2019 ASHRAE® HANDBOOK

Heating, Ventilating, and Air-Conditioning APPLICATIONS

SI Edition

ASHRAE, 1791 Tullie Circle, N.E., Atlanta, GA 30329
www.ashrae.org

DEDICATED TO THE ADVANCEMENT OF

THE PROFESSION AND ITS ALLIED INDUSTRIES

Volunteer members of ASHRAE Technical Committees and others compiled the information in this handbook, and it is generally reviewed and updated every four years. Comments, criticisms, and suggestions regarding the subject matter are invited. Any errors or omissions in the data should be brought to the attention of the Editor. Additions and corrections to Handbook volumes in print will be published in the Handbook published the year following their verification and, as soon as verified, on the ASHRAE Internet web site.

DISCLAIMER

ASHRAE has compiled this publication with care, but ASHRAE has not investigated, and ASHRAE expressly disclaims any duty to investigate, any product, service, process, procedure, design, or the like that may be described herein. The appearance of any technical data or editorial material in this publication does not constitute endorsement, warranty, or guaranty by ASHRAE of any product, service, process, procedure, design, or the like. ASHRAE does not warrant that the information in this publication is free of errors. The entire risk of the use of any information in this publication is assumed by the user.

ISBN 978-1-947192-13-3
ISSN 1078-6082

The paper for this book is both acid- and elemental-chlorine-free and was manufactured with pulp obtained from sources using sustainable forestry practices.

CONTENTS

Contributors

ASHRAE Technical Committees, Task Groups, and Technical Resource Groups

ASHRAE Research: Improving the Quality of Life

Preface

COMFORT APPLICATIONS

Chapter
1. **Residences** (TC 8.11, Unitary and Room Air Conditioners and Heat Pumps)
2. **Retail Facilities** (TC 9.8, Large Building Air-Conditioning Applications)
3. **Commercial and Public Buildings** (TC 9.8)
4. **Tall Buildings** (TC 9.12, Tall Buildings)
5. **Places of Assembly** (TC 9.8)
6. **Indoor Swimming Pools** (TC 9.8)
7. **Hotels, Motels, and Dormitories** (TC 9.8)
8. **Educational Facilities** (TC 9.7)
9. **Health Care Facilities** (TC 9.6, Healthcare Facilities)
10. **Justice Facilities** (TC 9.4, Justice Facilities)
11. **Automobiles** (TC 9.3, Transportation Air Conditioning)
12. **Mass Transit** (TC 9.3)
13. **Aircraft** (TC 9.3)
14. **Ships** (TC 9.3)

INDUSTRIAL APPLICATIONS

Chapter
15. **Industrial Air Conditioning** (TC 9.2, Industrial Air Conditioning)
16. **Enclosed Vehicular Facilities** (TC 5.9, Enclosed Vehicular Facilities)
17. **Laboratories** (TC 9.10, Laboratory Systems)
18. **Engine Test Facilities** (TC 9.2)
19. **Clean Spaces** (TC 9.11, Clean Spaces)
20. **Data Centers and Telecommunication Facilities** (TC 9.9, Mission Critical Facilities, Data Centers, Technology Spaces, and Electronic Equipment)
21. **Printing Plants** (TC 9.2)
22. **Textile Processing Plants** (TC 9.2)
23. **Photographic Material Facilities** (TC 9.2)
24. **Museums, Galleries, Archives, and Libraries** (TC 9.8)
25. **Environmental Control for Animals and Plants** (TC 2.2, Plant and Animal Environment)
26. **Drying and Storing Selected Farm Crops** (TC 2.2)
27. **Air Conditioning of Wood and Paper Product Facilities** (TC 9.2)
28. **Power Plants** (TC 9.2)
29. **Nuclear Facilities** (TC 9.2)
30. **Mine Ventilation and Air Conditioning** (TC 9.2)
31. **Industrial Drying** (TC 9.2)
32. **Ventilation of the Industrial Environment** (TC 5.8, Industrial Ventilation)
33. **Industrial Local Exhaust** (TC 5.8)
34. **Kitchen Ventilation** (TC 5.10, Kitchen Ventilation)

ENERGY-RELATED APPLICATIONS

Chapter 35. **Geothermal Energy** (TC 6.8, Geothermal Heat Pump and Energy Recovery Applications)
36. **Solar Energy Use** (TC 6.7, Solar Energy Utilization)

BUILDING OPERATIONS AND MANAGEMENT

Chapter 37. **Energy Use and Management** (TC 7.6, Building Energy Performance)
38. **Owning and Operating Costs** (TC 7.8, Owning and Operating Costs)
39. **Testing, Adjusting, and Balancing** (TC 7.7, Testing and Balancing)
40. **Operation and Maintenance Management** (TC 7.3, Operation and Maintenance Management)
41. **Computer Applications** (TC 1.5, Computer Applications)
42. **Building Energy Monitoring** (TC 7.6)
43. **Supervisory Control Strategies and Optimization** (TC 7.5, Smart Building Systems)
44. **HVAC Commissioning** (TC 7.9, Building Commissioning)

GENERAL APPLICATIONS

Chapter 45. **Building Envelopes** (TC 4.4, Building Materials and Building Envelope Performance)
46. **Building Air Intake and Exhaust Design** (TC 4.3, Ventilation Requirements and Infiltration)
47. **Air Cleaners for Gaseous Contaminants** (TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment)
48. **Design and Application of Controls** (TC 1.4, Control Theory and Application)
49. **Noise and Vibration Control** (TC 2.6, Sound and Vibration Control)
50. **Water Treatment: Deposition, Corrosion, and Biological Control** (TC 3.6, Water Treatment)
51. **Service Water Heating** (TC 6.6, Service Water Heating Systems)
52. **Snow Melting and Freeze Protection** (TC 6.5, Radiant Heating and Cooling)
53. **Evaporative Cooling** (TC 5.7, Evaporative Cooling)
54. **Fire and Smoke Control** (TC 5.6, Control of Fire and Smoke)
55. **Radiant Heating and Cooling** (TC 6.5)
56. **Seismic- and Wind-Resistant Design** (TC 2.7, Seismic and Wind Resistant Design)
57. **Electrical Considerations** (TC 1.9, Electrical Systems)
58. **Room Air Distribution** (TC 5.3, Room Air Distribution)
59. **Indoor Airflow Modeling** (TC 4.10)
60. **Integrated Building Design** (TC 7.1, Integrated Building Design)
61. **HVAC Security** (TG2, Heating, Ventilation, and Air-Conditioning Security)
62. **Ultraviolet Air and Surface Treatment** (TC 2.9, Ultraviolet Air and Surface Treatment)
63. **Smart Building Systems** (TC 7.5)
64. **Moisture Management in Buildings** (TC 1.12, Moisture Management in Buildings)
65. **Occupant-Centric Sensing and Controls** (MTG.OBB)
66. **Codes and Standards**

Additions and Corrections

Index

Composite index to the 2012 HVAC Systems and Equipment, 2013 Fundamentals, 2014 Refrigeration, and 2015 HVAC Applications volumes

Comment Pages

CONTRIBUTORS

In addition to the Technical Committees, the following individuals contributed significantly to this volume. The appropriate chapter numbers follow each contributor's name.

Dane Christianson, Ph.D. (1)
National Renewable Energy Lab

Scott Creamer (1)
Rheem Manufacturing Company

Ted Duffy, PE, CEM, LEED AP+ID&C (1)
Laars Heating Systems Company

Randy Palm (1)
Allied Air Enterprises

Ray Rite (1)
Ingersoll Rand

Scott Wujek, Ph.D. (1)
Apple

Vinay Ananthachar, PE (2)
Green Banyan Consulting

Mehdi Jaleyrian, PE, LEED AP (4)
Environmental Systems Desing, Inc.

Peter Simmonds, Ph.D., LEED AP (4)
Buildings and Systems Analytics

Dennis Wessel, PE, LEED AP (4)

Itzhak Maor (8)
Johnson Controls Inc.

Steven C. Snyder (8)
Johnson Controls Inc.

Zied Driss (9)
Camfil

Travis English (9)
Kaiser Permanente

Eric Granzow (9)
Specialized Engineering Solutions

Dan Koenigshofer, PE (9)
Dewberry Engineers, Inc.

Nicolas Lemire (9)
Pageau Morel and Associates Inc.

Pavel Likhonin, PE (9)
Dewberry Engineers, Inc.

Kenneth R. Mead (9)
CDC/NIOSH

Erica Stewart (9)
Kaiser Permanente National EH&S

E. Doug Fitts (10)
Fitts HVAC Consulting LLC

Richard B. Fox, Ph.D. (11,13)
Honeywell International

Gursaran D. Mathur, Ph.D., PE (11, 53)
Calsonic Kansei North America

Jerome I. Johnson (13)
The Boeing Company

Stephen M. Trent (13)
The Boeing Company

Kevin Glover, PE, HBDP (14)
Coefficient Engineers

Anthony Arens, PE (15)
GM

Michael C. Connor, PE (15)
WSP USA

Ravisankar Ganta, PE (15, 29)
Parsons

Troy Goldschmidt (16)
Greenheck

Andrew Louie (16)
WSP

Albert Hartman (17)
HED

Joel Foster (18)
DuPont

Charles (Chuck) Gulledge, PE, HBDP (18)
AC Corporation

Eileen Jensen, PE (18, 28)
Bonneville Power Administration

Yusuf Bhetasiwala (19)
Encon Expertise Pvt. Ltd.

Douglas Ebert (19)
Eli Lilly and Company

Phil Naughton, PE (19)
Applied Materials, Inc.

Gary Shamshoian, PE (19)
WAS USA

Wei Sun, PE (19)
Engsysco, Inc.

Mitchell Swann, PE (19)
MDC Systems

Ahmed Abdel-Salam, Ph.D. (20)
Nortek Air Solutions

Andrew R. Baxter (20)
Page Southerland Page, LLP

Mark Fisher (20)
Munters Corporation

Mark Hydeman (20)
Taylor Engineering, LLC

Robert E. McFarlane (20)
Shen Milsom & Wilke LLC

David C. Meadows II (20)
Stulz Air Technology Systems, Inc.

John P. O'Brien, PE (20)
Heapy Engineering

Roger Schmidt, Ph.D., PE (20)
IBM Corporation

Vali Sorell, PE (20)
Sorell Engineering

Casey Winkel (20)
Intel Corporation

Norm Maxwell, PE (21)
Environmental Air Quality

Andrew L. Cochrane (22)
Industrial Air Inc.

Vincent Beltran (24)
Getty Conservation Institute

Cecily Grzywacz (24)

Michael Henry (24)
Watson & Henry Associates

Jeremy Linden (24)
Linden Preservation Services, Inc.

Michal Lukomski (24)
Getty Conservation Institute

Stefan Michalski (24)
Canadian Conservation Institute

Joel Taylor (24)
Getty Conservation Institute

Jean Tétreault (24)
Canadian Conservation Institute

Kevin Marple (27)
Benz Air Engineering Co.

Thomas B. Axley, Jr., PE (28, 29)
DAV Energy Services

Deep Ghosh, PE (28, 29)
Southern Nuclear

John Riley, PE (28)

Matt R. Hargan, PE, FASHRAE (29, 31)
Hargan Engineering

John Scott MacMurray (29)
Savannah River National Laboratory

Erich Binder (30)
Erich Binder Consulting Limited

Douglass Abramson (31)
Handy Hubby

Jason Brown (34)
Melink Corporation

Frank Kohout, PE, BCxA (34)
Cyclone Energy Group

Fuoad Parvin, PE (34)
Halton Group Americas

Rich Swierczyna (34)
Frontier Energy

Michael Bernier, Ph.D. (35)
Polytechnique Montreal

Ryan Carda, PE (35)
Dandelion Energy

Andrew Chiasson, Ph.D. (35)
University of Dayton

Scott Hackel, MS, PE (35)
Seventhwave

Chuck High, MSME (35)

ASHRAE TECHNICAL COMMITTEES, TASK GROUPS, AND TECHNICAL RESOURCE GROUPS

SECTION 1.0—FUNDAMENTALS AND GENERAL

1.1 Thermodynamics and Psychrometrics
1.2 Instruments and Measurements
1.3 Heat Transfer and Fluid Flow
1.4 Control Theory and Application
1.5 Computer Applications
1.6 Terminology
1.7 Business, Management, and General Legal Education
1.8 Mechanical Systems Insulation
1.9 Electrical Systems
1.10 Cogeneration Systems
1.11 Electric Motors and Motor Control
1.12 Moisture Management in Buildings
1.13 Optimization

SECTION 2.0—ENVIRONMENTAL QUALITY

2.1 Physiology and Human Environment
2.2 Plant and Animal Environment
2.3 Gaseous Air Contaminants and Gas Contaminant Removal Equipment
2.4 Particulate Air Contaminants and Particulate Contaminant Removal Equipment
2.5 Global Climate Change
2.6 Sound and Vibration Control
2.7 Seismic and Wind Resistant Design
2.8 Building Environmental Impacts and Sustainability
2.9 Ultraviolet Air and Surface Treatment
TG2 Heating, Ventilation, and Air-Conditioning Security (HVAC)

SECTION 3.0—MATERIALS AND PROCESSES

3.1 Refrigerants and Secondary Coolants
3.2 Refrigerant System Chemistry
3.3 Refrigerant Contaminant Control
3.4 Lubrication
3.6 Water Treatment
3.8 Refrigerant Containment

SECTION 4.0—LOAD CALCULATIONS AND ENERGY REQUIREMENTS

4.1 Load Calculation Data and Procedures
4.2 Climatic Information
4.3 Ventilation Requirements and Infiltration
4.4 Building Materials and Building Envelope Performance
4.5 Fenestration
4.7 Energy Calculations
4.10 Indoor Environmental Modeling
TRG4 Indoor Air Quality Procedure Development

SECTION 5.0—VENTILATION AND AIR DISTRIBUTION

5.1 Fans
5.2 Duct Design
5.3 Room Air Distribution
5.4 Industrial Process Air Cleaning (Air Pollution Control)
5.5 Air-to-Air Energy Recovery
5.6 Control of Fire and Smoke
5.7 Evaporative Cooling
5.8 Industrial Ventilation
5.9 Enclosed Vehicular Facilities
5.10 Kitchen Ventilation
5.11 Humidifying Equipment

SECTION 6.0—HEATING EQUIPMENT, HEATING AND COOLING SYSTEMS AND APPLICATIONS

6.1 Hydronic and Steam Equipment and Systems
6.2 District Energy
6.3 Central Forced Air Heating and Cooling Systems
6.5 Radiant Heating and Cooling
6.6 Service Water Heating Systems
6.7 Solar Energy Utilization
6.8 Geothermal Heat Pump and Energy Recovery Applications
6.9 Thermal Storage
6.10 Fuels and Combustion

SECTION 7.0—BUILDING PERFORMANCE

7.1 Integrated Building Design
7.2 HVAC&R Construction and Design Build Technologies
7.3 Operation and Maintenance Management
7.4 Exergy Analysis for Sustainable Buildings (EXER)
7.5 Smart Building Systems
7.6 Building Energy Performance
7.7 Testing and Balancing
7.8 Owning and Operating Costs
7.9 Building Commissioning

SECTION 8.0—AIR-CONDITIONING AND REFRIGERATION SYSTEM COMPONENTS

8.1 Positive Displacement Compressors
8.2 Centrifugal Machines
8.3 Absorption and Heat Operated Machines
8.4 Air-to-Refrigerant Heat Transfer Equipment
8.5 Liquid-to-Refrigerant Heat Exchangers
8.6 Cooling Towers and Evaporative Condensers
8.7 Variable Refrigerant Flow (VRF)
8.8 Refrigerant System Controls and Accessories
8.9 Residential Refrigerators and Food Freezers
8.10 Mechanical Dehumidification Equipment and Heat Pipes
8.11 Unitary and Room Air Conditioners and Heat Pumps
8.12 Desiccant Dehumidification Equipment and Components

SECTION 9.0—BUILDING APPLICATIONS

9.1 Large Building Air-Conditioning Systems
9.2 Industrial Air Conditioning
9.3 Transportation Air Conditioning
9.4 Justice Facilities
9.6 Healthcare Facilities
9.7 Educational Facilities
9.8 Large Building Air-Conditioning Applications
9.9 Mission Critical Facilities, Data Centers, Technology Spaces and Electronic Equipment
9.10 Laboratory Systems
9.11 Clean Spaces
9.12 Tall Buildings

SECTION 10.0—REFRIGERATION SYSTEMS

10.1 Custom Engineered Refrigeration Systems
10.2 Automatic Icemaking Plants and Skating Rinks
10.3 Refrigerant Piping, Controls and Accessories
10.5 Refrigerated Distribution and Storage Facilities
10.6 Transport Refrigeration
10.7 Commercial Food and Beverage Refrigeration Equipment
10.8 Refrigeration Load Calculations

SECTION MTG—MULTIDISCIPLINARY TASK GROUPS

MTG.BD Building Dampness
MTG.BIM Building Information Modeling
MTG.CCDG Cold Climate Design Guide
MTG.ET Energy Targets
MTG.HCDG Hot Climate Design Guide
MTG.LowGWP Lower Global Warming Potential Alternative Refrigerants
MTG.O&MEE Operation and Maintenance Activities that Impact Energy Efficiency

ASHRAE Research: Improving the Quality of Life

ASHRAE is the world's foremost technical society in the fields of heating, ventilation, air conditioning, and refrigeration. Its members worldwide are individuals who share ideas, identify needs, support research, and write the industry's standards for testing and practice. The result is that engineers are better able to keep indoor environments safe and productive while protecting and preserving the outdoors for generations to come.

One of the ways that ASHRAE supports its members' and industry's need for information is through ASHRAE Research. Thousands of individuals and companies support ASHRAE Research annually, enabling ASHRAE to report new data about material properties and building physics and to promote the application of innovative technologies.

Chapters in the ASHRAE Handbook are updated through the experience of members of ASHRAE Technical Committees and through results of ASHRAE Research reported at ASHRAE conferences and published in ASHRAE special publications, *ASHRAE Transactions*, and ASHRAE's journal of archival research, *Science and Technology for the Built Environment*.

For information about ASHRAE Research or to become a member, contact ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329; telephone: 404-636-8400; www.ashrae.org.

Preface

The 2019 *ASHRAE Handbook—HVAC Applications* comprises 65 chapters covering a broad range of facilities and topics, written to help engineers design and use equipment and systems described in other Handbook volumes. Main sections cover comfort, industrial, energy-related, general applications, and building operations and management. ASHRAE Technical Committees in each subject area have reviewed all chapters and revised them as needed for current technology and design practice.

Full and associate ASHRAE members can download Handbook PDFs in I-P or SI units by going to technologyportal.ashrae.org. Nonmembers can purchase these PDFs at the same location, or purchase individual chapter PDFs from ashrae.org/bookstore.

This edition includes three new chapters:

- Chapter 6, Indoor Swimming Pools
- Chapter 59, Indoor Airflow Modeling
- Chapter 65, Occupant-Centric Sensing and Controls

Other particularly notable highlights include the following:

- Ch 8, Educational Facilities, provides updated design criteria, and a new section on central plant optimization for higher education campuses and educational facilities for students with disabilities.
- Ch. 9, Health Care Facilities, has been extensively rewritten to address current health care requirements.
- Ch. 16, Enclosed Vehicular Facilities, has new material on parking garage ventilation and updated ventilation flow rates.
- Ch. 20, Data Centers and Telecommunication Facilities, includes updates to reflect the current ASHRAE Datacom series, and text updates to reflect changes in the industry and new technologies such as PoE lighting and lithium-ion batteries.
- Ch. 34, Kitchen Ventilation, now discusses solid-fuel cooking, and life-cycle cost analysis, with updates from research and SSPC 154.
- Ch. 35, Geothermal Energy, has new content on direct exchange systems and pressure considerations for deep boreholes, calculation methods for design, and an updated example.
- Ch. 36, Solar Energy, added updated guidance on solar thermal collectors and photovoltaic applications, with new information on design and performance of photovoltaic systems and on installation and operation guidelines for photovoltaic systems, with new practical examples
- Ch. 40, Operation and Maintenance Management, has been extensively rewritten to address current best practices
- Ch. 41, Computer Applications, was extensively rewritten to more directly focus on immediate concerns of HVAC engineers
- Ch. 51, Service Water Heating, added discussion of water heater redundancy in large systems, and has updated information about new uniform energy factor (UEF) ratings, diversified electrical demand of whole-house/large tankless electric water heaters, and a new figure describing recommended tank and plumbing layout for heat pump water heater (HPWH) systems, showing series/parallel arrangement of HPWH and conventional water heaters.
- Ch. 52, Snow Melting, added guidance for recommended values by application type and for concrete strength and maximum temperature difference, as well as discussion of new research.
- Ch. 54, Fire and Smoke Control, has new sections on balanced approach and smoke feedback, plus extensively revised discussion of dampers, pressurization system design, and stairwells with open doors.
- Ch. 60, Integrated Building Design, has been completely rewritten to give more detail on IBD process.
- Ch. 64, Mold and Moisture, revised the order of risk factors for mold to better reflect their relative importance, and added information from ASHRAE research project RP-1712 to advise on components and configuration of dedicated outdoor air (DOAS) systems to help avoid mold growth in schools, universities, and military barracks during extended periods of unoccupied-mode HVAC operation.

This volume is published as a bound print volume and in electronic format as a downloadable PDF and online, in two editions: one using inch-pound (I-P) units of measurement, the other using the International System of Units (SI).

Corrections to the 2016, 2017, and 2018 Handbook volumes can be found on the ASHRAE web site at http://www.ashrae.org and in the Additions and Corrections section of this volume. Corrections for this volume will be listed in subsequent volumes and on the ASHRAE web site.

Reader comments are enthusiastically invited. To suggest improvements for a chapter, **please comment using the form on the ASHRAE web site** or write to Handbook Editor, ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329, or fax 678-539-2187, or e-mail hkennedy@ashrae.org.

CHAPTER 1

RESIDENTIAL SPACE CONDITIONING

Systems 1.1
Equipment Sizing 1.2
Single-Family Residences 1.3
Multifamily Residences 1.8
Manufactured Homes 1.9

SPACE-CONDITIONING systems for residential use vary with both local and application factors. Local factors include energy source availability (present and projected) and price; climate; socioeconomic circumstances; and availability of installation and maintenance skills. Application factors include housing type, construction characteristics, and building codes. As a result, many different systems are selected to provide combinations of heating, cooling, humidification, dehumidification, ventilation, and air filtering. This chapter emphasizes the more common systems for space conditioning of both single-family (i.e., traditional site-built and modular or manufactured homes) and multifamily residences. Low-rise multifamily buildings generally follow single-family practice because constraints favor compact designs; HVAC systems in high-rise apartment, condominium, and dormitory buildings are often of commercial types similar to those used in hotels. Retrofit and remodeling construction also adopt the same systems as those for new construction, but site-specific circumstances may call for unique designs.

1. SYSTEMS

Common residential systems are listed in Table 1. Four generally recognized groups are central forced air, central hydronic, zoned systems, and room or portable equipment. System selection and design involve such key decisions as (1) source(s) of energy, (2) means of distribution and delivery, and (3) terminal device(s).

Climate determines the services needed. Heating and cooling are generally required. Air cleaning, by filtration or electrostatic devices, is present in most systems. Humidification, when used, is provided in heating systems for thermal comfort (as defined in ASHRAE *Standard* 55), health, antiques or art preservation, and reduction of static electricity discharges. Cooling systems usually dehumidify air as well as lowering its temperature. Introduction of outdoor (fresh) air may be required in some applications. Typical forced-air residential installations are shown in Figures 1 and 2.

Table 1 Residential Heating and Cooling Systems

	Central Forced Air	Central Hydronic	Zoned	Room or Portable
Most common energy sources	Gas Oil Electricity	Gas Oil Electricity	Gas Electricity	Electricity
Heat source/ sink	Air Ground Water	Air Water	Air Ground Water	Air
Distribution medium	Air	Water Steam	Air Water Refrigerant	Air
Distribution system	Ducting	Piping	Ducting/dampers Piping or Free delivery	Ducting/free delivery

The preparation of this chapter is assigned to TC 8.11, Unitary and Room Air Conditioners and Heat Pumps.

Figure 1 shows a gas furnace, split-system air conditioner, humidifier, and air filter. Air from the space enters the equipment through a return air duct. It passes initially through the air filter. The circulating blower is an integral part of the furnace, which supplies heat during winter. An optional humidifier adds moisture to the heated air, which is distributed throughout the home via the supply duct. When cooling is required, heat and moisture are removed from the circulating air as it passes across the evaporator coil. Refrigerant lines connect the evaporator coil to a remote condensing unit located outdoors. Condensate from the evaporator is removed through a drain line with a trap.

Figure 2 shows a split-system heat pump, supplemental electric resistance heaters, humidifier, and air filter. The system functions as follows: air from the space enters the equipment through the return air duct (or sometimes through an opening in the equipment itself), and passes through a filter. The circulating blower is an integral part of the indoor air-handling portion of the heat pump system, which supplies heat through the indoor coil during the heating season. Optional electric heaters supplement heat from the heat pump during

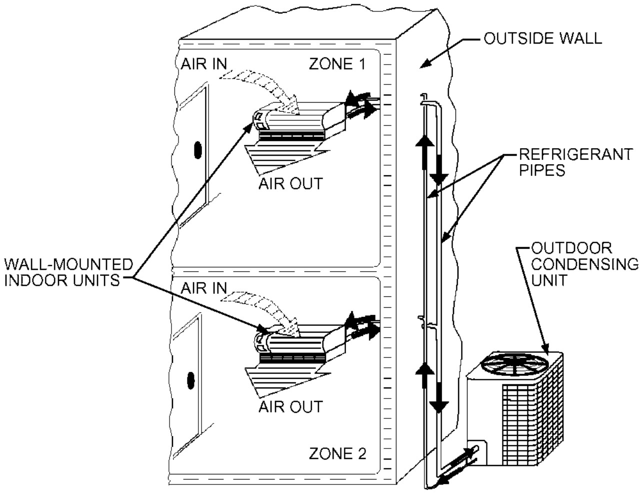

Fig. 3 Example of Two-Zone, Ductless Multisplit System in Typical Residential Installation

periods of low outdoor temperature and counteract indoor airstream cooling during periodic defrost cycles. This supplemental heat is also referred to as emergency heat since it may function as a backup heat source. Systems referred to as dual fuel apply a furnace to provide some of the functionality of the electric supplemental heat. An optional humidifier adds moisture to the heated air, which is distributed throughout the home through the supply duct. When cooling is required, heat and moisture are removed from the circulating air as it passes across the evaporator coil. Refrigerant lines connect the indoor coil to the outdoor unit. Condensate from the indoor coil is removed through a drain line with a trap.

Minisplit and multisplit systems, which are similar to split systems but are typically ductless, are increasingly popular worldwide. A typical two-zone, ductless multisplit system installation is shown in Figure 3. In this example, the system consists mainly of two sections: an outdoor condensing unit and two indoor air-handling units that are usually installed on perimeter walls of the house. Each indoor air handler serves one zone and is controlled independently from the other indoor unit. Figure 3 shows a top-discharge condensing unit. Side-discharge outdoor units are also widely applied.

Single-package unitary systems, such as window-mounted, through-the-wall, or rooftop units where all equipment is contained in one cabinet, are also popular. Ducted versions are used extensively in regions where residences have duct systems in crawlspaces beneath the main floor and in areas such as the southwestern United States, where rooftop-mounted packages connect to attic duct systems.

Central hydronic heating systems are popular both in Europe and in parts of North America where central cooling has not normally been provided. New construction, especially in multistory homes, now typically includes forced-air cooling.

Zoned systems are designed to condition only part of a home at any one time. Systems may be ducted, duct free, or hydronic. They may consist of individual room units or central systems with zoned distribution networks. Multiple central systems that serve individual floors or the sleeping and common portions of a home separately are sometimes used in large single-family residences.

The energy source is a major consideration in system selection. According to 2015 data from the U.S. Energy Information Administration (EIA 2017), for heating, about 47% of homes use natural gas, followed by electricity (36%), propane (5%), fuel oil/kerosene (5%), and wood (2%). Relative prices, safety, and environmental concerns (both indoor and outdoor) are further factors in heating energy source selection. Where various sources are available, economics strongly influence the selection. Electricity is the dominant energy source for cooling.

2. EQUIPMENT SIZING

The heat loss and gain of each conditioned room and of ductwork or piping run through unconditioned spaces in the structure must be accurately calculated to select equipment with the proper heating and cooling capacity. To determine heat loss and gain accurately, the floor plan and construction details, including information on wall, ceiling, and floor construction as well as the type and thickness of insulation, must be known. Window design and exterior door details are also needed. With this information, heat loss and gain can be calculated using the Air-Conditioning Contractors of America (ACCA) *Manual* J® or similar calculation procedures. From there, equipment selections can be made using ACCA *Manual* S® or other equipment selection procedures. To conserve energy, many jurisdictions require that the building be designed to meet or exceed the requirements of ASHRAE *Standard* 90.2 or similar requirements.

Proper matching of equipment capacity to the building heat loss and gain is essential. Building loads vary throughout the day and across seasons, so matching capacity to load can be a challenge. Variable and multistage equipment have a wide capacity range, so oversizing is less of an issue. The heating capacity of air-source heat pumps is usually supplemented by auxiliary heaters, most often of the electric resistance type; in some cases, however, fossil fuel furnaces or solar systems are used.

Undersized equipment will be unable to maintain the intended indoor temperature under extreme outdoor temperatures. Some oversizing may be desirable to enable recovery from setback and to maintain indoor comfort during outdoor conditions that are more extreme than the nominal design conditions. Grossly oversized equipment can cause discomfort because of short *on*-times, wide indoor temperature swings, and inadequate dehumidification when cooling. Gross oversizing may also contribute to higher energy use by increasing cyclic losses. Excessive cycling is also a reliability concern. Variable-capacity equipment (heat pumps, air conditioners, and furnaces) can more closely match building loads over broad ambient temperature ranges, usually reducing these losses and improving comfort levels; in the case of heat pumps, supplemental heat needs may also be reduced.

Residences of tight construction may have high indoor humidity and a build-up of indoor air contaminants at times. Air-to-air heat recovery equipment may be used to provide tempered ventilation air to tightly constructed houses. See Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for additional information on air-to-air heat recovery. Outdoor air intakes connected to the return duct of central systems may also be used when reducing installed costs is important. Simple exhaust systems with or without passive air intakes are also popular. Natural ventilation by operable windows is also popular in some climates. Excessive accumulation of radon is of concern in all buildings; lower-level spaces should not be depressurized, which causes increased migration of soil gases into buildings. All ventilation schemes increase heating and cooling loads and thus the required system capacity, thereby resulting in greater energy consumption. In all cases, minimum ventilation rates, as described in ASHRAE *Standards* 62.1 and 62.2, as applicable, should be maintained.

3. SINGLE-FAMILY RESIDENCES

Furnaces

Furnaces are fueled either by electricity, or by combustible materials; gas (natural or propane), oil, and wood are most common. Electric furnaces are comprised of electric resistance heaters and a blower fan.

Combustion furnaces may draw combustion air from inside the house or from outdoors. If the furnace space is located such that combustion air is drawn from the outdoors, the arrangement is called an **isolated combustion system (ICS)**. Furnaces are generally rated on an ICS basis. Outdoor air is ducted to the combustion chamber (a direct-vent system) for manufactured home applications and some mid- and high-efficiency equipment designs. Using outdoor air for combustion eliminates both infiltration losses associated with using indoor air for combustion and stack losses associated with atmospherically induced draft-hood-equipped furnaces.

Two available types of high-efficiency gas furnaces are noncondensing and condensing. Both increase efficiency by adding or improving heat exchanger surface area and reducing heat loss during furnace off times. Noncondensing furnaces usually have combustion efficiencies below 85%, and condensing furnaces have combustion efficiencies higher than 90%. The higher-efficiency condensing type recovers more energy by condensing water vapor from combustion products. Condensate is formed in a corrosion-resistant heat exchanger and is disposed of through a drain line. Care must be taken to prevent freezing the condensate when the furnace is installed in an unheated space such as an attic. Noncondensing furnaces use metallic vents, whereas condensing furnaces generally use PVC for vent pipes and condensate drains.

Chapters 31 and 33 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* include more detailed information on furnaces and furnace efficiency.

Hydronic Heating Systems

With the growth of demand for central cooling systems, hydronic systems have declined in popularity in new construction, but still account for a significant portion of existing systems in colder climates. The fluid is heated in a central boiler and distributed by piping to terminal units in each room. Terminal units are typically either radiators or baseboard convectors. Other terminal units include fan-coils and radiant panels. Most recently installed residential systems use a forced-circulation, multiple-zone hot-water system with a series-loop piping arrangement. Chapters 13 and 36 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* have more information on hydronics, and Chapter 32 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides more information on boilers.

Design water temperature is based on economic and comfort considerations. Generally, higher temperatures result in lower first costs because smaller terminal units are needed. However, losses tend to be greater, resulting in higher operating costs and reduced comfort because of the concentrated heat source. Typical design temperatures for radiator systems range from 80 to 95°C. For radiant panel systems, design temperatures range from 45 to 75°C. The preferred control method allows the water temperature to decrease as outdoor temperatures rise. Provisions for expansion and contraction of piping and heat distributing units and for eliminating air from the hydronic system are essential for quiet, leak-tight operation.

Fossil fuel systems that condense water vapor from the flue gases must be designed for return water temperatures in the range of 50 to 55°C for most of the heating season. Noncondensing systems must maintain high enough water temperatures in the boiler to prevent this condensation. If rapid heating is required, both terminal unit and boiler size must be increased, although gross oversizing should be avoided.

Another concept for multi- or single-family dwellings is a combined water-heating/space-heating system that uses water from the domestic hot-water storage tank to provide space heating. Water circulates from the storage tank to a hydronic coil in the system air handler. Space heating is provided by circulating indoor air across the coil. A split-system central air conditioner with the evaporator located in the system air handler can be included to provide space cooling.

Solar Heating

Both active and passive solar thermal energy systems are sometimes used to heat residences. In typical active systems, flat-plate collectors heat air or water. Air systems distribute heated air either to the living space for immediate use or to a thermal storage medium (e.g., a rock pile). Water systems pass heated water from the collectors through a heat exchanger and store heat in a water tank. Because of low delivered-water temperatures, radiant floor panels requiring moderate temperatures are often used. A water-source heat pump between the water storage tank and the load can be used to increase temperature differentials.

Trombe walls, direct-gain, and greenhouse-like sunspaces are common passive solar thermal systems. Glazing facing south (in the northern hemisphere), with overhangs to reduce solar gains in the summer, and movable night insulation panels reduce heating requirements.

Some form of back-up heating is generally needed with solar thermal energy systems. Solar electric systems are not normally used for space heating because of the high energy densities required and the economics of photovoltaics. However, hybrid collectors, which combine electric and thermal capabilities, are available. Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* has information on sizing solar heating equipment.

Heat Pumps

Heat pumps for single-family houses are normally centrally ducted unitary or duct-free unitary split systems, as shown in Figures 2 and 3.

Most commercially available heat pumps, particularly in North America, are reversible, electrically powered, air-source systems. The direction of flow of the refrigerant can be switched to provide cooling or heating to the home.

Heat pumps may be classified by thermal source and distribution medium in the heating mode as well as the type of fuel used. The most common classifications of heat pump equipment are air-to-air and water-to-air. Air-to-water and water-to-water types are also used.

Heat pump systems are generally described as air-source or ground-source. The thermal sink for cooling is generally assumed to be the same as the thermal source for heating.

Air-Source Systems. Air-source systems using ambient air as the heat source/sink can be installed in almost any application and are generally the least costly to install and thus the most commonly used.

Ground-Source (Geothermal) Systems. Ground-source systems usually use water-to-air heat pumps to extract heat from the ground using groundwater or a buried heat exchanger. As a heat source/sink, groundwater (from individual wells or supplied as a utility from community wells) offers the following advantages over ambient air: (1) heat pump capacity is independent of ambient air temperature, reducing supplemental heating requirements; (2) no defrost cycle is required; (3) although operating conditions for establishing rated efficiency are not the same as for air-source systems, seasonal efficiency is usually higher for heating and for cooling; and (4) peak heating energy consumption is usually lower.

