auditor and the client's specifications. The Level I audit is most applicable when there is some doubt about the energy savings potential of a building, or when an owner wishes to establish which buildings in a portfolio have the greatest potential savings. The results can be used to develop a priority list for a Level II or III audit.

Level II: Energy Survey and Engineering Analysis. This includes a more detailed building survey and energy analysis, including a breakdown of energy use in the building, a savings and cost analysis of all practical measures that meet the owner's constraints, and a discussion of any effect on operation and maintenance procedures. It also lists potential capital-intensive improvements that require more thorough data collection and analysis, along with an initial judgment of potential costs and savings. This level of analysis is adequate for most buildings.

Level III: Detailed Analysis of Capital-Intensive Modifications. This focuses on potential capital-intensive projects identified during Level II and involves more detailed field data gathering and engineering analysis. It provides a detailed projection of cost and savings, with the high level of confidence necessary for major capital investment decisions.

The levels of energy audits do not have sharp boundaries. They are general categories for identifying the type of information that can be expected and an indication of the level of confidence in the results. In a complete energy management program, Level II audits should be performed on all facilities.

A thorough systems approach produces the best results. This approach has been described as starting at the end rather than at the beginning. For example, consider a factory with steam boilers in constant operation. An expedient (and often cost-effective) approach is to measure the combustion efficiency of each boiler and to improve boiler efficiency. Beginning at the end requires finding all or most of the end uses of steam in the plant, which could reveal the existence of considerable waste, such as venting to the atmosphere, defective steam traps, uninsulated lines, and lines through unused heat exchangers. Eliminating end-use waste can produce greater savings than improving boiler efficiency.

A detailed process for conducting energy audits is outlined in ASHRAE (2011).

An effective water audit estimates and reduces water use that is not accounted for, including loss through leaks, unmetered use, and inoperative system control (blow-off valves, etc.). In addition to the standard procedure above, information gathering before a water audit may include the following items (NCDENR 1998):

- Inventory of plumbing fixtures, and water-use equipment with the manufacturers' flow rate
- Review of plumbing risers, diagrams, and irrigation plans
- Obtaining the service vendors' contact information
- For service providers, recording number of meals served, number of rooms, and occupancy data (restaurants, hotels, hospitals, military base, schools, etc.) and calculation of the water usage per service
- For manufacturers, recording the number of products and calculation of the water usage per product
- Identifying the amount of water used to provide services or products

6. IMPROVING DISCRETIONARY OPERATIONS

Basic Energy and Water Management

Control Energy System and Water Use. The most effective method to reduce energy and water costs is through discretionary operations, such as turning off equipment when not needed. Improvement of operations by discretionary means should not compromise safety or environmental health. Ways to conserve energy and water include (but are not limited to) the following:

- Shutting down HVAC&R systems when operation is not required
- Reducing air leakage
- Reducing ventilation rates during periods of low occupancy
- Shutting down exhaust fans when they are not required
- Sealing or repairing leaks in ducts and pipes
- Reducing water leakage
- Turning off lighting: removal of unnecessary lighting, addition of switched circuits and dimming capabilities, use of motion sensors and light-sensitive controls
- Use of temperature setup and setback
- Cooling with outdoor air (free cooling)
- Sealing unused vents and ducts to the outside
- Performing proper maintenance and tune up before heating and cooling seasons begin
- Taking transformers offline during idle periods

Purchase Lower-Cost Energy. This is the second most effective method for reducing energy costs. Building operators and managers must understand all the options for purchasing energy and design systems to take advantage of changing energy costs. The following options should be considered:

- Choosing or negotiating lower-cost utility rates
- Procuring electricity or fuels through brokers
- Correcting power factor penalties
- Controlling peak electricity billing demand
- Utility-sponsored demand response programs
- Transportation and interruptible natural gas rates
- Cogeneration
- Lower-cost liquid fuels
- Increasing volume for on-site storage
- Avoiding sales or excise taxes where possible
- Incentive rebates from utilities and manufacturers

Optimize Energy Systems Operation and Water Use. The third most effective method for reducing costs is to tune systems to optimal performance, an ongoing process combining training, preventive maintenance, and system adjustment. Tasks for optimizing performance include

- Training operating personnel on equipment operations and maintenance
- Tuning combustion equipment and adjusting gas burners to operate at optimal efficiency
- Following an established maintenance program for all equipment
- Reusing condensate or process water for heating or cooling applications (when this would not compromise health)
- Cleaning or replacing filters
- Cleaning fan blades and ductwork
- Cycling ventilation systems to coincide with occupied spaces
- Fine-tuning water treatment based on test results
- Periodically monitoring runtimes to prevent short-cycling

Purchase Efficient Replacement Systems. This method is more expensive than the other three, presents energy managers with the greatest liability, and may be less cost effective. It is critical to ensure that possible equipment or system replacements are objectively evaluated to confirm both the replacement costs and benefits to the owner. The optimum time for replacing less-efficient equipment and related components is near the end of its expected life or when major repairs are needed. Systems commonly replaced include

- Lighting systems and lamps
- Heating and cooling equipment
- Faucets and water fixtures
- Water heaters and pumps
- Energy distribution systems (pumps and fans)
- Motors
- Thermal envelope components such as insulation and windows
- Building automation control systems, energy management systems, and lighting control systems

Optimizing More Complex System Operation

As the complexity of building systems increases, additional strategies are needed to optimize energy systems. According to ASHRAE *Guideline* 0-2005, approaches include **recommissioning** (applied to a project that has been delivered using the commissioning process), **retrocommissioning** (applied to an existing facility that was not previously commissioned), and **ongoing commissioning** (continuation of the commissioning process well into the occupancy and operations phase to verify that a project continues to meet current and evolving owner's project requirements). See Chapter 44 for more information.

These approaches typically require a strong team effort from the facility staff and third-party consultants to identify and fix comfort problems as well as aggressively optimize HVAC operation and control. Some important measures typically include

- Optimizing supply temperature reset schedules
- Optimizing duct static pressure reset schedules
- Optimizing pump control and hydronic system pressure setback
- Optimizing terminal unit settings and control
- Optimizing sequencing and hydronic system temperature reset schedules for heating, cooling, and domestic water
- Identifying and repairing stuck or leaky valves and dampers
- Training operating personnel in optimum operating strategies
- Setting up monitoring and reporting of key system performance indicators

Implementing these measures has been found to reduce energy use by an average of about 20% (Claridge et al. 1998). Approaches to commissioning and optimizing operation of existing buildings can be found in ASHRAE *Guideline* 1.1-2007, Claridge and Liu (2000), Haasl and Sharp (1999), Kurt et al. (2003), Liu et al. (1997), Poulos (2007), and Tseng (2005).

7. ENERGY- AND WATER-EFFICIENCY MEASURES

Identifying Energy- and Water-Efficiency Measures

It is important to apply strategy in identifying energy-efficiency measures (EEMs) and water-efficiency measures (WEMs). Various EEMs and WEMs can be quantitatively evaluated from end-use energy and water use breakdown profiles, and this is often the most strategic starting point. Focusing on end-use systems that consume the bulk of site energy/water is likely to yield larger potential savings than spending time assessing systems that consume little energy or water

When identifying EEMs and WEMs, a useful strategy is to do the following:

1. **Minimizing waste** focuses on matching the need, which usually involves reducing equipment operation through decreasing hours of operation, turning unnecessary equipment off, reducing running hours or flows, fixing leaks, and turning set points up or down.
2. **Maximizing efficiency** involves lowering power requirements of equipment. This may include cleaning and tuning equipment, and replacing old equipment with more efficient technology.
3. **Optimizing supply** improves how energy or water is supplied to a system. This may involve heat recovery, water reclamation, procurement of lower-cost energy, and conversion to renewable energy technologies, such as solar or geothermal.

For example, when working with a hydronic heating system using a natural gas boiler, the auditor should first identify measures that minimize waste (e.g., lower set points, night setback, warm weather shutdown), then look to measures that maximize efficiency (e.g., replacing with high-efficiency condensing boilers), and finally measures that optimize supply (e.g., recovering waste process heat to offset natural gas consumption). If these three steps are not applied in this order, the auditor risks missing the most cost-effective strategies for improving energy performance. Also, the minimizing waste measures are often low or no cost, so it is important to first give attention to these.

With mechanical measures, starting the assessment at the point of end use is often the most strategic approach. For a fan system with zone-level flow and temperature control, the auditor should start by assessing the system at the zone (room) level first. Once zone-level operation has been optimized, the auditor should focus on upstream components such as the fan, economizer, and heating/cooling coils. In this example, if EEMs were instead considered at the fan level first, subsequent EEMs identified at the zone level may alter the impact of the fan-level EEMs, leading to rework or lost opportunity.

Accurate energy savings calculations can be made only if system interaction is allowed for and fully understood. Annual simulation models may be necessary to accurately estimate the interactions between various EEMs. ASHRAE *Standard* 100 provides a list of EEMs for use in models.

Using average costs per unit of energy in calculating the energy cost avoidance of a particular measure is likely to result in erroneous calculations, because actual energy cost avoidance may not be proportional to the energy saved, depending on the billing method for energy used. In addition, previously implemented energy-efficiency measures should be evaluated to (1) ensure that devices are in good working order and measures are still effective, and (2) consider revising them to reflect changes in technology, building use, and/or energy cost.