Two other system types are ground-coupled and surface-water-coupled systems. **Ground-coupled systems** offer the same advantages, but because surface water temperatures track fluctuations in air temperature, **surface-water-coupled systems** may not offer the same benefits as other ground-source systems. Both system types circulate brine or water in a buried or submerged heat exchanger to transfer heat from the ground or water. **Direct-expansion ground-source systems**, with evaporators buried in the ground, also are available but are seldom used. **Water-source systems** that extract heat from surface water (e.g., lakes or rivers) or city (tap) water are sometimes used where local conditions allow. See Chapter 49 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for further information.

Water supply, quality, and disposal must be considered for groundwater systems. Caneta Research (1995) and Kavanaugh and Rafferty (2014) provide detailed information on these subjects. Secondary coolants for ground-coupled systems are discussed in Caneta Research (1995) and in Chapter 31 of the 2017 *ASHRAE Handbook—Fundamentals*. Buried heat exchanger configurations may be horizontal or vertical, with the vertical including both multiple-shallow- and single-deep-well configurations. Ground-coupled systems avoid water quality, quantity, and disposal concerns but are sometimes more expensive than groundwater systems. However, ground-coupled systems are usually more efficient, especially when pumping power for the groundwater system is considered. Proper installation of the ground coil(s) is critical to success.

Hybrid or Dual-Fuel Systems. In add-on systems, typically called dual-fuel or hybrid, a heat pump is added (often as a retrofit) to an existing furnace or boiler/fan-coil system. The heat pump and combustion device are operated in one of two ways: (1) alternately, depending on which is most cost-effective, or (2) in parallel. Bivalent heat pumps, factory-built with the heat pump and combustion device grouped in a common chassis and cabinets, provide similar benefits at lower installation costs.

Fuel-Fired Heat Pumps. Fuel-fired heat pumps for residential applications are available in North America and Europe. Usually, these systems take the form of absorption cycles. For results of one investigation on these heat pumps, see Grossman et al. (1995).

Water-Heating Options. Heat pumps may be equipped with desuperheaters (either integral or field-installed) to reclaim heat for domestic water heating when operated in cooling mode. Integrated space-conditioning and water-heating heat pumps with an additional full-size condenser for water heating are also available. ASHRAE *Standard* 124 provides a method of test for rating combination space- and water-heating appliances.

Zoned Heating and Cooling Systems

Most moderate-cost residences in North America have single-thermal-zone HVAC systems with one thermostat. Multizoned systems, however, offer the potential for improved thermal comfort. Lower operating costs are possible with zoned systems because unoccupied areas (e.g., common areas at night, sleeping areas during the day) can be kept at lower temperatures in the winter.

One form of this system consists of individual equipment located in each room. Room heaters are usually electric or gas-fired. Electric heaters are available in the following types: baseboard free-convection, wall insert (free-convection or forced-fan), radiant panels for walls and ceilings, and radiant cables for walls, ceilings, and floors. Matching equipment capacity to heating requirements is critical for individual room systems. Heating delivery cannot be adjusted by adjusting air or water flow, so greater precision in room-by-room sizing is needed. Most individual heaters have integral thermostats that limit the ability to optimize unit control without continuous fan operation.

Room air conditioners are typically electrically operated. Window, room, and packaged terminal air conditioners (PTACs) provide both sensible and latent cooling. Window air conditioners are inexpensive and simple to install where a central system does not exist or does not provide sufficient comfort in one room or zone. Room air conditioners are similar to window air conditioners, except the condenser typically pulls air from the indoors rather than outdoors, and the appliance is floor standing with ducts to a small window-mounted panel to reject condenser heat to the outdoors. PTACs are designed to mount in a framed wall opening, so are a permanent rather than seasonal addition to a building. Some PTACs are heat pumps, so can provide both heating and cooling. In dry climates, direct-evaporative coolers (“swamp coolers”) can improve comfort, and room humidifiers or dehumidifiers can be used in any climate. Ceiling and portable fans are also widely used to improve comfort within a room. Each of these room appliances typically has its own dedicated sensors and controls in the same room. Some new room equipment can be connected to the Internet, enabling coordination of service across the whole house.

Individual heat pumps for each room or group of rooms (zone) are another form of zoned electric heating. For example, two or more small unitary heat pumps can be installed in two-story or large one-story homes.

The multisplit heat pump consists of a central compressor and an outdoor heat exchanger to serve multiple indoor zones. Each zone uses one or more fan-coils, with separate thermostatic controls for each zone. These systems are used in both new and retrofit construction. These are also known as **variable-refrigerant-volume (VRV)** or **variable-refrigerant-flow (VRF) systems**, and may include a heat recovery mode where some indoor units operate in heating and some in cooling simultaneously. For more information on VRF systems, see Chapter 18 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

A method for zoned heating and cooling in central ducted systems is the zone-damper system. This consists of individual zone dampers and thermostats combined with a zone control system. Both variable-air-volume (damper position proportional to zone demand) and on/off (damper fully open or fully closed in response to thermostat) types are available. These systems sometimes include a provision to modulate to lower capacities when only a few zones require conditioning. Because weather is the primary influence on the load, the cooling or heating load in each room changes from hour to hour. Therefore, the owner or occupant should be able to make seasonal or more frequent adjustments to the air distribution system to improve comfort. Adjustments may involve opening additional outlets in second-floor rooms during summer and throttling or closing heating outlets in some rooms during winter. Manually adjustable balancing dampers may be provided to facilitate these adjustments. Other possible refinements are installing a heating and cooling system sized to meet heating requirements, with additional self-contained cooling units serving rooms with high summer loads, or separate central systems for the upper and lower floors of a house. Alternatively, zone-damper systems can be used. Another way of balancing cooling and heating loads is to use variable-capacity compressors in heat pump systems.

Operating characteristics of both heating and cooling equipment must be considered when zoning is used. For example, reducing air quantity to one or more rooms may reduce airflow across the evaporator to such a degree that frost forms on the fins. Reduced airflow on heat pumps during the heating season can cause overloading if airflow across the indoor coil is not maintained above 45 L/s per kilowatt. Reduced air volume to a given room reduces the air velocity from the supply outlet and might cause unsatisfactory air distribution in the room. Manufacturers of zoned systems normally provide guidelines for avoiding such situations. Some hydronic systems use valve manifolds near the boiler to provide hydronic heat on a zonal basis. Each room's radiator or convector is served by dedicated piping from the valve manifold, with a common return pipe. The variable valves are all independently controlled by room thermostats, based on thermal demand.

Unitary Air Conditioners

In forced-air systems, the same air distribution duct system can be used for both heating and cooling. Split-system central cooling, as shown in Figure 1, is the most widely used forced-air system. Upflow, downflow, and horizontal-airflow indoor units are available. Condensing units are installed on a noncombustible pad outdoor and contain a motor- or engine-driven compressor, condenser, condenser fan and fan motor, and controls. The condensing unit and evaporator coil are connected by refrigerant tubing that is normally field-supplied. However, precharged, factory-supplied tubing with quick-connect couplings is also common where the distance between components is not excessive.

A distinct advantage of split-system central cooling is that it can readily be added to existing forced-air heating systems. Airflow rates are generally set by the cooling requirements to achieve good performance, but most existing heating duct systems are adaptable to cooling. Airflow rates of 45 to 60 L/s per kilowatt of refrigeration are normally recommended for good cooling performance. Specialty systems such as small-duct high-velocity (SDHV) systems have lower airflows and are used in applications where retrofitting larger supply ducts is not possible. As with heat pumps, split-system central cooling may be fitted with desuperheaters for domestic water heating.

Some cooling equipment includes forced-air heating as an integral part of the product. Year-round heating and cooling packages with a gas, oil, or electric furnace for heating and a vapor-compression system for cooling are available. Air-to-air and water-source heat pumps provide cooling and heating by reversing the flow of refrigerant.

Distribution. Duct systems for cooling (and heating) should be designed and installed in accordance with accepted practice. Useful information is found in ACCA *Manuals* D® and S®.

There is renewed interest in quality duct design, because it can make a large difference in the effectiveness of the residential unitary cooling and heating system. There is a trend toward placing as much ductwork as possible in the conditioned space, to reduce duct thermal losses and lessen the effect of any leaks that exist. For a given diameter, flexible ducts have higher pressure drop than metal ducts, and this should be taken into consideration. Flexible duct must be stretched and properly supported or it can sag, increasing airflow resistance. Minimizing duct system airflow resistance helps minimize energy consumption throughout the life of the system.

Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals* provides the theory behind duct design. In the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, Chapter 10 discusses air distribution design for small heating and cooling systems, Chapter 19 addresses duct construction and code requirements, and Chapter 49 provides more detailed information on unitary air conditioners and heat pumps.

Special Considerations. In residences with more than one story, cooling and heating are complicated by air buoyancy, also known as the **stack effect**. In many such houses, especially with single-zone systems, the upper level tends to overheat in winter and undercool in summer. Multiple air outlets, some near the floor and others near the ceiling, have been used with some success on all levels. To control airflow, the homeowner opens some outlets and closes others from season to season. Free air circulation between floors can be reduced by locating returns high in each room and keeping doors closed.

In existing homes, the cooling that can be added is limited by the air-handling capacity of the existing duct system. Although the existing duct system size is usually satisfactory for normal occupancy, it may be inadequate during large gatherings. When new cooling (or heating) equipment is installed in existing homes, supply air ducts and outlets should be checked for acceptable air-handling capacity and air distribution. Maintaining upward airflow at an effective velocity is important when converting existing heating systems with floor or baseboard outlets to both heat and cool. It is not necessary to change the deflection from summer to winter for registers located at the perimeter of a residence. Registers located near the floor on the indoor walls of rooms may operate unsatisfactorily if the deflection is not changed from summer to winter.

A residence without a forced-air heating system may be cooled by one or more central systems with separate duct systems, by individual room air conditioners (window-mounted or through-the-wall), or by minisplit room air conditioners.

Cooling equipment must be located carefully. Because cooling systems require higher indoor airflow rates than most heating systems, sound levels generated indoors are usually higher. Thus, indoor air-handling units located near sleeping areas may require sound attenuation. Outdoor noise levels should also be considered when locating the equipment. Many communities have ordinances regulating the sound level of mechanical devices, including cooling equipment. Manufacturers of unitary air conditioners often rate the sound level of their products according to an industry standard (Air-Conditioning, Heating, and Refrigeration Institute [AHRI] *Standard* 270). AHRI *Standard* 275 gives information on how to predict the sound level in dBA when the AHRI sound rating number, the equipment location relative to reflective surfaces, and the distance to the property line are known.

An effective and inexpensive way to reduce noise is to put distance and natural barriers between sound source and listener. However, airflow to and from air-cooled condensing units must not be obstructed; for example, plantings and screens must be porous and placed away from units so as not to restrict intake or discharge of air. Most manufacturers provide recommendations on acceptable distances between condensing units and natural barriers. Outdoor units should be placed as far as is practical from porches and patios, which may be used while the house is being cooled. Locations near bedroom windows and occupied spaces of neighboring homes should also be avoided. In high-crime areas, consider placing units on roofs or other semisecure areas.

Evaporative Coolers

In climates that are dry throughout the entire cooling season, evaporative coolers can be used to cool residences. They must be installed and maintained carefully to reduce the potential for water and thus air quality problems. Further details on evaporative coolers can be found in Chapter 41 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and in Chapter 52 of this volume.

Humidifiers

For improved winter comfort, equipment that increases indoor relative humidity may be needed. In a ducted heating system, a central whole-house humidifier can be attached to or installed within a supply plenum or main supply duct, or installed between the supply and return duct systems. When applying supply-to-return duct humidifiers on heat pump systems, take care to maintain proper airflow across the indoor coil. Self-contained portable or tabletop humidifiers can be used in any residence. Even though this type of humidifier introduces all the moisture to one area of the home, moisture migrates and raises humidity levels in other rooms.

Overhumidification should be avoided: it can cause condensate to form on the coldest surfaces in the living space (usually windows). Also, because moisture migrates through all structural materials, vapor retarders should be installed near the warmer indoor surface of insulated walls, ceilings, and floors in most temperature climates. Lack of attention to this construction detail allows moisture to migrate from indoors to outdoors, causing damp insulation, mold, possible structural damage, and exterior paint blistering. Chapters 25 to 27 of the 2017 *ASHRAE Handbook—Fundamentals* provide further details.

Central humidifiers may be rated in accordance with AHRI *Standard* 611. This rating is expressed in the number of litres per day evaporated by 49°C entering air. Selecting the proper size humidifier is important and is outlined in AHRI *Guideline* F.

Humidifier cleaning and maintenance schedules must be followed to maintain efficient operation and prevent bacteria build-up. Chapter 22 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* contains more information on residential humidifiers.

Dehumidifiers

Many homes also use dehumidifiers to remove moisture and control indoor humidity levels. In cold climates, dehumidification is sometimes required during the summer in basement areas to control mold and mildew growth and to reduce zone humidity levels. Traditionally, portable dehumidifiers have been used to control humidity in this application. Although these portable units are not always as efficient as central systems, their low first cost and ability to serve a single zone make them appropriate in many circumstances.

In hot, humid climates, providing sufficient dehumidification with sensible cooling is important. Although conventional air-conditioning units provide some dehumidification as a consequence of sensible cooling, in some cases space humidity levels can still exceed comfortable levels. Residential dehumidifiers almost exclusively rely on direct-expansion refrigeration systems, operating with evaporator temperatures below the process air's dew point, to dehumidify the air through condensation.

Several dehumidification enhancements to conventional air-conditioning systems are possible to improve moisture removal characteristics and lower the space humidity level. Some simple improvements include lowering the supply airflow rate to overcool the airstream, and eliminating off-cycle fan operation. Additional equipment options such as condenser/reheat coils, sensible-heat-exchanger-assisted evaporators (e.g., heat pipes), and subcooling/reheat coils can further improve dehumidification performance. Desiccants, applied as either thermally activated units or heat recovery systems (e.g., enthalpy wheels), can also increase dehumidification capacity and lower the indoor humidity level. Some dehumidification options add heat to the conditioned zone that, in some cases, increases the load on the sensible cooling equipment. Dehumidifiers are rated in accordance with Association of Home Appliance Manufacturers (AHAM) *Standard* DH-1. Chapter 25 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* contains more information on residential dehumidifiers.

Air Filters

Most comfort conditioning systems that circulate air incorporate some form of air filter. Usually, they are disposable or cleanable filters that have relatively low air-cleaning efficiency. Alternatives with higher air-cleaning efficiencies include pleated media filters and electronic air filters. These filters may have higher static pressure drops. The air distribution system should be carefully evaluated before installing such filters so that airflow rates are not overly reduced with their use. Airflow must be evaluated both when the filter is new and when it is in need of replacement or cleaning.

Air filters are mounted in the return air duct or plenum and operate whenever air circulates through the duct system. Air filters are rated in accordance with AHRI *Standard* 681, which was based on ASHRAE *Standard* 52.2. Atmospheric dust spot efficiency levels are generally less than 20% for disposable filters and vary from 60 to 90% for electronic air filters. However, increasingly, the minimum efficiency rating value (MERV) from ASHRAE *Standard* 52.2 is given instead; a higher MERV implies greater particulate removal, but also typically increased air pressure drop for the same filter depth.

To maintain optimum performance, the collector cells of electronic air filters must be cleaned periodically. Automatic indicators are often used to signal the need for cleaning. Electronic air filters have higher initial costs than disposable or pleated filters, but generally last the life of the air-conditioning system. Also available are gas-phase filters such as those that use activated carbon. Chapter 29 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* covers the design of residential air filters in more detail.

Ultraviolet (UV) germicidal light as an air filtration system for residential applications has become popular recently. UV light has been successfully used in health care facilities, food-processing plants, schools, and laboratories. It can break organic molecular bonds, which translates into cellular or genetic damages for microorganisms. Single or multiple UV lamps are usually installed in the return duct or downstream of indoor coils in the supply duct. Direct exposure of occupants to UV light is avoided because UV light does not pass through metal, glass, or plastic. This air purification method effectively reduces the transmission of airborne germs, bacteria, molds, viruses, and fungi in the airstreams without increasing duct pressure losses. The power required by each UV lamp might range between 30 and 100 W, depending on the intensity and exposure time required to kill the various microorganisms. Chapter 17 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and Chapter 60 of this volume cover the design and application of UV lamp systems in more detail.

Ventilation

Historically, residential buildings have not required active mechanical ventilation. They were built without focus on airtightness, so in general natural infiltration along with some use of spot ventilation was sufficient to maintain indoor air quality at a safe and comfortable level. Because recent construction codes have increased energy efficiency, mechanical ventilation is generally necessary for energy-efficient housing. ASHRAE *Standard* 62.2 provides guidance on selecting ventilation airflow rates, based on the method used for distributing that air throughout the home. Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals* provides additional information on residential ventilation.

Controls

Residential heating and cooling equipment is controlled by one or more thermostats, which call for heating and cooling from the equipment's embedded control board, and a zone control system if installed. A useful guideline is to install thermostats on an interior wall in a frequently occupied area, about 1.5 m from the floor and away from exterior walls and registers to avoid unintended short-cycling of the equipment when cold or hot air blows on the thermostat. A typical simple wall thermostat contains a temperature sensor and microelectronics that request the heating and cooling equipment operate when the measured temperature falls outside of a dead band, typically ±0.56 K centered at the owner's desired set point.

Programmable thermostats can set heating and cooling equipment at different temperature levels, depending on the time of day or week. This has led to night setback, workday, and vacation control to reduce energy demand and operating costs. For heat pump equipment, electronic thermostats can incorporate night setback with an appropriate scheme to limit use of resistance heat during recovery. Several manufacturers offer thermostats that measure and display relative humidity and actively change the evaporator blower speed to improve latent cooling during times of high humidity.

Modern thermostats use additional sensors, such as remote room temperature, humidity, and motion sensors, or integrate with external computing platforms (e.g., mobile phones) to monitor occupants' locations and enable automatic return when people enter a geographic radius from the home. The use of machine learning, geofencing, and other emerging features is very promising for reducing energy consumption and costs while maintaining or improving user comfort. These so-called **smart thermostats** can be integrated with both noncommunicating and communicating HVAC systems. Some communicating systems require a smart thermostat, often by the same manufacturer, to take advantage of the improved efficiency and fault detection/diagnostic features that a communicating HVAC system provides. For example, most minisplit heat pumps are accompanied by a remote controller that contains the system thermostat, a display, and other user controls. Chapter 47 contains more details about automatic control systems.

In traditional (noncommunicating) systems, the thermostat uses relay logic, or discrete on/off voltage signals, to control the operation of the HVAC system. This results in having to run many wires from the thermostat to the indoor unit and outdoor unit. Some residential systems require 12 wires to be connected and therefore have high risk of being miswired during installation.

A communicating system replaces the many wires with serial communications over two, three, or four wires only, as depicted in Figure 4. In a communicating HVAC system, the indoor unit, outdoor unit, and thermostat act as nodes on a network that send and receive messages to and from each other across a limited number of wires. Each node (device) has its own unique electronic address. Messages are packaged into a common format called a communications protocol and transported to their destinations on the network. In retrofits, these systems offer the ease of plug-and-play installation using existing wiring. A homeowner can replace an existing single-stage furnace and air conditioner with two-stage or variable-capacity equipment and not need to run additional wires. In theory, communications between nodes could also be wireless if they were equipped with radio transceivers.

Communicating systems are a relatively recent addition to residential HVAC, having shown their usefulness in commercial HVAC. The advent of electronics to control the evaporator coil (by modulating both the electronic expansion valve and the blower) and the condensing unit (primarily through monitoring and modulating the compressor) enable systems to take advantage of communications. Communicating systems are easier to install than noncommunicating systems and offer more options to the HVAC engineer.

Communicating HVAC systems also allow an advanced level of system diagnostics. Because nodes communicate in messages, not signals, unlimited amounts of information could be transferred across the few wires of a communicating system. Messages could convey commands or just carry information. This contrasts with having to add a new wire for each additional (analog) signal, as is the case of noncommunicating systems. For example, in a communicating system, the outdoor unit could announce that it has a variable-capacity compressor and the thermostat could command the compressor to turn on and to ramp to a certain speed. The thermostat could ask the outdoor unit for the measured ambient temperature to display it on its screen, or the outdoor unit could send a message to the thermostat to alert the homeowner that a pressure switch is open.

For an HVAC system to be communicating, each device (node) must have an electronic circuit board with a microprocessor. The board gets data from sensors and other HVAC components that are connected to it (e.g., compressor contactor, pressure switches, reversing valve, blower fan, indoor electric heater). The microprocessor packages the data collected from those components into messages and sends them to other nodes on the network. The microprocessor of each node also receives messages from other nodes intended for that node. Although many new residential HVAC systems have some electronics in them, to be considered communicating, the microprocessor must be able to handle the additional burden of implementing the communications protocol as well as handling the traffic of messages on the network. Currently, all communicating systems use proprietary protocols and do not allow matching indoor and outdoor equipment using different protocols.

Networking the components of a residential HVAC system to form a communicating system provides a framework for sharing information within the network as well as with external devices. A wired or wireless gateway, either stand-alone or integrated into any of the communicating nodes, is often used to facilitate data transfer. This enables the HVAC system to be remotely

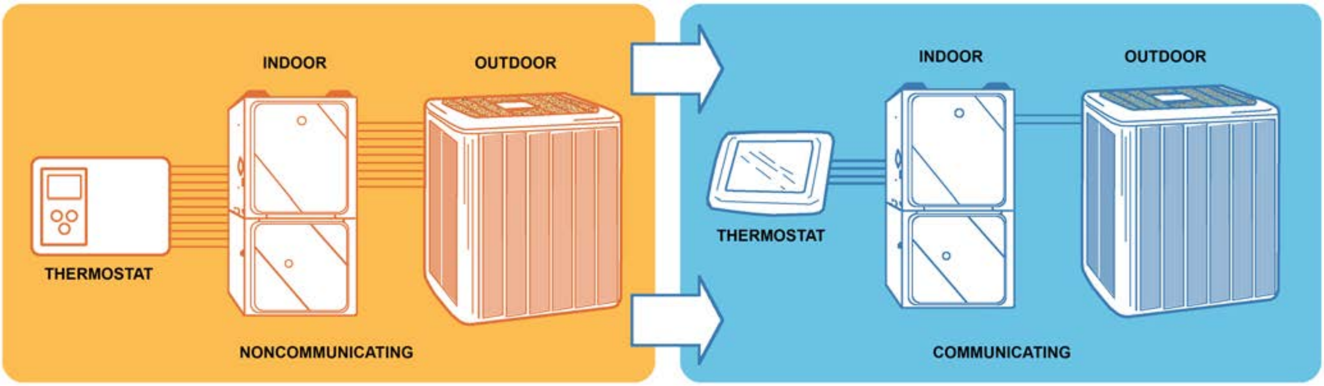

Fig. 4 Communicating HVAC Systems Simplify Wiring

accessible to networked devices such as smart phones, laptops, mobile devices, the electric utility company's smart meter, or cloud services. This remote accessibility, together with the wealth of system information available in a communicating system, allows innovations in the way HVAC systems are maintained and managed. For example, a homeowner could monitor the sensed temperature at the thermostat, check/set the thermostat set-point temperature, change thermostat schedules, and receive maintenance notifications using a smart phone. Electric utilities can supply a signal to reduce electrical demand, and the communicating control system can acknowledge and act on this signal.

4. MULTIFAMILY RESIDENCES

Attached homes and low-rise multifamily apartments generally use heating and cooling equipment comparable to applications used in single-family dwellings. Separate systems for each unit allow individual control to suit the occupant and facilitate individual metering of energy use; separate metering and direct billing of occupants encourages energy conservation.

Forced-Air Systems

High-rise multifamily structures may use unitary, minisplit, or multisplit heating or cooling equipment similar to applications in single-family dwellings. Equipment may be installed in a separate mechanical equipment room in the apartment, on a balcony, or above a dropped ceiling over a hallway or closet. Split system (condensing or heat pump) outdoor units are often placed on roofs, balconies, or the ground. Other common applications include through-the-wall or wall-mounted systems.

Small residential warm-air furnaces may also be used, but a means of providing combustion air and venting combustion products from gas- or oil-fired furnaces is required. It may be necessary to use a multiple-vent chimney or a manifold-type vent system. Local codes must be consulted. Direct-vent furnaces that are placed near or on an outer wall are also available for apartments.

Hydronic Systems

Individual heating and cooling units are not always possible or practical in high-rise structures. In this case, applied central systems are used. Two- or four-pipe hydronic central systems are widely used in high-rise apartments. Each dwelling unit has either individual room units or ducted fan-coil units.

An on-demand water heater may also be used as a source of heat for the hydronic coil instead of a central system. In these applications, the on-demand water heater serves as a source of heat and hot water for the individual apartment. Cooling may come from a central hydronic system, window air conditioner, or typical unitary condenser, as described in the section on Forced-Air Systems.

The most flexible hydronic system with usually the lowest operating costs is the four-pipe type, which provides heating or cooling for each apartment dweller. The two-pipe system is less flexible because it cannot provide heating and cooling simultaneously. This limitation causes problems during the spring and fall when some apartments in a complex require heating while others require cooling because of solar or internal loads. This spring/fall problem may be overcome by operating the two-pipe system in a cooling mode and providing the relatively low amount of heating that may be required by means of individual electric resistance heaters.

See the section on Hydronic Heating Systems for description of a combined water-heating/space-heating system for multi- or single-family dwellings. Chapter 13 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* discusses hydronic design in more detail.

Through-the-Wall Units

Through-the-wall room air conditioners, packaged terminal air conditioners (PTACs), packaged terminal heat pumps (PTHPs), single-package vertical air conditioners (SPVACs), and single-package vertical heat pumps (SPVHPs) can be used for conditioning single rooms. Each room with an outer wall may have such a unit. These units are used extensively in renovating old buildings because they are self-contained and typically do not require complex piping or ductwork renovation.

Room air conditioners have integral controls and may include resistance or heat pump heating. PTACs and PTHPs have special indoor and outdoor appearance treatments, making them adaptable to a wider range of architectural needs. PTACs can include gas, electric resistance, hot water, or steam heat. Integral or remote wall-mounted controls are used for both PTACs and PTHPs. Further information may be found in Chapter 50 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and in AHRI *Standard* 310/380.

Water-Loop Heat Pumps

Any mid- or high-rise structure having interior zones with high internal heat gains that require year-round cooling can efficiently use a water-loop heat pump. Such systems have the flexibility and control of a four-pipe system but use only two pipes. Water-source heat pumps allow individual metering of each apartment. The building owner pays only the utility cost for the circulating pump, cooling tower, and supplemental boiler heat. Existing buildings can be retrofitted with heat flow meters and timers on fan motors for individual metering.

In some applications, the ground can be used as a heat sink with a geothermal heat pump. This type of application can be advantageous in areas where the water table is high and the soil is porous.

Special Concerns for Apartment Buildings

Many ventilation systems are used in apartment buildings. Local building codes generally govern outdoor air quantities. ASHRAE *Standard* 62.2 provides guidance on selecting ventilation airflow rates based on the method used for distributing that air throughout the building. Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals* provides additional information on residential ventilation.

Buildings using exhaust and supply air systems may benefit from air-to-air heat or energy recovery devices (see Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*). Such recovery devices can reduce energy consumption by transferring 40 to 80% of the sensible heat and some equipment latent heat between the exhaust air and supply airstreams. In some buildings with centrally controlled exhaust and supply systems, the systems are operated on time clocks for certain periods of the day. In other cases, the outdoor air is reduced or shut off during extremely cold periods. If known, these factors should be considered when estimating heating and cooling loads.

Frequently, long line lengths and elevation changes may be required. For these situations, refrigerant piping must be designed to meet requirements on refrigerant charge migration, pressure drop, and oil return to the compressor. For further information, see Chapter 49 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment.*

Another important load, frequently overlooked, is heat gain from piping for hot-water services.

Infiltration loads in high-rise buildings without ventilation openings for perimeter units are not controllable year-round by general building pressurization. When outer walls are penetrated to supply outdoor air to unitary or fan-coil equipment, combined wind and thermal stack effects create other infiltration problems.

Interior public corridors in apartment buildings need conditioning and smoke management to meet their ventilation and thermal needs, and to meet the requirements of fire and life safety codes. Stair towers, however, are normally kept separate from hallways to maintain fire-safe egress routes and, if needed, to serve as safe havens until rescue. Therefore, great care is needed when designing buildings with interior hallways and stair towers. Chapter 53 provides further information.

Air-conditioning equipment must be isolated to reduce noise generation or transmission. The design and location of cooling towers must be chosen to avoid disturbing occupants within the building and neighbors in adjacent buildings. Also, for cooling towers, prevention of *Legionella* is a serious concern. Further information on cooling towers is in Chapter 40 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

In large apartment houses, a central building energy management system may allow individual apartment air-conditioning systems or units to be monitored for maintenance and operating purposes.

5. MANUFACTURED HOMES

Manufactured homes are constructed in factories rather than site built. In 2015, they constituted approximately 6% of all housing units in the United States (EIA 2017). Heating and cooling systems in manufactured homes, as well as other facets of construction such as insulation levels, are regulated in the United States by the Housing and Urban Development (HUD) Manufactured Housing Construction and Safety Standards Act. Each complete home or home section is assembled on a transportation chassis, which is used to transport the home from the factory to the home site and serves as the base of the structure. Manufactured homes vary in size from small, single-floor section units starting at 37 m^2 to large, multiple sections, which when joined together can provide over 280 m^2 and have an appearance similar to site-constructed homes.

Heating systems are factory-installed and are primarily forced-air downflow units feeding main supply ducts built into the subfloor, with floor registers located throughout the home. A small percentage of homes in the far southern and southwestern United States use upflow units feeding overhead ducts in the attic space. Typically, there is no return duct system. Air returns to the air handler from each room through door undercuts, hallways, and a grilled door or louvered panel. The complete heating system is a reduced-clearance type with the air-handling unit installed in a small closet or alcove, usually in a hallway. Sound control measures may be required if large forced-air systems are installed close to sleeping areas. Gas, oil, and electric furnaces or heat pumps may be installed by the home manufacturer to satisfy market requirements.

Gas and oil furnaces are compact direct-vent types approved for installation in a manufactured home. The special venting arrangement used is a vertical through-the-roof concentric pipe-in-pipe system that draws all air for combustion directly from the outdoors and discharges combustion products through a windproof vent terminal. Gas furnaces must be easily convertible from liquefied petroleum gas (LPG) to natural gas and back as required at the final site. In the United States, 54% of manufactured homes use electricity for their heat source, around 22% use natural gas, and 12% use propane (EIA 2017).

Manufactured homes may be cooled with add-on split or single-package air-conditioning systems when supply ducts are adequately sized and rated for that purpose according to HUD requirements. The split-system evaporator coil may be installed in the integral coil cavity provided with the furnace. A high-static-pressure blower is used to overcome resistance through the furnace, evaporator coil, and compact air distribution system. Single-package air conditioners are connected with flexible air ducts to feed existing factory in-floor or overhead ducts. Flexible ducts are installed underneath the mobile home to connect multiple sections; because of their location, these ducts may be susceptible to damage by water or animals. Dampers or other means are required to prevent the cooled, conditioned air from backflowing through a furnace cabinet.

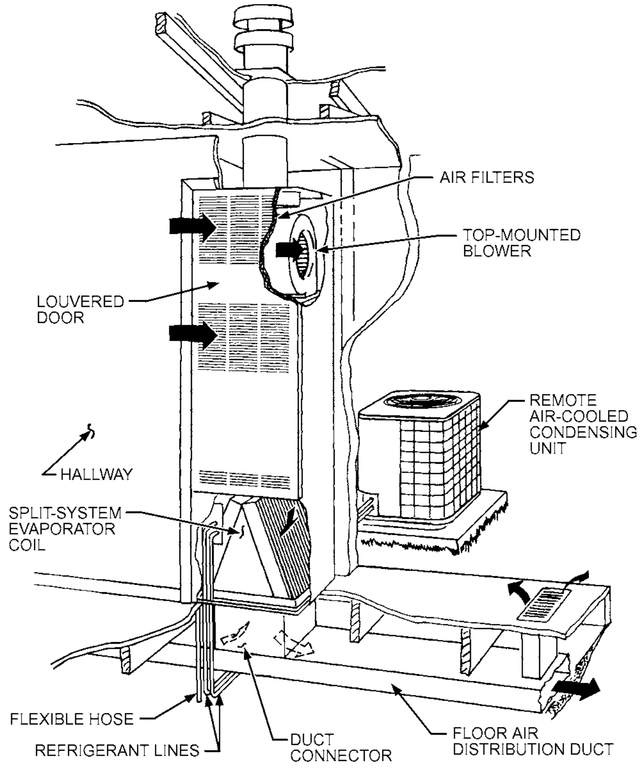

Fig. 5 Typical Installation of Heating and Cooling Equipment for Manufactured Home

A typical installation of a downflow gas or oil furnace with a split-system air conditioner is shown in Figure 5. Air enters the furnace from the hallway, passing through a louvered door on the front of the furnace. The air then passes through air filters and is drawn into the top-mounted blower, which during winter forces air down over the heat exchanger, where it picks up heat. For summer cooling, the blower forces air through the furnace heat exchanger and then through the split-system evaporator coil, which removes heat and moisture from the passing air. During heating and cooling, conditioned air then passes through the floor base via a duct connector before flowing into the floor air distribution duct. The evaporator coil is connected with refrigerant lines to a remote air-cooled condensing unit. The condensate collected at the evaporator is drained by a flexible hose, routed to the exterior through the floor construction, and connected to a suitable drain. Cooling equipment sizing guidelines are provided by the Department of Energy through the ENERGY STAR program for manufactured homes in the continental United States (DOE 2005).

CHAPTER 2

RETAIL FACILITIES

General Criteria 2.1
Small Stores 2.1
Discount, Big-Box, and Supercenter Stores 2.2
Supermarkets 2.3
Department Stores 2.5
Convenience Centers 2.6
Regional Shopping Centers 2.7
Multiple-Use Complexes 2.7
Sustainability and Energy Efficiency 2.8

THIS chapter covers design and application of air-conditioning and heating systems for various retail merchandising facilities. Load calculations, systems, and equipment are covered elsewhere in the Handbook series.

1. GENERAL CRITERIA

To apply equipment properly, the construction of the space to be conditioned, its use and occupancy, the time of day in which greatest occupancy occurs, physical building characteristics, and lighting layout must be known.

The following must also be considered:

- Electric power: size of service
- Heating: availability of steam, hot water, gas, oil, or electricity
- Cooling: availability of chilled water, well water, city water, and water conservation equipment
- Internal heat gains
- Equipment locations
- Structural considerations
- Rigging and delivery of equipment
- Obstructions
- Ventilation: opening through roof or wall for outdoor air duct
- Exposures and number of doors
- Orientation of store
- Code requirements
- Utility rates and regulations
- Building standards

Specific design requirements, such as the increase in outdoor air required to make up for kitchen exhaust, must be considered. Ventilation requirements of ASHRAE *Standard* 62.1 must be followed. Objectionable odors may necessitate special filtering, exhaust, and additional outdoor air intake.

Security requirements must be considered and included in the overall design and application. Minimum considerations require secure equipment rooms, secure air-handling systems, and outdoor air intakes located on the top of facilities. More extensive security measures should be developed based on overall facility design, owner requirements, and local authorities.

Load calculations should be made using the procedures outlined in the *ASHRAE Handbook—Fundamentals*.

Almost all localities have some form of energy code in effect that establishes strict requirements for insulation, equipment efficiencies, system designs, etc., and places strict limits on fenestration and lighting. The requirements of ASHRAE *Standard* 90.1 must be met as a minimum guideline for retail facilities. The *Advanced Energy Design Guide for Small Retail Buildings* (ASHRAE 2006) provides additional energy savings suggestions. In addition, see ASHRAE *Standards* 90.1 and 189.1 for guidance on achieving further energy savings.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

Retail facilities often have a high internal sensible heat gain relative to the total heat gain. However, the quantity of outdoor air required by ventilation codes and standards may result in a high latent heat removal demand at the equipment. The high latent heat removal requirement may also occur at outdoor dry-bulb temperatures below design. Unitary HVAC equipment and HVAC systems should be designed and selected to provide the necessary sensible and latent heat removal. The equipment, systems, and controls should be designed to provide the necessary temperature, ventilation, filtration, and humidity conditions.

HVAC system selection and design for retail facilities are normally determined by economics. First cost is usually the determining factor for small stores. For large retail facilities, owning, operating, and maintenance costs are also considered. Decisions about mechanical systems for retail facilities are typically based on a cash flow analysis rather than on a full life-cycle analysis.

HVAC system provisions are provided initially in most retail facilities, including strip centers, malls, and retail centers in high-rise buildings. Provisions may include condenser water pipes or stub out for fresh air intake in multiple points to satisfy a 93 m^2 module. In strip centers, roof top unit provisions should be provided.

2. SMALL STORES

Small stores are typically located in convenience centers and may have at least the store front exposed to outdoor weather, although some are free standing. Large glass areas found at the front of many small stores may cause high peak solar heat gain unless they have northern exposures or large overhanging canopies. High heat loss may be experienced on cold, cloudy days in the front of these stores. The HVAC system for this portion of the small store should be designed to offset the greater cooling and heating requirements. Entrance vestibules, entry heaters, and/or air curtains may be needed in some climates.

Design Considerations

System Design. Single-zone unitary rooftop equipment is common in store air conditioning. Using multiple units to condition the store involves less ductwork and can maintain comfort in the event of partial equipment failure. Prefabricated and matching curbs simplify installation and ensure compatibility with roof materials.

Air to air heat pumps, offered as packaged equipment, are readily adaptable to small-store applications. Ground-source and other closed-loop heat pump systems have been provided for small stores where the requirements of several users may be combined. Winter design conditions, utility rates, maintenance costs, and operating costs should be compared to those of conventional heating HVAC systems before this type of system is chosen. Consider providing a defrost cycle: in cold climates, snow cover may not allow fresh air into the building.

Water-cooled unitary equipment is available for small-store air conditioning. However, many communities restrict the use of city water and groundwater for condensing purposes and may require installation of a cooling tower. Water-cooled equipment generally operates efficiently and economically.

Air Distribution. External static pressures available in small-store air-conditioning units are limited, and air distribution should be designed to keep duct resistances low. Duct velocities should not exceed 6 m/s, and pressure drop should not exceed 0.8 Pa/m. Average air quantities, typically range from 47 to 60 L/s per kilowatt of cooling in accordance with the calculated internal sensible heat load.

Pay attention to suspended obstacles (e.g., lights, soffits, ceiling recesses, and displays) that interfere with proper air distribution.

The duct system should contain enough dampers for air balancing. Volume dampers should be installed in takeoffs from the main supply duct to balance air to the branch ducts. Dampers should be installed in the return and outdoor air ducts for proper outdoor air/return air balance and for economizer operation.

Control. Controls for small stores should be kept as simple as possible while still providing the required functions. Unitary equipment is typically available with manufacturer-supplied controls for easy installation and operation.

Automatic dampers should be placed in outdoor air inlets and in exhausts to prevent air entering when the fan is turned off.

Heating controls vary with the nature of the heating medium. Duct heaters are generally furnished with manufacturer-installed safety controls. Steam or hot-water heating coils require a motorized valve for heating control. Take care in preventing coil freezing.

Open platform units for any direct digital control (DDC) should provide the necessary options for remote control. Time clock control can limit unnecessary HVAC operation. Unoccupied reset controls should be provided in conjunction with timed control.

Maintenance. To protect the initial investment and ensure maximum efficiency, maintenance of air-conditioning units in small stores should be provided by a reliable service company on a yearly basis. The maintenance agreement should clearly specify responsibility for filter replacements, lubrication, belts, coil cleaning, adjustment of controls, refrigeration cycle maintenance, replacement of refrigerant, pump repairs, electrical maintenance, winterizing, system start-up, and extra labor required for repairs.

Improving Operating Cost. Outdoor air economizers can reduce the operating cost of cooling in most climates. They are generally available as factory options or accessories with roof-mounted units. Increased exterior insulation generally reduces operating energy requirements and may in some cases allow the size of installed equipment to be reduced. Most codes now include minimum requirements for insulation and fenestration materials. The *Advanced Energy Design Guide for Small Retail Buildings* (ASHRAE 2006) provides additional energy savings suggestions.

3. DISCOUNT, BIG-BOX, AND SUPERCENTER STORES

Large discount, big-box, and supercenter stores attract customers with discount prices. These stores typically have high-bay fixture displays and usually store merchandise in the sales area. They feature a wide range of merchandise and may include such diverse areas as a food service area, auto service area, supermarket, pharmacy, bank, and garden shop. Some stores sell pets, including fish and birds. This variety of activity must be considered in designing the HVAC systems. The design and application suggestions for small stores also apply to discount stores.

Each specific area is typically treated as a traditional stand-alone facility would be. Conditioning outdoor air for all areas must be considered to limit the introduction of excess moisture that will migrate to the freezer aisles of a grocery area.

Hardware, lumber, furniture, etc., is also sold in big-box facilities. A particular concern in this type of facility is ventilation for merchandise and material-handling equipment, such as forklift trucks.

In addition, areas such as stockrooms, rest rooms, break rooms, offices, and special storage rooms for perishable merchandise may require separate HVAC systems or refrigeration.

Load Determination

Operating economics and the spaces served often dictate indoor design conditions. Some stores may base summer load calculations on a higher indoor temperature (e.g., 27°C db) but then set the thermostats to control at 22 to 24°C db. This reduces the installed equipment size while providing the desired indoor temperature most of the time.

Heat gain from lighting is not uniform throughout the entire area. For example, jewelry and other specialty displays typically have lighting heat gains of 65 to 85 W/m^2 of floor area, whereas the typical sales area has an average value of 20 to 40 W/m^2. For stockrooms and receiving, marking, toilet, and rest room areas, a value of 20 W/m^2 may be used. When available, actual lighting layouts rather than average values should be used for load computation. With LED lighting, these watt gains should be reduced substantially. See ASHRAE *Standard* 189.1 for further ideas for reduction.

ASHRAE *Standards* 62.1 and 90.1 provide data and population density information to be used for load determination. Chapter 34 of this volume has specific information on ventilation systems for kitchens and food service areas. Ventilation and outdoor air must be provided as required in ASHRAE *Standard* 62.1 and local codes.

Data on the heat released by special merchandising equipment, such as amusement rides for children or equipment used for preparing specialty food items (e.g., popcorn, pizza, frankfurters, hamburgers, doughnuts, roasted chickens, cooked nuts, etc.), should be obtained from the equipment manufacturers.

Design Considerations

Heat released by installed lighting is often sufficient to offset the design roof heat loss. Therefore, interior areas of these stores need cooling during business hours throughout the year. Perimeter areas, especially the storefront and entrance areas, may have highly variable heating and cooling requirements. Proper zone control and HVAC design are essential. Location of checkout lanes in the storefront or entrance areas makes proper environmental zone control even more important.

System Design. The important factors in selecting discount, big-box, and supercenter store air-conditioning systems are (1) installation costs, (2) floor space required for equipment, (3) maintenance requirements, (4) equipment reliability, and (5) simplicity of control. Roof-mounted units are most commonly used.

Air Distribution. The air supply for large interior sales areas should generally be designed to satisfy the primary cooling requirement. For perimeter areas, the variable heating and cooling requirements must be considered.

Because these stores require high, clear areas for display and restocking, air is generally distributed from heights of 4.3 m and greater. Air distribution at these heights requires high discharge velocities in the heating season to overcome the buoyancy of hot air. This discharge air velocity creates turbulence in the space and induces airflow from the ceiling area to promote complete mixing. Space-mounted fans, and radiant heating at the perimeter, entrance heaters, and air curtains may be required.

Control. Because the controls are usually operated by personnel who have little knowledge of air conditioning, systems should be kept as simple as possible while still providing the required functions. Unitary equipment is typically available with manufacturer-supplied controls for easy installation and operation.

Automatic dampers should be placed in outdoor air inlets and in exhausts to prevent air entering when the fan is turned off.

Heating controls vary with the nature of the heating medium. Duct heaters are generally furnished with manufacturer-installed safety controls. Steam or hot-water heating coils require a motorized valve for heating control.

Open-platform DDC control should provide the necessary options for remote control.

Maintenance. Most stores do not employ trained HVAC maintenance personnel; they rely instead on service contracts with either the installer or a local service company. (See the section on Small Stores).

Improving Operating Cost. See the section on Small Stores.

4. SUPERMARKETS

Load Determination

Heating and cooling loads should be calculated using the methods outlined in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*. In supermarkets, space conditioning is required both for human comfort and for proper operation of refrigerated display cases. The air-conditioning unit should introduce a minimum quantity of outdoor air, either the volume required for ventilation based on ASHRAE *Standard* 62.1 or the volume required to maintain slightly positive pressure in the space, whichever is larger.

Many supermarkets are units of a large chain owned or operated by a single company. The standardized construction, layout, and equipment used in designing many similar stores simplify load calculations.

It is important that the final air-conditioning load be correctly determined. Refer to manufacturers' data for information on total heat extraction, sensible heat, latent heat, and percentage of latent to total load for display cases. Engineers report considerable fixture heat removal (case load) variation as the relative humidity and temperature vary in comparatively small increments. Relative humidity above 55% substantially increases the load; reduced absolute humidity substantially decreases the load, as shown in Figure 1. Trends in store design, which include more food refrigeration and more efficient lighting, reduce the sensible component of the load even further.

To calculate the total load and percentage of latent and sensible heat that the air conditioning must handle, the refrigerating effect imposed by the display fixtures must be subtracted from the building's gross air-conditioning requirements (Table 1).

Modern supermarket designs have a high percentage of closed refrigerated display fixtures. These vertical cases have large glass display doors and greatly reduce the problem of latent and sensible heat removal from the occupied space. The doors do, however, require heaters to minimize condensation and fogging. These heaters should cycle by automatic control.

For more information on supermarkets, see Chapter 15 in the 2018 *ASHRAE Handbook—Refrigeration*.

Design Considerations

Store owners and operators frequently complain about cold aisles, heaters that operate even when the outdoor temperature is above 21°C, and air conditioners that operate infrequently. These problems are usually attributed to spillover of cold air from open refrigerated display equipment.

Although refrigerated display equipment may cause cold stores, the problem is not excessive spillover or improperly operating equipment. Heating and air-conditioning systems must compensate for the effects of open refrigerated display equipment. Design considerations include the following:

- Increased heating requirement because of removal of large quantities of heat, even in summer.
- Net air-conditioning load after deducting the latent and sensible refrigeration effect. The load reduction and change in sensible-latent load ratio have a major effect on equipment selection.
- Need for special air circulation and distribution to offset the heat removed by open refrigerating equipment.
- Need for independent temperature and humidity control.

*These figures are general magnitudes for fixtures adjusted for average desired product temperatures and apply to store ambients in front of display cases of 22.2 to 23.3°C with 50 to 55% rh. Raising the dry bulb only 2 to 3 K and the humidity to 5 to 10% can increase loads (heat removal) 25% or more. Lower temperatures and humidities, as in winter, have an equally marked effect on lowering loads and heat removal from the space. Consult display case manufacturer's data for the particular equipment to be used.

Each of these problems is present to some degree in every supermarket, although situations vary with climate and store layout. Methods of overcoming these problems are discussed in the following sections. Energy costs may be extremely high if the year-round air-conditioning system has not been designed to compensate for the effects of refrigerated display equipment.

Heat Removed by Refrigerated Displays. The display refrigerator not only cools a displayed product but also envelops it in a blanket of cold air that absorbs heat from the room air in contact with it. Approximately 80 to 90% of the heat removed from the room by vertical refrigerators is absorbed through the display opening. Thus, the open refrigerator acts as a large air cooler, absorbing heat from the room and rejecting it via the condensers outside the building. Occasionally, this conditioning effect can be greater than the design air-conditioning capacity of the store. The heat removed by the refrigeration equipment *must* be considered in the design of the air-conditioning and heating systems because this heat is being removed constantly, day and night, summer and winter, regardless of the store temperature. Display cases should be provided with sliding doors to minimize heat loss (see ASHRAE *Standard* 189.1).

Display cases increase the building heating requirement such that heat is often required at unexpected times. The following example shows the extent of this cooling effect. The desired store temperature is 24°C. Store heat loss or gain is assumed to be 8 kW/K of temperature difference between outdoor and store temperature. (This value varies with store size, location, and exposure.) The heat removed by refrigeration equipment is 56 kW. (This value varies with the number of refrigerators.) The latent heat removed is assumed to be 19% of the total, leaving 81% or 45.4 kW sensible heat removed, which cools the store 45.4/8 = 5.7 K. By constantly removing sensible heat from its environment, the refrigeration equipment in this store will cool the store 5.7 K below outdoor temperature in winter and in summer. Thus, in mild climates, heat must be added to the store to maintain comfort conditions.

The designer can either discard or reclaim the heat removed by refrigeration. If economics and store heat data indicate that the heat should be discarded, heat extraction from the space must be included in the heating load calculation. If this internal heat loss is not included, the heating system may not have sufficient capacity to maintain design temperature under peak conditions.

The additional sensible heat removed by the cases may change the air-conditioning latent load ratio from 32% to as much as 50% of the net heat load. Removing a 50% latent load by refrigeration alone is very difficult. Normally, it requires specially designed equipment with reheat or chemical adsorption.

Multishelf refrigerated display equipment requires 55% rh or less. In the dry-bulb temperature ranges of average stores, humidity in excess of 55% can cause heavy coil frosting, product zone frosting in low-temperature cases, fixture sweating, and substantially increased refrigeration power consumption.

A humidistat can be used during summer cooling to control humidity by transferring heat from the condenser to a heating coil in the airstream. The store thermostat maintains proper summer temperature conditions. Override controls prevent conflict between the humidistat and the thermostat.

The equivalent result can be accomplished with a conventional air-conditioning system by using three- or four-way valves and reheat condensers in the ducts. This system borrows heat from the standard condenser and is controlled by a humidistat. For higher energy efficiency, specially designed equipment should be considered. Desiccant dehumidifiers and heat pipes have also been used.

Humidity. Cooling from refrigeration equipment does not preclude the need for air conditioning. On the contrary, it increases the need for humidity control.

With increases in store humidity, heavier loads are imposed on the refrigeration equipment, operating costs rise, more defrost periods are required, and the display life of products is shortened. The dew point rises with relative humidity, and sweating can become so profuse that even nonrefrigerated items such as shelving superstructures, canned products, mirrors, and walls may sweat.

Lower humidity results in lower operating costs for refrigerated cases. There are three methods to reduce the humidity level: (1) standard air conditioning, which may overcool the space when the latent load is high and sensible load is low; (2) mechanical dehumidification, which removes moisture by lowering the air temperature to its dew point, and uses hot-gas reheat when needed to discharge at any desired temperature; and (3) desiccant dehumidification, which removes moisture independent of temperature, supplying warm air to the space unless postcooling is provided to discharge at any desired temperature.

Each method provides different dew-point temperatures at different energy consumption and capital expenditures. The designer should evaluate and consider all consequential trade-offs. Standard air conditioning requires no additional investment but reduces the space dew-point temperature only to 16 to 18°C. At 24°C space temperature this results in 60 to 70% rh at best. Mechanical dehumidifiers can provide humidity levels of 40 to 50% at 24°C. Supply air temperature can be controlled with hot-gas reheat between 10 and 32°C. Desiccant dehumidification can provide levels of 35 to 40% rh at 24°C. Postcooling supply air may be required, depending on internal sensible loads. A desiccant is reactivated by passing hot air at 80 to 121°C through the desiccant base. Consider adding a heat recovery system to maintain low humidity and using the recovered heat for reheat.

System Design. The same air-handling equipment and distribution system are generally used for both cooling and heating. The entrance area is the most difficult section to heat. Many supermarkets in the northern United States are built with vestibules provided with separate heating equipment to temper the cold air entering from the outdoors. Auxiliary heat may also be provided at the checkout area, which is usually close to the front entrance. Methods of heating entrance areas include the use of (1) air curtains, (2) gas-fired or electric infrared radiant heaters, and (3) waste heat from the refrigeration condensers.

Air-cooled condensing units are the most commonly used in supermarkets. Typically, a central air handler conditions the entire sales area. Specialty areas like bakeries, computer rooms, or warehouses are better served with a separate air handler because the loads in these areas vary and require different control than the sales area.

Most installations are made on the roof of the supermarket. If air-cooled condensers are located on the ground outside the store, they must be protected against vandalism as well as truck and customer traffic. If water-cooled condensers are used on the air-conditioning equipment and a cooling tower is required, provisions should be made to prevent freezing during winter operation.

Air Distribution. Designers overcome the concentrated load at the front of a supermarket by discharging a large portion of the total air supply into the front third of the sales area.

The air supply to the space with a standard air-conditioning system is typically 5 L/s per square metre of sales area. This value should be calculated based on the sensible and latent internal loads. The desiccant system typically requires less air supply because of its high moisture removal rate, typically 2.5 L/s per square metre. Mechanical dehumidification can fall within these parameters, depending on required dew point and suction pressure limitations.

Being denser, air cooled by the refrigerators settles to the floor and becomes increasingly colder, especially in the first 900 mm above the floor. If this cold air remains still, it causes discomfort and does not help to cool other areas of the store that need more cooling. Cold floors or areas in the store cannot be eliminated by

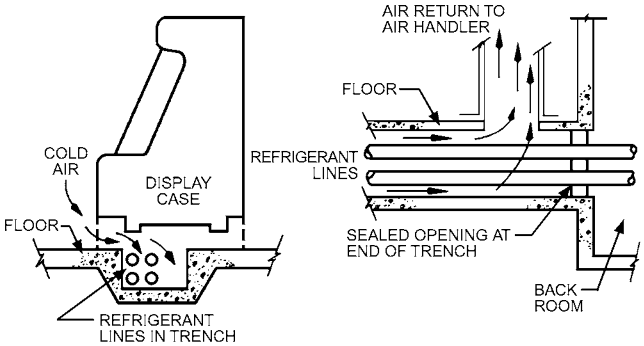

Fig. 2 Floor Return Ducts

the simple addition of heat. Reduction of air-conditioning capacity without circulation of localized cold air is analogous to installing an air conditioner without a fan. To take advantage of the cooling effect of the refrigerators and provide an even temperature in the store, the cold air must be mixed with the general store air.

To accomplish the necessary mixing, air returns should be located at floor level; they should also be strategically placed to remove the cold air near concentrations of refrigerated fixtures. Returns should be designed and located to avoid creating drafts. There are two general solutions to this problem:

- **Return Ducts in Floor.** This is the preferred method and can be accomplished in two ways. The floor area in front of the refrigerated display cases is the coolest area. Refrigerant lines are run to all of these cases, usually in tubes or trenches. If the trenches or tubes are enlarged and made to open under the cases for air return, air can be drawn in from the cold area (Figure 2). The air is returned to the air-handling unit through a tee connection to the trench before it enters the back room area. The opening through which the refrigerant lines enter the back room should be sealed.

  If refrigerant line conduits are not used, air can be returned through inexpensive underfloor ducts. If refrigerators have insufficient undercase air passage, consult the manufacturer. Often they can be raised off the floor approximately 40 mm. Floor trenches can also be used as ducts for tubing, electrical supply, and so forth.

  Floor-level return relieves the problem of localized cold areas and cold aisles and uses the cooling effect for store cooling, or increases the heating efficiency by distributing the air to areas that need it most.
- **Fans Behind Cases.** If ducts cannot be placed in the floor, circulating fans can draw air from the floor and discharge it above the cases (Figure 3). Although this approach prevents objectionable cold aisles in front of the refrigerated display cases, it does not prevent an area with a concentration of refrigerated fixtures from remaining colder than the rest of the store.

Control. Store personnel should only be required to change the position of a selector switch to start or stop the system or to change from heating to cooling or from cooling to heating. Control systems for heat recovery applications are more complex and should be coordinated with the equipment manufacturer.

Maintenance and Heat Reclamation. Most supermarkets, except large chains, do not employ trained maintenance personnel, but rather rely on service contracts with either the installer or a local service company. This relieves store management of the responsibility of keeping the air conditioning operating properly.

Heat extracted from the store and heat of compression may be reclaimed for heating cost saving. One method of reclaiming rejected heat is to use a separate condenser coil located in the air conditioner's air handler, either alternately or in conjunction with the

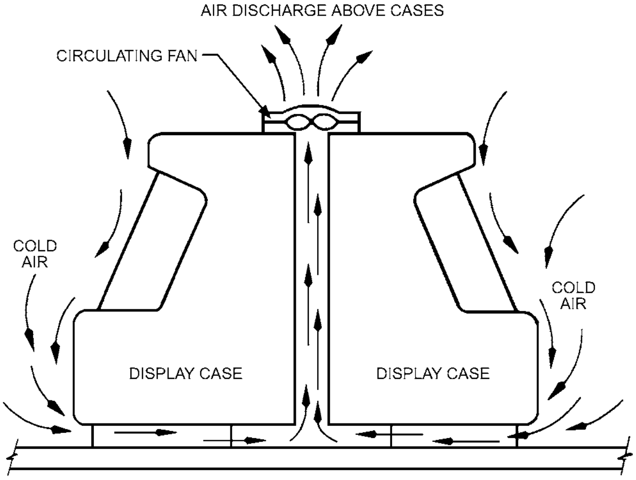

Fig. 3 Air Mixing Using Fans Behind Cases

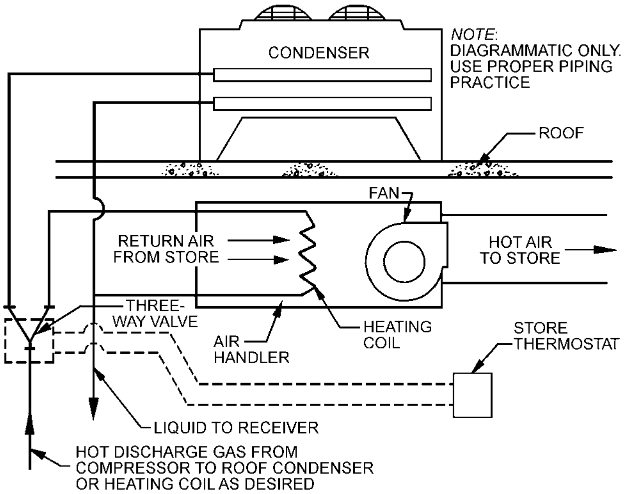

Fig. 4 Heat Reclaiming Systems

main refrigeration condensers, to provide heat as required (Figure 4). Another system uses water-cooled condensers and delivers its rejected heat to a water coil in the air handler.

The heat rejected by conventional machines using air-cooled condensers may be reclaimed by proper duct and damper design (Figure 5). Automatic controls can either reject this heat to the outdoors or recirculate it through the store. Consider using warm liquid defrost for evaporator coils on refrigerated cases, coolers, and freezers (Mei et al. 2002).

5. DEPARTMENT STORES

Department stores vary in size, type, and location, so air-conditioning design should be specific to each store. Essential features of a quality system include (1) an automatic control system properly designed to compensate for load fluctuations, (2) zoned air distribution to maintain uniform conditions under shifting loads, and (3) use of outdoor air for cooling during favorable conditions. It is also desirable to adjust indoor temperature for variations in outdoor temperature. Although close control of humidity is not necessary, a properly designed system should operate to maintain relative humidity at 50% or below. This humidity limit eliminates musty odors and retards perspiration, particularly in fitting rooms.

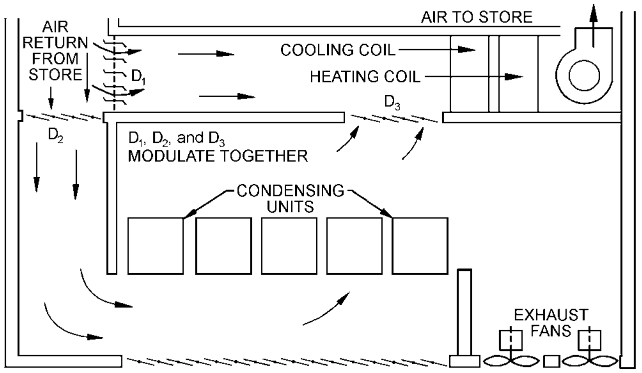

Fig. 5 Machine Room with Automatic Temperature Control Interlocked with Store Temperature Control

Table 2 Approximate Lighting Load for Older Department Stores

Area	W/m²
Basement	30 to 50
First floor	40 to 70
Upper floors, women's wear	30 to 50
Upper floors, house furnishings	20 to 30

Load Determination

Because the occupancy (except store personnel) is transient, indoor conditions are commonly set not to exceed 26°C db and 50% rh at outdoor summer design conditions, and 21°C db at outdoor winter design conditions. Winter humidification is seldom used in store air conditioning.

ASHRAE *Standard* 62.1 provides population density information for load determination purposes. Energy codes and standards restrict installed lighting watt density for newly constructed facilities. However, older facilities may have increased lighting watt densities. Values in Table 2 are approximations for older facilities.

Other loads, such as those from motors, beauty parlors, restaurant equipment, and any special display or merchandising equipment, should be determined.

Minimum outdoor air requirements should be as defined in ASHRAE *Standard* 62.1 or local codes.

Paint shops, alteration rooms, rest rooms, eating places, and locker rooms should be provided with positive exhaust ventilation, and their requirements must be checked against local codes.

Design Considerations

Before performing load calculations, the designer should examine the store arrangement to determine what will affect the load and the system design. For existing buildings, actual construction, floor arrangement, and load sources can be surveyed. For new buildings, examination of the drawings and discussion with the architect or owner is required.

Larger stores may contain beauty parlors, food service areas, extensive office areas, auditoriums, warehouse space, etc. Some of these special areas may operate during hours in addition to the normal store-open hours. If present or future operation could be compromised by such a strategy, these spaces should be served by separate HVAC systems. Because of the concentrated load and exhaust requirements, beauty parlors and food service areas should be provided with separate ventilation and air distribution.

Future plans for the store must be ascertained because they can have a great effect on the type of air conditioning and refrigeration to be used.

System Design. Air conditioning systems for department stores may use unitary or central station equipment. Selection should be based on owning and operating costs as well as special considerations for the particular store, such as store hours, load variations, and size of load.

Large department stores have often used central-station systems consisting of air-handling units having chilled-water cooling coils, hot-water heating coils, fans, and filters. Some department stores now use large unitary units. Air systems must have adequate zoning for varying loads, occupancy, and usage. Wide variations in people loads may justify considering variable-volume air distribution systems. Water chilling and heating plants distribute water to the various air handlers and zones and may take advantage of some load diversity throughout the building.

Air-conditioning equipment should not be placed in the sales area; instead, it should be located in mechanical equipment room areas or on the roof whenever practicable. Ease of maintenance and operation must be considered in the design of equipment rooms and locations.

Many locations require provisions for smoke removal. This is normally accommodated through the roof and may be integrated with the HVAC system.

Air Distribution. All buildings must be studied for orientation, wind exposure, construction, and floor arrangement. These factors affect not only load calculations, but also zone arrangements and duct locations. In addition to entrances, wall areas with significant glass, roof areas, and population densities, the expected locations of various departments should be considered. Flexibility must be left in the duct design to allow for future movement of departments. It may be necessary to design separate air systems for entrances, particularly in northern areas. This is also true for storage areas where cooling is not contemplated.

Air curtains may be installed at entrance doorways to limit infiltration of unconditioned air, at the same time providing greater ease of entry.

Control. Space temperature controls are usually operated by personnel who have little knowledge of air conditioning. Therefore, exposed sensors and controls should be kept as simple as possible while still providing the required functions.

Control must be such that correctly conditioned air is delivered to each zone. Outdoor air intake should be automatically controlled to operate at minimum cost while providing required airflow. Partial or full automatic control should be provided for cooling to compensate for load fluctuations. Completely automatic refrigeration plants should be considered.

Heating controls vary with the nature of the heating medium. Duct heaters are generally furnished with manufacturer-installed safety controls. Steam or hot-water heating coils require a motorized valve for heating control.

Time clock control can limit unnecessary HVAC operation. Unoccupied reset controls should be provided in conjunction with timed control.

Automatic dampers should be placed in outdoor air inlets and in exhausts to prevent air entering when the fan is turned off.

Maintenance. Most department stores employ personnel for routine housekeeping, operation, and minor maintenance, but rely on service and preventive maintenance contracts for refrigeration cycles, chemical treatment, central plant systems, and repairs.

Improving Operating Cost. An outdoor air economizer can reduce the operating cost of cooling in most climates. These are generally available as factory options or accessories with the air-handling units or control systems. Heat recovery and desiccant dehumidification should also be analyzed.

6. CONVENIENCE CENTERS

Many small stores, discount stores, supermarkets, drugstores, theaters, and even department stores are located in convenience centers. The space for an individual store is usually leased. Arrangements for installing air conditioning in leased space vary. Typically, the developer builds a shell structure and provides the tenant with an allowance for usual heating and cooling and other minimum interior finish work. The tenant must then install an HVAC system. In another arrangement, developers install HVAC units in the small stores with the shell construction, often before the space is leased or the occupancy is known. Larger stores typically provide their own HVAC design and installation.

Design Considerations

The developer or owner may establish standards for typical heating and cooling that may or may not be sufficient for the tenant's specific requirements. The tenant may therefore have to install systems of different sizes and types than originally allowed for by the developer. The tenant must ascertain that power and other services will be available for the total intended requirements.

The use of party walls in convenience centers tends to reduce heating and cooling loads. However, the effect an unoccupied adjacent space has on the partition load must be considered.

7. REGIONAL SHOPPING CENTERS

Regional shopping centers generally incorporate an enclosed, heated and air-conditioned mall. These centers are normally owned by a developer, who may be an independent party, a financial institution, or one of the major tenants in the center.

Some regional shopping centers are designed with an open pedestrian mall between rows of stores. This open-air concept results in tenant spaces similar to those in a convenience center. Storefronts and other perimeters of the tenant spaces are exposed to exterior weather conditions.

Major department stores in shopping centers are typically considered separate buildings, although they are attached to the mall. The space for individual small stores is usually leased. Arrangements for installing air conditioning in the individually leased spaces vary, but are similar to those for small stores in convenience centers.

Table 3 presents typical data that can be used as check figures and field estimates. However, this table should not be used for final determination of load, because the values are only averages.

Design Considerations

The owner or developer provides the HVAC system for an enclosed mall. The regional shopping center may use a central plant or unitary equipment. The owner generally requires that the individual tenant stores connect to a central plant and includes charges for heating and cooling services. Where unitary systems are used, the owner generally requires that the individual tenant install a unitary system of similar design. Because of different functions and load profiles, systems should be designed to recover heat transfer from one area and transfer to the other to save annual energy consumption.

Table 3 Typical Installed Cooling Capacity and Lighting Levels: Midwestern United States

Type of Space	Area per Unit of Installed Cooling, m²/kW	Installed Cooling per Unit of Area, W/m²	Lighting Density of Area, W/m²	Annual Lighting Energy Use,[a] kWh/m²
Dry retail[b]	9.69	104.1	43.1	174.4
Restaurant	3.59	277.6	21.5	87.2
Fast food				
Food court tenant area	4.23	236.6	32.3	131.3
Food court seating area	3.88	258.7	32.3	131.3
Mall common area	7.61	135.6	32.3	131.3[c]
Total	6.97	142.0	38.8	157.2

Source: Based on 2001 Data—Midwestern United States.
[a]Hours of operating lighting assumes 12 h/day and 6.5 days/week.
[b]Jewelry, high-end lingerie, and some other occupancy lighting levels are typically 65 to 85 120 W/m² and can range to 120 W/m². Cooling requirements for these spaces are higher.
[c]62.4 kWh/m² for centers that shut off lighting during daylight, assuming 6 h/day and 6.2 days/week.

The owner may establish standards for typical heating and cooling systems that may or may not be sufficient for the tenant's specific requirements. Therefore, the tenant may have to install systems of different sizes than originally allowed for by the developer.

Leasing arrangements may include provisions that have a detrimental effect on conservation (such as allowing excessive lighting and outdoor air or deleting requirements for economizer systems). The designer of HVAC for tenants in a shopping center must be well aware of the lease requirements and work closely with leasing agents to guide these systems toward better energy efficiency.

Many regional shopping centers contain specialty food court areas that require special considerations for odor control, outdoor air requirements, kitchen exhaust, heat removal, and refrigeration equipment.

System Design. Regional shopping centers vary widely in physical arrangement and architectural design. Single-level and smaller centers usually use unitary systems for mall and tenant air conditioning; multilevel and larger centers usually use a central system. The owner sets the design of the mall and generally requires that similar systems be installed for tenant stores.

A typical central system may distribute chilled air to individual tenant stores and to the mall air-conditioning system and use variable-volume control and electric heating at the local use point. Some plants distribute both hot and chilled water. Some all-air systems also distribute heated air. Central plant systems typically provide improved efficiency and better overall economics of operation. Central systems may also provide the basic components required for smoke removal.

Air Distribution. Air distribution in individual stores should be designed for the particular space occupancy. Some tenant stores maintain a negative pressure relative to the public mall for odor control.

The total facility HVAC system should maintain a slight positive pressure relative to atmospheric pressure and a neutral pressure relative between most of the individual tenant stores. Exterior entrances should have vestibules.

Smoke management is required by many building codes, so air distribution should be designed to easily accommodate smoke control requirements.

Maintenance. Methods for ensuring the operation and maintenance of HVAC systems in regional shopping centers are similar to those used in department stores. Individual tenant stores may have to provide their own maintenance.

Improving Operating Cost. Methods for lowering operating costs in shopping centers are similar to those used in department stores. Some shopping centers have successfully used cooling tower heat exchanger economizers.

Central plant systems for regional shopping centers typically have lower operating costs than unitary systems. However, the initial cost of the central plant system is typically higher.

8. MULTIPLE-USE COMPLEXES

Multiple-use complexes are being developed in many metropolitan areas. These complexes generally combine retail facilities with other facilities such as offices, hotels, residences, or other commercial space into a single site. This consolidation of facilities into a single site or structure provides benefits such as improved land use; structural savings; more efficient parking; utility savings; and opportunities for more efficient electrical, fire protection, and mechanical systems.

Load Determination

The various occupancies may have peak HVAC demands that occur at different times of the day or year. Therefore, the HVAC loads of these occupancies should be determined independently. Where a combined central plant is considered, a block load should also be determined.

Design Considerations

Retail facilities are generally located on the lower levels of multiple-use complexes, and other commercial facilities are on upper levels. Generally, the perimeter loads of the retail portion differ from those of the other commercial spaces. Greater lighting and population densities also make HVAC demands for the retail space different from those for the other commercial space.

The differences in HVAC characteristics for various occupancies within a multiple-use complex indicate that separate air handling and distribution should be used for the separate spaces. However, combining the heating and cooling requirements of various facilities into a central plant can achieve a substantial saving. A combined central heating and cooling plant for a multiple-use complex also provides good opportunities for heat recovery, thermal storage, and other similar functions that may not be economical in a single-use facility.

Many multiple-use complexes have atriums. The stack effect created by atriums requires special design considerations for tenants and space on the main floor. Areas near entrances require special measures to prevent drafts and accommodate extra heating requirements.

System Design. Individual air-handling and distribution systems should be designed for the various occupancies. The central heating and cooling plant may be sized for the block load requirements, which may be less than the sum of each occupancy's demand.

Control. Multiple-use complexes typically require centralized control. It may be dictated by requirements for fire and smoke control, security, remote monitoring, billing for central facilities use, maintenance control, building operations control, and energy management.

9. SUSTAINABILITY AND ENERGY EFFICIENCY

Many large retail chains have made significant advances in implementing sustainability programs. Many retailers have added leaders who focus on energy efficiency and sustainability to their executive leadership teams, and some even establish and report sustainability goals (Jamieson et al. 2013). ASHRAE *Standard* 90.1 and appropriate design guides and tools should be used to achieve energy efficiency and sustainable design in a retail facility.

A dedicated integrated design group is helpful in developing and implementing energy efficient design strategies. The design team should be open to new and innovative energy-efficient designs that may include geothermal heating and cooling, high-performance lighting, heat recovery systems, high-efficiency HVAC, and renewable energy systems (Duarte 2013; Genest and Charneux 2005).

Design engineers should take advantage of ASHRAE's *Advanced Energy Design Guides* (www.ashrae.org/technical-resources/aedgs) to reduce energy-related expenses and to achieve retailer's corporate sustainability targets. While incorporating energy efficiency measures, HVAC design engineers should consider items such as heating and cooling loads, ventilation, energy management systems, variable-speed fan controls, variable-speed pumps, variable-frequency drives, and energy recovery systems; it is most important, however, to understand the needs of the facility. When energy-efficient measures are properly implemented, they can lead to achieving a retailer's corporate sustainable mission, higher employee morale, and reduced energy costs. Integrated design process (IDP), described in Chapter 60, should be used. IDP promotes collaboration between a retailer's sustainability goals and actual energy-saving strategies. In IDP, all stakeholders work together on a common goal, "result[ing] in a coordinated, constructible, and cost-effective design" (ASHRAE 2011).