WEMs may be identified by looking at common uses of water in facilities. Typical water use by commercial, institutional, and industrial customers include

1. Domestic (restrooms, kitchens, and laundries)
2. Cooling and heating
3. Landscaping irrigation
4. Process-related

Evaluating Energy- and Water-Efficiency Measures

In establishing EEM and WEM priorities, the capital cost, cost-effectiveness, effect on indoor environment, and resources available must be considered. Factors involved in evaluating the desirability of measures are

- Rate of return (simple payback, life-cycle cost, net present value)
- Total savings (energy, water, cost avoidance)
- Initial cost (required investment)
- Other benefits (safety, comfort, improved system reliability, improved productivity)
- Alignment with corporate goals
- Life of the measure
- Energy/water measurement and verification requirements
- Liabilities (increased maintenance costs, potential obsolescence)
- Risk of failure (confidence in predicted savings, rate of increase in energy costs, maintenance complications, success of others with the same measures)

Project success also depends on the availability of

- Management attention, commitment, and follow-through
- Technical expertise
- Personnel, and involvement and input of operational staff throughout the project
- Investment capital

Some owners are reluctant to implement EEMs and WEMs because of bad experiences with prior projects. To reduce the risk of failure, documented performance of measures in similar situations should be obtained and evaluated. One common problem is that consumption for individual end uses is overestimated during the audit or evaluation phase, and the predicted savings are not achieved once implemented. When doubt exists about energy or water consumption, temporary monitoring or spot measurements should be taken and evaluated.

Interactive Effects. Electrical equipment and appliances, from lighting systems and office equipment to motors and water heaters, provide useful services; however, the electrical energy they use eventually appears as heat within the building, which can either be useful or detrimental, depending on the season. In cold weather, heat produced by electrical equipment can help reduce the load on the building's heating system (albeit in an uncontrolled manner and potentially at higher cost per unit of heat). In contrast, during warm weather, it adds to the air-conditioning load.

Energy-efficient equipment and appliances consume less energy to produce the same useful work, and also produce less heat. Thus, efficient electrical equipment may increase the load on heating systems in winter and may reduce the load on air-conditioning systems in summer. Effects of energy-efficient equipment and appliances on energy use for building heating and air conditioning systems are commonly called **interactive effects** or **cross effects**.

Heat from electrical equipment and appliances (lighting systems and office equipment to motors and water heaters) eventually appears as heat load in the building, which can either be useful or detrimental, depending on the season. In cold weather, heat produced by electrical equipment can help reduce the load on the building's heating system. In contrast, during warm weather, it adds to the air-conditioning load.

When considering the overall net savings of an energy-efficiency measure, it is important to consider its interactive effects on building heating, cooling, and refrigeration systems. Weighing the interactive effects results in better-informed decisions and realistic expectations of savings.

The percentage of heat that is useful in a specific building or room depends on several factors, including the following:

- Location of light fixtures
- Location of heaters and their thermostats or other sensors
- Type of ceiling
- Size of building
- Whether room is an interior or exterior space
- Internal heat gains (people, equipment, solar)
- Extent of heating and cooling seasons
- Type of heating, ventilation, and air-conditioning system used in each room

Unfortunately, interactive effects are often quite complex and may require assessment by a specialist; for details, see Rundquist et al. (1993).

Exploring Financing Options

Financing alternatives also need to be considered. When evaluating proposed projects, particularly those with a significant capital cost, it is important to include a life-cycle cost analysis. This not only provides good information about the financial merits (or otherwise) of a project, but also assures management that the project has been carefully considered and evaluated before presentation.

Several life-cycle cost procedures are available. Chapter 38 contains details on these and other factors that should be considered in such an analysis.

Capital for audits and efficiency improvements is often available from various public and private sources, and can be accessed through a wide and flexible range of financing instruments. There are variations and combinations, but the five common mechanisms for financing investments in energy efficiency are the following:

- **Internal funds**, or direct allocations from an organization's own internal capital or operating budget
- **Debt financing**, with capital borrowed directly by an organization from private lenders
- **Lease** or **lease-purchase agreements**, in which equipment is acquired through an operating or financing lease with little or no up-front costs, and payments are made over five to ten years
- **Energy performance contracts**, in which improvements are financed, installed, and maintained by a third party, which guarantees savings and payments based on those savings
- **Utility (or other) incentives**, such as rebates, grants, public/private partnerships, or other financial assistance offered by an energy utility or public benefits fund for design and purchase of energy/water-efficient systems and equipment

An organization may use several of these financing mechanisms in various combinations. The most appropriate set of options depends on the type of organization (public or private), size and complexity of a project, internal capital constraints, in-house expertise, and other factors (Turner 2001).

8. IMPLEMENTING ENERGY-EFFICIENCY MEASURES

When all desirable EEMs have been considered and a list of recommendations developed, a report should be prepared for management. Each recommendation should include the following:

- Present condition of the system or equipment to be modified
- Recommended action
- Who should accomplish the action
- Necessary documentation or follow-up required
- Measurement and verification protocol to be used
- Potential interferences to successful completion
- Disruption to workplace or production
- Staff effort and training required
- Risk of failure
- Interactions with other end uses and EEMs
- Economic analysis (including payback, investment cost, and estimated savings figures) using corporate economic evaluation criteria
- Schedule for implementation

The energy manager must be prepared to sell the plans to upper management. Energy-efficiency measures must be financially justified if they are to be adopted. Every organization has limited funds available that must be used in the most effective way. The energy manager competes with others in the organization for the same funds. A successful plan should be presented in a form that is easily understood by the decision makers. Finally, the energy manager must present nonfinancial benefits, such as improved product quality or the possibility of postponing other expenditures.

After approval by management, the energy manager directs the completion of energy-efficiency measures. If utility rebates are used, the necessary approvals should be acquired before proceeding with the work. Some measures require that an architect or engineer prepare plans and specifications for the retrofit. The package of services required usually includes drawings, specifications, assistance in obtaining competitive bids, evaluation of the bids, selection of contractors, construction observation, final check-out, and assistance in training personnel in the proper application of the revisions.

9. MONITORING RESULTS

Once energy-efficiency measures are under way, procedures need to be established to record (regularly) energy consumption and costs for each building and/or end-use category in a manner consistent with functional cost accountability. Turner et al. (2001) found that consumption increased by more than 5% over two years because of component failures and controls changes after implementing optimum practices in a group of 10 buildings. Data may be obtained from the utility, but additional metering may be needed to monitor energy consumption accurately. Metering can use devices that automatically read and transmit data to a central location, or less expensive metering devices that require regular readings by building maintenance and/or security personnel. Costs for automatic metering devices, such as adding points to a DDC system, must be weighed against the benefits. Many energy managers find it helpful to collect energy consumption information hourly.

The energy manager should review data while they are current and take immediate action if profiles indicate a trend in the wrong direction. These trends could be caused by uncalibrated controls, changes in operating practices, or mechanical system failure, which should be isolated and corrected as soon as possible.

10. EVALUATING SUCCESS AND ESTABLISHING NEW GOALS

Comparing facility performance before and after implementing EEMs helps keep operating staff on track with their energy-efficiency efforts, ensuring that performance is maintained. Evaluating and reporting energy performance involves four steps:

1. Establishing key performance indicators
2. Tracking performance
3. Developing or updating goals
4. Reporting

Establishing Key Performance Indicators

It is important to determine performance factors of the energy management program. These are expressed in terms of key performance indicators (KPIs). The definition of key performance indicators determines what data need to be collected, how often to collect it, and how to present it to senior management. Suggested basic key performance indicators are

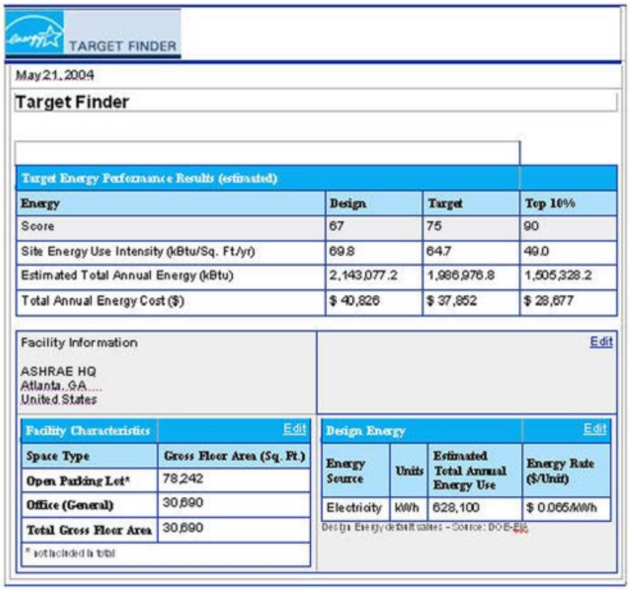
- Energy use index (EUI): total energy use per unit of gross floor area, or per unit of production
- Water use index (WUI): total water use per unit of gross floor area, per occupant, or per unit of production
- Cost utilization index (CUI): total energy or water cost per unit of total gross floor area, or per unit of production
- Electrical energy use per unit of total gross floor area, or per unit of production

Energy Policy Act of 2005. The Energy Policy Act (109th Congress 2005) set goals for federal buildings to decrease their energy consumption by 2% per year between 2006 and 2015, compared to a baseline of 2004 consumption. Thus, by 2010, for example, the target percentage reduction from 2004 values was 10%. For this initiative, the following sample KPI definitions could be used:

- 2004 benchmark measurement (energy use per unit area) reduced by 4% to set 2007 target, and by 10% to set the 2010 target, and by 16% to set the 2013 target
- Energy use data, summed monthly and annually for reporting against targets

Energy Independence Security Act of 2007. The Energy Independence Security Act (110th Congress 2007) set higher goals than the Energy Policy Act for federal buildings to decrease their energy consumption by 5% between 2007 and 2008 and 3% per year between 2008 and 2015, compared to a baseline of 2004 consumption. Thus, by 2015, for example, the target percentage reduction from 2004 values was 30%. For this initiative, the same sample KPI definitions used for the Energy Policy Act could be used.

Executive Order 13693, March 2015. Executive Order 13693 (NARA 2015) further set goals for U.S. federal agencies to develop and implement strategic energy sustainability plans through 2025 to reduce buildings' energy use intensity (EUI), improve buildings' water use efficiency and management, increase renewable energy use, obtain net-zero-energy buildings by 2030, and ensure that all products and services are ENERGY STAR or Federal Energy Management Program (FEMP) designated. Water efficient products may also be designated by the WaterSense program.