Important elements of IDP are

- Project kickoff
- Programming and project design
- Schematic design
- Design development
- Construction documents
- Bid phase
- Construction administration
- Commissioning
- Operations and maintenance
- Continuous improvement
- Controlling costs

Building energy modeling and energy benchmarking tools should be used to estimate energy consumptions, building behavior, evaluation of energy use, and tracking. Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals* provides more information on energy modeling methodologies. Commonly used benchmarking tools include U.S. EPA ENERGY STAR Portfolio Manager (portfoliomanager.energystar.gov) and Lawrence Berkeley National Laboratory's (LBNL) Standard Energy Efficiency Data Platform™ (www.energy.gov/eere/buildings/standard-energy-efficiency-data-platform). To achieve sustainability and energy efficiency in a retail facility, combined heat and power (CHP) and renewable energy technologies such as solar thermal, solar photovoltaic, wind, and biomass can be considered in conjunction with energy-efficient measures.

CHAPTER 3

COMMERCIAL AND PUBLIC BUILDINGS

Office Buildings 3.1
Transportation Centers 3.6
Warehouses and Distribution Centers 3.8
Sustainability and Energy Efficiency 3.9
Commissioning and Retrocommissioning 3.12
Seismic and Wind Restraint Considerations 3.12

THIS chapter contains technical, environmental, and design considerations to assist the design engineer in the proper application of HVAC systems and equipment for commercial and public buildings.

1. OFFICE BUILDINGS

General Design Considerations

Despite cyclical market fluctuations, office buildings are considered the most complex and competitive segments of real estate development. Survey data of 824 000 office buildings (EIA 2003) demonstrate the distribution of the U.S. office buildings by the numbers and the area, as shown in Table 1.

According to Gause (1998), an office building can be divided into the following categories:

Class. The most basic feature, class represents the building's quality by taking into account variables such as age, location, building materials, building systems, amenities, lease rates, etc. Office buildings are of three classes: A, B, and C. **Class A** is generally the most desirable building, located in the most desirable locations, and offering first-rate design, building systems, and amenities. **Class B** buildings are located in good locations, have little chance of functional obsolescence, and have reasonable management. **Class C** buildings are typically older, have not been modernized, are often functionally obsolete, and may contain asbestos. These low standards make Class C buildings potential candidates for demolition or conversion to another use.

Size and Flexibility. Office buildings are typically grouped into three categories: **high rise** (16 stories and above), **mid rise** (four to 15 stories), and **low rise** (one to three stories).

Table 1 Data for U.S. Office Buildings

	Number of Buildings (Thousands)	Percent of Total Number of Buildings	Total Floor Space (Million m^2)	Percent of Total Floor Space
Total	824	100.0	1135	100.0
93 to 465 m^2	503	61.0	128	11.32
466 to 929 m^2	127	15.4	87	7.68
930 to 2323 m^2	116	14.1	175	15.46
2324 to 4647 m^2	43	5.2	140	12.34
4648 to 9264 m^2	17	2.1	112	9.90
9265 to 18 587 m^2	11	1.3	133	11.70
18 588 to 46 468 m^2	5	0.6	139	12.23
>46 468 m^2	2	0.2	220	19.37

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

Location. An office building is typically in one of three locations: **downtown** (usually high rises), **suburban** (low- to mid-rise buildings), or **business/industrial park** (typically one- to three-story buildings).

Floorplate (Floor Space Area). Size typically ranges from 1670 to 2800 m^2 and averages from 1860 to 2320 m^2.

Use and Ownership. Office buildings can be single tenant or multitenant. A single-tenant building can be owned by the tenant or leased from a landlord. From an HVAC&R systems standpoint, a single tenant/owner is more cautious considering issues such as life-cycle cost and energy conservation. In many cases, the systems are not selected based on the lowest first cost but on life-cycle cost. Sometimes, the developer may wish to select a system that allows individual tenants to pay directly for the energy they consume.

Building Features and Amenities. Examples typically include parking, telecommunications, HVAC&R, energy management, restaurants, security, retail outlets, and health club.

Typical areas that can be found in office buildings are

Offices

- Offices: (private or semiprivate acoustically and/or visually).
- Conference rooms

Employee/Visitor Support Spaces

- Convenience store, kiosk, or vending machines
- Lobby: central location for building directory, schedules, and general information
- Atria or common space: informal, multipurpose recreation and social gathering space
- Cafeteria or dining hall
- Private toilets or restrooms
- Child care centers
- Physical fitness area
- Interior or surface parking areas

Administrative Support Spaces

- May be private or semiprivate acoustically and/or visually.

Operation and Maintenance Spaces

- General storage: for items such as stationery, equipment, and instructional materials
- Food preparation area or kitchen
- Computer/information technology (IT) closets
- Maintenance closets
- Mechanical and electrical rooms

A well-designed and functioning HVAC system should provide the following:

- Comfortable and consistent temperature and humidity
- Adequate amounts of outdoor air at all time to satisfy ventilation requirements
- Remove odors and contaminates from circulated air

The major factors affecting sizing and selection of the HVAC systems are as follows:

- Building size, shape and number of floors
- Amount of exterior glass
- Orientation, envelope
- Internal loads, occupants, lighting
- Thermal zoning (number of zones, private offices, open areas, etc.)

Office HVAC systems generally range from small, unitary, decentralized cooling and heating up to large systems comprising central plants (chillers, cooling towers, boilers, etc.) and large air-handling systems. Often, several types of HVAC systems are applied in one building because of special requirements such as continuous operation, supplementary cooling, etc. In office buildings, the class of the building also affects selection of the HVAC systems. For example, in a class A office building, the HVAC&R systems must meet more stringent criteria, including individual thermal control, noise, and flexibility; HVAC systems such as single-zone constant-volume, water-source heat pump, and packaged terminal air conditioners (PTACs) might be inapplicable to this class, whereas properly designed variable-air-volume (VAV) systems can meet these requirements.

Design Criteria

A typical HVAC design criteria covers parameters required for thermal comfort, indoor air quality (IAQ), and sound. Thermal comfort parameters (temperature and humidity) are discussed in ASHRAE *Standard* 55-2010 and Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*. Ventilation and IAQ are covered by ASHRAE *Standard* 62.1-2010, the user's manual for that standard (ASHRAE 2010), and Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals*. Sound and vibration are discussed in Chapter 49 of this volume and Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*.

Thermal comfort is affected by air temperature, humidity, air velocity, and mean radiant temperature (MRT), as well as nonenvironmental factors such as clothing, gender, age, and physical activity. These variables and how they correlate to thermal comfort can be evaluated by the *Thermal Comfort Tool CD* (ASHRAE 1997) in conjunction with ASHRAE *Standard* 55. General guidelines for temperature and humidity applicable for areas in office buildings are shown in Table 2.

All office, administration, and support areas need outdoor air for ventilation. Outdoor air is introduced to occupied areas and then exhausted by fans or exhaust openings, removing indoor air pollutants generated by occupants and any other building-related sources.

Table 2 Typical Recommended Indoor Temperature and Humidity in Office Buildings

Area	Indoor Design Conditions: Temperature, °C/ Relative Humidity, % — Winter	Summer	Comments
Offices, conference rooms, common areas	20.3 to 24.2 20 to 30%	23.3 to 26.7 50 to 60%	
Cafeteria	21.1 to 23.3 20 to 30%	25.8 50%	
Kitchen	21.1 to 23.3	28.9 to 31.1	No humidity control
Toilets	22.2		Usually not conditioned
Storage	17.8		No humidity control
Mechanical rooms	16.1		Usually not conditioned

ASHRAE *Standard* 62.1 is used as the basis for many building codes. To define the ventilation and exhaust design criteria, consult local applicable ventilation and exhaust standards. Table 3 provides recommendations for ventilation design based on the ventilation rate procedure method and filtration criteria for office buildings.

Acceptable noise levels in office buildings are important for office personnel; see Table 4 and Chapter 49.

Load Characteristics

Office buildings usually include both peripheral and interior zone spaces. The peripheral zone extends 3 to 3.6 m inward from the

Table 3 Typical Recommended Design Criteria for Ventilation and Filtration for Office Buildings

Category	Ventilation and Exhaust[a,b]: Combined Outdoor Air (Default Value) L/s per Person	Occupant Density,[f] per 100 m²	Outdoor Air: L/(s·m²)	Outdoor Air: L/s per Unit	Minimum Filtration Efficiency, MERV[c]
Office areas	8.5	5			6 to 8
Reception areas	3.5	30			6 to 8
Main entry lobbies	5.5	10			6 to 8
Telephone/data entry	3.0	60			6 to 8
Cafeteria	4.7	100			6 to 8
Kitchen[d,e]			3.5 (exhaust)		NA
Toilets				35 (exhaust)	NA
Storage[g]			0.6		1 to 4

Notes:
[a]Based on ASHRAE *Standard* 62.1-2010, Tables 6-1 and 6-4. For systems serving multiple zones, apply multiple-zone calculations procedure. If DCV is considered, see the section on Demand Control Ventilation (DCV).
[b]This table should not be used as the only source for design criteria. Governing local codes, design guidelines, ANSI/ASHRAE *Standard* 62.1-2010 and user's manual, (ASHRAE 2010) must be consulted.
[c]MERV = minimum efficiency reporting values, based on ASHRAE *Standard* 52.2-2007.
[d]See Chapter 34 for additional information on kitchen ventilation. For kitchenette use 1.5 L/(s·m²).
[e]Consult local codes for kitchen exhaust requirements.
[f]Use default occupancy density when actual occupant density is not known.
[g]This recommendation for storage might not be sufficient when the materials stored have harmful emissions.

Table 4 Typical Recommended Design Guidelines for HVAC-Related Background Sound for Areas in Office Buildings

Category	Sound Criteria[a,b]: RC (N); QAI ≤ 5 dB	Comments
Executive and private office	25 to 35	
Conference rooms	25 to 35	
Teleconference rooms	≤25	
Open-plan office space	≤40 ≤35	 With sound masking
Corridors and lobbies	40 to 45	
Cafeteria	35 to 45	Based on service/support for hotels
Kitchen	35 to 45	Based on service/support for hotels
Storage	35 to 45	Based on service/support for hotels
Mechanical rooms	35 to 45	Based on service/support for hotels

Notes:
[a]Based on Table 1 in Chapter 49.
[b]RC (room criterion), QAI (quality assessment index) from Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*.

outer wall toward the interior of the building, and frequently has a large window area. These zones may be extensively subdivided. Peripheral zones have variable loads because of changing sun position and weather. These zones typically require heating in winter. During intermediate seasons, one side of the building may require cooling, while another side requires heating. However, the interior zone spaces usually require a fairly uniform cooling rate throughout the year because their thermal loads are derived almost entirely from lights, office equipment, and people. Interior space conditioning is often by systems that have VAV control for low- or no-load conditions.

Most office buildings are occupied from approximately 8:00 AM to 6:00 PM; many are occupied by some personnel from as early as 5:30 AM to as late as 7:00 PM. Some tenants' operations may require night work schedules, usually not beyond 10:00 PM. Office buildings may contain printing facilities, information and computing centers, or broadcasting studios, which could operate 24 h per day. Therefore, for economical air-conditioning design, the intended uses of an office building must be well established before design development.

Occupancy varies considerably. In accounting or other sections where clerical work is done, the maximum density is approximately one person per 7 m^2 of floor area. Where there are private offices, the density may be as little as one person per 19 m^2. The most serious cases, however, are the occasional waiting rooms, conference rooms, or directors' rooms, where occupancy may be as high as one person per 2 m^2.

The lighting load in an office building can be a significant part of the total heat load. Lighting and normal equipment electrical loads average from 10 to 50 W/m^2 but may be considerably higher, depending on the type of lighting and amount of equipment. Buildings with computer systems and other electronic equipment can have electrical loads as high as 50 to 110 W/m^2. The amount, size, and type of computer equipment anticipated for the life of the building should be accurately appraised to size the air-handling equipment properly and provide for future installation of air-conditioning apparatus.

Total lighting heat output from recessed fixtures can be withdrawn by exhaust or return air and thus kept out of space-conditioning supply air requirements. By connecting a duct to each fixture, the most balanced air system can be provided. However, this method is expensive, so the suspended ceiling is often used as a return air plenum with air drawn from the space to above the suspended ceiling.

Miscellaneous allowances (for fan heat, duct heat pickup, duct leakage, and safety factors) should not exceed 12% of the total load.

Building shape and orientation are often determined by the building site, but some variations in these factors can increase refrigeration load. Shape and orientation should therefore be carefully analyzed in the early design stages.

Design Concepts

The variety of functions and range of design criteria applicable to office buildings have allowed the use of almost every available air-conditioning system. Multistory structures are discussed here, but the principles and criteria are similar for all sizes and shapes of office buildings.

Attention to detail is extremely important, especially in modular buildings. Each piece of equipment, duct and pipe connections, and the like may be duplicated hundreds of times. Thus, seemingly minor design variations may substantially affect construction and operating costs. In initial design, each component must be analyzed not only as an entity, but also as part of an integrated system. This systems design approach is essential for achieving optimum results.

As discussed under General Design Considerations, there are several classes of office buildings, determined by the type of financing required and the tenants who will occupy the building. Design evaluation may vary considerably based on specific tenant requirements; it is not enough to consider typical floor patterns only. Many larger office buildings include stores, restaurants, recreational facilities, data centers, telecommunication centers, radio and television studios, and observation decks.

Built-in system flexibility is essential for office building design. Business office procedures are constantly being revised, and basic building services should be able to meet changing tenant needs.

The type of occupancy may have an important bearing on air distribution system selection. For buildings with one owner or lessee, operations may be defined clearly enough that a system can be designed without the degree of flexibility needed for a less well-defined operation. However, owner-occupied buildings may require considerable design flexibility because the owner will pay for all alterations. The speculative builder can generally charge alterations to tenants. When different tenants occupy different floors, or even parts of the same floor, the degree of design and operation complexity increases to ensure proper environmental comfort conditions to any tenant, group of tenants, or all tenants at once. This problem is more acute if tenants have seasonal and variable overtime schedules.

Certain areas may have hours of occupancy or design criteria that differ substantially from those of the office administration areas; such areas should have their own air distribution systems and, in some cases, their own heating and/or refrigeration equipment.

Main entrances and lobbies are sometimes served by a separate and self contained system because they buffer the outdoor atmosphere and the building interior. Some engineers prefer to have a lobby summer temperature 2 to 3.5 K above office temperature to reduce operating cost and temperature shock to people entering or leaving the building. In cases where lobbies or main entrances have longer (or constant) operation, a dedicated/self-contained HVAC system is recommended to allow turning off other building systems.

The unique temperature and humidity requirements of server rooms or computer equipment/data processing installations, and the fact that they often run 24 h per day for extended periods, generally warrant separate refrigeration and air distribution systems. Separate back-up systems may be required for data processing areas in case the main building HVAC system fails. Chapter 20 has further information.

The degree of air filtration required should be determined. Service cost and effect of air resistance on energy costs should be analyzed for various types of filters. Initial filter cost and air pollution characteristics also need to be considered. Activated charcoal filters for odor control and reduction of outdoor air requirements are another option to consider.

Providing office buildings with continuous 100% outdoor air (OA) is seldom justified, so most office buildings are designed to minimize outdoor air use, except during economizer operation. However, attention to indoor air quality may dictate higher levels of ventilation air. In addition, the minimum volume of outdoor air should be maintained in variable-volume air-handling systems. Dry-bulb- or enthalpy-controlled economizer cycles should be considered for reducing energy costs. Consult ASHRAE *Standard* 90.1-2010 for the proper air economizer system (dry-bulb or enthalpy). When an economizer cycle is used, systems should be zoned so that energy is not wasted by heating outdoor air. This is often accomplished by a separate air distribution system for the interior and each major exterior zone. A dedicated outdoor air system (DOAS) can be considered where the zones are served by in-room terminal systems (fan coils, induction unit systems, etc.) or decentralized systems [e.g., minisplit HVAC, water-source heat pump (WSHP)]. Because the outdoor air supply is relatively low in office buildings, air-to-air heat recovery is not cost effective; instead, a DOAS with enhanced cooling and dehumidification systems can be used.

These systems typically use hot-gas reheat or other means of free reheat (e.g., heat pipes, plate-frame heat exchangers). In hot, humid climates, these systems can significantly improve space conditions. By having a DOAS, the OA supply can be turned off during unoccupied hours (which can be significant in office buildings). In unoccupied mode, the in-room unit needs to maintain only the desired space conditions (e.g., night/weekend setback temperature).

High-rise office buildings have traditionally used perimeter fan-powered VAV terminals, induction, or fan-coil systems. Separate all-air systems have generally been used for the interior and/or the exterior for the fan-powered VAV perimeter terminals; modulated air diffusers and fan-powered perimeter unit systems have also been used. If variable-air-volume systems serve the interior, perimeters are usually served by variable-volume fan-powered terminals, typically equipped with hydronic (hot-water) or electric reheat coils. In colder climates, perimeter baseboard heaters are commonly applied. Baseboards are typically installed under windows to minimize the effect of the cold surface.

Many office buildings without an economizer cycle have a bypass multizone unit installed on each floor or several floors with a heating coil in each exterior zone duct. VAV variations of the bypass multizone and other floor-by-floor, all-air, or self-contained systems are also used. These systems are popular because of their low fan power and initial cost, and the energy savings possible from independent operating schedules between floors occupied by tenants with different operating hours.

Perimeter radiation or infrared systems with conventional, single-duct, low-velocity air conditioning that furnishes air from packaged air-conditioning units may be more economical for small office buildings. The need for a perimeter system, which is a function of exterior glass percentage, external wall thermal value, and climate severity, should be carefully analyzed.

A perimeter heating system separate from the cooling system is preferable, because air distribution devices can then be selected for a specific duty rather than as a compromise between heating and cooling performance. The higher cost of additional air-handling or fan-coil units and ductwork may lead the designer to a less expensive option, such as fan-powered terminal units with heating coils serving perimeter zones in lieu of a separate heating system. Radiant ceiling panels for perimeter zones are another option.

Interior space use usually requires that interior air-conditioning systems allow modification to handle all load situations. Variable-air-volume systems are often used. When using these systems, low-load conditions should be carefully evaluated to determine whether adequate air movement and outdoor air can be provided at the proposed supply air temperature without overcooling. Increases in supply air temperature tend to nullify energy savings in fan power, which are characteristic of VAV systems. Low-temperature air distribution for additional savings in transport energy is seeing increased use, especially when coupled with an ice storage system.

In small to medium-sized office buildings, air-source heat pumps or minisplit systems (cooling only, heat pump, or combination) such as variable refrigerant flow (VRF) may be chosen. VRF systems that can cool and heat simultaneously are available and allow users to provide heating in perimeter zones and cooling in interior zones in a similar fashion to four-pipe fan coil (FPFC) systems. In larger buildings, water-source heat pump (WSHP) systems are feasible with most types of air-conditioning systems. Heat removed from core areas is rejected to either a cooling tower or perimeter circuits. The water-source heat pump can be supplemented by a central heating system or electrical coils on extremely cold days or over extended periods of limited occupancy. Removed excess heat may also be stored in hot-water tanks. Note that in-room systems (e.g., VRF, WSHP) might need a DOAS to provide the required outdoor air.

Many heat recovery or water-source heat pump systems exhaust air from conditioned spaces through lighting fixtures. This reduces required air quantities and extends lamp life by providing a much cooler ambient operating environment.

Suspended-ceiling return air plenums eliminate sheet metal return air ductwork to reduce floor-to-floor height requirements. However, suspended-ceiling plenums may increase the difficulty of proper air balancing throughout the building. Problems often connected with suspended ceiling return plenums include

- Air leakage through cracks, with resulting smudges
- Tendency of return air openings nearest to a shaft opening or collector duct to pull too much air, thus creating uneven air motion and possible noise
- Noise transmission between office spaces

Air leakage can be minimized by proper workmanship. To overcome drawing too much air, return air ducts can be run in the suspended ceiling pathway from the shaft, often in a simple radial pattern. Ends of ducts can be left open or dampered. Generous sizing of return air grilles and passages lowers the percentage of circuit resistance attributable to the return air path. This bolsters effectiveness of supply-air-balancing devices and reduces the significance of air leakage and drawing too much air. Structural blockage can be solved by locating openings in beams or partitions with fire dampers, where required.

Systems and Equipment Selection

Selection of HVAC equipment and systems depends on whether the facility is new or existing, and whether it is to be totally or partially renovated. For minor renovations, existing HVAC systems are often expanded in compliance with current codes and standards with equipment that matches the existing types. For major renovations or new construction, new HVAC systems and equipment should be installed. When applicable, the remaining useful life of existing equipment and distribution systems should be considered.

HVAC systems and equipment energy use and associated life cycle costs should be evaluated. Energy analysis may justify new HVAC equipment and systems when an acceptable return on investment can be shown. The engineer must review all assumptions in the energy analysis with the owner. Other considerations for existing facilities are (1) whether the central plant is of adequate capacity to handle additional loads from new or renovated facilities; (2) age and condition of existing equipment, pipes, and controls; and (3) capital and operating costs of new equipment.

Chapter 1 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides general guidelines on HVAC systems analysis and selection procedures. Although in many cases system selection is based solely on the lowest first cost, it is suggested that the engineer propose a system with the lowest life-cycle cost (LCC). LCC analysis typically requires hour-by-hour building energy simulation for annual energy cost estimation. Detailed first and maintenance cost estimates of proposed design alternatives, using sources such as R.S. Means (R.S. Means 2010a, 2010b), can also be used for the LCC analysis along with software such as BLCC 5.1 (FEMP 2003). Refer to Chapters 38 and 60 and the Value Engineering and Life-Cycle Cost Analysis section of this chapter for additional information.

System Types. HVAC systems for office buildings may be centralized, decentralized, or a combination of both. Centralized systems typically incorporate secondary systems to treat the air and distribute it. The cooling and heating medium is typically water or brine that is cooled and/or heated in a primary system and distributed to the secondary systems. Centralized systems comprise the following systems:

Secondary Systems

- Air handling and distribution (see Chapter 4 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)

- In-room terminal systems (see Chapter 5 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)
- Dedicated outdoor air systems (DOAS) with chilled water for cooling and hot water, steam, or electric heat for heating (for special areas when required)

Primary Systems

- Central cooling and heating plant (see Chapter 3 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)

More detailed information on systems selection by application can be found in Table 5.

Typical decentralized systems (dedicated systems serving a single zone, or packaged systems such as packaged variable air volume) include the following:

- Water-source heat pumps (WSHP), also known as water-loop heat pumps (WLHP)
- Geothermal heat pumps (e.g., groundwater heat pumps, ground-coupled heat pumps)
- Hybrid geothermal heat pumps (combination of groundwater heat pumps, ground-coupled heat pumps, and an additional heat rejection device) for cases with limited area for the ground-coupled heat exchanger or where it is economically justified
- Packaged single-zone and variable-volume units
- Light commercial split systems
- Minisplit and variable refrigerant flow (VRF) units

Chapters 2, 9, 49, and 50 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provide additional information on decentralized HVAC systems. Additional information on geothermal energy can be found in Chapter 35 of this volume.

Whereas small office buildings (<2320 m^2) normally apply packaged unitary and split systems equipment, larger office buildings can use a combination of packaged, unitary, split, and/or centralized systems, or large packaged rooftop systems. The building class also must be considered during system selection.

Systems Selection by Application. Table 5 shows the applicability of several systems for office buildings.

Special Systems

The following is a list of systems that can be considered for special areas in office buildings. Chapter 58 of this volume, Chapter 6 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, and Skistad et al. (2002) provide additional information of these systems.

- Displacement ventilation
- Underfloor air distribution (UFAD)
- Active (induction) and passive chilled beams

Demand-Controlled Ventilation (DCV). Demand-controlled ventilation can reduce the operating cost of HVAC systems. Areas such as auditoriums, large conference rooms, and other spaces designed for large numbers of occupants and intermittent occupancy can use DCV. This approach is most cost effective when one dedicated air handling system serves each of these zones. Special attention is required when DCV is applied to VAV systems. In these cases, it is insufficient to use only one CO_2 sensor in the return air plenum of the central AHU, because the readings are the average of all the zones. To address properly DCV in a VAV system, a CO_2 sensor is required in every controlled zone.

Spatial Requirements

Total office building electromechanical space requirements vary tremendously based on types of systems planned; however, the average is approximately 8 to 10% of the gross area. Clear height required for fan rooms varies from approximately 3 to 5.5 m, depending on the distribution system and equipment complexity. On office floors, perimeter fan-coil or induction units require approximately 1 to 3% of the floor area. Interior air shafts and pipe chases require approximately 3 to 5% of the floor area. Therefore, ducts, pipes, and equipment require approximately 4 to 8% of each floor's gross area.

Where large central units supply multiple floors, shaft space requirements depend on the number of fan rooms. In such cases, one mechanical equipment room usually furnishes air requirements for 8 to 20 floors (above and below for intermediate levels), with an average of 12 floors. The more floors served, the larger the duct shafts and equipment required. This results in higher fan room heights and greater equipment size and mass.

The fewer floors served by an equipment room, the greater the flexibility in serving changing floor or tenant requirements. Often, one mechanical equipment room per floor and complete elimination of vertical shafts requires no more total floor area than fewer larger mechanical equipment rooms, especially when there are many small rooms and they are the same height as typical floors. Equipment can also be smaller, although maintenance costs are higher. Energy costs may be reduced with more equipment rooms serving fewer areas, because equipment can be shut off in unoccupied areas, and high-pressure ductwork is not required. Equipment rooms on upper levels generally cost more to install because of rigging and transportation logistics.

In all cases, mechanical equipment rooms must be thermally and acoustically isolated from office areas.

Cooling Towers. Cooling towers can be the largest single piece of equipment required for air-conditioning systems. Cooling towers require approximately 1 m^2 of floor area per 400 m^2 of total building area and are 4 to 12 m high. If towers are located on the roof, the building structure must be able to support the cooling tower and dunnage, full water load (approximately 590 to 730 kg/m^2), and seismic and wind load stresses.

Where cooling tower noise may affect neighboring buildings, tower design should include sound traps or other suitable noise baffles. This may affect tower space, mass of the units, and motor

Table 5 Applicability of Systems to Typical Office Buildings

	Cooling/Heating Systems							Heating Only	
	Centralized			Decentralized					
Building Area/Stories	SZ*	VAV/ Reheat	Fan Coil (Two-and Four-Pipe)	PSZ/SZ*/ Split/ VRF	PVAV/ Reheat	WSHP	Geothermal Heat Pump and Hybrid Geothermal Heat Pump	Perimeter Baseboard/ Radiators	Unit Heaters
<2320 m^2, one to three stories				X		X	X	X	Special areas
2230 to 13 940 m^2, one to five stories	X	X	X	X	X	X	X	X	Special areas
>13 940 m^2, low rise and high rise	X	X	X			X	X	X	Special areas

*SZ = single zone
VAV = variable-air-volume
PSZ = packaged single zone
PVAV = packaged variable-air-volume
WSHP = water-source heat pump
VRF = variable refrigerant flow

power. Slightly oversizing cooling towers can reduce noise and power consumption because of lower speeds and also the ability to reduce the condenser water temperature, which reduces cooling energy. The size increase may increase initial cost.

Cooling towers are sometimes enclosed in a decorative screen for aesthetic reasons; therefore, calculations should ascertain that the screen has sufficient free area for the tower to obtain its required air quantity and to prevent recirculation.

If the tower is placed in a rooftop well or near a wall, or split into several towers at various locations, design becomes more complicated, and initial and operating costs increase substantially. Also, towers should not be split and placed on different levels because hydraulic problems increase. Finally, the cooling tower should be built high enough above the roof so that the bottom of the tower and the roof can be maintained properly.

Special Considerations

Office building areas with special ventilation and cooling requirements include elevator machine rooms, electrical and telephone closets, electrical switchgear, plumbing rooms, refrigeration rooms, and mechanical equipment rooms. The high heat loads in some of these rooms may require air-conditioning units for spot cooling.

In larger buildings with intermediate elevator, mechanical, and electrical machine rooms, it is desirable to have these rooms on the same level or possibly on two levels. This may simplify horizontal ductwork, piping, and conduit distribution systems and allow more effective ventilation and maintenance of these equipment rooms.

An air-conditioning system cannot prevent occupants at the perimeter from feeling direct sunlight. Venetian blinds and drapes are often provided but seldom used. External shading devices (screens, overhangs, etc.) or reflective glass are preferable.

Tall buildings in cold climates experience severe stack effect. The extra amount of heat provided by the air-conditioning system in attempts to overcome this problem can be substantial. The following features help combat infiltration from stack effect:

- Revolving doors or vestibules at exterior entrances
- Pressurized lobbies or lower floors
- Tight gaskets on stairwell doors leading to the roof
- Automatic dampers on elevator shaft vents
- Tight construction of the exterior skin
- Tight closure and seals on all dampers opening to the exterior

2. TRANSPORTATION CENTERS

Major transportation facilities include transit facilities (rail transit, bus terminals), airports, and cruise terminals. Other areas that can be found in transportation centers are airplane hangars and freight and mail buildings, which can be treated as warehouse facilities. Bus terminals are covered partially in this chapter, but Chapter 16 provides more detail.

Airports

Airports are large, complex, and highly profitable enterprise. Most U.S. airports are public nonprofits, run directly by government entities or by government-created authorities known as airport or port authorities. There are three main types of airports:

- **International airports** serving over 20 million passengers a year.
- **National airports** serving between 2 to 20 million passengers a year.
- **Regional airport** serving up to 2 million passengers a year.

Airports typically consists the following:

- Runways and taxiing areas
- Air traffic control buildings
- Aircraft maintenance buildings and hangars
- Passenger terminals and car parking (open, partially open, or totally enclosed)
- Freight warehouses
- Lodging facilities (hotels)

In addition, support areas such as administration buildings, central utility plants, and transit facilities (rail and bus) are common in airport facilities.

Areas such as hangars, hotels, and car parking are not covered in this section. Information about hotels and parking garages can be found in Chapters 7 and 16, respectively. Warehouses are discussed in the next section of this chapter.

Most terminals can be divided into the following sections and subsections:

Departure

- Entrance concourse
- Check-in and ticketing
- Security and passports
- Shops, restaurants, banks, medical services, conference and business facilities, etc.
- Departure lounge
- Departure gates

Arrival

- Arrival lounge
- Baggage claim
- Customs, immigration, and passport control
- Exit concourse

Cruise Terminals

Cruise terminals typically have three main areas: departure/arrival concourse, ticketing, and baggage handling. These areas are open and large, and are designed to provide acceptable thermal comfort to the passenger during embarkation and debarkation.

Design Criteria

Transportation centers consist of a variety of areas, such as administration, large open areas, shops, and restaurants. Design criteria for these areas should be based on information on relevant chapters from this volume or ASHRAE *Standard* 62.1.

Load Characteristics

Airports, cruise terminals, and bus terminals operate on a 24 h basis, with a reduced schedule during late night and early morning hours. To better understand the load characteristics of these facilities, computer-based building energy modeling and simulation tools should be used; this chapter provides basic information and references for energy modeling. Given the dynamic nature of transportation facilities, well-supported assumptions of occupancy schedules should be established during the analysis process.

Airports. Terminal buildings consist of large, open circulating areas, one or more floors high, often with high ceilings, ticketing counters, and various types of stores, concessions, and convenience facilities. Lighting and equipment loads are generally average, but occupancy varies substantially. Exterior loads are, of course, a function of architectural design. The largest single problem often is thermal drafts created by large entranceways, high ceilings, and long passageways that have openings to the outdoors.

Cruise Terminals. Freight and passenger docks consist of large, high-ceilinged structures with separate areas for administration, visitors, passengers, cargo storage, and work. The floor of the dock is usually exposed to the outdoors just above the water level. Portions of the sidewalls are often open while ships are in port. In addition, the large ceiling (roof) area presents a large heating and cooling load. Load characteristics of passenger dock terminals generally require roof and floors to be well insulated. Occasional heavy occupancy loads in visitor and passenger areas must be considered.

Bus Terminals. These buildings consist of two general areas: the terminal, which contains passenger circulation, ticket booths, and stores or concessions; and the bus loading area. Waiting rooms and passenger concourse areas are subject to a highly variable occupant load: density may reach 1 m^2 per person and, at extreme periods, 0.3 to 0.5 m^2 per person. Chapter 16 has further information on bus terminals.

Design Concepts

Heating and cooling is generally centralized or provided for each building or group in a complex. In large, open-circulation areas of transportation centers, any all-air system with zone control can be used. Where ceilings are high, air distribution is often along the side wall to concentrate air conditioning where desired and avoid disturbing stratified air. Perimeter areas may require heating by radiation, a fan-coil system, or hot air blown up from the sill or floor grilles, particularly in colder climates. Hydronic perimeter radiant ceiling panels may be especially suited to these high-load areas.

Airports. Airports generally consist of one or more central terminal buildings connected by long passageways or trains to rotundas containing departure lounges for airplane loading. Most terminals have portable telescoping-type loading bridges connecting departure lounges to the airplanes. These passageways eliminate heating and cooling problems associated with traditional permanent passenger-loading structures.

Because of difficulties in controlling the air balance and because of the many outdoor openings, high ceilings, and long, low passageways (which often are not air conditioned), the terminal building (usually air conditioned) should be designed to maintain a substantial positive pressure. Zoning is generally required in passenger waiting areas, in departure lounges, and at ticket counters to take care of the widely variable occupancy loads.

Main entrances may have vestibules and windbreaker partitions to minimize undesirable air currents in the building.

Hangars must be heated in cold weather, and ventilation may be required to eliminate possible fumes (although fueling is seldom permitted in hangars). Gas-fired, electric, and low- and high-intensity radiant heaters are used extensively in hangars because they provide comfort for employees at relatively low operating costs.

Hangars may also be heated by large air blast heaters or floor-buried heated liquid coils. Local exhaust air systems may be used to evacuate fumes and odors that occur in smaller ducted systems. Under some conditions, exhaust systems may be portable and may include odor-absorbing devices.

Cruise Terminals. In severe climates, occupied floor areas may contain heated floor panels. The roof should be well insulated, and, in appropriate climates, evaporative spray cooling substantially reduces the summer load. Freight docks are usually heated and well ventilated but seldom cooled.

High ceilings and openings to the outdoors may present serious draft problems unless the systems are designed properly. Vestibule entrances or air curtains help minimize cross drafts. Air door blast heaters at cargo opening areas may be quite effective.

Ventilation of the dock terminal should prevent noxious fumes and odors from reaching occupied areas. Therefore, occupied areas should be under positive pressure and cargo and storage areas exhausted to maintain negative air pressure. Occupied areas should be enclosed to simplify any local air conditioning.

In many respects, these are among the most difficult buildings to heat and cool because of their large open areas. If each function is properly enclosed, any commonly used all-air or large fan-coil system is suitable. If areas are left largely open, the best approach is to concentrate on proper building design and heating and cooling of the openings. High-intensity infrared spot heating is often advantageous (see Chapter 16 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*). Exhaust ventilation from tow truck and cargo areas should be exhausted through the roof of the dock terminal.

Bus Terminals. Conditions are similar to those for airport terminals, except that all-air systems are more practical because ceiling heights are often lower, and perimeters are usually flanked by stores or office areas. The same systems are applicable as for airport terminals, but ceiling air distribution is generally feasible.

Properly designed radiant hydronic or electric ceiling systems may be used if high-occupancy latent loads are fully considered. This may result in smaller duct sizes than are required for all-air systems and may be advantageous where bus-loading areas are above the terminal and require structural beams. This heating and cooling system reduces the volume of the building that must be conditioned. In areas where latent load is a concern, heating-only panels may be used at the perimeter, with a cooling-only interior system.

The terminal area air supply system should be under high positive pressure to ensure that no fumes and odors infiltrate from bus areas. Positive exhaust from bus loading areas is essential for a properly operating total system (see Chapter 16).

Systems and Equipment Selection

Given the size and magnitude of the systems in airports and cruise terminals, the selection of the HVAC equipment and systems tend to be centralized. Depending on the area served and site limitations, decentralized systems can also be considered for these specific cases.

Centralized systems typically incorporate secondary systems to treat and distribute air. The cooling and heating medium is typically water or brine that is cooled and/or heated in a primary system and distributed to the secondary systems. Centralized systems comprise the following systems:

Secondary Systems

- Air handling and distribution (see Chapter 4 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)
- In-room terminal systems (see Chapter 5 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)
- Secondary systems such as variable air volume (VAV) are common in airports. Small, single-zone areas can be treated by constant-volume systems or fan coils.

Primary Systems

- Central cooling and heating plant (see Chapter 3 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)
- For cases where decentralized systems (dedicated systems serving a single zone or packaged systems such as packaged variable air volume) are:
- Water-source heat pumps (WSHP) (also known as water-loop heat pumps or WLHP)
- Packaged single-zone and variable-volume units
- Light commercial split systems
- Mini-split and variable-refrigerant-flow (VRF) units

Special Considerations

Airports. Filtering outdoor air with activated charcoal filters should be considered for areas subject to excessive noxious fumes from jet engine exhausts. However, locating outdoor air intakes as remotely as possible from airplanes is a less expensive and more positive approach.

Where ionization filtration enhancers are used, outdoor air quantities are sometimes reduced because the air is cleaner. However, care must be taken to maintain sufficient amounts of outdoor air for space pressurization.

Cruise Terminals. Ventilation design must ensure that fumes and odors from forklifts and cargo in work areas do not penetrate occupied and administrative areas.

Bus Terminals. The primary concerns with enclosed bus loading areas are health and safety problems, which must be handled by proper ventilation (see Chapter 16). Although diesel engine fumes are generally not as noxious as gasoline fumes, bus terminals often have many buses loading and unloading at the same time, and the total amount of fumes and odors may be disturbing.

In terms of health and safety, enclosed bus loading areas and automobile parking garages present the most serious problems. Three major problems are encountered, the first and most serious of which is emission of carbon monoxide (CO) by cars and oxides of nitrogen (NO_x) by buses, which can cause serious illness and possibly death. Oil and gasoline fumes, which may cause nausea and headaches and can create a fire hazard, are also of concern. The third issue is lack of air movement and the resulting stale atmosphere caused by increased CO content in the air. This condition may cause headaches or grogginess. Most codes require a minimum ventilation rate to ensure that the CO concentration does not exceed safe limits. Chapter 16 covers ventilation requirements and calculation procedures for enclosed vehicular facilities in detail.

All underground garages should have facilities for testing the CO concentration or should have the garage checked periodically. Problems such as clogged duct systems; improperly operating fans, motors, or dampers; or clogged air intake or exhaust louvers may not allow proper air circulation. Proper maintenance is required to minimize any operational defects.

3. WAREHOUSES AND DISTRIBUTION CENTERS

General Design Considerations

Warehouses can be defined as facilities that provide proper environment for the purpose of storing goods and materials. They are also used to store equipment and material inventory at industrial facilities. At times, warehouses may be open to the public. The buildings are generally not air conditioned, but often have sufficient heat and ventilation to provide a tolerable working environment. In many cases, associated facilities occupied by office workers, such as shipping, receiving, and inventory control offices, are air conditioned. Warehouses must be designed to accommodate the loads of materials to be stored, associated handling equipment, receiving and shipping operations and associated trucking, and needs of operating personnel. Types of warehouses include the following:

- **Heated and unheated general warehouses** provide space for bulk, rack, and bin storage, aisle space, receiving and shipping space, packing and crating space, and office and toilet space. As indicated some areas are typically equipped with small-decentralized air-conditioning systems for the support personnel.
- **Conditioned general warehouses** are similar to heated and unheated general warehouses, but can provide space cooling to meet the stored goods' requirements.
- **Refrigerated warehouses** are designed to preserve the quality of perishable goods and general supply materials that require refrigeration. This includes freeze and chill spaces, processing facilities, and mechanical areas. For information on this type of warehouse, see Chapters 23 and 24 in the 2018 *ASHRAE Handbook—Refrigeration*.
- **Controlled humidity (CH) and dry-air storage warehouses** are similar to general warehouses except that they are constructed with vapor barriers and contain humidity control equipment to maintain humidity at desired levels. For additional information, see Chapter 29 of Harriman et al. (2001).
- **Specialty warehouses** includes storing facilities with special and in some instances strict requirements for temperature, humidity, cleanliness, minimum ventilation rates, etc. These facilities are typically conditioned to achieve the required space conditions. These warehouses can be found in industrial and manufacturing facilities or can be standalone buildings. Examples include
  - Pharmaceutical and life sciences facilities. Good manufacturing practices (GMP) may be required.
  - Liquid storage (fuel and nonpropellants), flammable and combustible storage, radioactive material storage, hazardous chemical storage, and ammunition storage.
  - Automated storage and retrieval systems (AS/RS), which are designed for maximum storage and minimum personnel on site. They are built for lower-temperature operation with minimal heat and light needed, but require a tall structure with extremely level floors. In some cases, specialty HVAC equipment is required for servers and other computer areas in AS/RS facility.

Features already now common in warehouse designs are higher bays, sophisticated materials-handling equipment, broadband connectivity access, and more distribution networks. A wide range of storage alternatives, picking alternatives, material-handling equipment, and software exist to meet the physical and operational requirements. Warehouse spaces must also be flexible to accommodate future operations and storage needs as well as mission changes.

Areas that can be found in warehouses and distribution centers include the following:

- Storage areas
- Office and administrative areas
- Loading docks
- Light industrial spaces
- Computer/server rooms

Other areas can be site specific.

Design Criteria

Design criteria (temperature, humidity, noise, etc.) for warehouses are space specific; the designer should refer to the relevant sections and chapters (e.g., the section on Office Buildings for office and administration areas). For conditioned storage areas, the special requirements of the product stores dictate the design conditions.

Outdoor air for ventilation of office, administration, and support areas should be based on local code requirements or ASHRAE *Standard* 62.1. For general warehouses where special ventilation or minimum ventilation rates are not specifically defined, *Standard* 62.1 can be used as the criterion for minimum outdoor air. To define the specific ventilation and exhaust design criteria, consult local applicable ventilation and exhaust standards. Table 6-1 of *Standard* 62.1 recommends 0.3 L/(s·m^2) of ventilation as a design criterion for warehouse ventilation, although this amount may be insufficient when stored materials have harmful emissions.

Load Characteristics

Given the variety of warehouses facilities, every case should be analyzed carefully. In general, internal loads from lighting, people, and miscellaneous sources are low. Most of the load is thermal transmission and infiltration. An air-conditioning load profile tends to flatten where materials stored are massive enough to cause the peak load to lag. In humid climates, special attention should be given to the sensible and latent loads' variations for cases where the warehouse or distribution center is conditioned or cooled by thermostatically controlled packaged HVAC equipment. In these climates, it is common to satisfy the space temperature (i.e., very low or no sensible cooling load), but, because of infiltration of moist air and without proper cooling (i.e., the cooling equipment is off), for space humidity to be unacceptably high.

Design Concepts

Most warehouses are only heated and ventilated. Forced-flow unit heaters may be located near entrances and work areas. Large central heating and ventilating units are also widely used. Even though comfort for warehouse workers may not be considered, it may be necessary to keep the temperature above 4°C to protect sprinkler piping or stored materials from freezing.

A building designed for adding air conditioning at a later date requires less heating and is more comfortable. For maximum summer comfort without air conditioning, excellent ventilation with noticeable air movement in work areas is necessary. Even greater comfort can be achieved in appropriate climates by adding roof-spray cooling. This can reduce the roof's surface temperature, thereby reducing ceiling radiation inside. Low- and high-intensity radiant heaters can be used to maintain the minimum ambient temperature throughout a facility above freezing. Radiant heat may also be used for occupant comfort in areas permanently or frequently open to the outdoors.

If the stored product requires specific inside conditions, an air-conditioning system must be added. Using only ventilation may help maintain lower space temperatures, but care should be taken not to damage the stored product with uncontrolled humidity. Direct or indirect evaporative cooling may also be an option.

Systems and Equipment Selection

Selection of HVAC equipment and systems depends on type of warehouse. As indicated previously, the warehouse might need only heating/cooling in admin areas, or in some cases, highly sophisticated HVAC systems to address special ambient conditions required by the product stored in this warehouse. The same principles and procedures of selecting the HVAC systems described in the office building section of this chapter should be followed.

Selection by Application. Table 6 depicts typical systems applied for warehouse facilities. Centralized systems refer to warehouses where central chilled-water and/or hot-water/steam system is available. Decentralized systems are typically direct expansion (DX) systems with gas-fired heating or other available heating source.

Special systems are typically required when special ambient conditions have to be maintained: usual examples are desiccant dehumidification, mechanical dehumidification, and humidification.

In hot and humid climates, a combination of desiccant-based dehumidification equipment along with standard DX, packaged, single-zone units can be considered. This approach allows separation of sensible cooling load from latent load, thereby enhancing humidity control under most ambient conditions, reducing energy consumption, and allowing optimal equipment sizing and use.

Table 6 Applicability of Systems to Typical Warehouse Building Areas

	Cooling/Heating Systems		Heating Only	
	Centralized	Decentralized		
Warehouse Area	SZ	PSZ/SZ Split/VRF	Heating and Ventilating Units	Local Unit Heaters
Storage areas	X	X	X	X
Office and administration areas	X	X		
Loading docks			X	X
Light industrial spaces	X	X	X	
Computer/server rooms	X (also CHW, CRAC Unit)	X (also DX, CRAC Unit)		

SZ = single zone
PSZ = packaged single zone
VRF = variable refrigerant flow
CHW = chilled water
CRAC = computer room air conditioning

Spatial Requirements

Total building electromechanical space requirements vary based on types of systems planned. Typically, the HVAC equipment can be roof mounted, slab, indoor, or ceiling mounted. Ductwork and air discharge plenums usually are not concealed; often, the systems are free discharge.

Special Considerations

Forklifts and trucks powered by gasoline, propane, and other fuels are often used inside warehouses. Proper ventilation is necessary to alleviate build-up of CO and other noxious fumes. Proper ventilation of battery-charging rooms for electrically powered forklifts and trucks is also required.

4. SUSTAINABILITY AND ENERGY EFFICIENCY

In the context of this chapter, sustainable refers to a building that minimizes the use of energy, water, and other natural resources and provides a healthy and productive indoor environment (e.g., IAQ, lighting, noise). The HVAC&R designer plays a major role in supporting the design team in designing, demonstrating, and verifying these goals, particularly in the areas of energy efficiency and indoor environmental quality (mainly IAQ).

Several tools and mechanisms are available to assist the HVAC&R designer in designing and demonstrating sustainable commercial facilities; see the References and Bibliography in this chapter, the Sustainability and Energy Efficiency section in Chapter 8, and Chapter 35 in the 2017 *ASHRAE Handbook—Fundamentals*.

Energy Considerations

Energy standards such as ANSI/ASHRAE/IESNA *Standard* 90.1-2007 and local energy codes should be followed for minimum energy conservation criteria. Note that additional aspects such as lighting, motors/drives, building envelope, and electrical services should also be considered for energy reduction. Energy procurement/supply-side opportunities should also be investigated for energy cost reduction. Table 14 in Chapter 8 depicts a list of selected energy conservation opportunities.

Energy Efficiency and Integrated Design Process for Commercial Facilities

The integrated design process (IDP) is vital for the design of high-performance commercial facilities. For background and details on integrated building design (IBD) and IDP, see Chapter 60.

Unlike the sequential design process (SDP), where the elements of the built solution are defined and developed in a systematic and sequential manner, IDP encourages holistic collaboration of the project team during the all phases of the project, resulting in cost-effective and environmentally friendly design. IDP responds to the project objectives, which typically are established by the owner before team selection. Typical IDP includes the following elements:

- Owner planning
- Predesign
- Schematic design
- Schematic design
- Design development
- Construction documents
- Procurement
- Construction
- Operation

Detailed information on each element can be found in Chapter 60.

In high-performance buildings, these objectives are typically sustainable sites, water efficiency, energy and atmosphere quality, materials and resources, and indoor environmental quality. These objectives are the main components of several rating systems. Energy use objectives are typically the following:

- Meeting minimum prescriptive compliance (mainly local energy codes, ASHRAE *Standard* 90.1, etc.)
- Improving energy performance by an owner-defined percentage beyond the applicable code benchmark
- Demonstrating minimum energy performance (or prerequisite) and enhanced energy efficiency (for credit points) for sustainable design rating [e.g., U.S. Green Building Council (USGBC) Leadership in Energy and Environmental Design (LEED®)]
- Providing a facility/building site energy density [e.g., energy utilization index (EUI)] less than an owner-defined target [e.g., U.S. Environmental Protection Agency (EPA) ENERGY STAR guidelines)
- Provide an owner-defined percentage of facility source energy from renewable energy

Building Energy Modeling

Building energy modeling has been one of the most important tools in the process of IDP and sustainable design. Building energy modeling uses sophisticated methods and tools to estimate the energy consumption and behavior of buildings and building systems. To better illustrate the concept of energy modeling, the difference between HVAC sizing and selection programs and energy modeling tools will be described.

Design, sizing selection, and equipment sizing tools are typically used for design and sizing of HVAC&R systems, normally at the **design** process. Examples include cooling/heating load calculations tools, ductwork design software, piping design programs, acoustics software, and selection programs for specific types of equipment. The results are used to specify cooling and heating capacities, airflow, water flow, equipment size, etc., during the design as defined and agreed by the client.

Energy modeling [also known as building modeling and simulation (BMS)] is used to model the building's thermal behavior and the building energy systems' performance. Unlike design tools, which are used for one design point (or for sizing), the building energy simulation analyzes the building and the building systems up to 8760 times: hour by hour, or even in smaller time intervals.

A building energy simulation tool is a computer program consisting of mathematical models of building elements and HVAC&R equipment. To run a building energy simulation, the user must define the building elements, equipment variables, energy cost, etc. The simulation engine then solves mathematical models of the building elements, equipment, and so on 8760 times (one for every hour), usually through a sequential process. Common results include annual energy consumption, annual energy cost, hourly profiles of cooling loads, and hourly energy consumption. Chapter 19 of the 2018 *ASHRAE Handbook—Fundamentals* provides detailed information on energy modeling techniques.

Typically, energy modeling tools must meet minimum requirements to be accepted by rating authorities such as USGBC or local building codes. The following is typical of minimum modeling capabilities:

- 8760 h per year
- Hourly variations in occupancy, lighting power, miscellaneous equipment power, thermostat set points, and HVAC system operation, defined separately for each day of the week and holidays
- Thermal mass effects
- Ten or more thermal zones
- Part-load performance curves for mechanical equipment
- Capacity and efficiency correction curves for mechanical heating and cooling equipment
- Air-side economizers with integrated control
- Design load calculations to determine required HVAC equipment capacities and air and water flow rates in accordance with generally accepted engineering standards and practice
- Tested according to ASHRAE *Standard* 140

Energy modeling is typically used in the following ways:

- As a decision support tool for energy systems in new construction and retrofit projects; that is, it allows analyzing several design alternatives and the selection of the optimal solution for a given criterion
- To provide vital information to the engineer about the building behavior and systems performance during design
- To demonstrates compliance with energy standards such as ASHRAE *Standard* 90.1 (energy cost budget method)
- To support USGBC LEED certification in the Energy and Atmosphere (EA) section
- To model existing buildings and systems and analyzing proposed energy conservation measures (ECMs) by performing calibrated simulation
- Demonstrate energy cost savings as part of measurements and verification (M&V) protocol (by using calibrated simulation procedures)

Energy modeling is used intensively in LEED for New Construction (USGBC 2009), Energy & Atmosphere (EA), prerequisite 2 (minimum energy performance), and for EA credit 1 (Optimize Energy Performance). An energy simulation program (with the requirements shown above) along with ASHRAE *Standard* 90.1 is used to perform whole-building energy simulation for demonstrating energy cost savings. The number of credits awarded is in correlation to the energy cost reduction.

Energy Benchmarking and Benchmarking Tools

Energy benchmarking is an important element of energy use evaluation and tracking. It involves comparing building normalized energy consumption to that of other similar buildings. The most common normalization factor is the gross floor area. Energy benchmarking is less accurate then other energy analysis methods, but can provide a good overall picture of relative energy use.

Relative energy use is commonly expressed by the energy utilization index (EUI), which is the energy use per unit area per year. Typically, EUI is defined in terms of MJ/m^2 per year. In some cases, the user is interested in energy cost benchmarking, which is known as the cost utilization index (CUI). CUI units are $/$m^2$ per year. It is important to differentiate between site EUI (actual energy used on site) and source EUI (energy used at the energy source); about two-thirds of the primary energy that goes into an electric power plant is lost in the process as waste heat.

One of the most important sources of energy benchmarking data is the Commercial Building Energy Consumption Survey (CBECS) by the U.S. Department of Energy's Energy Information Administration (DOE/EIA). Table 2 of Chapter 37 shows an example of EUI calculated based on DOE/EIA 2003 CBECS; the mean site EUI for mixed-use office space is 89 MJ/($m^2 \cdot$yr). Other EUIs for commercial facilities can be found in the same table.

Common energy benchmarking tools include the following:

- U.S. EPA ENERGY STAR Portfolio Manager (http://www.energystar.gov/benchmark)
- Lawrence Berkeley National Laboratory (LBNL) ARCH (http://poet.lbl.gov/arch/)
- CAL-ARCH for the state of California (http://poet.lbl.gov/cal-arch/)

Comprehensive information on energy benchmarking and available benchmarking tools can be found in Glazer (2006) and Chapter 37.

Combined Heat and Power in Commercial Facilities

Combined heat and power (CHP) plants and building cooling heating and power (BCHP) can be considered for large facilities such as large office buildings and campuses and airports when economically justifiable. Chapter 7 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and other sources such as Meckler and Hyman (2010), Orlando (1996), and Petchers (2002) provide information on CHP systems. Additional Internet-based sources for CHP include the following:

- U.S. EPA Combined Heat and Power (CHP) Partnership at http://www.epa.gov/chp/; procedures for feasibility studies and evaluations for CHP integration are available at http://www.epa.gov/chp/project-development/index.html
- U.S. Department of Energy, Energy Efficiency and Renewable Energy at http://www.energy.gov/eere/amo/chp-deployment
- A database of CHP installations can be found at http://www.eea-inc.com/chpdata/index.html

Maor and Reddy (2008) show a procedure to optimize the size of the prime mover and thermally operated chiller for large office buildings by combining a building energy simulation program and CHP optimization tools.

CHP systems can be applied in large district cooling and heating facilities and infrastructure to use waste heat efficiently. The type of the prime mover is heavily dependent on the electrical and thermal loads, ability to use waste heat efficiently, and utility rates. Table 1 in Chapter 7 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides information on the applicability of CHP.

Renewable Energy

Renewable energy (RE) technologies, including solar, wind, and biomass, can be considered when applicable and economically justifiable. Renewable energy use can add LEED credits (USGBC 2009) under Energy and Atmosphere (credit 2), depending on the percentage of renewable energy used.

Given the increased number and popularity of solar systems, only these systems will be discussed in this chapter. Geothermal energy is also considered to be renewable energy; these systems are discussed earlier in this chapter, and in more detail in Chapter 35.

Solar/Photovoltaic. Photovoltaic (PV) technology is the direct conversion of sunlight to electricity using semiconductor devices called solar cells. Photovoltaic are almost maintenance-free and seem to have a long lifespan. Given the longevity, no pollution, simplicity, and minimal resources, this technology is highly sustainable, and the proper financing mechanisms can make this system economically justifiable.

Airport facilities can be considered good candidates for PV technology for the following reasons:

- Large, low-rise buildings with available roof for PV collectors
- Little or no shading
- Large open area (open areas, parking lots, etc.)
- Hours and seasons of operation

The most common technology in use today is single-crystal PV, which uses wafers of silicon wired together and attached to a module substrate. Thin-film PV, such as amorphous silicon technology, uses silicon and other chemicals deposited directly on a substrate such as glass or flexible stainless steel. Thin films promise lower cost per unit area, but also have lower efficiency and produce less electricity per unit area compared to single-crystal PVs. Typical values for dc electrical power generation are around 0.56 W/m^2 for thin film and up to 1.4 W/m^2 for single-crystal PV.

PV panels produce direct current, not the alternating current used to power most building equipment. Direct current is easily stored in batteries; an inverter is required to transform the direct current to alternating current. The costs of an inverter and of reliable batteries to store electricity increase the overall cost of a system, which is usually $5 to $7/W (Krieth and Goswami 2007).

Another option is concentrated PV (CPV). CPV uses high-concentration lenses or mirrors to focus sunlight onto miniature solar cells. CPV systems must track the sun to keep the light focused on the PV cells. The main advantage of this system is higher efficiency than other technologies. Reliability, however, is an important technical challenge for this emerging technology: the systems generally require highly sophisticated tracking devices.

Being able to transfer excess electricity generated by a photovoltaic system back into the utility grid can be advantageous. Most utilities are required to buy excess site-generated electricity back from the customer. In many states, public utility commissions or state legislatures have mandated **netmetering**, which means that utilities pay and charge equal rates regardless of which way the electricity flows. A good source of rebates and incentives in the United States for solar systems and other renewable technologies is the Database of State Incentives for Renewable and Efficiency (DSIRE), available at http://www.dsireusa.org/ (North Carolina State University 2011). DSIRE is a comprehensive source of information on state, local, utility, and federal incentives and policies that promote renewable energy and energy efficiency, as well as state requirements for licensed solar contractors.

PV systems should be integrated during the early stages of the design. In existing facilities, a licensed contractor can be employed for a turnkey project, which includes sizing, analysis, economic analysis, design documents, specifications, permits, and documentation for incentives.

Available tools for analysis during design and installation of PV systems include the following:

- PVsyst, a PC software package for the study, sizing, simulation and data analysis of complete PV systems (University of Geneva 2010) at http://www.pvsyst.com
- Hybrid Optimization Modeling Software (HOMER 2010), a program for analyzing and optimizing renewable energy technologies (http://www.homerenergy.com/)
- RETScreen (Natural Resources Canada 2010), a free decision support tool (which supports 35 languages) developed to help evaluate energy production and savings, costs, emission reductions, financial viability, and risk for various types of renewable energy technologies, at http://www.retscreen.net/ang/home.php
- eQUEST (Quick Energy Simulation Tool), a full-scale building energy simulation program capable of performing a complete building energy evaluation, at http://www.doe2.com/

Financing PV projects in the public sector can be more complex because of tax exemptions and efficient allocation of public funds and leverage incentives. The primary mechanism for financing public-sector PV projects is a third-party ownership model, which allows the public sector to take advantage of all the federal tax and other incentives without large up-front outlay of capital. The public sector does not own the solar PV, but only hosts it on its property. The cost of electrical power generated is then secured at a fixed rate, which is lower than the retail price for 15 to 25 years. Cory et al. (2008) discuss solar photovoltaic financing for the public sector in detail.

Solar/Thermal. Some commercial facilities can consider active thermal solar heating systems. Solar hot-water systems usually can reduce the energy required for service hot water. Solar heating design and installation information can be found in ASHRAE (1988, 1991). Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and Krieth and Goswami (2007) are good sources of information for design and installation of active solar systems, as are Web-based sources such as U.S. Department of Energy's Energy Efficiency and Renewable Energy page at http://www.energy.gov/eere/renewables/solar.

Value Engineering and Life-Cycle Cost Analysis

Use of value engineering (VE) and life-cycle cost analysis (LCCA) studies is growing in all types of construction and as part of the integrated design process (IDP). VE and LCCA are logical, structured, systematic processes used as decision support tools to achieve overall cost reduction, but they are two distinct tools (Anderson et al. 2004).

Value engineering refers to a process where the project team examines the proposed design components in relation to the project objectives and requirements. The intent is to provide essential functions while exploring cost savings opportunities through modification or elimination of nonessential design elements. Examples are alternative systems, and substitute equipment. VE typically includes seven steps, as shown in Figure 11 of Chapter 8.

Life-cycle cost analysis is used as part of VE to evaluate design alternatives (e.g., alternative systems, equipment substitutions) that meet the facility design criteria with reduced cost or increased value over the life of the facility or system.

The combination of VE and LCCA is suitable for public facilities, which are often government funded and intended for longer lifespans than commercial facilities. Unfortunately, these tools often are not included in the early stages of the design, which results in a last-minute effort to reduce cost and stay within the budget, compromising issues such as energy efficiency and overall value of the facility. To avoid this, VE and LCCA should be deployed in the early stages of the project.

LCCA is recommended as part of any commercial building construction for economic evaluation. Chapters 38 and 60 discuss LCCA in detail. Other methodologies such as simple payback should be avoided because of inaccuracies and the need to take into account the time value of money. Life-cycle cost is more accurate because it captures all the major initial costs associated with each item, the costs occurring during the life of the system, and the value of money for the entire life of the system.

5. COMMISSIONING AND RETROCOMMISSIONING

Commissioning (Cx) is a quality assurance process for buildings from predesign through design, construction, and operations. It involves achieving, verifying, and documenting the performance of each system to meet the building operational needs. Given the growing demand for enhanced indoor air quality, thermal comfort, noise, etc., in commercial facilities and the application of equipment and systems such as DOAS, EMS, and occupancy sensors, it is important to follow the commissioning process as described in Chapter 44 and ASHRAE *Guideline* 0-2005. The technical requirements for the commissioning process are described in detail in ASHRAE *Guideline* 1.1-2007. Another source is ACG (2005). Proper commissioning ensures fully functional systems that can be operated and maintained properly throughout the life of the building. Although commissioning activities should be implemented by qualified commissioning professional [commissioning authority (CA)], it is important for other professionals to understand the basic definitions and processes in commissioning, such as the following:

- Owner project requirements (OPR), which is a written document that details the functional requirements of the project and the expectations of how it will be used and operated.
- Commissioning refers to a quality-focused process for enhancing the delivery of a project. The process focuses upon verifying and documenting that the facility and all its systems and assemblies are planned, installed, tested, and maintained to meet the OPR.
- Recommissioning is an application of the commissioning process to a project that has been delivered using the commissioning process.
- Retrocommissioning is applied to an existing facility that was not previously commissioned.
- Ongoing commissioning is a continuation of the commissioning process well into the occupancy and operation phase.

Commissioning: New Construction

Table 7 shows the phases of commissioning a new building, as defined by ASHRAE *Guideline* 1.1.

ACG 2005 refers to the following HVAC commissioning processes for new construction:

- Comprehensive HVAC commissioning starts at the inception of a building project from the predesign phase till postacceptance)
- Construction HVAC commissioning occurs during construction, acceptance, and postacceptance (predesign and design phases are not included in this process)

Commissioning is an important element in LEED for new construction (USGBC 2009). As a prerequisite (Energy and Atmosphere, prerequisite 1), commissioning must verify that the project's energy-related systems are installed and calibrated, and perform according to the OPR, BOD, and the construction document. Additional credits (Energy and Atmosphere, credit 3—Enhanced Commissioning) can be obtained by applying the entire commissioning process (or the comprehensive HVAC commissioning) as described previously.

Commissioning: Existing Buildings

HVAC commissioning in existing buildings covers the following:

- Recommissioning
- Retrocommissioning (RCx)
- HVAC systems modifications

Although the methodology for both is identical, there is a difference between recommissioning and retrocommissioning. Recommissioning is initiated by the building owner and seeks to resolve ongoing problems or to ensure that systems continue to meet the facility's requirements. There are can be changes in the building's occupancy or design strategies, outdated equipment, degraded equipment efficiency, occupant discomfort, and IAQ problems that can initiate the need for recommissioning. Typical recommissioning activities are shown in Table 8.

Commissioning is also an important element in existing buildings. USGBC (2009), *LEED for Existing Buildings & Operation Maintenance* awards up to six credits for commissioning systems in existing buildings in the Energy and Atmosphere (EA) section.

HVAC systems modifications can vary from minor modification to HVAC systems up to complete reconstruction of all or part of building HVAC system. The process for this type of project should follow the process described previously for new construction.

6. SEISMIC AND WIND RESTRAINT CONSIDERATIONS

Seismic bracing of HVAC equipment should be considered. Wind restraint codes may also apply in areas where tornados and hurricanes necessitate additional bracing. This consideration is especially important if there is an agreement with local officials to use the facility as a disaster relief shelter. See Chapter 56 for further information.

Table 7 Key Commissioning Activities for New Building

Phase	Key Commissioning Activities
Predesign	Preparatory phase in which the OPR is developed and defined.
Design	OPR is translated into construction documents, and basis of design (BOD) document is created to clearly convey assumptions and data used to develop the design solution. See informative annex k of ASHRAE *Guideline* 1.1-2007 for detailed structure and an example of a typical bod.
Construction	The commissioning team is involved to ensure that systems and assemblies installed and placed into service meet the OPR.
Occupancy and operation*	The commissioning team is involved to verify ongoing compliance with the OPR.

Source: ASHRAE *Guideline* 1.1-2007.
*Also known as acceptance and post-acceptance in ACG (2005).

Table 8 Key Commissioning Activities for Existing Building

Phase	Key Commissioning Activities
Planning	Define HVAC goals
	Select a commissioning team
	Finalize recommissioning scope
	Documentation and site reviews
	Site survey
	Preparation of recommissioning plan
Implementation	Hire testing and balancing (TAB) agency and automatic temperature control (ATC) contractor
	Document and verify tab and controls results
	Functional performance tests
	Analyze results
	Review operation and maintenance (O&M) practices
	O&M instruction and documentation
	Complete commissioning report

Water Distribution Systems 4.14
Vertical Transportation 4.17
Life Safety in Tall Buildings 4.17

TALL buildings have existed for more than 100 years and have been built in cities worldwide. Great heights only became possible after the invention of the elevator safety braking system in 1853; subsequent population and economic growth in cities made these taller buildings very popular. This chapter focuses on the specific HVAC system requirements unique to tall buildings.

ASHRAE Technical Committee (TC) 9.12, Tall Buildings, defines a tall building as one whose height is greater than 91 m. The Council on Tall Buildings and Urban Habitat (CTBUH 2014) defines a tall building as one in which the height strongly influences planning, design, or use; they classify recently constructed tall buildings as **supertall** (buildings taller than 300 m) and **megatall** (buildings taller than 600 m).

Traditionally, model codes in the United States were adopted on a regional basis, but recently the three leading code associations united to form the International Code Council (ICC 2018), which publishes the unified *International Building Code*® (IBC). Another important national code, developed by the National Fire Protection Association (NFPA), is NFPA *Standard* 5000®. These codes address the requirements of tall buildings to some extent, but many local or international locations may have their own modifications or alternatives to these model codes.

The overall cost of a tall building is affected by the floor-to-floor height. A small difference in this height, when multiplied by the number of floors and the area of the perimeter length of the building, results in an increase in the area that must be added to the exterior skin of the building. The final floor-to-floor height of the office occupancy floors of any building is jointly determined by the owner, architect, and structural, HVAC, and electrical engineers.

There are increasing numbers of tall buildings in the world (either planned or built) that will have a much greater height than 91 m. There is also a trend that most of the new tall buildings today are of the mixed-use type: for example, many will have a combination of commercial offices, hotel, apartments, observation deck, club floor, etc., stacked on top of each other. Tall buildings with these heights and mixed uses will significantly affect HVAC system design.

Much of the material in this chapter derives from Ross (2004).

1. STACK EFFECT

Stack effect occurs in tall buildings when the outdoor temperature is lower than the temperature of the spaces inside. A tall building acts like a chimney in cold weather, with natural convection of air entering at the lower floors, flowing through the building, and exiting from the upper floors. It results from the difference in density between the cold, denser air outside the building and the warm, less dense air inside the building. The pressure differential created by stack effect is directly proportional to building height as well as to the difference between the warm inside and cold outdoor temperatures.

When the temperature outside the building is warmer than the temperature inside the building, the stack effect phenomenon is reversed. This means that, in very warm climates, air enters the building at the upper floors, flows through the building, and exits at the lower floors. The cause of **reverse stack effect** is the same in that it is caused by the differences in density between the air in the building and the air outside the building, but in this case the heavier, denser air is inside the building.

Reverse stack effect is not as significant a problem in tall buildings in warm climates because the difference in temperature between inside and outside the building is significantly less than the temperatures difference in very cold climates. Accordingly, this section focuses on the problems caused by stack effect in cold climates. Note that these measures can be very different than those in hot and humid climates.

Theory

For a theoretical discussion of stack effect, see Chapter 16 in the 2017 *ASHRAE Handbook—Fundamentals*. That chapter describes calculation of the theoretical total stack effect for temperature differences between the inside and outside of the building. It also points out that every building has a **neutral pressure level (NPL)**: the point at which interior and exterior pressures are equal at a given temperature differential. The location of the NPL is governed by the actual building, the permeability of its exterior wall, the internal partitions, and the construction and permeability of stairs and shafts, including the elevator shafts and shafts for ducts and pipes. Other factors include the air-conditioning systems: exhaust systems that extend through the entire height of the building tend to raise the NPL, thereby increasing the total pressure differential experienced at the base of the building. This also increases infiltration of outdoor air, which tends to lower the NPL, thus decreasing the total pressure differential experienced at the base of the building. Finally, wind pressure, which typically increases with elevations and is stronger at the upper floors of a building, also can shift the neutral plane, and should be considered as an additional pressure to stack effect when locating the neutral plane.

Figure 1 depicts airflow into and out of a building when the outdoor temperature is cold (stack effect) and hot (reverse stack effect). Not shown is the movement of air up or down in the building as a function of stack effect. Assuming there are no openings in the building, the NPL is the point in the building elevation where air neither enters nor leaves the building. Vertical movement of air in the building occurs at the paths of least resistance, including but not limited to shafts and stairs in the building as well as any other openings at the slab edge or in vertical piping sleeves that are less than totally sealed. Figure 1 also indicates that air movement into and out of the building

The preparation of this chapter is assigned to TC 9.12, Tall Buildings.

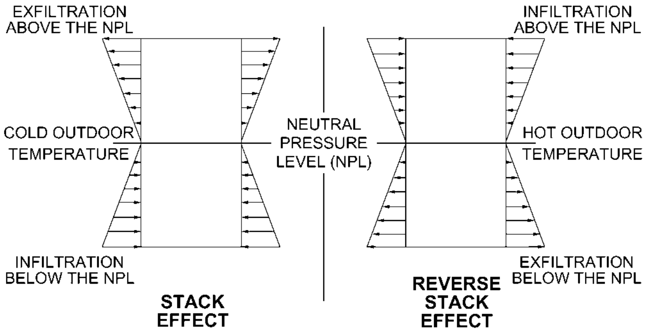

Fig. 1 Airflow from Stack Effect and Reverse Stack Effect
(Ross 2004)

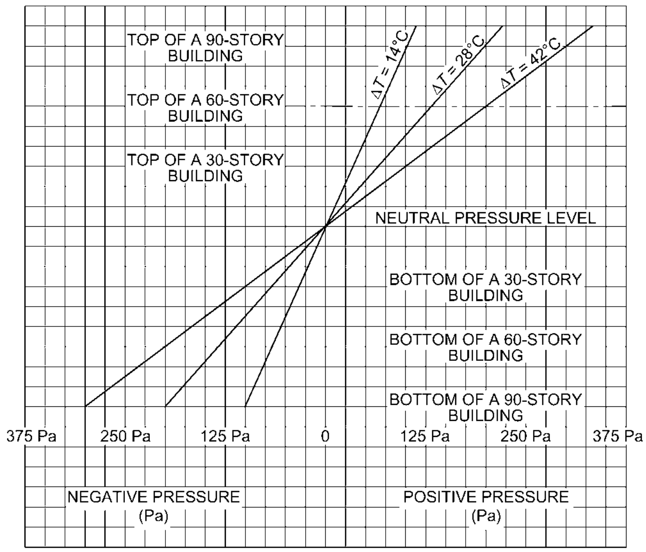
increases as the distance from the NPL increases. Elevator shafts, especially ones that connect the top and bottom of a tall building (e.g., a fire lift), are likely paths of least resistance for airflow. The total theoretical pressure differential can be calculated for a building of a given height and at various differences in temperature between indoor and outdoor air.

The theoretical stack effect pressure gradient for alternative temperature differences and building heights is shown in Figure 2. The diagram shows the potential maximum differentials that can occur (which are significant), but these plotted values are based on an idealized building with no internal subdivisions in the form of slabs and partitions. The plot, therefore, includes no provisions for resistance to airflow in the building. Further, the outer wall's permeability influences the values on the diagram and, as noted previously, the wind effect and operation of the building air-handling systems and fans also affect this theoretical value. Thus, the diagram should be considered an illustration of the possible magnitude of stack effect, not as an actual set of values for any building. The actual stack effect and location of the NPL in any building are difficult (if not in a practical sense impossible) to determine. A real building, especially a tall building, may have multiple neutral planes because of the effects of elevator and stair transfers. Each shaft section (e.g., low-rise elevator shaft) imparts its own stack effect and can create variations in the building pressure profile at the top and bottom of the shaft. Nevertheless, stack effect can be troublesome, and its possible effects must be recognized in the design documentation for a project.