TARGET FINDER

May 21, 2004

Target Finder

Target Energy Performance Results (estimated)			
Energy	Design	Target	Top 10%
Score	67	75	90
Site Energy Use Intensity (kBtu/Sq. Ft./yr)	69.8	64.7	49.0
Estimated Total Annual Energy (kBtu)	2,143,077.2	1,986,976.8	1,505,328.2
Total Annual Energy Cost ($)	$ 40,826	$ 37,852	$ 28,677

Fig. 4 ENERGY STAR Rating for Atlanta Building

ENERGY STAR Tools. The U.S. Environmental Protection Agency's (EPA) ENERGY STAR web site offers the free online benchmarking tool, Target Finder (I-P units only; accessible from portfoliomanager.energystar.gov/pm/targetFinder). This tool compares actual building performance to target values, and to other similar buildings. Figure 4 shows sample results for the Atlanta example building's general office space (omitting the computer center's floor space and electricity use). ENERGY STAR also offers an online Portfolio Manager (portfoliomanager.energystar.gov), which provides secure performance data management and benchmarking for multiple buildings. Annual benchmarking with these (or similar) tools helps track improvements, both over time and in comparison with other buildings.

Building Energy Labels

The ASHRAE Building Energy Quotient (Building EQ) labeling program rates new and existing buildings (Jarnagin 2009). Like the EPA's ENERGY STAR program, Building EQ focuses solely on energy, but provides additional features, including potential side-by-side comparison of operational and asset (as-designed) ratings; peak-demand reduction and demand management opportunities; on-site renewable energy; indoor environmental quality indicators; and a list of operational features, including commissioning activities, energy-efficiency improvements, and information on improving performance. The Building EQ scale allows differentiation among buildings at the highest levels of performance and encourages the design and operation of net-zero-energy buildings.

The Building EQ program provides an easily understood scale to convey a building's energy use to the public. Through an on-site assessment, the building owner is provided with building-specific information that can be used to improve the building. Documentation on previous energy-efficiency upgrades and commissioned systems is also included. With procedures for both an asset and operational rating, building owners can make side-by-side comparisons that could further reconcile differences between designed and measured energy use. More information is available at www.ashrae.org/technical-resources/building-eq/building-eq-portal.

The label itself is the most visible aspect of the program (Figure 5). It is simple to understand and is targeted at the general public. It

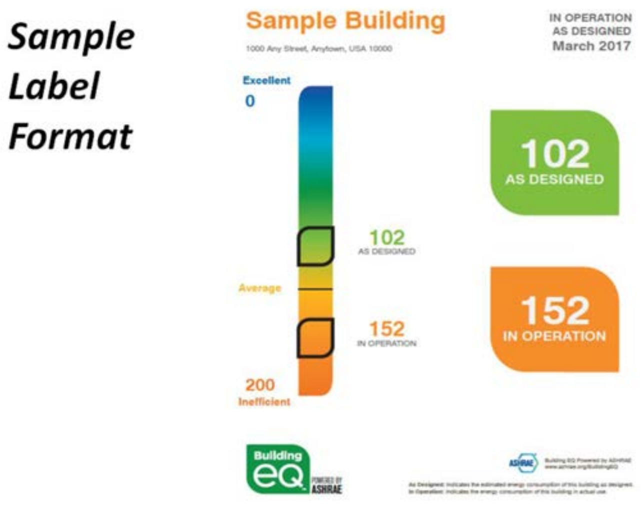

Fig. 5 ASHRAE Building EQ Label

could be posted in a building lobby and could satisfy compliance with many of the programs being developed at the state and local level requiring display of energy use. The certificate contains technical information that explains the score on the label and provides information useful to the building owner, prospective owners and tenants, and operations and maintenance personnel. This includes many of the value-added features described previously. The documentation accompanying the label and certificate provides background information useful for engineers, architects, and technically savvy building owners or prospective owners in determining the current state of the building and opportunities for improving its energy use. More information is available at buildingeq.com/.

Throughout the European Union, the European Commission's directive on the energy performance of buildings (EPBD) has been in effect since January 4, 2006. Despite difficulties, all EU member states have brought into effect national laws, regulations, and administrative provisions for setting minimum requirements on the energy performance of new buildings and for existing buildings that are being renovated, as well as energy performance certification of buildings. Additional requirements include regular inspection of building systems and installations, assessment of existing facilities, and provision of advice on possible improvements and alternative solutions. The objective is to properly design new buildings and renovate existing buildings in a manner that will use the minimum nonrenewable energy, produce minimum air pollution as a result of the building operating systems, and minimize construction waste, all with acceptable investment and operating costs, while improving the indoor environment for comfort, health, and safety.

An energy performance certificate (EPC) is issued when buildings are constructed, sold, or rented out. The EPC documents the energy performance of the building, expressed as a numeric indicator that allows benchmarking. The certificate includes recommendations for cost-effective improvement of the energy performance, and it is valid for up to 10 years.

According to the EPBD, minimum energy performance requirements are set for new buildings and for major renovations of large existing buildings in each EU member state. Energy performance should be upgraded to meet minimum requirements that are technically, functionally, and economically feasible. In the case of large new buildings, alternative energy supply systems should be considered (e.g., decentralized energy supply systems based on renewable energy, combined heat and power, district or block heating or cooling, heat pumps). The concerted action (CA) EPBD that was launched by the European Commission provides updated information on the implementation status in the various European countries (www.epbd-ca.eu).

Tracking Performance

The next step is to create a tracking mechanism to provide high-level KPI views, giving an overall indication of energy performance. Daily monitoring can be a valuable, proactive tool. Most building automation systems can monitor energy performance and notify the energy engineer when energy usage is off track.

For example, using the data presented in Table 1, a daily target usage/day could be determined based on outside air temperature and building occupancy schedule. If the daily use rises above the target use by a predetermined amount, the building automation system can indicate an alarm and send a notification. The energy manager can then investigate the cause of the discrepancy and correct any operational errors before long-term performance is affected. When implementing this type of performance-monitoring strategy, it is important that the measurement and verification plan provide standard operating procedures (SOPs) to facilitate troubleshooting of energy performance alarms. Procedures are discussed in ANSI/ASHRAE *Standard* 105.

Establishing New Goals

Implementing the baseline model is a three-step process: (1) the baseline period is selected, (2) the baseline model is created, and (3) one or more target models are identified to track energy performance. The baseline period should most closely reflect the current or expected building use and occupancy. Utility bill data can be used to create a steady-state baseline model of energy consumption for each building. Steady-state models are useful when using monthly, weekly, or daily data. Utility bills for an entire year are collected and used for baseline development. Many energy managers use spreadsheets or software packages to compile and compare the data. For more information on energy estimating using steady-state, data-driven models, see Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals*.

Cooling degree-days (CDDs) and heating degree-days (HDDs) are commonly used to track successes compared to EEM targets with respect to weather-dependent energy consumption. Local CDD and HDD information is traditionally based on a balance point of 18°C, which is not typically the actual balance point for any commercial or residential building; therefore, regional or local HDD values are only a general reference point. A building's weather-affected energy consumption may be calculated by using spreadsheets, regression analysis, or building energy modeling software.

For larger, more complex facilities, regression analysis can be used to analyze energy consumption if the energy manager has the analytical expertise. Through linear regression, utility bills are normalized to their daily average values. Repeated regression is done until the regression data represent the best fit to the utility bill data. Figure 6 shows the scatter plot of a best-fit baseline and target models. In this example, cooling degree-days significantly affected building energy consumption, with a best fit for a base temperature (balance point) of 12°C (Sonderegger 1998). Reducing the slope and intercept constants of the baseline by 20% creates a straight-line model equation that represents a target goal for a 20% energy reduction.

The utility bill data steady-state model is also referred to as whole-building measurement and verification. This section offers only an introduction to the subject. More information about this process can be found in ASHRAE *Guideline* 14 and EVO (2002).

Reporting

When developing presentation materials to document energy performance, make sure that report content shows performance as related to key performance indicators (KPIs) used by the organiza-

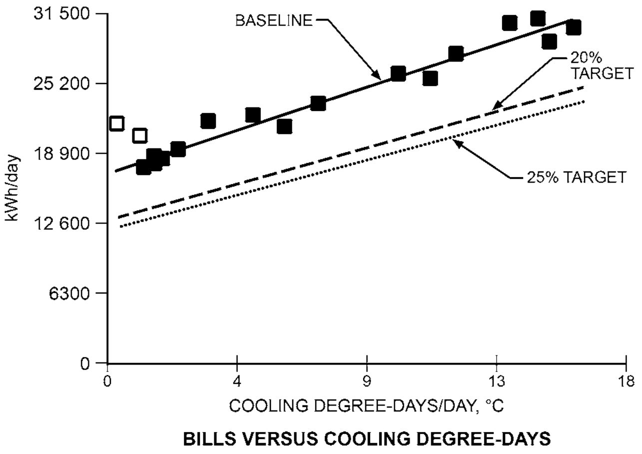

Fig. 6 Scatter Plot, Showing Best-Fit Baseline Model and Target Models

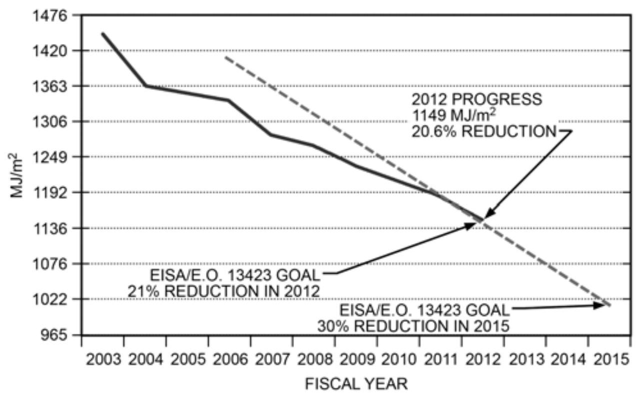

Fig. 7 Progress Toward Energy Reduction Goals for Federal Standard Buildings

tion. Reports should also be pertinent to the audience. Whereas a report to the company's administration would show how the energy management program affects operating and maintenance costs, a separate report to the operations staff might show how their daily decisions and actions change daily load profiles.

Figure 7 shows progress toward energy reduction goals for federal buildings presented to the U.S. Congress for fiscal year 2001 (DOE 2004). The figure compares energy performance against energy goals established in 1999.

Reports must be easy to understand by their readers. Often, less is more. Keep management aware of the progress of changes to resource consumption, utility costs, and any effects (positive or negative) on the indoor environment as perceived by staff. Provide information on any major activities, savings to date, and future planned activities. Provide narrative reports with pie charts or bar graphs of cost per resource.

11. BUILDING EMERGENCY ENERGY USE REDUCTION

This section provides information to help building owners and operators maintain the best operating condition for the facilities during various energy emergencies. The need for occasional short-term reductions in energy use has increased because of rising energy costs and supply reductions (voluntary or mandatory) or equipment failures. In limited instances, utilities have implemented rolling blackouts, requested voluntary reductions, and asked users to operate emergency generators.

Implementing Emergency Energy and Water Use Reductions

Each building manager or operator should identify an individual with the necessary authority and knowledge to review and fit recommendations into a building energy management plan. Because energy and water reduction requirements may arise with little or no advance notice, contingency plans should be developed and reviewed by the energy team. Each type of energy or water emergency requires a specific plan to reduce building energy use and still maintain the best possible building environment. The plan should include measures to reduce specific types of energy and water use in the building, as well as provisions for both slight and major energy and water use reduction. In some cases, existing building energy management systems can be used to implement demand shedding. The plan should be tested regularly. The following steps should be taken in developing a building emergency energy and water use reduction plan:

1. Develop a list of measures applicable to each building.
2. Estimate the amount and type of energy savings for each measure and appropriate combination of measures (e.g., account for air-conditioning savings from reduced lighting and other internal loads, account for water savings from reduced water ornamental and nonessential irrigation systems). Tabulate demand and usage savings separately for response to different types of emergencies.
3. For various levels of possible energy emergency, develop a plan that maintains the best building environment under the circumstances. Develop the plan so that actions taken can be energy- and water-source-specific. That is, group actions to be taken to reduce energy consumption for each type of energy used in the building. Include both short- and long-term measures in the plan. Operational changes may be implemented quickly and prove adequate for short-term emergencies.
4. Experiment with the plan; record energy consumption and demand reduction data, and revise the plan as necessary. Much of the experimentation may be done on weekends to minimize disruption.
5. Meet with the local utility provider(s) and back-up fuel suppliers to review the plan.
6. Meet with building occupants annually to review the plan to ensure that actions taken do not cause major disruptions, particularly with equipment or systems identified as mission critical or essential to the building or company operation, or compromise environmental health, life safety, or security provisions. Establish a procedure for notification of building occupants before actions are taken.
7. Be certain that there is a plan to minimize entrapment of occupants in elevators in case of emergency disruptions.
8. Review the plan annually with building security and the fire department to ensure that emergency efforts are not hindered by the plan and that security or emergency people know what to expect (reduced lighting, lower temperatures, elevators out of operation, etc.).
9. Review the plan with the designated environmental health and safety official to ensure that emergency efforts do not compromise the health of personnel working or visiting the building.
10. When preparing the plan, **do not**
    - Take lighting fixtures out of service that are on night lighting circuits, provide lighting for security cameras, or provide egress lighting during a power failure
    - Remove elevators or lifts from service that will be required for emergency or ADA purposes

- Reduce ventilation or exhaust in laboratories or other areas where hazardous conditions exist
- Remove electrical service provided to fire detection, alarm, and annunciation systems
- Alter or remove water flow to fire protection system

Some measures can be implemented permanently. Depending on the level of energy emergency and the building priority, the following actions may be considered in developing the plan for emergency energy reduction:

General

- Change operating hours
- Move personnel into other building areas (consolidation)
- Ensure that emergency generators are tuned up and run frequently enough to increase dependability, service the expected electrical load, and keep alternative fuel supply at optimal level
- Shut off nonessential equipment
- Review the amount of uninterruptible power supply (UPS) time available for critical equipment, and upgrade if necessary

Thermal Envelope

- Use all existing blinds, draperies, and window coverings
- Install interior window insulation and ensure that windows do not have broken sealant creating envelope exposures
- Caulk and seal around unused exterior doors and windows (but do not seal doors required for emergency egress or that may be required by the fire department in an emergency)
- Install solar shading devices in summer
- Seal all unused vents and ducts to outside

HVAC Systems and Equipment

- Modify controls or control set points to raise and lower temperature and humidity as necessary
- Shut off or isolate all nonessential equipment and spaces
- Lower thermostat set points in winter
- Raise chilled-water temperature
- Lower hot-water temperature (*Note*: Keep hot-water hydronic temperature higher than 63°C if a noncondensing gas boiler is used)
- Reduce or eliminate reheat and recool
- Reduce (and eliminate during unoccupied hours) mechanical ventilation and exhaust airflow
- Raise thermostat set points in summer or turn cooling equipment off

Lighting Systems

- Evaluate overlit areas and remove lamps or reduce lamp wattage
- Use task lighting where appropriate
- Move building functions to exterior or daylit areas
- Turn off electric lights in areas with adequate natural light
- Revise building cleaning and security procedures to minimize lighting periods
- Consolidate parking and turn off unused parking security lighting

Water Use Systems

- Shut off ornamental water displays, such as fountains. Ensure that lack of usage does not result in the introduction of pathogens (e.g. bacterial growth) in the plumbing system
- Reduce or eliminate landscape irrigation
- Reuse water if possible
- Monitor water usage frequently and identify possible leaks

Special Equipment

- Take transformers offline during periods of nonuse
- Shut off or regulate the use of vertical transportation systems
- Shut off unused or unnecessary equipment, such as photocopiers, music systems, and computers
- Reduce or turn off potable hot-water supply

Building Operation Demand Reduction

- Sequence or interlock heating or air-conditioning systems
- Disconnect or turn off all nonessential loads
- Reduce lighting levels
- Preheat or precool, if possible, before utility-imposed emergency periods

When Power Is Restored

- To prevent overloading the system, turn equipment back on gradually
- Test and verify proper operation of critical equipment, security, and fire and smoke alarms
- Check monitors on temperature-sensitive equipment
- Discuss lessons learned with staff and make any necessary changes to emergency plan
- Restock whatever emergency supplies were used, including alternative fuels

CHAPTER 38

OWNING AND OPERATING COSTS

Operating Costs 38.4
Maintenance Costs 38.7
Refrigerant Phaseouts 38.8
Other Issues 38.8
Economic Analysis Techniques 38.11
Symbols 38.13

OWNING and operating cost information for the HVAC system should be part of the investment plan of a facility. This information can be used for preparing annual budgets, managing assets, and selecting design options. Table 1 shows a representative form that summarizes these costs.

A properly engineered system must also be economical, but this is difficult to assess because of the complexities surrounding effective money management and the inherent difficulty of predicting future operating and maintenance expenses. Complex tax structures and the time value of money can affect the final engineering decision. This does not imply use of either the cheapest or the most expensive system; instead, it demands intelligent analysis of financial objectives and the owner's requirements.

Certain tangible and intangible costs or benefits must also be considered when assessing owning and operating costs. Local codes may require highly skilled or certified operators for specific types of equipment. This could be a significant cost over the life of the system. Similarly, intangible items such as aesthetics, acoustics, comfort, safety, security, flexibility, and environmental impact may vary by location and be important to a particular building or facility.

1. OWNING COSTS

The following elements must be established to calculate annual owning costs: (1) initial cost, (2) analysis or study period, (3) interest or discount rate, and (4) other periodic costs such as insurance, property taxes, refurbishment, or disposal fees. Once established, these elements are coupled with operating costs to develop an economic analysis, which may be a simple payback evaluation or an in-depth analysis such as outlined in the section on Economic Analysis Techniques.

Initial Cost

Major decisions affecting annual owning and operating costs for the life of the building must generally be made before completing contract drawings and specifications. To achieve the best performance and economics, alternative methods of solving the engineering problems peculiar to each project should be compared in the early stages of design. Oversimplified estimates can lead to substantial errors in evaluating the system.

The evaluation should lead to a thorough understanding of installation costs and accessory requirements for the system(s) under consideration. Detailed lists of materials, controls, space and structural requirements, services, installation labor, and so forth can be prepared to increase accuracy in preliminary cost estimates. A reasonable estimate of capital cost of components may be derived from cost records of recent installations of comparable design or from quotations submitted by manufacturers and contractors, or by consulting

Table 2 Initial Cost Checklist

Energy and Fuel Service Costs	
	Fuel service, storage, handling, piping, and distribution costs
	Electrical service entrance and distribution equipment costs
	Total energy plant
Heat-Producing Equipment	
	Boilers and furnaces
	Steam-water converters
	Heat pumps or resistance heaters
	Makeup air heaters
	Heat-producing equipment auxiliaries
Refrigeration Equipment	
	Compressors, chillers, or absorption units
	Cooling towers, condensers, well water supplies
	Refrigeration equipment auxiliaries
Heat Distribution Equipment	
	Pumps, reducing valves, piping, piping insulation, etc.
	Terminal units or devices
Cooling Distribution Equipment	
	Pumps, piping, piping insulation, condensate drains, etc.
	Terminal units, mixing boxes, diffusers, grilles, etc.
Air Treatment and Distribution Equipment	
	Air heaters, humidifiers, dehumidifiers, filters, etc.
	Fans, ducts, duct insulation, dampers, etc.
	Exhaust and return systems
	Heat recovery systems
System and Controls Automation	
	Terminal or zone controls
	System program control
	Alarms and indicator system
	Energy management system
Building Construction and Alteration	
	Mechanical and electric space
	Chimneys and flues
	Building insulation
	Solar radiation controls
	Acoustical and vibration treatment
	Distribution shafts, machinery foundations, furring

commercially available cost-estimating guides and software. Table 2 shows a representative checklist for initial costs.