Practical Considerations

Stack effect in tall buildings often presents major problems:

- **Elevator doors** may fail to close properly because of the pressure differential across the doors, which causes the door to bind in its guideway enough that the closing mechanism does not generate sufficient force to overcome it.
- **Elevator piston effect** may be exacerbated by stack effect because of uncontrolled airflow through elevator shafts, particularly in tall buildings with high-speed elevators and minimal shaft clearances around elevator cabs because of building core space restrictions.
- **Manual doors** may be difficult to open and close because of strong pressure created by stack effect.
- **Smoke and odor propagation** through the air path of stack effect can also occur.
- **Noise** from excessive airflow through shafts and doors may exist as whistling and whooshing.
- **Heating problems** can occur in lower areas of the building that may be difficult to heat because of a substantial influx of cold air through entrances and across the building's outer wall (caused by higher-than-anticipated wall permeability). Heating problems can be so severe as to freeze water in sprinkler system piping, cooling coils, and other water systems on lower floors. The National Association of Architectural Metal Manufacturers (NAAMM) specifies a maximum leakage per unit of exterior wall area of 0.00003 cm^3/m^2 at a pressure difference of 75 Pa exclusive of leakage through operable windows. In reality, tall buildings in cold climates can exceed this pressure difference through a combination of stack, wind, and HVAC system pressure. Even when leakage similar to the NAAMM criterion is included in project specification, it is not always met in actual construction, thereby causing potential operational problems.
- **Fan operational issues** may occur if systems fans are not designed and controlled to overcome the static pressure developed by stack effect.



NOTES:
1. ΔT equals differences between condition inside and outside building.
2. Floor-to-floor height for alternative buildings is assumed to be 4.0 m.

Fig. 2 Theoretical Stack Effect Pressure Gradient for Various Building Heights at Alternative Temperature Differences
(Ross 2004)

Calculation

Uncontrolled infiltration and ventilation is caused by climate, wind pressure, and stack effect; environmental factors associated with stack effect include wind pressure, stack pressure difference, airflow rate, outdoor and indoor temperature, building height, and building construction.

Wind creates a distribution of static pressure on the building envelope that depends on wind direction and velocity against the building envelope. The basic formula to determine this pressure can be expressed as

$$\Delta P_W = P_o + CC_p \rho V_w^2/2 \quad (1)$$

where

ΔP_W = wind pressure above outdoor air (OA) pressure, Pa
C = unit conversion factor, 0.0129
C_p = surface (location on building envelope) pressure coefficient, dimensionless
ρ = air density, kg/m^3 (about 1.2)
V_w = wind speed, m/s
o = outdoor

When using this equation, wind pressure is 25 Pa at 6.7 m/s on the windward side.

Air density varies with temperature. In cold weather, low-density air infiltrates the high-rise building and rises in the building's vertical shafts as it warms, creating stack effect pressure. The basic stack effect theory is expressed as

$$\Delta P_s = C_2 \rho_i g (h - h_{neutral})(T_i - T_o)/T_o \quad (2)$$

where

ΔP_s = stack pressure difference (indoor – outdoor), Pa
$C_2 \rho_i g$ = air density and gravity constant, 0.01444
h = building height, m
$h_{neutral}$ = height of neutral pressure level, m
i = indoor
T = temperature, K

When using Equation (2), the stack pressure is 274 Pa for a 60-story building with –23°C OA temperature.

Once the wind pressure ΔP_W and stack pressure difference ΔP_s are calculated, total pressure ΔP_{total} can be found, based on indoor and outdoor pressure difference, and used to calculate the airflow rate:

$$\Delta P_{total} = (P_o - P_i) + \Delta P_W + \Delta P_s \quad (3)$$

Calculation Example. For the calculation examples, New York was selected because it has many tall buildings and a significant range between warm summer and cold winter temperatures (stack effect influences buildings differently at different temperatures). The following example investigates performance in both summer and winter conditions.

ASHRAE climate data were used (see Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*) and show the winter and summer temperature and humidity levels, which can be used to calculate stack effect.

Table 1 gives the example parameters, and Figures 3 to 7 show various conditions. As shown in Figure 4, the biggest difference between internal and external pressure occurs in winter, when internal pressure increases along the building height; in summer, it decreases along the height. In addition, when the building gets taller, its NPL on the windward side rises: the extreme is for a building height of 800 m, for which the NPL on the windward side is almost on the top of the building.

Table 1 Parameters for New York Example Building

	Summer	Winter
Outdoor temperature, °C	32.8	–10.3
Indoor temperature, °C	24	20
Relative humidity, %	54	15
Height above sea level, m	54	54
Wind speed, km/h	22.7	22.7
Air pressure, kPa	101	101

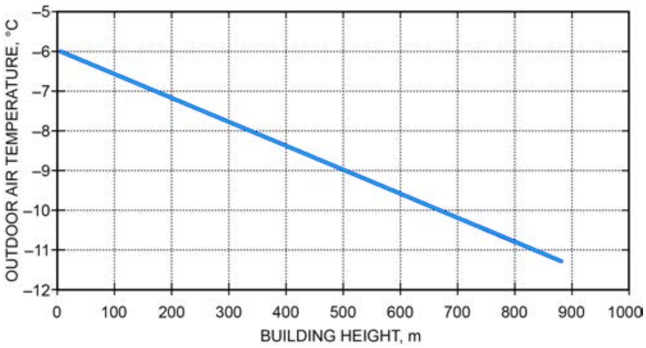


Fig. 3 Reduction in Ambient Temperature Over Height of Building in Cold Ambient Conditions

For the climate in New York, which is cold and dry in winter and warm and humid in summer, **stack effect** is much more intense than in warmer climates. Stack effect during cold outdoor conditions may cause problems, such as elevator doors not closing properly because of the pressure differential across the doors, causing the doors to stick in their guideways if the closing mechanism cannot overcome this friction.

Another difference for New York compared with other cities occurs in the wintertime, when **NPL** is slightly lower, or below the

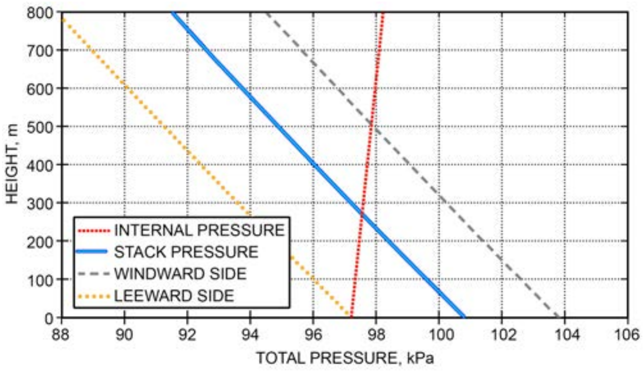

Fig. 4 Windward, Internal, Leeward, and Stack Pressures during Winter

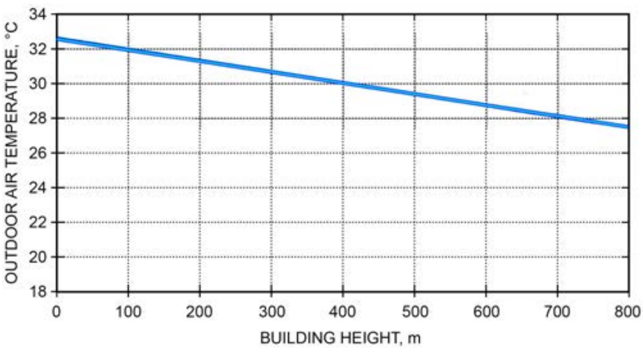

Fig. 5 Reduction in Ambient Temperature over Height of Building in Warm Ambient Conditions

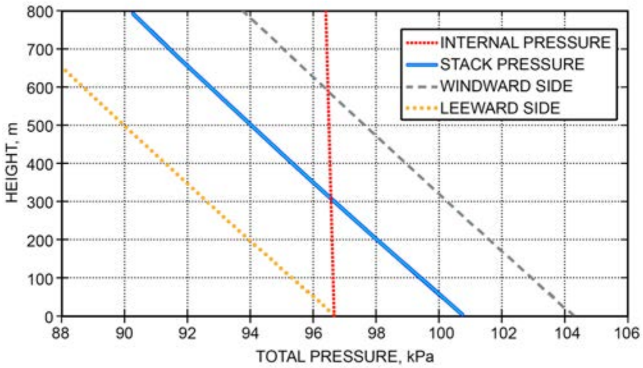

Fig. 6 Windward, Internal, Leeward, and Stack Pressures during Summer

middle of the building. During winter in a 800 m building in New York, the NPL is slightly below 300 m, which means the indoor air pressure is much higher at the upper level of the building than in many other cities. Therefore, for upper levels of the building, air exfiltration is much greater in New York than in other, warmer cities; the airflow rate is higher; and the building function is significantly affected. Stack effect must be addressed during design. Architects and engineers must pay close attention to solving the problems associated with stack effect, which are exacerbated in extremely cold climates.

Minimizing Stack Effect

During design, the architect and HVAC design engineer should take steps to minimize air leakage into or out of (and vertically within) the building. Although it is not possible to completely seal any building, this approach can help mitigate potential problems that could be caused by stack effect.

A tight building envelope and continuous curtainwall system, as well as isolation of vertical shafts from exterior environment through a minimum of two air barriers, are fundamental to protecting a building against uncontrolled air movement into and out of the building. A tight specification, testing, and careful monitoring during construction are required. Although most curtain walls are traditionally tested in the factory, increasingly more field tests (either spot tests or whole-building pressure tests) are specified in some buildings. A whole-building pressure test is difficult in tall buildings, and currently there is a limit on how many floors can be pressurized. Sectionalizing a tall building is required to perform a localized test.

Outdoor air infiltration points include building entry doors, doors that open to truck docks, outdoor air intake or exhaust louvers, construction overhangs with light fixtures, or other recessed items, located immediately above the ground level and are not properly sealed against leakage or provided with heat, and any small fissures in the exterior wall itself. Internally, the building allows air passage through fire stairs, elevator shafts, mechanical shafts for ducts and piping, and any other vertical penetrations for piping or conduit or at the edge of the floor slab at the exterior wall. All these are candidates for careful review to ensure, as much as possible, that the exterior wall is tight, all shafts are closed, and all penetrations sealed. Vestibules or airlocks can be provided for loading docks, with good door seals on the doors to and from the loading dock.

Entrances for tall buildings in cold and hot climates should use revolving doors. Doors of this type are balanced, with equal pressure in opposite directions on the panels on either side of the central pivot, making operation relatively simple and requiring no special effort to turn. Their gaskets also provide closure at all

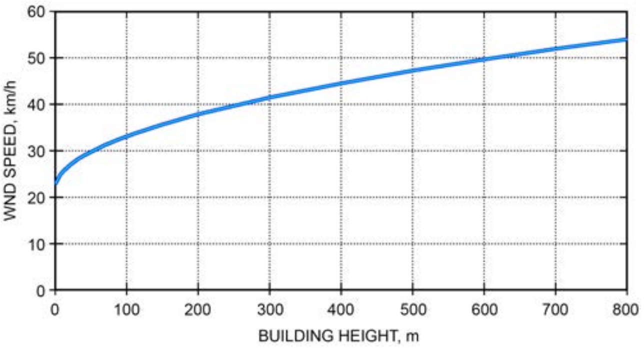

Fig. 7 External Wind Speed as Function of Building Height at Standard Atmospheric Conditions

times. Give special consideration to hotel entries where people carry large luggage through: larger revolving doors are required to avoid people bypassing the revolving doors altogether.

Design and layout of sky lobbies in super- and megatall buildings should be carefully considered to isolate building elevator shafts and exit stairs from the exterior environment. A vestibule may be added at the elevators to provide a second air barrier in addition to the building envelope.

Two-door vestibules are acceptable for the loading dock, assuming the doors are properly spaced to allow them to be operated independently and with one door to the vestibule always closed, and sufficient heat is provided in the space between the doors. If properly spaced, simultaneous opening of both doors on either side of the vestibule can be controlled. However, two-door vestibules in cold climates are inadequate for personnel entry because, with large numbers of people entering the building at various times, both doors will be open simultaneously and significant quantities of unconditioned outdoor air can enter the building. In cold climates, revolving doors are strongly recommended at all points of personnel entry.

To control airflow into the elevator shaft, consider adding doors at the entry to the elevator banks. This creates an elevator vestibule on each floor that minimizes flow through open elevator doors.

Elevator shafts are also a problem because an air opening may be required at the top of the shaft. In many tall buildings, however, the elevator hoistways are not vented for smoke, using sprinkler heads instead. Alternatively, some jurisdictions accept the installation of a motorized damper on the hoistway vent; the damper is initiated by a smoke detector and opens immediately when smoke is sensed in the hoistway. All shafts, however, can be sealed in their vertical faces to minimize inflow that would travel vertically in the shaft to the openings at its top.

Elevator cars can act as pistons to increase the pressure in elevator hoistways ahead of the moving cab. Careful sequencing of elevator cabs, especially when multiple cabs are located in a single shaft, must be considered to provide proper relief and sequencing of door openings.

It can be helpful to interrupt stairs intermittently with well-sealed doors to minimize vertical airflow through buildings. This is particularly useful for fire stairs that extend through the entire height of the building. Entrances to fire stairs should be provided with good door and sill gaskets. (See the section on Door-Opening Forces under Pressurization System Design in Chapter 54 for guidance on ensuring doors in fire stairs can be opened during an emergency.)

Building air supply and pressurization systems should be configured in a maximum of 20- to 40-floor increments to facilitate effective building pressurization corresponding to building stack effect and wind pressure profiles.

The last key item is to ensure a tight exterior wall, which requires specification, proper testing, and hiring a qualified contractor to erect the wall.

The preceding precautions involve the architect and allied trades. The HVAC designer primarily must ensure that mechanical air-conditioning and ventilation systems supply more outdoor air than they exhaust, to pressurize the building above atmospheric pressure. This is true of all systems where a full air balance should be used for the entire building, with a minimum of 5% more outdoor air than the combination of spill and exhaust air provided at all operating conditions, to ensure positive pressurization. In addition, it is good design, and often required by code for smoke control, to have a separate system for the entrance lobby. Although not always required, this system can be designed to operate in extreme winter outdoor air conditions with 100% outdoor air. This air is used to pressurize the building lobby, which is a point of extreme vulnerability in minimizing stack effect. Lastly, if two-door vestibules must be provided, consider pressurizing the vestibule with conditioned outdoor air.

Wind and Stack Effect Pressure Analysis

The world trend toward super- and megatall buildings suggests that both wind and stack effect will greatly affect designs of future tall building and HVAC systems. It is advisable to carry out both wind and stack effect analyses by computational fluid dynamic (CFD) or wind tunnel analysis during concept and schematic design phases of the project, such that advance precautionary measures could be implemented in the early design stage.

Safety Factors

System designers typically apply safety factors at various points in the design process to avoid undersizing equipment. Judicious use of safety factors is good engineering practice. However, safety factors are too often misapplied as a substitute for engineering design, and this practice typically results in grossly oversized equipment. Therefore, care is necessary in applying safety factors.

2. SYSTEMS

Systems used in tall buildings have evolved to address owners' goals, occupants' needs, energy costs, and environmental concerns (including indoor air quality).

Chapter 37 discusses mechanical maintenance and life-cycle costing, which may be useful in the evaluation process with regard to alternative systems. Chapter 1 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides guidelines for a quantitative evaluation of alternative systems that should be considered in the system selection process. Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals* provides means for estimating annual energy costs. Ross (2004) provides a more detailed discussion of systems to be considered.

3. SYSTEM SELECTION CONSIDERATIONS

In a fully developed building (including the core and shell as well as space developed for occupancy), the cost of mechanical and electrical trades (i.e., HVAC, electrical, plumbing, and fire protection) is typically 30 to 35%, and for a high-rise commercial building is usually over 25%, of the overall cost (exclusive of land). In addition, the mechanical and electrical equipment and associated shafts can consume 7 to 10% of the gross building area. The architectural design of the building's exterior and the building core is fundamentally affected by the system chosen. Consequently, HVAC system selection for any tall building should involve the entire building design team (i.e., owner, architect, engineers, and contractors), because the entire team is affected by this decision.

The points of concern and analysis methods do not differ in any way from the process that would be followed for a low-rise building. Possible alternative systems also are very similar, but the choices for high-rise buildings are typically more limited.

Air-Conditioning System Alternatives

Several alternative systems are used in tall buildings. Although the precise system configurations are subject to the experience and imagination of the design HVAC engineer, the most common ones are variations of generic all-air and air/water systems.

Unitary, refrigerant-based systems, such as through-the-wall units, are used in conjunction with all-air systems providing conditioned ventilation air from the interior zone, but this combined solution has been limited to retrofits of older buildings that were not previously air conditioned and smaller low-rise projects. They are seldom used in first-class tall commercial buildings.

Another option is panel-cooling-type systems, including chilled-ceiling and chilled-beam systems. Though not common in the United States, these systems are used in Europe as a retrofit alternative in existing buildings that were not previously air conditioned, because these systems can be installed with minimal effect on existing floor-to-ceiling dimension.

All-Air Variable-Air-Volume Systems. All-air variable-air-volume (VAV) systems in various configurations are one of the most common solutions in tall buildings. Conditioned air for VAV systems can be provided from a central fan room or from local floor-by-floor air conditioning units. These alternative means of delivering conditioned air are discussed in the section on Central Mechanical Equipment Room Versus Floor-by-Floor Fan Rooms. This section is primarily concerned with system functioning, configurations in use, and possible variations in system design.

VAV systems control space temperature by directly varying the quantity of cold supply air in response to the cooling load requirements. VAV terminals or boxes are available in many configurations; pressure-independent terminal units are recommended. Interior spaces that have a year-round cooling load regardless of outdoor air temperature can use any of the alternative types of VAV boxes:

- A **single-duct VAV terminal** reduces supply air volume directly with a reduction of the cooling load. This is a very common terminal in commercial projects, and has the smallest height of any terminal used in office buildings. Usually a stop is used to maintain minimum airflow, for proper ventilation.
- A **series-flow fan-powered VAV terminal** maintains constant airflow into a space by mixing the required amount of cold supply air with return air from the space. The VAV terminal contains a small fan to deliver constant airflow to the space. The fan operates any time the building is occupied. The primary advantage of the fan-powered box is that airflow in the space it supplies is constant at all conditions of load. This is of particular import if low-temperature air is used to reduce the distributed air quantity and the energy necessary to distribute the system air. In cold climates and when the perimeter serving terminal unit locations are at ideal distance from the perimeter wall, the series-flow fan-powered terminal continuously recovers internal heat to be used for partial heat of perimeter spaces.
- A **parallel-flow fan-powered VAV terminal** maintains variable airflow into a space and mixes the required amount of cold supply air at minimum flow requirements with return air from the space. The VAV terminal contains a small fan that starts only in heating mode to deliver mixed primary and return airflow to the space. The fan operates only when heating is required to deliver warm return air, mixed with cool primary air when the building is occupied. Unlike the series-flow box, this option delivers increased airflow to the space during heating but can also shut off primary air and operate only the fan to deliver return air during unoccupied periods. A box-mounted heating coil (hot-water or electric) supplements the heat provided by return air when heating requirements increase. The parallel approach does not ensure constant air volume to the space, as can be obtained with the series approach, but it does provide a minimum airflow at significantly lower operating cost.
- An **induction box** reduces supply air volume and induces room air to mix with supply air, thus maintaining a constant supply airflow to the space. These units require higher inlet static pressure to achieve velocities necessary for induction, with a concomitant increase in supply fan energy requirements. Moreover, operational problems have been experienced, especially at reduced primary airflow quantities. Thus, these boxes are now seldom used in commercial projects.

The exterior zone can use any VAV box type, but in geographical locations requiring heat, the system must be designed with an auxiliary means of providing the necessary heating. This can be done by installing hot-water baseboard, controlled either directly by thermostat or by resetting the hot-water temperature inversely with the outdoor air temperature. Other alternatives are thermostatically controlled electric baseboard on the exterior wall, or either electric or hot-water heating coils in the perimeter VAV boxes.

Low-Temperature-Air VAV Systems. All of the preceding variations can be designed using conventional temperature differentials (9 and 11 K) between the supply air and room temperature. Buildings have been successfully designed, installed, and operated for decades with low-temperature supply air between 8.9 and 10°C. This increases the temperature supply differential to approximately 16 K, thus dramatically reducing primary air quantities and subsequently reducing air-handling system size and air duct distribution.

This lower-temperature air can be obtained by operating the refrigeration machines with chilled water leaving at 4.4°C or by using ice storage. If the chiller supplies 4.4°C chilled water, operating costs of the refrigeration plant increase and the chiller must operate for a longer time before an economizer cycle can occur. Moreover, use of absorption refrigeration machines may not be possible, because they usually cannot provide chilled water as cold as 4.4°C.

However, the reduced quantity of air distributed also reduces fan power, which more than offsets the additional energy used by the chiller. This lower-temperature air requires series-flow fan-powered VAV terminals or induction-type air supply terminals to mitigate draft and dumping concerns at the diffuser due to supplying low-temperature air directly to the space. The air delivery terminals mix room and cold supply air to deliver warmer air to the space to offset heat gain.

Using low-temperature supply air requires elimination of air leaks and proper installation of the correct thickness of duct insulation to prevent moisture condensation. Note that the decrease in supply duct size when using cold air can make lower floor-to-floor heights more practical.

Underfloor Air Distribution (UFAD) Systems. In underfloor air distribution (UFAD) systems, the space beneath a raised floor is used as a distribution plenum. Most installations use manually adjustable supply diffusers or automatically controlled terminal units beneath the floor to control air delivered to the space above. (In contrast, for more traditional systems, terminal units are installed above the ceiling and supply air is delivered from above.) When properly designed, either underfloor or ceiling-mounted air distribution systems can meet occupants' comfort requirements. UFAD systems typically have a higher first cost because of the raised floor, but operating costs are usually lower because less fan power is required. However, if a raised floor is a design requirement for electrical distribution and information technology cabling, UFAD may offer savings in overall first and operating costs.

The UFAD system can use central fan rooms or floor-by-floor fan units. Conditioned air is typically provided at 16 to 18°C in the raised-floor plenum (between the structural slab and the raised floor), but in locations requiring dehumidification, the air must first be cooled to approximately 12.8°C to remove moisture and then blended with return air (often using an underfloor-mounted series fan-powered box or similar arrangement) to achieve supply air temperatures of 16 to 18°C. The suspended ceiling acts as a return plenum but can be reduced in depth because of the absence of supply ductwork.

A major concern with UFAD in tall buildings is the perimeter zone, which has widely varying loads between summer and winter conditions, especially in buildings with large glass exterior elements. Thermostatically controlled fan-coils beneath the floor or finned-tube radiation along the perimeter walls can be cost-effective solutions. Additionally, extreme caution is needed in sealing all structural floor penetrations to prevent short-circuiting of supply air.

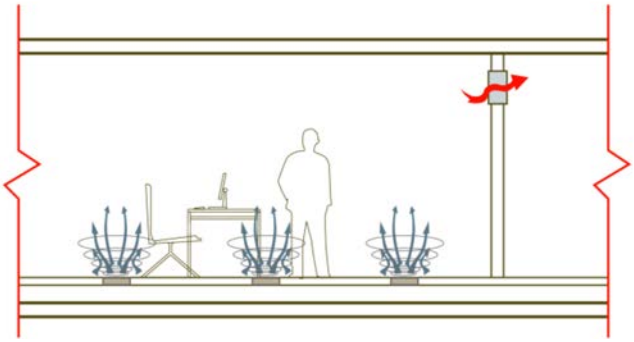

Fig. 8 Typical UFAD System

Underfloor air conditioning for a tall building must be selected early in the design process, because it affects architectural (e.g., floor-to-floor heights, exterior facade treatment, stairs, elevators), structural (e.g., depressed structural slabs), and electrical (e.g., plenum-rated cabling) design considerations. All design disciplines must be involved in this decision process.

The combination of system components and the resultant system configuration for a specific building are limited only by the designer's imagination. The chosen alternative is of interest and concern to the owner, architect, and other engineering consultants, and should be subjected to scrutiny and review by the entire design team before final selection is made.

Underfloor air-conditioning systems are a newer approach, where the space beneath the raised floor is used as a distribution plenum or where terminal units are installed beneath the raised floor (in contrast with more traditional systems, where the terminal units are installed above the ceiling). Either system, with ceiling-mounted terminals or one distributing air through the raised floor, when properly designed, will meet occupants' comfort requirements. The underfloor air-conditioning system typically has higher first cost than comparable overhead distribution systems because of the cost of the raised-floor system. The cost premium can vary as a function of design details for the project, and can be substantially offset if the owner decides to incorporate a raised floor for power wiring and information technology cable distribution. Without this fundamental decision, the increase in the cost of the floor itself and a possible increase in the floor-to-floor height, with the resultant premium that must be paid for the exterior wall and the extended internal shafts, piping, and stairs, may be too great to justify the inclusion of the underfloor distribution system. Figure 8 shows a typical underfloor conditioning/ventilation system.

Multiple variations of underfloor air-conditioning system design are possible. Underfloor air distribution systems use the principle of displacement ventilation. Designs typically are implemented with all-air systems in which air is distributed beneath the floor, with the void between the slab and the raised floor serving as a supply air plenum. The conditioned air is provided at relatively elevated temperatures of approximately 16 to 18°C by blending cold, dehumidified supply air with warm return air. This air then passes at low velocities from the air-conditioned floor through floor outlets and rises vertically to the ceiling through its own buoyancy, removing heat from occupants, office equipment, and lighting as it rises. The ceiling and the space above it function as a return air plenum where distributed air is collected and returns to the air-conditioning supply system, which can be either a central or floor-by-floor system. Because supply ductwork is not needed, the plenum above the ceiling can be reduced in depth compared to that required for an overhead distribution system.

A variation of the underfloor air-conditioning system is using all-air terminals or fan-coil units beneath the floor in the exterior zone.

A thermostatically controlled terminal can be advantageous in altering unit capacity in the exterior zone with its widely varying loads. In addition, using a fan-coil unit, which can modify its capacity output as the load varies and has an inherently greater capacity on a percent basis than an all-air terminal, may provide a more cost-effective solution for tall commercial buildings, particularly those with larger glass elements in the exterior wall. The design using fan-coil units is the same as with all-air terminal designs: air is distributed through floor grilles, with the ceiling acting as a return air plenum.

Many commercial and office projects in Europe include a raised floor for power wiring and information technology cabling, so underfloor distribution systems have been widely accepted throughout the continent. These systems have found more limited application in the United States, probably because raised floors are used infrequently and the *National Electric Code*® (NFPA *Standard* 70) requires that all cabling in an air plenum must be installed in conduit or carry a plenum rating if the raised floor is used for free discharge of supply air. (Where a raised floor is used for cable distribution only, conduit or plenum-rated cabling is not required.) This can increase the cost of cabling significantly and can therefore be a significant consideration in the decision process.

Underfloor distribution systems using variable-air-volume or fan-coil terminals are applied more widely. These systems have a lower space reconfiguration cost as occupancy changes, because all that is required is relocation of a floor diffuser to meet the altered space needs (akin to relocation of an electrical outlet to serve a new occupant layout). This lower cost of interior modifications should be fully considered by the owner and the design team.

Floor supply systems that mix with the total air mass in the occupied zone are not displacement systems. Displacement systems result in temperature gradients in the occupied space, whereas fully mixed systems minimize room temperature gradients.

The displacement system effectively delivers supply air to those parts of the space where heat gain occurs and not the whole occupied volume, so less supply air should be needed.

Fully mixed floor supply systems can handle spaces with high heat gains (>100 W/m^2), and have considerably greater capacity than displacement systems alone (~40 W/m^2). The floor supply system creates zones of discomfort near the outlet, between 1 and 1.5 m radius, where sedentary occupants should not be located. There is a relatively low air volume per outlet compared with high-level diffuser systems, which require the use of more supply outlets.

Because the air supply stream is delivered directly into the occupied zone, supply velocity and temperature are restricted, limiting maximum sensible cooling load to 40 W/m^2 for a 3 m high floor to ceiling height; higher loads can be handled where the floor-to-ceiling height is greater.

Use great caution with floor-to-ceiling heights less than 3 m, because the higher temperatures developed at the ceiling may cause uncomfortable radiant effects. System performance improves with ceiling height.

Consider using exhaust air heat recovery. Recirculation of room air should be minimized, because this air will be hot and vitiated, generally with a higher specific enthalpy than outdoor air.

If air patterns in the space are subject to considerable disruption (e.g., by occupant movement or high infiltration rates), system effectiveness will be reduced.

A displacement ventilation system should not be used for heating because the low-velocity heated air makes effective air distribution very difficult. A separate perimeter heating system should be provided.

Selection of supply outlets should be based on minimizing the zone of discomfort around the supply outlet; this entails using more small outlets rather than fewer large ones. The geometry of the supply outlet is not as critical as that for diffusers and registers used in conventional mixing systems.

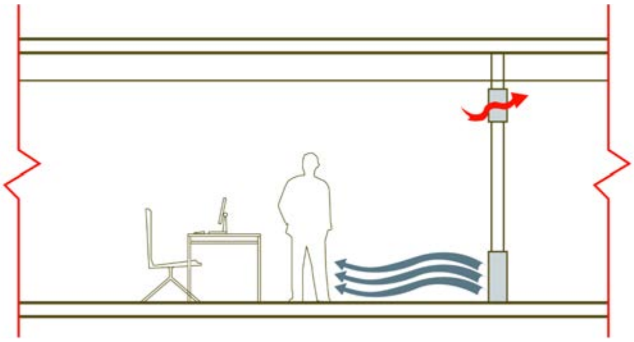

Fig. 9 Displacement Ventilation System Diagram

Match the supply volume flow to the volume flow rate of the plumes set up by internal heat sources at the given boundary height.

The height of the boundary plane depends on supply air volume: it will be higher if excessive air is delivered, and lower if supply air is insufficient.

4. DISPLACEMENT VENTILATION

Displacement ventilation effectiveness is improved compared to conventional mixed systems, which depend on dilution to reduce contaminants. However, system success relies on reasonable ceiling heights and maintaining relatively fragile air movement patterns.

The system works better with a high temperature difference between supply and exhaust air, and is not suitable for applications that require tight temperature and humidity control. In this respect, displacement ventilation functions better where a large floor-to-ceiling height exists and therefore favors applications such as industrial spaces or large auditoriums, atriums, concourses, and some office spaces, where higher ceiling heights mean higher extract temperatures can be tolerated.

Figure 9 shows the principle of a typical displacement ventilation system.

Displacement ventilation has the potential for improving energy efficiency and indoor air quality control for the following reasons:

- There is little mixing between contaminants and bulk air, thereby improving air quality.
- Ventilation is more effective, so fan energy requirements are lower.
- Higher supply temperature means greater use can be made of free cooling of outdoor air. There are, however, some potential pitfalls that may reduce the benefits, such as heating performance; disruption of air patterns in the space by infiltration, occupancy traffic, or other cooling sources (e.g., chilled beams); and dehumidification control.

Displacement ventilation is based on the concept of an ideal airflow pattern. Instead of total mixing achieved by other air distribution systems, the flow is unidirectional, with the minimum spreading of contaminants as possible. This ideal airflow pattern can be achieved by supplying air to the room at low level at a temperature slightly lower than that of the occupied zone, with the removal of hot, vitiated air at high level.

Supply air enters the occupied space at a low velocity and a relatively high temperature compared with conventional systems. This creates a pool of fresh air, which is distributed evenly across the floor. At local heat sources (e.g., occupants, machinery), the air temperature is raised. The natural buoyancy of the heated air gives rise to air currents.

Cool, clean air rises in the plume created by the heat source and replaces the warmed/contaminated air. The air plume generated from the heat source carries with it odors and gaseous and particulate contaminants emitted in the occupied space. These warm contaminated plumes spread out below the ceiling, and an upper contaminated layer is formed. The art of designing a displacement ventilation system is to ensure this hot contaminated region is outside the occupied zone. The supply and exhaust are balanced to produce a boundary layer above which the air is contaminated, and below which is clean, conditioned air in the occupied zone.

Air/Water Systems. Air/water systems historically included induction systems, but modern systems quite often use fan-coil units outside the building, with interior spaces typically supplied by an all-air variable-air-volume (VAV) system. Exterior zones are typically provided with a constant volume of air from either (1) the interior VAV system in sufficient quantities to meet requirements of ASHRAE *Standard* 62.1's multiple-spaces equation, or (2) a separate dedicated outdoor air system providing exterior-zone outdoor air ventilation. Fan-coil units in a tall building that requires winter heat are usually designed with a four-pipe secondary water system to provide coincidental building heating and cooling to different zones.

An advantage of the air/water system is that it reduces the required capacity of the central supply and return air systems and the size of distribution air ducts, compared to those needed with an all-air system (including low-temperature all-air). At the same time, it reduces the air-conditioning supply system's mechanical equipment room space needs. However, air/water systems require space for heat exchangers and pumps to obtain the hot and cold secondary water needed by the fan-coil unit system.

Chilled Beams

Chilled beams are a type of air/water system that have had increasing success in tall buildings. These units are available in both passive and active types, with active units offering higher capacity. Passive chilled-beam units rely on a combination of radiant and convective heat transfer to provide space conditioning from heated or chilled water delivered to the unit. With active units, primary supply air delivered to the unit causes induced room air to circulate through a hot- or chilled-water coil to provide additional conditioning capacity.

Chilled beams allow an overall reduction in the ductwork required to condition the space, because water has a greater heat-carrying capacity than air. Consequently, sheet metal costs and potentially space requirements for supply and return air ductwork can also be reduced. Use caution, however, because chilled-beam units have no condensate drain and should be designed without latent cooling capacity, so the primary supply air must be conditioned to deliver air at a low enough dew point to provide the required dehumidification of the space served.

Radiant Ceilings

Radiant cooling follows the same principles as radiant heating: heat transfer occurs between the space and the panels through a temperature differential. However, unlike in radiant heating, the colder ceiling absorbs thermal energy radiating from people and their surroundings. The major difference between cooled ceilings and air cooling is the heat transport mechanism. Air cooling uses convection only, whereas cooled ceilings use a combination of radiation and convection. The amount of radiative heat transfer can be as high as 55%; convection accounts for the remainder. With cold ceilings, the radiative heat transfer occurs through a net emission of electromagnetic waves from the warm occupants and their surroundings to the cool ceiling. On the other hand, convection first cools the room air because of contact with the cold ceiling, creating convection currents in the space, which transfers the heat from its source to the ceiling, where it is absorbed.

Because air quality must be maintained and radiant panels remove only sensible heat from the space, radiant cooling panels are used in conjunction with a small ventilation system. The panels provide most of the sensible cooling, and the air system provides ventilation and air moisture (latent load) control. To prevent high humidity levels in a room, the supply air must be drier than that of the supplied space, especially when there are additional moisture sources in the room. Consequently, outdoor air must be dehumidified, which is usually done by cooling to a dew point of approximately 15°C. If the environment is dry, the ventilation system is used to humidify the air. Because the ventilation system is used only to maintain the air quality and to regulate the latent load, the airflow required is small relative to conventional cooling systems. Best results are usually attained with a straight displacement ventilation system with no air recirculation. This system typically supplies air through outlets near or at the floor, at temperatures below that of the room air; this approach provides a uniform layer of fresh air at floor level. In turn, people and other heat sources create a passive convective flow of fresh air to the ceilings, where it can be exhausted. This reduced airflow and radiant panels' relatively high surface operating temperature (mean temperature of 16°C) make radiant cooling a more comfortable way of cooling a space than conventional systems.

A cooled ceiling operates in direct proportion to the heat load in the room. Typically, a person sitting at a desk emits 130 W of energy, whereas a computer emits 90 to 530 W to its surroundings. The radiant panel capacity should be determined by the operation conditions (water temperature and flow) and the space temperature. The greater the number of people and/or appliances and exposure to sunlight, the greater the space heat load (and therefore greater increased capacity of the cool ceiling). Generally, cool ceilings can handle between 100 and 225 W/m^2 with up to 50% of the ceiling space used for cooling.