Analysis Period

The time frame over which an economic analysis is performed greatly affects the results. The analysis period is usually determined by specific objectives, such as length of planned ownership or loan repayment period. However, as the length of time in the analysis period increases, there is a diminishing effect on net present-value calculations. The chosen analysis period is often unrelated to the equipment depreciation period or service life, although these factors may be important in the analysis.

Service Life

For many years, this chapter included estimates of service lives for various HVAC system components, based on a survey conducted in 1976 under ASHRAE research project RP-186 (Akalin 1978). These estimates have been useful to a generation of practitioners, but changes in technology, materials, manufacturing techniques, and maintenance practices now call into question the continued validity of the original estimates. Consequently, ASHRAE research project TRP-1237 (www.ashrae.org/database) developed an Internet-based data collection tool and database on HVAC equipment service life and maintenance costs, to allow equipment owning and operating cost data to be continually updated and current. The database was seeded with information gathered from a sample of 163 commercial office buildings located in major metropolitan areas across the United States. Abramson et al. (2005) provide details on the distribution of building size, age, and other characteristics. Table 3 presents estimates of median service life for various HVAC components in this sample.

Table 3 Median Service Life

Equipment Type	Median Service Life, Years	Total No. of Units	No. of Units Replaced
DX air distribution equipment	>24	1907	284
Chillers, centrifugal	>25	234	34
Cooling towers, metal	>22	170	24
Boilers, hot-water, steel gas-fired	>22	117	24
Controls, pneumatic	>18	101	25
electronic	>7	68	6
Potable hot-water heaters, electric	>21	304	36

Median service life in Table 3 is based on analysis of survival curves, which take into account the units still in service and the units replaced at each age (Hiller 2000). Conditional and total survival rates are calculated for each age, and the percent survival over time is plotted. Units still in service are included up to the point where the age is equal to their current age at the time of the study. After that point, these units are censored (removed from the population). Median service life in this table indicates the highest age at which the survival rate remains at or above 50% for a sample size of 30 or more. There is no hard-and-fast rule about the number of units needed in a sample before it is considered statistically large enough to be representative, but usually the number should be larger than 25 to 30 (Lovvorn and Hiller 2002). This rule of thumb is used because each unit removal represents greater than a 3% change in survival rate as the sample size drops below 30, and that percentage increases rapidly as the sample size gets even smaller.

The database initially developed and seeded under research project TRP-1237 (Abramson et al. 2005) is now available online, providing engineers with equipment service life and annual maintenance costs for a variety of building types and HVAC systems. The database, which includes more than 300 building types and service life data on more than 38 000 pieces of equipment, can be accessed at www.ashrae.org/database.

The database allows users to access up-to-date information to determine a range of statistical values for equipment owning and operating costs. Users are encouraged to contribute their own service life and maintenance cost data, further expanding the utility of this tool. Over time, this input will provide sufficient service life and maintenance cost data to allow comparative analysis of many different HVAC systems types in a broad variety of applications. Data can be entered by logging into the database and registering, which is free. With this, ASHRAE is providing the necessary methods and information to assist in using life-cycle analysis techniques to help select the most appropriate HVAC system for a specific application. This system of collecting data also greatly reduces the time between data collection and when users can access the information.

Figure 1 presents the survival curve for centrifugal chillers, based on data in Abramson et al. (2005). The point at which survival rate drops to 50% based on all data in the survey is 31 years. However, because the sample size drops below the statistically relevant number of 30 units at 25 years, the median service life of centrifugal chillers can only be stated with confidence as >25 years.

*N/A: Not enough data yet in Abramson et al. (2005). Note that data from Akalin (1978) for these categories may be outdated and not statistically relevant. Use these data with caution until enough updated data are accumulated in Abramson et al.

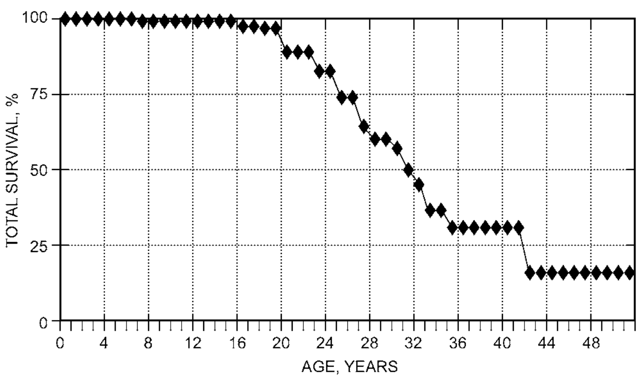

Fig. 1 Survival Curve for Centrifugal Chillers
[Based on data in Abramson et al. (2005)]

Table 4 compares the estimates of median service life in Abramson et al. (2005) with those developed with those in Akalin (1978). Most differences are on the order of one to five years.

Estimated service life of new equipment or components of systems not listed in Table 3 or 4 may be obtained from manufacturers, associations, consortia, or governmental agencies. Because of the proprietary nature of information from some of these sources, the variety of criteria used in compiling the data, and the diverse objectives in disseminating them, extreme care is necessary in comparing service life from different sources. Designs, materials, and components of equipment listed in Tables 3 and 4 have changed over time and may have altered the estimated service lives of those equipment categories. Therefore, establishing equivalent comparisons of service life is important.

As noted, service life is a function of the time when equipment is replaced. Replacement may be for any reason, including, but not limited to, failure, general obsolescence, reduced reliability, excessive maintenance cost, and changed system requirements (e.g., building characteristics, energy prices, environmental considerations). Service lives shown in the tables are based on the age of the equipment when it was replaced, regardless of the reason it was replaced.

Locations in potentially corrosive environments and unique maintenance variables affect service life. Examples include the following:

- **Coastal and marine environments**, especially in tropical locations, are characterized by abundant sodium chloride (salt) that is carried by sea spray, mist, or fog.

  Many owners require equipment specifications stating that HVAC equipment located along coastal waters will have corrosion-resistant materials or coatings. Design criteria for systems installed under these conditions should be carefully considered.

- **Industrial** applications provide many challenges to the HVAC designer. It is very important to know if emissions from the industrial plant contain products of combustion from coal, fuel oils, or releases of sulfur oxides (SO_2, SO_3) and nitrogen oxides (NO_x) into the atmosphere. These gases typically accumulate and return to the ground in the form of acid rain or dew.

  Not only is it important to know the products being emitted from the industrial plant being designed, but also the adjacent upwind or downwind facilities. HVAC system design for a plant located downwind from a paper mill requires extraordinary corrosion protection or recognition of a reduced service life of the HVAC equipment.

- **Urban** areas generally have high levels of automotive emissions as well as abundant combustion by-products. Both of these contain elevated sulfur oxide and nitrogen oxide concentrations.
- **Maintenance** factors also affect life expectancy. The HVAC designer should temper the service life expectancy of equipment with a **maintenance factor**. To achieve the estimated service life values in Table 3, HVAC equipment must be maintained properly, including good filter-changing practices and good maintenance procedures. For example, chilled-water coils with more than four rows and close fin spacing are virtually impossible to clean even using extraordinary methods; they are often replaced with multiple coils in series, with a maximum of four rows and lighter fin spacing.

Depreciation

Depreciation periods are usually set by federal, state, or local tax laws, which change periodically. Consult applicable tax laws for more information on depreciation.

Interest or Discount Rate

Most major economic analyses consider the opportunity cost of borrowing money, inflation, and the time value of money. **Opportunity cost** of money reflects the earnings that investing (or lending) the money can produce. **Inflation** (price escalation) decreases the purchasing or investing power (value) of future money because it can buy less in the future. **Time value** of money reflects the fact that money received today is more useful than the same amount received a year from now, even with zero inflation, because the money is available earlier for reinvestment.

The cost or value of money must also be considered. When borrowing money, a percentage fee or interest rate must normally be paid. However, the interest rate may not necessarily be the correct cost of money to use in an economic analysis. Another factor, called the **discount rate**, is more commonly used to reflect the true cost of money (see Fuller and Petersen [1996] for detailed discussions). Discount rates used for analyses vary depending on individual investment, profit, and other opportunities. Interest rates, in contrast, tend to be more centrally fixed by lending institutions.

To minimize the confusion caused by the vague definition and variable nature of discount rates, the U.S. government has specified particular discount rates to be used in economic analyses relating to federal expenditures. These discount rates are updated annually (Rushing et al. 2013) but may not be appropriate for private-sector economic analyses.

Periodic Costs

Regularly or periodically recurring costs include insurance, property taxes, income taxes, rent, refurbishment expenses, disposal fees (e.g., refrigerant recycling costs), occasional major repair costs, and decommissioning expenses.

Insurance. Insurance reimburses a property owner for a financial loss so that equipment can be repaired or replaced. Insurance often indemnifies the owner from liability, as well. Financial recovery may include replacing income, rents, or profits lost because of property damage.

Some of the principal factors that influence the total annual insurance premium are building size, construction materials, amount and size of mechanical equipment, geographic location, and policy deductibles. Some regulations set minimum required insurance coverage and premiums that may be charged for various forms of insurable property.

Property Taxes. Property taxes differ widely and may be collected by one or more agencies, such as state, county, or local governments or special assessment districts. Furthermore, property taxes may apply to both real (land, buildings) and personal (everything else) property. Property taxes are most often calculated as a percentage of assessed value, but are also determined in other ways, such as fixed fees, license fees, registration fees, etc. Moreover, definitions of assessed value vary widely in different geographic areas. Tax experts should be consulted for applicable practices in a given area.

Income Taxes. Taxes are generally imposed in proportion to net income, after allowance for expenses, depreciation, and numerous other factors. Special tax treatment is often granted to encourage certain investments. Income tax professionals can provide up-to-date information on income tax treatments.

Other Periodic Costs. Examples of other costs include changes in regulations that require unscheduled equipment refurbishment to eliminate use of hazardous substances, and disposal costs for such substances.

Replacement Costs and Salvage Value. Replacement costs and salvage value should be evaluated when calculating owning cost. Replacement cost is the cost to remove existing equipment and install new equipment. Salvage value is the value of equipment or its components for recycling or other uses. Equipment's salvage value may be negative when removal, disposal, or decommissioning costs are considered.

2. OPERATING COSTS

Operating costs are those incurred by the actual operation of the system. They include costs of fuel and electricity, wages, supplies, water, material, and maintenance parts and services. Energy is a large part of total operating costs. Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals* outlines how fuel and electrical requirements are estimated. Because most energy management activities are dictated by economics, the facility manager must understand the utility rates that apply to each facility. Electric rates are usually more complex than gas or water rates. In addition to general commercial or institutional electric rates, special rates may exist such as time of day, interruptible service, on-peak/off-peak, summer/winter, and peak demand. Electric rate schedules vary widely in North America. The facility manager should work with local utility companies to identify the most favorable rates and to understand how to qualify for them. The local utility representative can help the facility manager develop the most cost-effective methods of metering and billing. The facility manager must understand the utility rates, including the distinction between marginal and average costs and, in the case of demand-based electric rates, how demand is computed.

Note that, in general, total energy consumption cannot be multiplied by a per-unit energy cost to arrive at a correct annual utility cost, because rate schedules (especially for electricity) often have a sliding scale of prices that vary with consumption, time of day, and other factors.

Future energy costs used in discounted payback analyses must be carefully evaluated. Energy costs have historically escalated at a different rate than the overall inflation rate as measured by the consumer price index. To assist in life-cycle cost analysis, fuel price escalation rate forecasts by end-use sector and fuel type are updated annually by the National Institute of Standards and Technology and published in the *Annual Supplement to NIST Handbook* 135 (Rushing et al. 2010). There are no published projection rates for water prices for use in life-cycle cost analyses. Water escalation rates should be obtained from the local water utility when possible. Building designers should use energy price projections from their local utility in place of regional forecasts whenever possible, especially when evaluating alternative fuel types.

Deregulation in some areas may allow increased access to nontraditional energy providers and pricing structures; in other areas, traditional utility infrastructures and practices may prevail. The amount and profile of the energy used by the facility will also determine energy cost. Unbundling energy services (having separate contracts for energy and for its transportation to point of use) may dictate separate agreements for each service component or may be packaged by a single provider. Contract length and price stability are factors in assessing nontraditional versus traditional energy suppliers when estimating operating costs. The degree of energy supply and system reliability and price stability considered necessary by the owner/occupants of a building may require considerable deliberation. The sensitivity of a building's functionality to energy-related variables should dictate the degree of attention allocated in evaluating these factors.

Electrical Energy

The total cost of electricity is determined by a rate schedule and is usually a combination of several components: consumption (megajoules), demand (kilowatts) fuel adjustment charges, special allowances or other adjustments, and applicable taxes. Of these, consumption and demand are the major cost components and the ones the owner or facility manager may be able to affect.

Electricity Consumption Charges. Most electric rates have step-rate schedules for consumption, and the cost of the last unit consumed may be substantially different from that of the first. The last unit is usually cheaper than the first because the fixed costs to the utility may already have been recovered from earlier consumption costs. Because of this, the energy analysis cannot use average costs to accurately predict savings from implementation of energy conservation measures. Average costs will overstate the savings possible between alternative equipment or systems; instead, marginal (or incremental) costs must be used.

To reflect time-varying operating costs or to encourage peak shifting, electric utilities may charge different rates for consumption according to the time of use and season, with higher costs occurring during the peak period of use.

Fuel Adjustment Charge. Because of substantial variations in fuel prices, electric utilities may apply a fuel adjustment charge to recover costs. This adjustment may not be reflected in the rate schedule. The fuel adjustment is usually a charge per unit of consumption and may be positive or negative, depending on how much of the actual fuel cost is recovered in the energy consumption rate. The charge may vary monthly or seasonally.

Allowances or Adjustments. Special discounts or rates may be available for customers who can receive power at higher voltages or for those who own transformers or similar equipment. Special rates or riders may be available for specific interruptible loads such as domestic water heaters.

Certain facility electrical systems may produce a low power factor (i.e., ratio of real [active] kilowatt power to apparent [reactive] kVA power), which means that the utility must supply more current on an intermittent basis, thus increasing their costs. These costs may be passed on as an adjustment to the utility bill if the power factor is below a level established by the utility.

When calculating power bills, utilities should be asked to provide detailed cost estimates for various consumption levels. The final calculation should include any applicable special rates, allowances, taxes, and fuel adjustment charges.

Demand Charges. Electric rates may also have demand charges based on the customer's peak kilowatt demand. Whereas consumption charges typically cover the utility's operating costs, demand charges typically cover the owning costs.

Demand charges may be formulated in a variety of ways:

- *Straight charge*. Cost per kilowatt per month, charged for the peak demand of the month.
- *Excess charge*. Cost per kilowatt above a base demand (e.g., 50 kW), which may be established each month.

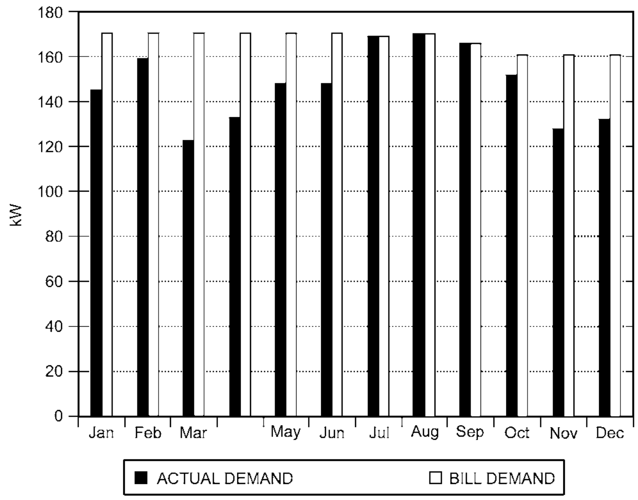

Fig. 2 Bill Demand and Actual Demand for Atlanta Example Building, 2004

- *Maximum demand (ratchet)*. Cost per kilowatt for maximum annual demand, which may be reset only once a year. This established demand may either benefit or penalize the owner.
- *Combination demand*. Cost per hour of operation of demand. In addition to a basic demand charge, utilities may include further demand charges as demand-related consumption charges.

  The actual demand represents the peak energy use averaged over a specific period, usually 15, 30, or 60 min. Accordingly, high electrical loads of only a few minutes' duration may never be recorded at the full instantaneous value. Alternatively, peak demand is recorded as the average of several consecutive short periods (i.e., 5 min out of each hour).

  The particular method of demand metering and billing is important when load shedding or shifting devices are considered. The portion of the total bill attributed to demand may vary greatly, from 0% to as high as 70%.
- *Real-time* or *time-of-day rates*. Cost of electricity at time of use. An increasing number of utilities offer these rates. End users who can shift operations or install electric load-shifting equipment, such as thermal storage, can take advantage of such rates. Because these rates usually reflect a utility's overall load profile and possibly the availability of specific generating resources, contact with the supplying utility is essential to determine whether these rates are a reasonable option for a specific application.

Understanding Electric Rates. To illustrate a typical commercial electric rate with a ratchet, electricity consumption and demand data for an example building are presented in Table 5.

The example building in Table 5 is on a ratcheted rate, and bill demand is determined as a percentage of actual demand in the summer. How the ratchet operates is shown in Figure 2.

Table 5 shows that the actual demand in the first six months of 2004 had no effect on the billing demand, and therefore no effect on the dollar amount of the bill. The same is true for the last three months of the year. Because of the ratchet, the billing demand in the first half of 2004 was set the previous summer. Likewise, billing demand for the last half of 2004 and first half of 2005 was set by the peak actual demand of 180 kW in July 2003. This tells the facility manager to pay attention to demand in the summer months (June to September) and that demand is not a factor in the winter (October to May) months for this particular rate. (Note that Atlanta's climate is hot and humid; in other climates, winter electric demand is an

Table 5 Electricity Data Consumption and Demand for ASHRAE Headquarters, 2003 to 2004

important determinant of costs.) Consumption must be monitored all year long.

Understanding the electric rates is key when evaluating the economics of energy conservation projects. Some projects save electrical demand but not consumption; others save mostly consumption but have little effect on demand. Electric rates must be correctly applied for economic analyses to be accurate. Chapter 56 contains a thorough discussion of various electric rates.

Natural Gas

Rates. Conventional natural gas rates are usually a combination of two main components: (1) utility rate or base charges for gas consumption and (2) purchased gas adjustment (PGA) charges.

Although gas is usually metered by volume, it is often sold by energy content. The utility rate is the amount the local distribution company charges per unit of energy to deliver the gas to a particular location. This rate may be graduated in steps; the first 10 GJ of gas consumed may not be the same price as the last 10 GJ. The PGA is an adjustment for the cost of the gas per unit of energy to the local utility. It is similar to the electric fuel adjustment charge. The total cost per unit of energy is then the sum of the appropriate utility rate and the PGA, plus taxes and other adjustments.

Interruptible Gas Rates and Contract/Transport Gas. Large industrial plants usually have the ability to burn alternative fuels and can qualify for special interruptible gas rates. During peak periods of severe cold weather, these customers' supply may be curtailed by the gas utility, and they may have to switch to propane, fuel oil, or some other back-up fuel. The utility rate and PGA are usually considerably cheaper for these interruptible customers than they are for firm-rate (noninterruptible) customers.

Deregulation of the natural gas industry allows end users to negotiate for gas supplies on the open market. The customer actually contracts with a gas producer or broker and pays for the gas at the source. Transport fees must be negotiated with the pipeline companies carrying the gas to the customer's local gas utility. This can be a very complicated administrative process and is usually economically feasible only for large gas users. Some local utilities have special rates for delivering contract gas volumes through their system; others simply charge a standard utility fee (PGA is not applied because the customer has already negotiated with the supplier for the cost of the fuel itself).

When calculating natural gas bills, be sure to determine which utility rate and PGA and/or contract gas price is appropriate for the particular interruptible or firm-rate customer. As with electric bills, the final calculation should include any taxes, prompt payment discounts, or other applicable adjustments.