Condensation Control

Condensation on the surface of the panels is not a problem with radiant cooling as long as the supply water temperature is properly controlled. Because condensation of water occurs when the panel temperature reaches the space dew-point temperature, proper water temperature control helps avoid condensation. The space dew-point temperature should be monitored by a sensor linked to a controller, which modulates the inlet water temperature accordingly. Therefore, if there is risk of condensation, the water temperature is raised or water flow is shut off. However, the lower the panel's inlet temperature is, the more work the panels do; the inlet temperature should be at least 1 K above the room's dew-point temperature. Consequently, the cooling capacity of a radiant cooling system is generally limited by the minimum allowable temperature of the inlet water relative to the dew-point temperature of the room air.

Variable-Frequency-Drive (VFD) Fan-Coils

Fan-coil units, either vertical stacked or horizontal, are often used in tall hospitality or residential buildings. Built-in variable-frequency drives provide an energy advantage to the overall building energy consumption, as well as improving temperature control in spaces conditioned by these units. For details, see the section on Fan-Coil Unit Systems in Chapter 20 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

These units can be either complete with cabinets (which can be exposed in the space) or built into the general construction (less obtrusive to building aesthetics). Vertical units are even available with vertical pipe risers factory installed, reducing field-installed piping and overall construction costs. Although these internal components are generally designed and tested for elevated pressure capabilities, the actual pressure on these components for a particular building height should be investigated.

Variable-Refrigerant-Flow (VRF) Systems

VRF systems for heating and cooling are becoming more prevalent for reducing energy consumption in space conditioning. This system option is viable for use in a tall building, particularly the newly available water-cooled condensing unit option. Air-cooled conditioning may also be viable, but requires significant amounts of space outside the building, and tall buildings typically have small roof areas and limited space on the ground. In addition, the refrigerant lift available from these units is limited, which typically makes air-cooled options less desirable. For details, see Chapter 18 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

5. CENTRAL MECHANICAL EQUIPMENT ROOM VERSUS FLOOR-BY-FLOOR FAN ROOMS

Project needs for conditioned air can be met by one or more central mechanical equipment room(s) serving multiple floors, or by systems installed in separate, local fan rooms on each floor, supplying air only to the floor on which the system is installed. Either chilled-water cooling or self-contained air-conditioning units in the floor-by-floor scheme can be used. The choice of any of the three alternative schemes is one of the most fundamental decisions made during the conceptual design phase. This issue concerns the owner, each member of the design team, and the constructing contractors, because it affects space requirements, space distribution, standard versus custom HVAC equipment, and piping and electrical distribution costs.

Central Fan Room (Alternative 1)

In central fan rooms, the supply of conditioned air for each office floor originates from multiple air-handling systems located in one or more central fan room(s), which are frequently identified as central mechanical equipment rooms (MERs). Each air-handling system can be provided with an outdoor air economizer through minimum and variable outdoor air dampers, as dictated by the annual ambient temperature and humidity conditions and building code requirements. Multiple systems in a fan room can be interconnected by delivering supply air into a common discharge plenum from all supply systems on that floor.

Air from the central fan room(s) is distributed to each floor by means of vertical duct risers in fire-rated shafts (typically 2 h rated) within the core of the building. At each floor, horizontal duct taps are made into each riser. This horizontal duct tap contains a fire damper or a fire/smoke damper, as required by the local building code, that must be installed where the supply air duct exits the rated shaft enclosure. In many situations, an automatic, remotely controlled two-position damper, which can be rated as a smoke damper, provides individual-floor overtime operation and smoke control. The position (open or closed) is typically controlled by the building management system either on an occupancy schedule or by occupancy sensor or manual reset switch.

Return air from each floor's ceiling plenum also enters the vertical shaft though a return air fire damper at each floor.

Return air is often not ducted within the shaft, so the air is carried back to the central fan room in the 2 h rated drywall shaft. In each central fan room, multiple return air fans draw return air from the return air shafts and deliver it to a headered return air duct system in the central room and then to each air-handling unit.

With an outdoor air economizer, return air is either returned to the supply air system or exhausted to atmosphere, as determined by the relative dry-bulb temperature (or enthalpy) of the return air and the outdoor air being provided to the building. Quantities of outdoor and return air depend on the season and the resultant outdoor temperature and humidity. In warmer climates where the systems operate on minimum outdoor air at all times, return air is always returned to the supply air system except during morning start-up or where the fans are operating in smoke-control mode.

A typical central fan room and supply and return air shaft arrangements are shown in Figure 10.

Floor-by-Floor Fan Rooms with Chilled-Water Units (Alternative 2)

The air supply for each office floor under this alternative originates from a local floor fan room, typically located in the building core. This room contains a chilled-water air-handling unit with a cooling coil, filters, and fan(s). Morning heating at start-up in cold climates can be provided by a heating coil in the air-handling unit, a unit heater installed in the local fan room, or heating coils in the VAV or fan-powered VAV (FPVAV) boxes. The unit on a given floor usually only supplies the floor on which the unit is installed. Typically, one unit is installed on each floor, but multiple units may be used with interconnected air systems on large floors. Chilled water for the cooling coil is provided by a central chilled-water plant in the building, sized to meet the combined capacity requirements of all of the cooling and heating needs. The supply air fan in the air-conditioning system both supplies air and returns it from the zone served. Return air is typically directed to the fan room through the ceiling plenum, but may be either ducted or unducted in the fan room. In most cases, however, the fan room acts as a return air plenum.

This system typically operates on minimum outdoor air during all periods of occupancy. Outdoor air for the system is provided by an air-handling unit serving as a dedicated outdoor air system (DOAS), located on the roof or in a central mechanical equipment room. This unit provides conditioned outdoor air to the unit on each floor by a vertical air riser routed to each air-handling unit. The outdoor air unit may include preheat and cooling coils to treat incoming outdoor air, and should contain filtration to clean this air. This unit can contain heat recovery to precondition the outdoor air by recovering heat or cool from exhaust air, which may be required by the applicable energy code.

Although chilled water is typically provided by a central refrigeration plant, economizer requirements can be provided by cooling the chilled water in mild weather by condenser water from the cooling tower. During periods of low wet-bulb temperature, the condenser water cools the chilled water through a heat exchanger in the central chilled-water plant or by refrigerant migration through the refrigeration unit.

A typical local fan room supply, return, and outdoor air arrangement is shown in Figure 11. The unit heater shown provides morning heat. It can use electric energy or hot water as its heat source.

As shown in Figure 11, the walls around the local floor fan room are not fire rated because the duct penetration serves only this floor. The vertical shaft that contains the outdoor air duct from the central fan room, and perhaps the smoke exhaust ducts, constitute a fire-rated shaft. Accordingly, fire dampers are only provided at the point where ducts penetrate the shaft wall, not as they leave or enter the local floor fan room itself. Although fire dampers are shown in the smoke exhaust ducts, many codes prohibit their use in an engineered smoke control system to avoid the possibility of having a closed damper when smoke removal is required.

Floor-by-Floor Fan Rooms with Direct-Expansion Units (Alternative 3)

A variation of the floor-by-floor alternative consists of a floor-by-floor air-conditioning supply system that is virtually identical to that in the chilled-water alternative. In this alternative, a packaged, self-contained, water-cooled direct-expansion (DX) unit, complete with one or more refrigeration compressors and water-cooled condensers, is used to produce the cooling. The heat of rejection from the compressor is handled by a circulating condenser water system and cooling tower. If geographic location dictates an economizer,

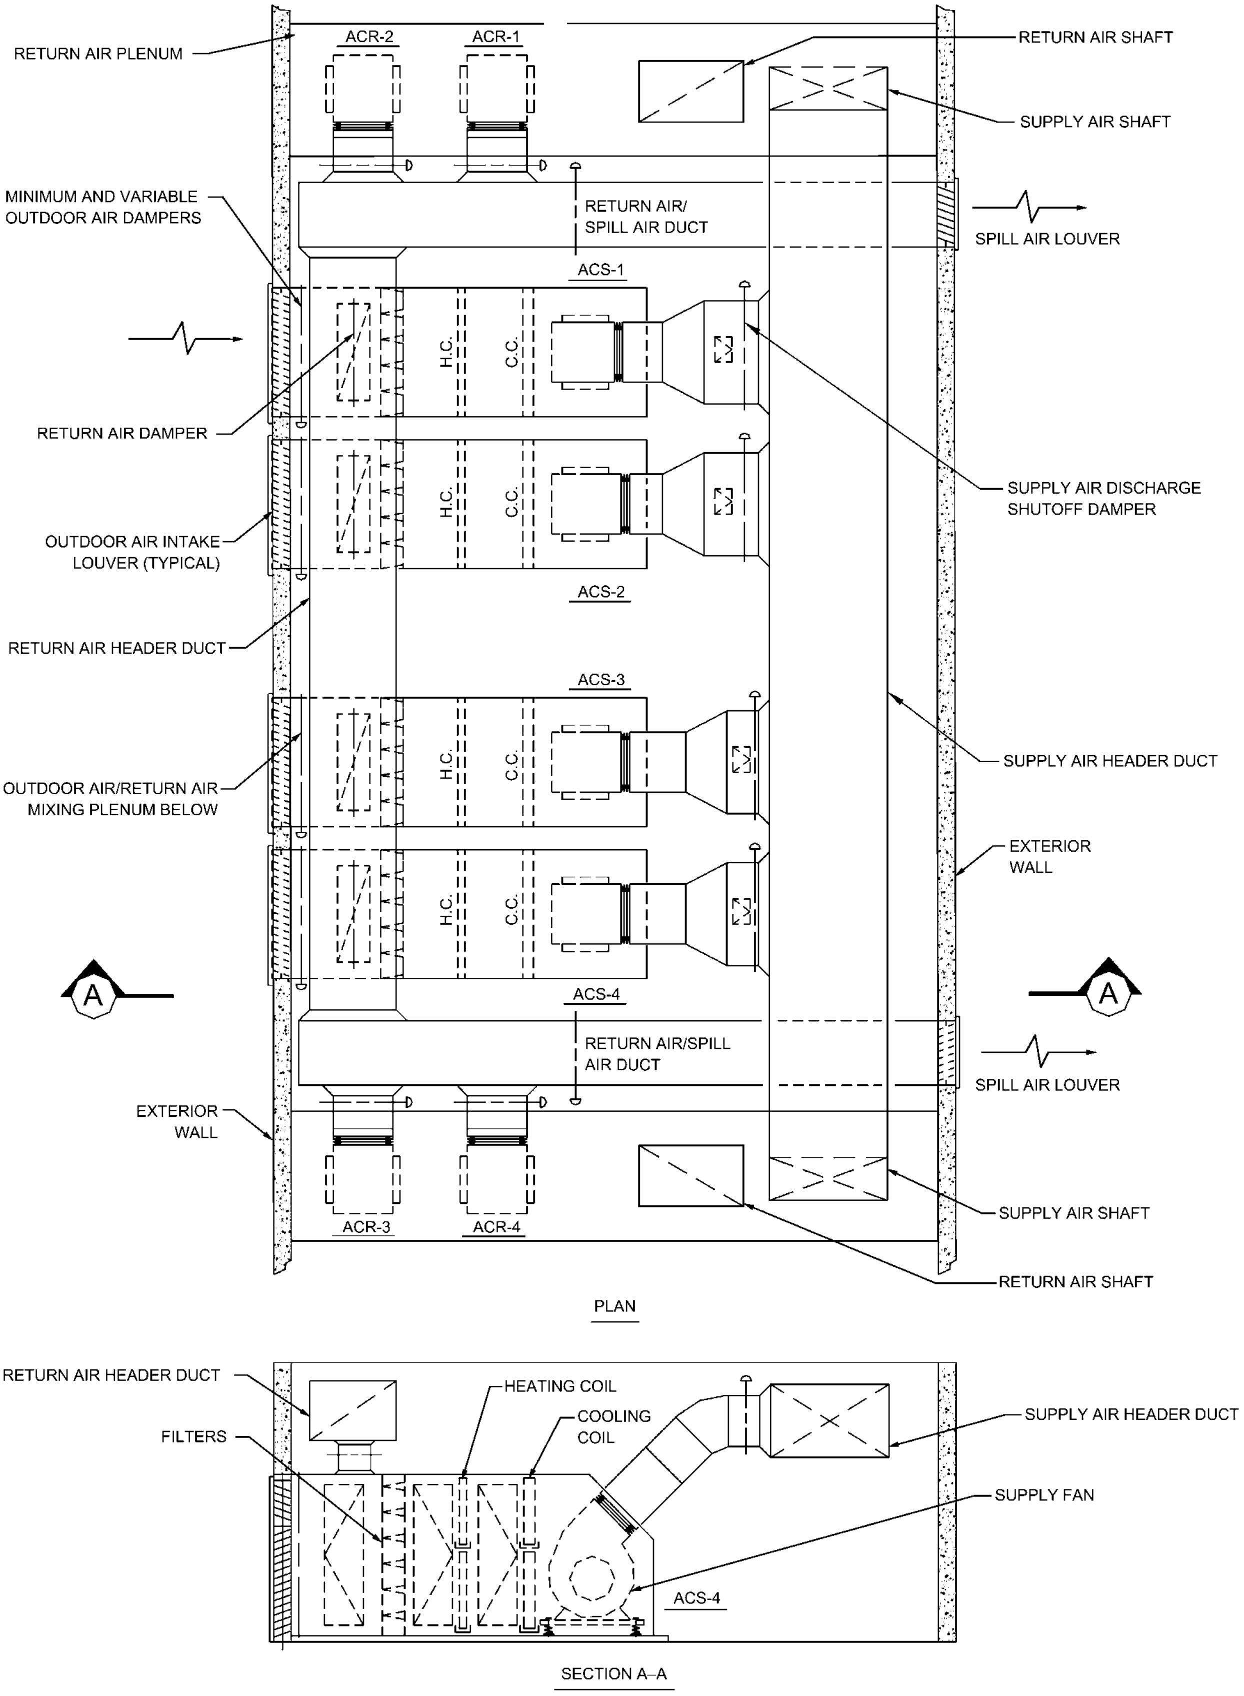

Fig. 10 Central Fan Room Arrangement

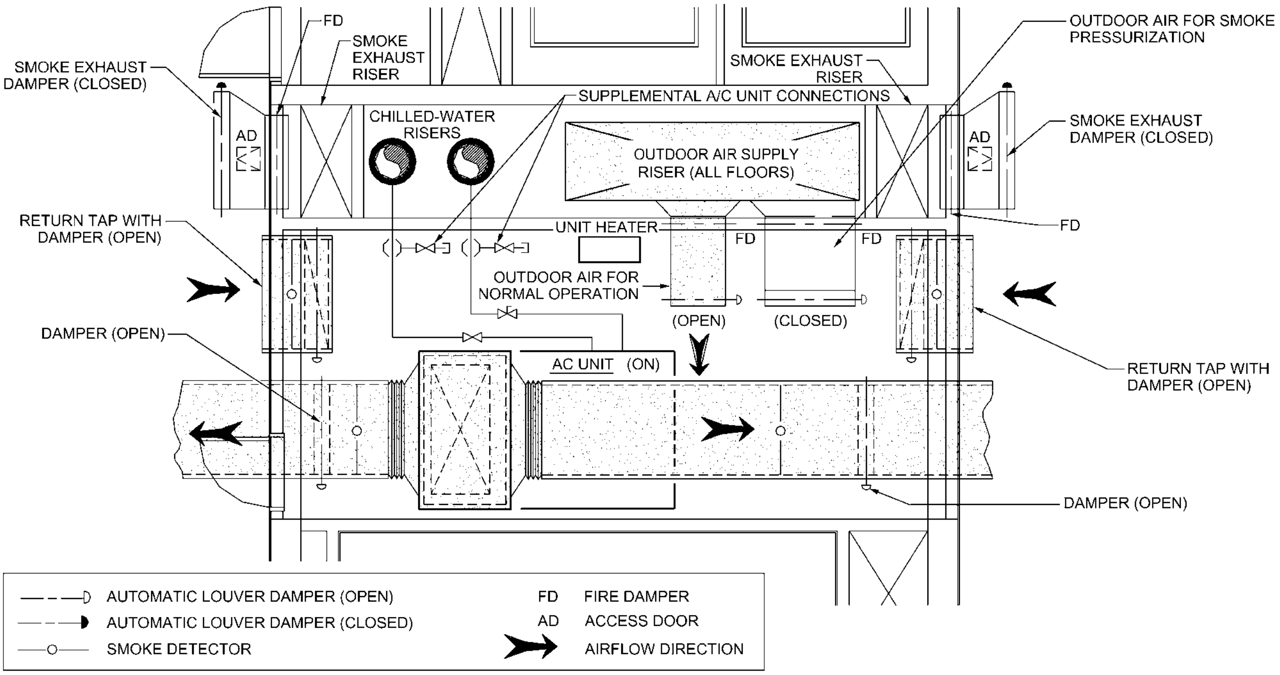

Fig. 11 Floor-By-Floor Air-Conditioning Unit Layout (Normal Operation)

this need can be met by a free-cooling coil installed in the packaged unit that will only operate when condenser water delivered to the unit is cold enough to provide effective cooling. The only central cooling equipment is a cooling tower, condenser water pumps, and the central outdoor air supply unit. If an open tower system is used, consider providing a way to remove particulates from the circulating condenser water. Depending on the size of anticipated particles, typical options include sand filtration, media filtration, and centrifugal separators. For an open system, condensers should be cleanable. Bear in mind that significant water will end up on the floor during condenser cleaning, so it is important to ensure that the room has a recessed floor drain and that the floor is moisture sealed.

The physical arrangement of the supply air unit does not differ from that shown in Figure 11, except that the chilled-water risers are replaced by condenser water piping.

Floor-by-Floor Units Located on Outer Wall (Alternative 4)

A popular variant location for a packaged floor-by-floor unit is on an outer wall. This location obviates the need for a separate outdoor air unit in a central fan room. Outdoor air can be directly introduced to the floor-by-floor unit through a louver and automatic louver damper for each unit. Moreover, this arrangement may allow using an air-cooled condenser to handle heat of rejection. If the location requires an economizer, include a minimum and variable air damper behind the outdoor air louver.

Several precautions are necessary. If an outdoor air economizer is used, the return air spill damper must be located carefully to ensure that outdoor air and spill air do not mix. Similar care must be taken to avoid air-cooled condenser intake air mixing with air previously spilled to atmosphere. There must be no possibility of mixing heated discharge air with either the condenser intake air or the outdoor ventilation air for the supply air-conditioning unit. This can become a complicated arrangement, which may necessitate locating the air-cooled condenser remote from the local fan room.

Comparison of Alternative Schemes

An accurate comparison of alternative schemes can only be made with a developed set of schematic plans in sufficient detail to allow a cost estimate to be completed by the contracting team or a professional estimating service. For an example, see Table 2.

Acoustics

Acoustical criteria should be established for the various types of occupancy that are expected in the building. For example, open-plan office space can be designed to meet a noise criteria level of NC-40, whereas private and executive offices or conference rooms should be no higher than NC-35, and may be required to be even lower. The acoustical engineer on a project sets these levels, and it is the responsibility of the HVAC designer to work with the acoustician to see that the criteria established are achieved in the final installation. (For details on sound levels, see Chapter 49 in this volume and Chapter 8 in the 2017 *ASHRAE Handbook—Fundamentals*).

Equipment and system selection affects the required sound treatment and resultant noise levels in occupied areas. It is important that project acoustical standards and the final design are reviewed by the acoustical consultant to ensure that the desired noise levels can be achieved, particularly when floor-by-floor fan rooms are used.

6. CENTRAL HEATING AND COOLING PLANTS

Many, but not all, tall buildings require a central plant to provide chilled and hot water or steam to meet the cooling and heating needs of the building. If packaged direct-expansion equipment is used on a floor-by-floor basis, as discussed previously, then a chilled-water plant is not required. Similarly, in climates where heat is necessary in colder weather, if electric resistance heat (either along the base of the outer wall or in an overhead fan-powered air conditioning terminal supplying the periphery of a building) is used, then central hot-water or steam boilers are not required. In some locations, chilled water and/or steam or hot water are available from a central utility.

Table 2 Comparison of Construction Alternatives

Alternative 1	Alternative 2	Alternative 3
Central Fan Systems Central Chilled Water	Floor-by-Floor Fan Systems Central Chilled Water	Floor-by-Floor DX Systems Central Cooling Tower
First-Cost Considerations		
HVAC		
Fewer units, field erected.	More units, factory-fabricated and assembled.	More units, factory-fabricated and assembled.
More complex and expensive duct systems.	Simpler ductwork.	Simpler ductwork.
More complex field-installed controls.	Field-installed control system.	Factory-installed control system.
Central chilled-water plant.	Central chilled-water plant.	No central chilled-water plant; cooling tower only.
Building Management System		
Complex controls and interface with building management system (BMS) and smoke control system.	Controls are relatively simple but field installed. Interface with BMS and smoke control system less complex.	Unit controls provided by manufacturer. Interface with BMS and smoke control system simple.
Electrical		
Electrical loads concentrated in central location. Probably lowest electrical cost.	Minor cost premium for distributed fan motors. Probably higher electrical cost than alternative 1.	Additional cost for electrical distribution to local DX units. Highest electrical cost.
General Construction		
Additional gross floor space needed. No separate outdoor air or smoke exhaust shaft.	Additional cost of sound treatment of local floor-by-floor fan room. Need separate outdoor air and smoke exhaust shaft.	Additional cost of sound treatment of local floor-by-floor fan room. Need separate outdoor air and smoke exhaust shaft.
Construction Schedule		
General Complexity of Installation		
Central mechanical equipment room space and complex construction technology for both chiller plant and fan systems locations. Requires piping of a major chiller plant. Chiller plant location critical to construction schedule. Heavier slab construction at central mechanical equipment room. Extensive complex ductwork in central mechanical equipment room.	Chiller plant space is required, with need for more complex construction technology. Requires piping a major chiller plant. Chiller plant location critical to construction schedule. Heavier slab construction for chiller plant only. Limited ductwork, repetitive fan room arrangement on each floor.	Areas that contain complex construction technology are limited. No major chiller plant. Cooling tower only. Chiller plant is not required. Very limited special slab construction. Limited ductwork, repetitive fan room arrangement on each floor.
Owner Issues		
Marketing/Electric Metering		
Tenant lights and small power can be metered directly. Fan energy and chiller plant energy, as well as heating energy, operating costs are allocated unless heating is by electric resistance heat. Other common building operating costs are allocated.	Tenant lights, small power, and fan energy can be metered directly for any floor with a single tenant. Multitenanted floors require allocation of fan energy only. Chiller plant energy, as well as heating energy, operating costs are allocated unless heating is by electric resistance heat. Other common building operating costs are allocated.	Tenant lights, small power, fan, and cooling energy can all be metered for any floor with a single tenant. Multitenanted floors require allocation of fan energy and cooling energy only. Heating energy operating cost must be allocated unless heating is by electric resistance heat. Other common building operating costs are allocated.
Operating Costs		
For normal operating day, operating costs for all floors occupied are lower than alternative 3. Approximately equal to alternative 2. Overtime operation requires the chiller plant to operate in the summer. With variable-speed fan control and headered supply and return fans, energy costs equal to alternative 2. Operation more cumbersome. Fan and chiller plant costs must be allocated. Larger central fan system has limited turndown capability. Overtime operation of a single floor is more difficult to accommodate.	For summer operating day, operating costs for all floors occupied are lower because of lower energy consumption than alternative 3. Approximately equal to alternative 1. Overtime operation requires chiller plant to operate in summer but otherwise is simple. Chiller plant cost must be allocated.	For the summer operating day, operating costs for all floors occupied are higher because of higher energy consumption than alternatives 1 or 2 because of less efficient DX compressors. Overtime operation simplest but probably higher in cost than alternatives 1 or 2. Single-floor tenant cost for cooling tower only must be allocated.

Table 2 Comparison of Construction Alternatives (*Continued*)

Alternative 1	Alternative 2	Alternative 3
Equipment Issues		
Equipment Maintenance		
All equipment is installed in central mechanical equipment room with centralized maintenance.	Requires more maintenance than alternative 1 but less than alternative 3, because of larger number of units with filters, motors, fan drives, bearings, etc. Chiller is in central mechanical equipment room, allowing centralized maintenance.	Requires more maintenance than alternatives 1 or 2 because of larger number of units with filters, motors, fan drives, bearings, etc., plus compressor equipment on each floor.
Equipment Redundancy and Flexibility		
Can operate in reduced mode in case of limited failure because of headered fan arrangement. Can handle changing cooling loads and/or uneven cooling loads on a floor-by-floor basis within limits. Larger central fan system may only be able to turn down to supply air to minimum of two to three floors.	If unit fails, floor is without air conditioning. Cannot handle changing cooling loads or uneven cooling loads on a floor-to-floor basis without building in additional system capacity at design.	If unit fails, floor is without air conditioning. Cannot handle changing cooling loads or uneven cooling loads on a floor-to-floor basis without building in additional system capacity at design.
Equipment Life Expectancy		
Life expectancy of equipment is in excess of 25 years.	Life expectancy of equipment is in excess of 25 years.	Compressor life expectancy is probably approximately 10 years. Remainder of installation life expectancy is in excess of 25 years.
Architectural Issues		
Building Massing		
Central fan rooms usually require two-story MER.	Local fan room fits within floor-to-floor height of the office floor.	Local fan room fits within floor-to-floor height of the office floor.
Chiller plant room usually requires two-story MER.	Chiller plant room usually requires two-story MER.	No central chiller plant room required.
Usable Area		
Takes the least area per office floor.	Takes a greater area per floor.	Takes a greater area per floor.
Maximum usable area per office floor.	Less usable area per office floor than alternative 1.	Less usable area per office floor than alternative 1.
Gross Area		
Takes more gross building area than alternatives 2 or 3.	Takes more gross building area than alternative 3 but less than alternative 1.	Takes less gross building area than alternatives 1 or 2.

For most other installations, a central chilled-water plant with refrigeration machines and a central boiler plant are required. Factors that should be considered when deciding the type and location of the heating and cooling plant include the following:

- Weight, space requirements, and effect on structural system
- Effect on construction schedule
- Specific changes in mechanical equipment room detailing and slab construction
- Acoustical considerations
- Ease and cost of operation and maintenance
- Available energy sources
- Annual operating costs and possibly life-cycle costs of each alternative

Calculation of owning and operating costs is discussed in Chapter 38. Alternative refrigeration technologies are detailed in Chapters 1 to 3 of the 2018 *ASHRAE Handbook—Refrigeration*, and boilers are covered in Chapter 32 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Useful reference information is also contained in ASME (2013).

Plant Economic Considerations

Detailed analysis is needed to determine the cooling method that should be installed in a project. The choices are usually limited to either centrifugal refrigeration or absorption chilled-water machines, although recent developments have made screw chillers more relevant for use in tall buildings. Centrifugal machines can be electric drive or steam drive; screw machines are available only with electric motor drives, and both are almost always water-cooled. Absorption machines can be single or double effect, but the latter require high-pressure steam to achieve their lower energy costs. High-pressure steam is rare in today's commercial projects unless the steam is available from a central utility.

Air-cooled refrigeration machines have been installed in tall buildings, but infrequently: commercially available sizes of air-cooled refrigeration equipment are limited, and space requirements are comparatively excessive. The largest air-cooled refrigeration machine that currently can be purchased this time is approximately 1400 kW. Tall buildings, by nature, are typically large, and the number of air-cooled refrigeration machines and relatively large equipment space that would be required usually make air cooling not viable. In addition, air-cooled equipment's operating costs may be higher because of higher condensing temperatures developed by the refrigeration equipment caused by outdoor dry-bulb temperatures that are higher than the coincident wet-bulb temperature. Water-cooled equipment's refrigerant condensing temperature, on the other hand, is driven by the lower outdoor air wet-bulb temperature. This operating cost difference exists even though there is no cooling tower fan or condenser water pump.

Air-cooled equipment may, however, find application in tall buildings where water for cooling tower makeup either is not available or is prohibitively expensive.

For tall buildings that do not use electric resistance heat, the fuel-fired heating plant includes boilers fired by oil or gas, by both fuels (with oil as a standby fuel), or by electricity. These boilers provide hydronic heat and low-pressure steam for distribution to spaces in the building, or act as supplements to heat pumps or heat recovery systems. Choosing the correct solution for a building is subject to an economic analysis that considers space requirements, first cost, and operating expense.

Central Plant Location

Further complicating the energy transfer source decision is the location of the equipment within the building. This affects structural costs, architectural design, construction time, and availability of cooling or heating relative to the initial occupancy schedule. A below-grade location could potentially provide early heating availability, but also could complicate the design process and result in higher overall project costs. Locating cooling and heating plants on floors above grade, up to and including space immediately below the roof, is common and may be desirable for simplicity of construction and ease of providing the necessary ventilation air and other services to the equipment. Moreover, the two types of plants need not be installed at the same level in the building, because there is usually no direct interconnection of the two plants.

Virtually any location in a tall building can be used for the heating and cooling equipment. When choosing the location, consider the following:

- If a boiler is installed above grade, fuel (i.e., oil, gas, electricity) must be brought to the boiler and a flue and combustion air, in the case of a fuel-fired boiler, must be taken from the boiler to atmosphere.
- Boiler plant location should be determined by analysis following previously outlined parameters.
- Regardless of where it is installed, the design must include appropriate acoustical design considerations and vibration isolation.

Considerations for the refrigeration plant location are more complex. Not only must electricity, gas, oil, or steam be brought to the machine to operate the equipment, but chilled and condenser water also must be pumped from the refrigeration plant to the air-conditioning supply equipment. In addition, the cooling tower and the working pressure of the refrigeration machines, piping, fittings, and valves must be reviewed based on the static height of liquid above this equipment, as discussed in Ross (2004) and Chapter 40 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Because of the world trend of increasing building height and because tall buildings tend to be mixed use, split chiller and boiler plants are becoming more common: part of the heating and cooling production plant is located at the top part of the building, and part at the basement. The reason for this split is to limit pressure on both halves of the plant distribution systems.

In addition, installing a cogeneration or trigeneration plant in tall buildings to meet green and sustainability initiatives is becoming popular. These facilities use engine- or turbine-driven generators to deliver electricity to the building and generate either chilled water through absorption chilling and/or heating water.

Acoustical Considerations of Central Plant Locations

Acoustics and vibration also are key considerations during architectural, structural, and mechanical design. The HVAC designer and project acoustician should place mechanical equipment to achieve the desired acoustical levels in spaces above, below, or adjacent to the central plant. Achieving the proper solution involves understanding the characteristics of sound generated by the equipment and the various paths (e.g., through floors, ceilings, walls, building structure) for transmission of that noise and vibration to occupied areas of the building.

Regardless of the type of equipment being installed on a project, it is prudent to specify a maximum permissible sound level for equipment. Sound and vibration generation, transmission, and correction are discussed in Chapter 49 in this volume and in Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals*.

Effect of Central Plant Location on Construction Schedule

The locations of the boiler and chiller plant also affect the construction schedule. This concern is especially critical for the refrigeration plant, which is a complex installation that involves a significant amount of labor because of the need to complete the chilled-water, condenser water, and possible steam piping as well as provide for the electrical capacity requirements of the machines. The heaviest piping and most difficult installation process for piping in the building occur at the refrigeration plant. As a result, if the refrigeration plant is on the uppermost level of the building, installation of the machines and their associated piping can delay the overall schedule. Accordingly, if the refrigeration equipment cannot be installed in the below-grade level because that space has other priorities (e.g., parking, storage), the refrigeration plant may be best located above the lobby level and below the uppermost levels of the building.

7. WATER DISTRIBUTION SYSTEMS

Water distribution systems for a tall building require special consideration, primarily because the building height creates high static pressure on the piping system. This pressure can affect the design of the piping systems, including domestic water and sprinkler piping systems. This section addresses chilled-, hot-, and condenser water systems.

The chilled- and hot-water systems are always closed systems (i.e., pumped fluid is not exposed to the atmosphere), whereas the condenser water system is usually open. Closed systems contain an expansion tank, which can be either open or closed. An open expansion tank is located at the highest point of the piping system and is open to atmosphere; the exposed surface area of the water in the open tank is insignificant and the system is still considered closed.

In an open system, the pumped fluid is exposed to atmospheric pressure at one or more points in the piping system. The condenser water piping distribution system is typically considered open because the water is exposed to atmosphere by the clean break in the piping at the open cooling tower.

As stated in Chapter 13 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, "one major difference in hydraulics between open and closed systems is that some hydraulic characteristics of open systems cannot occur in closed systems. For example, in contrast to the hydraulics of an open system, in a closed system (1) flow cannot be motivated by static pressure differences, (2) pumps do not provide static lift, and (3) the entire piping system is always filled with water."

If an evaporative cooler or dry cooler (commonly called an industrial fluid cooler) were used for the condenser water rather than a cooling tower, the piping system would be closed rather than open. Using evaporative or dry coolers for an entire large commercial office building is extremely rare. However, they are used in portions of tall buildings to handle the heat of rejection from supplemental cooling systems that may be required for spaces or equipment that require additional cooling capacity.

Hydrostatic Considerations

A major consideration in piping system design for a tall building is the hydrostatic pressure created by the height of the building. This hydrostatic pressure affects not only the piping and its associated valves and fittings, but also equipment in the building; in the chilled-water system, this includes refrigeration machines, casings for chilled-water pumps, cooling coils in air-conditioning systems, heat exchangers, and any fan-coil units at the exterior wall of the building. A similar list of devices beyond piping, valves, and fittings can be developed for other pumped systems such as the condenser water or any hot-water system.

Dynamic pressures created by the pumps also must be added to the static pressure to determine the working pressure on any element in the piping system. This dynamic pressure is the total of the following elements:

- Friction loss through piping, valves, and fittings
- Residual pressure required at the most remote piece of heat transfer equipment for its proper operation (includes pressure loss through the equipment's control valve as well as drop through the equipment itself)
- Any excess pressure caused by pumps operating at reduced flow close to their shutoff pressure

The working pressure of the piping and connected equipment at various elevations in the building must be known. This is found by adding the hydrostatic pressure at the specific location to the dynamic pressure that can be developed by the pumps at that location. The dynamic pressure at any point should include the pump pressure at or close to pump shutoff at full speed, even if variable-speed pumps are used, because it is possible for the pumps to operate at this shutoff point in the event of a VFD failure. This working pressure on piping and equipment invariably lessens as the static pressure at a specific location is reduced.

The trend of ever-greater height makes piping system hydrostatic pressure zoning design very important for both technical and economical reasons. Check the pressure rating of all major air-conditioning equipment to confirm whether the required pressure-rated equipment is economically available in the market.

Effect of Refrigeration Machine Location

The level on which the refrigeration machines and the supporting chilled- and condenser water pumps are located in a building can affect the cost of refrigeration equipment, the pumps, the piping, and the fittings and valves associated with the piping. There is economic impact because of the working pressure to which the equipment, piping, fittings and valves will be subjected by the height of the system above.

Using the following information, calculate the effect of alternative chiller locations in a tall building: at basement level, a midlevel mechanical equipment room, and a mechanical equipment room on the roof. There would be an open expansion tank at the top of the building (the highest point in the system) in all three alternatives. If a closed expansion tank is used, the maximum pressure must be established and considered in the determination of the system's working pressure.

Example 1. For 2000 kPa fittings, work backwards to calculate the static building height that will not exceed 2000 kPa when the pumps are not operating. Hydrostatic pressure in a liquid can determined using the following equation:

$$P = \rho g h$$

where

P = pressure in fluid, Pa
ρ = density of liquid = 1000 kg/m^3
g = acceleration of gravity = 9.81 m/s^2
h = height of fluid column at which the pressure is measured, m

$$P = (1000)(9.81)(200) = 1962 \text{ kPa}$$

It is therefore recommended to have a pressure break every 200 m in a supertall and megatall building. Fittings with pressure higher than 2000 kPa can also be used, but at a substantial increase in cost.

Alternative refrigeration plant locations (at midlevel and top of the building) must also be calculated. For a 70-story, 274 m building, working pressure would be 1758 kPa at the midlevel location, and 448 kPa at the top of the building.

The standard working pressure for coolers and condensers on large refrigeration machines from all of the major manufacturers in the United States is 1000 kPa. These machines can be manufactured for any working pressure above 1000 kPa for additional cost. The incremental increase in the cost of a given vessel becomes larger with each unit of increase in the working pressure. Accordingly, it is necessary for the HVAC design engineer to accurately determine and separately specify the working pressure on both the cooler and the condenser of the refrigeration machines.