Other Fossil Fuels

Propane, fuel oil, and diesel are examples of other fossil fuels in widespread use. Calculating the cost of these fuels is usually much simpler than calculating typical utility rates.

The cost of the fuel itself is usually a simple charge per unit volume or per unit mass. The customer is free to negotiate for the best price. However, trucking or delivery fees must also be included in final calculations. Some customers may have their own transport trucks, but most seek the best delivered price. If storage tanks are not customer-owned, rental fees must be considered. Periodic replacement of diesel-type fuels may be necessary because of storage or shelf-life limitations and must also be considered. The final fuel cost calculation should include any of these costs that are applicable, as well as appropriate taxes.

It is usually difficult, however, to relate usage of stored fossil fuels (e.g., fuel oil) with their operating costs. This is because propane or fuel oil is bought in bulk and stored until needed, and normally not metered or measured as it is consumed, whereas natural gas and power are metered and billed for as they are used.

Energy Source Choices

In planning for a new facility, the designer may undertake **energy master planning**. One component of energy master planning is choice of fuels. Typical necessary decisions include, for example, whether the building should be heated by electricity or natural gas, how service hot water should be produced, whether a hybrid heating plant (i.e., a combination of both electric and gas boilers) should be considered, and whether emergency generators should be fueled by diesel or natural gas.

Decision makers should consider histories or forecasts of price volatility when selecting energy sources. In addition to national trending, local energy price trends from energy suppliers can be informative. These evaluations are particularly important where relative operating costs parity exists between various fuel options, or where selecting more efficient equipment may help mitigate utility price concerns.

Many sources of historic and projected energy costs are available for reference. In addition to federal projections, utility and energy supplier annual reports and accompanying financial data may provide insight into future energy costs. Indicators such as constrained or declining energy supply or production may be key factors in projecting future energy pricing trends. Pricing patterns that suggest unusual levels of energy price volatility should be carefully analyzed and tested at extreme predicted price levels to assess potential effects on system operating costs.

Under conditions of rapidly evolving energy prices or new pricing options, imminent technological improvements, or pending environmental standards and mandates, the adaptability of design options must be carefully evaluated. Where appropriate, contingency planning for accommodating foreseeable alterations to building systems may be prudent. Using diverse energy sources or suppliers in lieu of single sourcing may reduce cost of shifting energy use in the event that single-source pricing becomes volatile, and may even provide negotiating leverage for facility owners.

Water and Sewer Costs

Water and sewer costs have risen in many parts of the country and should not be overlooked in economic analyses. Fortunately, these rates are usually very simple and straightforward: commonly, a charge per unit volume for water and a different charge per unit volume for sewer. Because water consumption is metered and sewage is not, most rates use the water consumption quantity to compute the sewer charge. If an owner uses water that is not returned to sewer, there may be an opportunity to receive a credit or refund. Owners frequently use irrigation meters for watering grounds when the water authority has a special irrigation rate with no sewer charge. Another opportunity that is sometimes overlooked is to separately meter makeup water for cooling towers. This can be done with an irrigation meter if the costs of setting the meter can be justified; alternatively, it may be done by installing an in-line water meter for the cooling tower, in which case the owner reports the usage annually and applies for a credit or refund.

Because of rising costs of water and sewer, water recycling and reclamation is becoming more cost effective. For example, it may now be cost effective in some circumstances to capture cooling coil condensate and pump it to a cooling tower for makeup water.

3. MAINTENANCE COSTS

The quality of maintenance and maintenance supervision can be a major factor in overall life-cycle cost of a mechanical system. The maintenance cost of mechanical systems varies widely depending upon configuration, equipment locations, accessibility, system complexity, service duty, geography, and system reliability requirements. Maintenance costs can be difficult to predict, because each system or facility is unique.

Dohrmann and Alereza (1986) obtained maintenance costs and HVAC system information from 342 buildings located in 35 states in the United States. In 1983 U.S. dollars, data collected showed a mean HVAC system maintenance cost of $3.40/m^2 per year, with a median cost of $2.60/m^2 per year. Building age has a statistically significant but minor effect on HVAC maintenance costs. Analysis also indicated that building size is not statistically significant in explaining cost variation. The type of maintenance program or service agency that building management chooses can also have a significant effect on total HVAC maintenance costs. Although extensive or thorough routine and preventive maintenance programs cost more to administer, they usually extend equipment life; improve reliability; and reduce system downtime, energy costs, and overall life-cycle costs.

Some maintenance cost data are available, both in the public domain and from proprietary sources used by various commercial service providers. These sources may include equipment manufacturers, independent service providers, insurers, government agencies (e.g., the U.S. General Services Administration), and industry-related organizations (e.g., the Building Owners and Managers Association [BOMA]) and service industry publications. More traditional, widely used products and components are likely to have statistically reliable records. However, design changes or modifications necessitated by industry changes, such as alternative refrigerants, may make historical data less relevant.

Newer HVAC products, components, system configurations, control systems and protocols, and upgraded or revised system applications present an additional challenge. Care is required when using data not drawn from broad experience or field reports. In many cases, maintenance information is proprietary or was sponsored by a particular entity or group. Particular care should be taken when using such data. It is the user's responsibility to obtain these data and to determine their appropriateness and suitability for the application being considered.

Table 6 Comparison of Maintenance Costs Between Studies

Survey	Cost per m^2, as Reported		Consumer Price Index	Cost per m^2, 2004 Dollars	
	Mean	Median		Mean	Median
Dohrmann and Alereza (1983)	$3.44	$2.58	99.6	$6.57	$4.95
Abramson et al. (2005)	$5.06	$4.74	188.9	$5.06	$4.74

ASHRAE research project TRP-1237 (Abramson et al. 2005) developed a standardized Internet-based data collection tool and database on HVAC equipment service life and maintenance costs. The database was seeded with data on 163 buildings from around the country. Maintenance cost data were gathered for total HVAC system maintenance costs from 100 facilities. In 2004 dollars, the mean HVAC maintenance cost from these data was $5.06/m^2, and the median cost was $4.74/m^2. Table 6 compares these figures with estimates reported by Dohrmann and Alereza (1983), both in terms of contemporary dollars, and in 2004 dollars, and shows that the cost per square metre varies widely between studies.

Estimating Maintenance Costs

Total HVAC maintenance cost for new and existing buildings with various types of equipment may be estimated several ways, using several resources. Equipment maintenance requirements can be obtained from the equipment manufacturers for large or custom pieces of equipment. Estimating in-house labor requirements can be difficult; BOMA (2003) provides guidance on this topic. Many independent mechanical service companies provide preventative maintenance contracts. These firms typically have proprietary estimating programs developed through their experience, and often provide generalized maintenance costs to engineers and owners upon request, without obligation.

When evaluating various HVAC systems during design or retrofit, the absolute magnitude of maintenance costs may not be as important as the relative costs. Whichever estimating method or resource is selected, it should be used consistently throughout any evaluation. Mixing information from different resources in an evaluation may provide erroneous results.

Applying simple costs per unit of building floor area for maintenance is highly discouraged. Maintenance costs can be generalized by system types. When projecting maintenance costs for different HVAC systems, the major system components need to be identified with a required level of maintenance. The potential long-term costs of environmental issues on maintenance costs should also be considered.

Factors Affecting Maintenance Costs

Maintenance costs are primarily a measure of labor activity. System design, layout, and configuration can significantly affect the amount of time and effort required for maintenance and, therefore, the maintenance cost. Factors to consider when evaluating maintenance costs include the following:

- **Quantity and type of equipment.** Each piece of equipment requires a core amount of maintenance and time, regardless of its size or capacity. A greater number of similar pieces of equipment are generally more expensive to maintain than larger but fewer units. For example, one manufacturer suggests the annual maintenance for centrifugal chillers is 24 h for a nominal 3500 kW chiller and 16 h for a nominal 1800 kW chiller. Therefore, the total maintenance labor for a 3500 kW chiller plant with two 1800 kW chillers would be 32 h, or 1/3 more than a single 3500 kW chiller.

- **Equipment location and access.** The ability to maintain equipment in a repeatable and cost-effective manner is significantly affected by the equipment's location and accessibility. Equipment that is difficult to access increases the amount of time required to maintain it, and therefore increases maintenance cost. Equipment maintenance requiring erection of ladders and scaffolding or hydraulic lifts increases maintenance costs while likely reducing the quantity and quality of maintenance performed. Equipment location may also dictate an unusual working condition that could require more service personnel than normal. For example, maintenance performed in a confined space (per OSHA [Annual] definitions) requires an additional person to be present, for safety reasons.
- **System run time.** The number of hours of operation for an HVAC system affects maintenance costs. Many maintenance tasks are dictated by equipment run time. The greater the run time, the more often these tasks need to be performed.
- **Critical systems.** High-reliability systems require more maintenance to ensure uninterrupted system operation. Critical system maintenance is also usually performed with stringent shutdown and failsafe procedures that tend to increase the amount of time required to service equipment. An office building system can be turned off for a short time with little effect on occupants, allowing maintenance almost any time. Shutdown of a hospital operating room or pharmaceutical manufacturing HVAC system, on the other hand, must be coordinated closely with the operation of the facility to eliminate risk to patients or product. Maintenance on critical systems may sometimes incur labor premiums because of unusual shutdown requirements.
- **System complexity.** More complex systems tend to involve more equipment and sophisticated controls. Highly sophisticated systems may require highly skilled service personnel, who tend to be more costly.
- **Service environment.** HVAC systems subjected to harsh operating conditions (e.g., coastal and marine environments) or environments like industrial operations may require more frequent and/or additional maintenance.
- **Local conditions.** The physical location of the facility may require additional maintenance. Equipment in dusty or dirty areas or exposed to seasonal conditions (e.g., high pollen, leaves) may require more frequent or more difficult cleaning of equipment and filters. Additional maintenance tasks may be needed.
- **Geographical location.** Maintenance costs for remote locations must consider the cost of getting to and from the locations. Labor costs for the number of anticipated trips and their duration for either in-house or outsourced service personnel to travel to and from the site must be added to the maintenance cost to properly estimate the total maintenance cost.
- **Equipment age.** The effect of age on equipment repair costs varies significantly by type of HVAC equipment. Technologies in equipment design and application have changed significantly, affecting maintenance costs.
- **Available infrastructure.** Maintenance costs are affected by the availability of an infrastructure that can maintain equipment, components, and systems. Available infrastructure varies on a national, regional, and local basis and is an important consideration in the HVAC system selection process.

4. REFRIGERANT PHASEOUTS

Production phaseout of many commonly used refrigerants has required building owners to decide between replacing existing equipment or retrofitting for alternative refrigerants. Several factors must be considered, including

- **Initial Cost.** New equipment may have a significantly higher installed cost than retrofitting existing equipment. For example, retrofitting an existing centrifugal chiller to operate on R-123 may cost 50% of the cost for a new chiller, making the installation cost of a new chiller seem a prudent alternative. Conversely, the cost of rigging a new unit may significantly raise the installed cost, improving the first-cost advantage of refrigerant conversion.
- **Operating Costs.** The overall efficiency of new equipment is often substantially better than that of existing equipment, depending on age, usage, and level of maintenance performed over the life of the existing unit. In addition, conversion to alternative refrigerants may reduce capacity and/or efficiency of the existing equipment.
- **Maintenance Costs.** The maintenance cost for new equipment is generally lower than that for existing equipment. However, the level of retrofit required to attain compatibility between existing equipment and new refrigerant often includes replacement or remanufacture of major unit components, which can bring the maintenance and repair costs in line with those expected of new equipment.
- **Equipment Useful Life.** The effect of a retrofit on equipment useful life is determined by the extent of modification required. Complete remanufacture of a unit should extend the remaining useful life to a level comparable to that of new equipment.

Replacing existing equipment or converting to alternative refrigerants can improve overall system efficiency. Reduced capacity requirements and introduction of new technologies such as variable-speed drives and microprocessor-based controllers can substantially reduce annual operating costs and significantly improve a project's economic benefit.

Information should be gathered to complete Table 1 for each alternative. The techniques described in the section on Economic Analysis Techniques may then be applied to compare the relative values of each option.

Other Sources

The DOE's Federal Energy Management Program (FEMP) (energy.gov/eere/femp/find-product-categories-covered-efficiency-programs) has up-to-date information on energy-efficient federal procurement. Products that qualify for the EPA/DOE ENERGY STAR label are listed, as are efficiency recommendations, cost effectiveness examples, and purchasing guidance. FEMP also provides web-based cost-calculator tools that simplify the energy cost comparison between products with different efficiencies.

The General Services Administration (GSA) has a basic ordering agreement (BOA) that offers a streamlined procurement method for some HVAC products based on lowest life-cycle cost. For chillers purchased through commercial sources, the BOA can still be used as a guide in preparing specifications.

5. OTHER ISSUES

Financing Alternatives

Alternative financing is commonly used in third-party funding of projects, particularly retrofit projects, and is variously called privatization, third-party financing, energy services outsourcing, performance contracting, energy savings performance contracting (ESPC), or innovative financing. In these programs, an outside party performs an energy study to identify or quantify attractive energy-saving retrofit projects and then (to varying degrees) designs, builds, and finances the retrofit program on behalf of the owner or host facility. These contracts range in complexity from simple projects such as lighting upgrades to more detailed projects involving all aspects of energy consumption and facility operation.

Alternative financing can be used to accomplish any or all of the following objectives:

- Upgrade capital equipment
- Provide for maintenance of existing facilities
- Speed project implementation
- Conserve or defer capital outlay
- Save energy
- Save money

The benefits of alternative financing are not free. In general terms, these financing agreements transfer the risk of attaining future savings from the owner to the contractor, for which the contractor is paid. In addition, these innovative owning and operating cost reduction approaches have important tax consequences that should be investigated on a case-by-case basis.

There are many variations of the basic arrangements and nearly as many terms to define them. Common nomenclature includes guaranteed savings (performance-based), shared savings, paid from savings, guaranteed savings loans, capital leases, municipal leases, and operating leases. For more information, see the U.S. Department of Energy's website and DOE (2007). A few examples of alternative financing techniques follow.

Leasing. Among the most common methods of alternative financing is the lease arrangement. In a true lease or lease-purchase arrangement, outside financing provides capital for construction of a facility. The institution then leases the facility at a fixed monthly charge and assumes responsibility for fuel and personnel costs associated with its operation. Leasing is also commonly available for individual pieces of equipment or retrofit systems and often includes all design and installation costs. Equipment suppliers or independent third parties retain ownership of new equipment and lease it to the user.

Outsourcing. For a cogeneration, steam, or chilled-water plant, either a lease or an energy output contract can be used. An energy output contract enables a private company to provide all the capital and operating costs, such as personnel and fuel, while the host facility purchases energy from the operating company at a variable monthly charge.

Energy Savings. Retrofit projects that lower energy usage create an income stream that can be used to amortize the investment. In **paid-from-savings** programs, utility payments remain constant over a period of years while the contractor is paid out of savings until the project is amortized. In **shared savings** programs, the institution receives a percentage of savings over a longer period of years until the project becomes its property. In a **guaranteed savings** program, the owner retains all the savings and is guaranteed that a certain level of savings will be attained. A portion of the savings is used to amortize the project. In any type of energy savings project, building operation and use can strongly affect the amount of savings actually realized.

Low-Interest Financing. In this arrangement, the supplier offers equipment with special financing arrangements at below-market interest rates.

Cost Sharing. Several variations of cost-sharing programs exist. In some instances, two or more groups jointly purchase and share new equipment or facilities, thereby increasing use of the equipment and improving the economic benefits for both parties. In other cases, equipment suppliers or independent third parties (such as utilities) who receive an indirect benefit may share part of the equipment or project cost to establish a market foothold for the product.

Alternative Property-Based Financing for Building and Energy-Related Upgrades. One common challenge for implementing energy-efficient upgrades (even with excellent internal rate of return or savings-to-investment parameters) is simply getting someone to commit the financing or credit line to fund the project. This is especially problematic in a building where tenant occupancy is high. Although the overall energy savings gained by the project might yield a great payback, the challenge stems from uncertainty as to how tenants will benefit and building owner concerns over not having a method for recouping the investment.

Property assessment for clean energy (PACE) is a method for providing financing that is based on increasing the municipal tax base for funding energy reduction methods (ERMs). This approach can yield energy savings for the building and does not affect the building or property owner's credit rating or their ability to borrow. The goal is to offset the added tax costs with the energy savings of the ERMs. Life-cycle costs over the life of the funding must be carefully considered and maintained to accepted ASHRAE standards.

PACE relies on being recognized, accepted, and adopted into local tax laws. Over half the U.S. states have accepted PACE, but it is not currently well developed or even accepted in all locations. The structure and interest rate of PACE is a function of firms providing the PACE process and the actual funding.

Currently, 16 states have approved this type of municipal tax-based funding for specifically energy-efficient upgrades in buildings. The exact mechanics for the program vary by location and by state), but typically involve an investment-grade building energy audit to ASHRAE standards. This provides a reasonably reliable method with which to pick the internal rate of return (see the section on Internal Rate of Return, under Economic Analysis Techniques) of different ERMs.

Once the different ERMs are evaluated, the life-cycle cost analysis can be completed (see the section on Life-Cycle Costs, under Economic Analysis Techniques). The goal is for the ERMs to save more energy than the increase to the municipal tax base, so that the overall ownership or life-cycle costs are decreased. To pass on energy savings to a building's tenants, condo owners, and other occupants without putting a financial burden on the building owner(s), the following must be achieved:

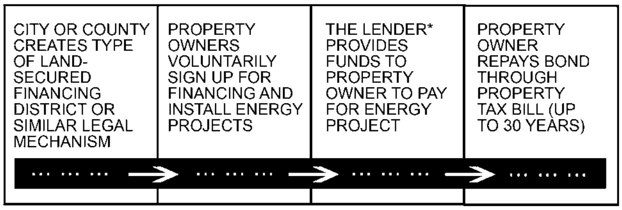
- A skillfully executed, investment-grade energy audit executed to ASHRAE standards
- Selection of effective ERMs
- Proper life-cycle operation
- Proper maintenance of the ERMs

The U.S. Department of Energy (DOE) and other material in the Bibliography are good sources for more in-depth information. Note that the way PACE is administered by local municipalities changes according to location.

Property owners who choose to participate in a PACE program repay their ERMs over a set period (typically 5 to 30 years) through property assessments. Such assessments are secured by the property itself and become an added payment on the owner's property tax bills or are ultimately paid for by the tenants or businesses through common-area maintenance fees or operational costs. When PACE projects are properly structured and maintained, the energy savings achieved can be greater than the costs of owning and operating the building and provide a realized monthly savings from the first year through the life of the improvement. PACE projects present a solution for owners and tenants who do not want to commit credit resources to provide needed ERMs and building improvements. If the building is sold, the assessment or financing stays with the property in the form of a tax assessment.

A general sequence of PACE process is shown in Figure 3.

Because the PACE assessment is a debt that is tied to the property and not the property owners, depending on state laws, the assessment can transfer with the building and the repayment obligation does not affect building owners. This lack of obligation for the property owner eliminates a key opposition to investing in ERMs,



*Depending on program structure, lender may be private capital provider or local jurisdiction.

Fig. 3 PACE Process
(based on DOE 2013)

Table 7 Key Pros and Cons of PACE

Pros	Cons
Allows for secure financing of comprehensive projects over terms up to 30 years	Available only to property owners; renters cannot access programs directly
Repayment obligation passes with ownership, overcoming hesitancy to invest in longer payback measures	Cannot finance portable items
Senior lien municipal financing may lead to low interest rates	Requires dedicated staff time
Interest portion of assessment repayments are tax deductible	High legal and administrative expenses to set up
Lower transaction costs compared to private loans	Not appropriate for investments below $50 000