Working pressure on the refrigeration machine can be reduced by locating the chilled-water pump on the discharge side rather than the suction side. If this is done, the residual pump pressure on the refrigeration machine water boxes is reduced to the sum of the hydrostatic pressure and this nominal value of dynamic pressure from the pumps. This can reduce the cost of the refrigeration machines, but does not alter the pressure on the pump casing and flanges, which must still be the sum of the static and dynamic pressures.

Chilled-Water Pressure Reduction

Pressure on (and cost of) refrigeration equipment can be reduced by locating it above the basement; this, however, will not alter the maximum pressure experienced by the pipe, fittings, and valves at any location that is used. It is possible, however, to reduce the chilled-water working pressure on both the machines and piping by using plate-and-frame heat exchangers, which segregate groups of floors into separate static pressure zones.

In the 274 m tall example building with the refrigeration machine in the basement, it is possible to break the chilled-water system into three separate zones (Figure 12).

Each zone has static pressure of one-third of the total building height, or 91 m. All of the pumps are located on the discharge side of the refrigeration machines or the secondary zone heat exchangers. The result is that the maximum head of each zone is 986 kPa, which is below the threshold design pressure of 1000 kPa, or the point at which an increased pressure rating for the chiller and other heat transfer equipment must be considered.

The working pressure of the primary chilled-water pump in the basement will not change substantially from that required where no secondary systems were included, because the primary chilled-water pump must now overcome the loss through the flat-plate heat exchanger. In addition, motor-driven pumps are added at each secondary water heat exchanger. Finally, with the two additional zones and the resultant chilled-water temperature increase, there is a requisite increase in the volume of water flowing through the systems on the upper floors. Accordingly, although there are benefits in the reduction in pressure, there are partially offsetting considerations that must be analyzed to determine the overall cost effectiveness of using flat-plate heat exchangers to reduce the operating pressure on the equipment, pipe, valves, and fittings at a given level.

Use of flat-plate heat exchangers and their location in a chilled-water piping system is subject to an economic analysis by the design HVAC engineer to determine the first cost of alternative arrangements as well as the operating cost differentials, if any, for any scheme.

Using a flat-plate heat exchanger to reduce working pressure on the condenser, although feasible, is not often considered, because the condenser water piping is usually in a single shaft with minimal

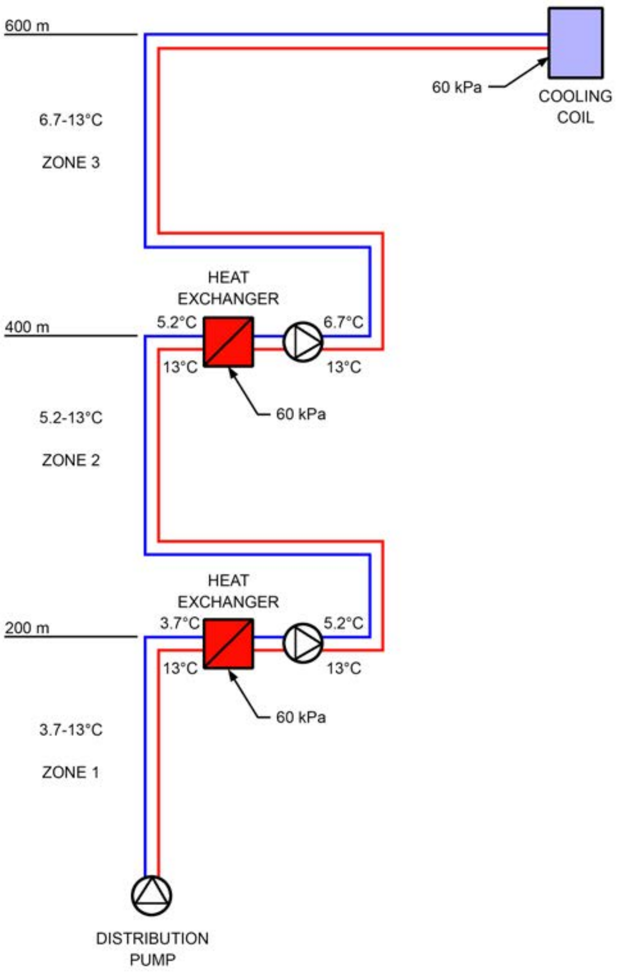

Fig. 12 Typical Chilled-Water Distribution System for Supertall or Megatall Building

(if any) offsets and a resultant small number of fittings. Valves are also only installed at the machines and are few in number. This limited number of fittings and valves may not be sufficient to offset the cost of the flat-plate heat exchanger and its valving as well as the added pump on the secondary side of the heat exchanger. Beyond that, there is an increase in the temperature of the condenser water, which increases the cost of operating the refrigeration machines.

Piping, Valves, and Fittings

The working pressure on the piping, valves, and fittings at various levels in a building must be determined so that proper piping material can be specified. In the United States, with steel pipe, Schedule 40 pipe is the standard wall thickness for pipes up to 250 mm diameter. For pipes 300 mm and larger, the pipe standard that is used has a wall thickness of 9.5 mm. Either of these standards would accommodate the working pressures experienced in any expected pipe diameter in any tall building. The allowable pressures for various pipe diameters can be found in ASME *Standard* A17.1 and the *Boiler and Pressure Vessel Code* (ASME 2013) and in the publications of various pipe manufacturers. The valves used should be reviewed in the valve manufacturers' literature to ensure their ability to meet the project's requirements.

For steam condensate piping or for condenser water piping, where corrosion is a possible concern, pipe with a heavier wall thickness should be considered, although not because of the working pressure on either system.

Piping materials other than steel are often used. For pipe sizes below about 100 mm, in the cases of runouts or in open condenser water piping where corrosion is a concern, copper is the usual choice. Copper pipe is rare, but copper tubing is common. The limiting factor in the use of copper tubing is usually at the joints, where the ability to handle higher working pressure is restricted.

Piping Design Considerations

Other factors piping design should consider include

- Expansion and contraction in the piping and its static and dynamic loads, because they are reflected in the structural steel framing system of the building
- Access to expansion joints and the anchors and guides for the piping, which should be inspected periodically after the building is constructed
- Firestopping between the pipe and the sleeve located at all penetrations of rated slabs, walls, and partitions
- Seismic restraints (if required) on the piping systems and pumps

In addition to expansion and contraction of the piping caused by changes in the ambient temperature or of the pumped fluid in the piping, frame shortening can be a problem in concrete buildings. Concrete shrinks as it cures: over time, this shortening can be in the range of 3 mm per floor. Although this movement is relatively small, it amounts to about 225 mm for a 70-story building. This condition requires that pipes above, below, and between anchor points be flexible enough to allow for pipe movement with respect to the structure. To properly design for this condition, the HVAC designer should obtain from the structural engineer the exact amount of movement that the piping system can experience.

Economics of Temperature Differentials

Traditionally, rules of thumb for selecting refrigeration machines in the United States have used a 5.6 or 6.7 K temperature differential between entering and leaving water in the chiller and a 5.6 K differential or 0.054 mL/J of capacity for the condenser. These guidelines are appropriate for small buildings, because they have little effect on project cost, but may be less ideal for large buildings, particularly tall buildings. In projects of this type, the capital costs of piping, valves, and fittings can be substantially reduced, with a possible penalty in refrigeration machine operating cost, by using larger temperature differentials with lower water flow and a consequent reduction in piping diameter.

For a large project with a total cooling capacity requirement of 14 000 kW and chilled-water flow at a 5.6 K temperature differential, 600 L/s is circulated through 500 mm piping at approximately 3.0 m/s. If an 8.9 K temperature differential is used, total flow from the refrigeration plant is 380 L/s and the piping is 400 mm. Cost savings on the piping using the greater temperature differential would be significant. Also, although the kilowatts per unit of cooling under both conditions should be studied, with the same discharge temperature, the operating energy consumption probably is unchanged.

For the 14 000 kW refrigeration plant with a 5.6 K differential, the condenser water flow is 760 L/s and 600 mm piping is required. If this temperature differential were increased to 8.3 K, condenser water would be reduced to 500 L/s, and the piping to 500 mm. Again, this change results in a significant first-cost savings, depending on the distance between the refrigeration machines and the cooling towers.

Energy consumption for the refrigeration machines might marginally increase, because the condensing temperature of the refrigerant and the resultant energy usage is largely (but not solely) a function of the leaving condenser water temperature. Increases in chiller energy consumption may be partly or fully offset by reduced pumping energy. Furthermore, large chiller plants designed to maximize chilled- and condenser-water temperature differentials (lower flow and smaller piping) can offer substantial savings in piping system installation cost.

8. VERTICAL TRANSPORTATION

The HVAC designer's main involvement with elevators in a tall building is to provide cooling in the elevator machine room to ensure reliable operation. Many codes now require that this machine room be conditioned by a separate HVAC system that is independent of other building systems. This section addresses the possible code requirement of elevator shaft and machine room ventilation to atmosphere.

Elevator Machine Room Cooling

The elevator machine room's cooling loads consist not only of the electric motor that drives the hoisting mechanism but also of extensive heat-generating electronic elevator controls. The electronic components that are part of the system require that the elevator machine room be maintained at a temperature between 27 and 16°C. This can be accomplished by means of a packaged DX condenser water-cooled unit in the elevator machine room; however, because of possible significant operational availability restrictions on the use of water in the machine room, the HVAC designer should review this alternative with the building developer and possibly code officials. Using a packaged DX condenser water unit may be necessary for a low- or mid-rise elevator bank with its machine room in the middle of the building, without easy access to outdoor air unless the remainder of the floor is used as a mechanical equipment room. At the top of the building, the cooling equipment can be air cooled.

The ultimate size of DX units is determined by information provided by the elevator manufacturer. The elevator consultant can provide the necessary general information to allow the design to proceed through bidding. The amount of cooling for this equipment can be significant: as much as 35 to 52 kW for a single elevator equipment room.

Elevator Hoistway and Machine Room Venting

All elevators installed in the United States must conform to ASME *Standard* A17.1, as modified by local authority and applicable building code. One requirement of many codes is to include a vent opening at the top of each elevator shaft that is 3.5% of the plan area of the hoistway or 0.27 m^2 per elevator, whichever is greater. The purpose of this requirement is to allow venting of smoke during a building fire. To accomplish this, a duct must be provided from the vent to atmosphere. This is simple at the top of the building, but for low- and mid-rise elevators, where the elevator equipment room is not located in a mechanical room with perimeter access, extending the connecting duct to atmosphere may be difficult.

Under many codes, including the model *International Building Code*® (IBC [ICC 2015]), for a building that is fully sprinklered, the need for the vent and its extension to atmosphere may be waived for passenger elevators, except for buildings where there is overnight sleeping (e.g., hotels, residences). The vent is typically still required for a dedicated service elevator car.

In addition, under the IBC, the vent may be closed under normal building operating conditions by including an automatic damper in the atmospheric vent or, under some code jurisdictions, by installing a piece of glass that will break in a fire. This damper must open on detection of smoke by any of the elevator lobby smoke detectors. Dampers have a distinct advantage in that they are manually and remotely resettable.

Where elevator speeds are greater than 7 m/s, vents at the bottom of the shafts may be required by code to allow rapid escape of air when the high-speed car is descending.

Elevator Shaft Pressurization

In super- and megatall buildings, express (or shuttle) elevators are provided to quickly carry occupants to upper-level occupancies, typically in hotels or residential uses. These elevators are commonly used as evacuation elevators in emergency situations. To maintain the safety of these elevators for this use, the elevator shaft(s) should be pressurized to keep the shaft and cars free of smoke. Refer to the section on Smoke Management for more details.

Air-Conditioning Equipment Delivery by Freight Elevators

If part of the chilled-water or boiler plant is located in the top zone of the supertall buildings, the freight elevator should have sufficient capacity and cab size to deliver and transfer all major equipment from the ground level to the area where the upper plant is located, to aid in maintenance of the equipment located there.

9. LIFE SAFETY IN TALL BUILDINGS

Life safety challenges for tall buildings are similar to those of shorter high-rise buildings. It is impractical to rely on stairs as the means of egress to grade. Elevators should play a major role in safe evacuation of occupants and response of emergency forces. Areas or floors of refuge are needed to provide staging points for occupants evacuating and emergency forces responding. Codes have developed means to confront this challenge. The following provides a brief review of those life safety measures.

Codes and Standards

In the United States, the *International Building Code*® (IBC) is the predominant building code; in Canada, it is the *National Building Code of Canada* (NRC 2010). The National Fire Protection Association's (NFPA) *Standard* 5000 generally incorporates NFPA *Standard* 101. These codes do not define a "tall building," but have additional requirements for a high-rise building greater than or equal to 128 m in height.

Components of Life Safety Systems for Tall Buildings

Tall buildings share many of the code requirements of other high-rise buildings. The IBC (ICC 2018) defines a high-rise building as "a building with an occupied floor located more than 22 860 mm above the lowest level of fire department vehicle access." Additional requirements are imposed for buildings 36.6 and 128 m above grade. No specific definition of "tall building" is contained in the codes.

Key fire safety provisions for tall buildings should include the following:

- Smoke detection for elevator lobbies, elevator machine rooms, and HVAC systems
- Complete automatic sprinkler protection
- Fire standpipe system
- Smoke management system for enclosed exits, stairs, elevators, and areas or floors of refuge
- Emergency power for life safety systems
- Fire department or first-responder elevator
- Redundant exit stair or elevator emergency evacuation provisions
- Area or floor of refuge
- Fire command center

Detection

Automatic smoke detection should be provided in elevator lobbies, elevator machine rooms, mechanical and electrical equipment rooms, and any other spaces not provided with automatic sprinklers. The detection system should be connected to the automatic fire alarm system. Duct smoke detectors should be provided in the main return air and exhaust air plenum of each air-conditioning system with a capacity greater than 0.94 m^3/s. Duct smoke detectors are also needed at each connection to a vertical duct or riser serving two or more floors from a return air duct or plenum.

The smoke detection system should be designed in accordance with NFPA *Standard* 72.

Residential buildings should have smoke alarms in each room used for sleeping purposes and on the ceiling or wall outside of each separate sleeping area. The smoke alarms should be interconnected so that activation of any smoke alarm in the dwelling unit activates all of the smoke alarms in that unit. This does not require activating smoke alarms in other apartments in the building.

Automatic Sprinkler Protection

Complete automatic sprinkler protection should be provided in accordance with NFPA *Standard* 13.

Standpipe System

Standpipe systems should be provided in accordance with NFPA *Standard* 14.

Smoke Management

The essential features of smoke management design are described in Chapter 54. Additional information is contained in NFPA *Standard* 92A.

The IBC requires exit stairs to be smoke protected. One way to achieve this is with a smokeproof tower of pressurized stairs. To enhance egress for buildings 128 m high or more, the codes require either an additional exit stairway beyond those required by the typical exit calculations, or pressurization of the elevator shafts. To prevent smoke spread through the elevator without elevator shaft pressurization, elevator vestibules with a minimum 1 h fire resistance rating are required.

Codes also require an elevator for use by emergency responders, with access from a vestibule directly connected to an egress stair.

Elevators to be used for occupants in an emergency require special protection, including pressurized elevator shafts, an emergency voice/alarm communication system, elevator lobbies with direct access to a exit enclosure, and a means to protect the elevator from automatic sprinkler system water infiltrating the hoistway enclosure. Automatic sprinklers are prohibited from the elevator machine room, and shunt trips for elevators shutdown should not be provided.

Emergency Power

All life safety systems are required to have standby power designed and installed in accordance with NFPA *Standards* 110 and 111, as appropriate.

Fire Command Center

A fire command center is required in a protected location at or near grade to monitor all fire safety and emergency systems. It should also have controls for the smoke management system and emergency power system.

CHAPTER 5

PLACES OF ASSEMBLY

General Criteria 5.1
Houses of Worship 5.3
Auditoriums 5.3
Arenas and Stadiums 5.4
Convention and Exhibition Centers 5.5
Fairs and Other Temporary Exhibits 5.6
Atriums 5.6

ASSEMBLY rooms are generally large, have relatively high ceilings, and are few in number for any given facility. They usually have a periodically high density of occupancy per unit floor area, as compared to other buildings, and thus have a relatively low design sensible heat ratio.

This chapter summarizes some of the design concerns for enclosed assembly buildings. (Chapter 3, which covers general criteria for commercial and public buildings, also includes information that applies to public assembly buildings.)

1. GENERAL CRITERIA

Energy conservation codes and standards must be considered because they have a major impact on design and performance.

Assembly buildings may have relatively few hours of use per week and may not be in full use when maximum outdoor temperatures or solar loading occur. Often they are fully occupied for as little as 1 to 2 h, and the load may be materially reduced by precooling. The designer needs to obtain as much information as possible about the anticipated hours of use, particularly times of full seating, so that simultaneous loads may be considered to optimize performance and operating economy. Dehumidification requirements (full and part load) should be considered before determining equipment size. The intermittent or infrequent nature of the cooling loads may allow these buildings to benefit from thermal storage systems.

Occupants usually generate the major room cooling and ventilation load. The number of occupants is best determined from the seat count, but when this is not available, it can be estimated at 0.7 to 0.9 m^2 per person for the entire seating area, including exit aisles but not the stage, performance areas, or entrance lobbies.

Safety and Security

Assembly buildings may need new safety and security considerations regarding extraordinary incidents. Designers should follow the recommendations outlined in Chapter 61.

Outdoor Air

Outdoor air ventilation rates as prescribed by ASHRAE *Standard* 62.1 can be a major portion of the total load. The latent load (dehumidification and humidification) and energy used to maintain relative humidity within prescribed limits are also concerns. Humidity must be maintained at proper levels to prevent mold and mildew growth and for acceptable indoor air quality and comfort.

Lighting Loads

Lighting loads are one of the few major loads that vary from one type of assembly building to another. Levels can vary from 1600 lux in convention halls where television cameras are expected to be used, to virtually nothing, as in a movie theater. In many assembly buildings, lights are controlled by dimmers or other means to present a suitably low level of light during performances, with much higher lighting levels during cleanup, when the house is nearly empty. The designer should ascertain the light levels associated with maximum occupancies, not only for economy but also to determine the proper room sensible heat ratio.

Indoor Air Conditions

Indoor air temperature and humidity should follow ASHRAE comfort recommendations in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* and ASHRAE *Standard* 55. In addition, the following should be considered:

- In arenas, stadiums, gymnasiums, and movie theaters, people generally dress informally. Summer indoor conditions may favor the warmer end of the thermal comfort scale, and the winter indoor temperature may favor the cooler end.
- In churches, concert halls, and theaters, most men wear jackets and ties and women often wear suits. The temperature should favor the middle range of design, and there should be little summer-to-winter variation.
- In convention and exhibition centers, the public is continually walking. The indoor temperature should favor the lower range of comfort conditions both in summer and in winter.
- In spaces with a high population density or with a sensible heat factor of 0.75 or less, reheat should be considered.
- Energy conservation codes must be considered in both the design and during operation.

Assembly areas generally require some reheat to maintain the relative humidity at a suitably low level during periods of maximum occupancy. Refrigerant hot gas or condenser water is well suited for this purpose. Face-and-bypass control of low-temperature cooling coils is also effective. In colder climates, it may also be desirable to provide humidification. High rates of internal gain may make evaporative humidification attractive during economizer cooling.

Filtration

Most places of assembly are minimally filtered with filters rated at 30 to 35% efficiency, as tested in accordance with ASHRAE *Standard* 52.1. Where smoking is permitted, however, filters with a minimum rating of 80% are required to remove tobacco smoke effectively. Filters with 80% or higher efficiency are also recommended for facilities having particularly expensive interior decor. Because of the few operating hours of these facilities, the added expense of higher-efficiency filters can be justified by their longer life. Low-efficiency prefilters are generally used with high-efficiency filters to extend their useful life. Consider using ionization and chemically reactive filters where high concentrations of smoke or odors are present.

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

Noise and Vibration Control

The desired noise criteria (NC) vary with the type and quality of the facility. The need for noise control may be minimal in a gymnasium, but it is important in a concert hall. Multipurpose facilities require noise control evaluation over the entire spectrum of use.

In most cases, sound and vibration control is required for both equipment and duct systems, as well as in diffuser and grille selection. When designing a performance theater or concert hall, consult an experienced acoustics engineer because the quantity and quality or characteristic of the noise is very important.

Transmission of vibration and noise can be decreased by mounting pipes, ducts, and equipment on a separate structure independent of the music hall. If the mechanical equipment space is close to the music hall, the entire mechanical equipment room may need to be floated on isolators, including the floor slab, structural floor members, and other structural elements such as supporting pipes or similar materials that can carry vibrations. Properly designed inertia pads are often used under each piece of equipment. The equipment is then mounted on vibration isolators.

Manufacturers of vibration isolating equipment have devised methods to float large rooms and entire buildings on isolators. Where subway and street noise may be carried into the structure of a music hall, it is necessary to float the entire music hall on isolators. If the music hall is isolated from outdoor noise and vibration, it also must be isolated from mechanical equipment and other internal noise and vibrations.

External noise from mechanical equipment such as cooling towers should not enter the building. Avoid designs that allow noises to enter the space through air intakes or reliefs and carelessly designed duct systems.

For more details on noise and vibration control, see Chapter 48 of this volume and Chapter 49 in the 2017 *ASHRAE Handbook—Fundamentals*.

Ancillary Facilities

Ancillary facilities are generally a part of any assembly building; almost all have some office space. Convention centers and many auditoriums, arenas, and stadiums have restaurants and cocktail lounges. Churches may have apartments for clergy or a school. Many facilities have parking structures. These varied ancillary facilities are discussed in other chapters of this volume. However, for reasonable operating economy, these facilities should be served by separate systems when their hours of use differ from those of the main assembly areas.

Air Conditioning

Because of their characteristic large size and need for considerable ventilation air, assembly buildings are frequently served by single-zone or variable-volume systems providing 100% outdoor air. Separate air-handling units usually serve each zone, although multi-zone, dual-duct, or reheat types can also be applied with lower operating efficiency. In larger facilities, separate zones are generally provided for entrance lobbies and arterial corridors that surround the seating space. Low-intensity radiant heating is often an efficient alternative. In some assembly rooms, folding or rolling partitions divide the space for different functions, so a separate zone of control for each resultant space is best. In extremely large facilities, several air-handling systems may serve a single space, because of the limits of equipment size and also for energy and demand considerations.

Peak Load Reduction

There are several techniques currently in use to help address peak loads. **Thermal storage** is discussed in Chapter 51 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Another popular technique, **precooling**, can be managed by the building operator. Precooling the building mass several degrees below the desired indoor temperature several hours before it is occupied allows it to absorb a part of the peak heat load. This cooling reduces the equipment size needed to meet short-term loads. The effect can be used if cooling time of at least 1 h is available prior to occupancy, and then only when the period of peak load is relatively short (2 h or less).

The designer must advise the owner that the space temperature will be cold to most people as occupancy begins, but will warm up as the performance progresses; this should be understood by all concerned before proceeding with precooling. Precooling works best when the space is used only occasionally during the hotter part of the day and when provision of full capacity for an occasional purpose is not economically justifiable.

Stratification

Because most assembly buildings have relatively high ceilings, some heat may be allowed to stratify above the occupied zone, thereby reducing load on the equipment. Heat from lights can be stratified, except for the radiant portion (about 50% for fluorescent and 65% for incandescent or mercury-vapor fixtures). Similarly, only the radiant effect of the upper wall and roof load (about 33%) reaches the occupied space. Stratification only occurs when air is admitted and returned at a sufficiently low elevation so that it does not mix with the upper air. Conversely, stratification may increase heating loads during periods of minimal occupancy in winter. In these cases, ceiling fans, air-handling systems, or high/low air distribution may be desirable to reduce stratification. Balconies may also be affected by stratification and should be well ventilated.

Air Distribution

In assembly buildings with seating, people generally remain in one place throughout a performance, so they cannot move away from drafts. Therefore, good air distribution is essential. Airflow modeling software could prove helpful in predicting potential problem areas.

Heating is seldom a major problem, except at entrances or during warm-up before occupancy. Generally, the seating area is isolated from the exterior by lobbies, corridors, and other ancillary spaces. For cooling, air can be supplied from the overhead space, where it mixes with heat from the lights and occupants. Return air openings can also aid air distribution. Air returns located below seating or at a low level around the seating can effectively distribute air with minimum drafts; however, register velocities over 1.4 m/s may cause objectionable drafts and noise.

Because of the configuration of these spaces, supply jet nozzles with long throws of 15 to 45 m may need to be installed on sidewalls. For ceiling distribution, downward throw is not critical if returns are low. This approach has been successful in applications that are not particularly noise-sensitive, but the designer needs to select air distribution nozzles carefully.

The air-conditioning systems must be quiet. This is difficult to achieve if supply air is expected to travel 9 m or more from sidewall outlets to condition the center of the seating area. Because most houses of worship, theaters, and halls are large, high air discharge velocities from the wall outlets are required. These high velocities can produce objectionable noise levels for people sitting near the outlets. This can be avoided if the return air system does some of the work. The supply air must be discharged from the air outlet (preferably at the ceiling) at the highest velocity consistent with an acceptable noise level. Although this velocity does not allow the conditioned air to reach all seats, the return air registers, which are located near seats not reached by the conditioned air, pull the air to cool or heat the audience, as required. In this way, supply air blankets the seating area and is pulled down uniformly by return air registers under or beside the seats.

A certain amount of exhaust air should be taken from the ceiling of the seating area, preferably over the balcony (if there is one) to prevent pockets of hot air, which can produce a radiant effect and cause discomfort, as well as increase the cost of air conditioning. Where the ceiling is close to the audience (e.g., below balconies and mezzanines), specially designed plaques or air-distributing ceilings should be provided to absorb noise.

Regular ceiling diffusers placed more than 9 m apart normally give acceptable results if the diffusers are carefully selected. Because large air quantities are generally involved and because the building is large, fairly large capacity diffusers are frequently selected, but these tend to be noisy. Linear diffusers are more acceptable architecturally and perform well if selected properly. Integral dampers in diffusers should not be used as the only means of balancing because they generate intolerable amounts of noise, particularly in larger diffusers.

Mechanical Equipment Rooms

The location of mechanical and electrical equipment rooms affects the degree of sound attenuation treatment required. Those located near the seating area are more critical because of the normal attenuation of sound through space. Those near the stage area are critical because the stage is designed to project sound to the audience. If possible, mechanical equipment rooms should be in an area separated from the main seating or stage area by buffers such as lobbies or service areas. The economies of the structure, attenuation, equipment logistics, and site must be considered in selecting locations for mechanical equipment rooms.

At least one mechanical equipment room is placed near the roof to house the toilet exhaust, general exhaust, cooling tower, kitchen, and emergency stage exhaust fans, if any. Individual roof-mounted exhaust fans may be used, thus eliminating the need for a mechanical equipment room. However, to reduce sound problems, mechanical equipment should not be located on the roof over the music hall or stage but rather over offices, storerooms, or auxiliary areas.

2. HOUSES OF WORSHIP

Houses of worship seldom have full or near-full occupancy more than once a week, but they have considerable use for smaller functions (meetings, weddings, funerals, christenings, or daycare) throughout the rest of the week. It is important to determine how and when the building will be used. When thermal storage is used, longer operation of equipment before occupancy may be required because of the structure's high thermal mass. Seating capacity is usually well defined. Some houses of worship have a movable partition to form a single large auditorium for special holiday services. It is important to know how often this maximum use is expected.

Houses of worship test a designer's ingenuity in locating equipment and air diffusion devices in architecturally acceptable places. Because occupants are often seated, drafts and cold floors should be avoided. Many houses of worship have high, vaulted ceilings, which create thermal stratification. Where stained glass is used, a shade coefficient equal to solar glass (SC = 0.70) is assumed.

Houses of worship may also have auxiliary rooms that should be air conditioned. To ensure privacy, sound transmission between adjacent areas should be considered in the air distribution scheme. Diversity in the total air-conditioning load requirements should be evaluated to take full advantage of the characteristics of each area.

It is desirable to provide some degree of individual control for the platform, sacristy, and bema or choir area.

3. AUDITORIUMS

The types of auditoriums considered are movie theaters, playhouses, and concert halls. Auditoriums in schools and the large auditoriums in some convention centers may follow the same principles, with varying degrees of complexity.

Movie Theaters

Movie theaters are the simplest of the auditorium structures discussed here. They run continuously for periods of 8 h or more and, thus, are not a good choice for precooling techniques, except for the first matinée peak. They operate frequently at low occupancy levels, and low-load performance must be considered. Additionally, they tend to have lower sensible heat factors; special care must be taken to ensure proper relative humidity levels can be maintained without overcooling the space.

Motion picture studios often require that movie theaters meet specific noise criteria. Consequently, sound systems and noise control are as critical in these applications as they are in other kinds of theaters. The lobby and exit passageways in a motion picture theater are seldom densely occupied, although some light to moderate congestion can be expected for short times in the lobby area. A reasonable design for the lobby space is one person per 1.8 to 2.8 m^2.

Lights are usually dimmed when the house is occupied; full lighting intensity is used only during cleaning. A reasonable value for lamps above the seating area during a performance is 5 to 10% of the installed wattage. Designated smoking areas should be handled with separate exhaust or air-handling systems to avoid contamination of the entire facility.

Projection Booths. The projection booth represents a larger challenge in movie theater design. For large theaters using high-intensity lamps, projection room design must follow applicable building codes. If no building code applies, the projection equipment manufacturer usually has specific requirements. The projection room may be air conditioned, but it is normally exhausted or operated at negative pressure. Exhaust is normally taken through the housing of the projectors. Additional exhaust is required for the projectionist's sanitary facilities. Other heat sources include sound and dimming equipment, which require a continuously controlled environment and necessitate a separate system.

Smaller theaters have fewer requirements for projection booths. It is a good idea to condition the projection room with filtered supply air to avoid soiling lenses. In addition to the projector light, heat sources in the projection room include the sound equipment, as well as the dimming equipment.

Performance Theaters

Performance theaters differ from motion picture theaters in the following ways:

- Performances are seldom continuous. Where more than one performance occurs in a day, performances are usually separated by 2 to 4 h. Accordingly, precooling techniques are applicable, particularly for afternoon performances.
- Performance theaters generally play to a full or near-full house.
- Performance theaters usually have intermissions, and the lobby areas are used for drinking and socializing. The intermissions are usually relatively short, seldom exceeding 15 to 20 min; however, the load may be as dense as one person per 0.5 m^2.
- Because sound amplification is less used than in motion picture theaters, background noise control is more important.
- Stage lighting contributes considerably to the total cooling load in performance theaters. Lighting loads can vary from performance to performance.

Stages. The stage presents the most complex problem. It consists of the following loads:

- A heavy, mobile lighting load
- Intricate or delicate stage scenery, which varies from scene to scene and presents difficult air distribution requirements
- Actors, who may perform tasks that require exertion

Approximately 40 to 60% of the lighting load can be eliminated by exhausting air around the lights. This procedure works for lights around the proscenium. However, it is more difficult to place exhaust air ducts directly above lights over the stage because of the scenery and light drops. Careful coordination is required to achieve an effective and flexible layout.

Conditioned air should be introduced from the low side and back stages and returned or exhausted around the lights. Some exhaust air must be taken from the top of the tower directly over the stage containing lights and equipment (i.e., the fly). Air distribution design is further complicated because pieces of scenery may consist of light materials that flutter in the slightest air current. Even the vertical stack effect created by the heat from lights may cause this motion. Therefore, low air velocities are essential and air must be distributed over a wide area with numerous supply and return registers.

With multiple scenery changes, low supply or return registers from the floor of the stage are almost impossible to provide. However, some return air at the footlights and for the prompter should be considered. Air conditioning should also be provided for the stage manager and control board areas.

In many theaters with overhead flies, the stage curtain billows when it is down. This is primarily caused by the stack effect created by the height of the main stage tower, heat from lights, and the temperature difference between the stage and seating areas. Proper air distribution and balancing can minimize this phenomenon. Bypass damper arrangements with suitable fire protection devices may be feasible.

In cold climates, loading docks adjacent to stages should be heated. Doors to these areas may be open for long periods (e.g., while scenery is being loaded or unloaded for a performance).

On the stage, local code requirements must be followed for emergency exhaust ductwork or skylight (or blow-out hatch) requirements. These openings are often sizable and should be incorporated in the early design concepts.

Concert Halls

Concert halls and music halls are similar to performance theaters. They normally have a full stage, complete with fly gallery, and dressing areas for performers. Generally, the only differences between the two are in size and decor, with the concert hall usually being larger and more elaborately decorated.

Air-conditioning design must consider that the concert hall is used frequently for special charity and civic events, which may be preceded or followed by parties (and may include dancing) in the lobby area. Concert halls often have cocktail lounge areas that become very crowded, possibly with heavy smoking during intermissions. These areas should be equipped with flexible exhaust-recirculation systems. Concert halls may also have full restaurant facilities.

As in theaters, noise control is important. Design must avoid characterized or narrow-band noises in the level of audibility. Much of this noise is structure-borne, resulting from inadequate equipment and piping vibration isolation. An experienced acoustical engineer is essential for help in the design of these applications.

4. ARENAS AND STADIUMS

Functions at arenas and stadiums may be quite varied, so the air-conditioning loads will vary. Arenas and stadiums are not only used for sporting events such as basketball, ice hockey, boxing, and track meets but may also house circuses; rodeos; convocations; social affairs; meetings; rock concerts; car, cycle, and truck events; and special exhibitions such as home, industrial, animal, or sports shows. For multipurpose operations, the designer must provide highly flexible systems. High-volume ventilation may be satisfactory in many instances, depending on load characteristics and outdoor air conditions.

Load Characteristics

Depending on the range of use, the load may vary from a very low sensible heat ratio for events such as boxing to a relatively high sensible heat ratio for industrial exhibitions. Multispeed fans often improve performance at these two extremes and can aid in sound control for special events such as concerts or convocations. When using multispeed fans, the designer should consider the performance of the air distribution devices and cooling coils when the fan is operating at lower speeds.

Because total comfort cannot be ensured in an all-purpose facility, the designer must determine the level of discomfort that can be tolerated, or at least the type of performances for which the facility is primarily intended.

As with other assembly buildings, seating and lighting combinations are the most important load considerations. Boxing events, for example, may have the most seating, because the boxing ring area is very small. For the same reason, however, the area that needs to be intensely illuminated is also small. Thus, boxing matches may represent the largest latent load situation. Other events that present large latent loads are rock concerts and large-scale dinner dances, although the audience at a rock concert is generally less concerned with thermal comfort. Ventilation is also essential in removing smoke or fumes at car, cycle, and truck events. Circuses, basketball, and hockey have a much larger arena area and less seating. The sensible load from lighting the arena area improves the sensible heat ratio. The large expanse of ice in hockey games considerably reduces both latent and sensible loads. High latent loads caused by occupancy or ventilation can create severe problems in ice arenas such as condensation on interior surfaces and fog. Special attention should be paid to the ventilation system, air distribution, humidity control, and construction materials. See Chapter 44 of the 2018 *ASHRAE Handbook—Refrigeration* for more details on ice rinks.

Enclosed Stadiums

An enclosed stadium may have either a retractable or a fixed roof. When the roof is closed, ventilation is needed, so ductwork must be run in the permanent sections of the stadium. The large air volumes and long air throws required make proper air distribution difficult to achieve; thus, the distribution system must be very flexible and adjustable.

Some open stadiums have radiant heating coils in the floor slabs of the seating areas. Gas-fired or electric high- or low-intensity radiant heating located above the occupants is also used.

Open racetrack stadiums may present a ventilation problem if the grandstand is enclosed. The grandstand area may have multiple levels and be in the range of 400 m long and 60 m deep. The interior (ancillary) areas must be ventilated to control odors from toilet facilities, concessions, and the high population density. General practice provides about four air changes per hour for the stand seating area and exhausts air through the rear of the service areas. More efficient ventilation systems may be selected if architectural considerations allow. Window fogging is a winter concern with glass-enclosed grandstands. This can be minimized by double glazing, humidity control, moving dry air across the glass, or a radiant heating system for perimeter glass areas.

Air-supported structures require continuous fan operation to maintain a properly inflated condition. The possibility of condensation on the underside of the air bubble should be considered. The U-factor of the roof should be sufficient to prevent condensation at the lowest expected ambient temperature. Heating and air-conditioning functions can be either incorporated into the inflating system or furnished separately. Solar and radiation control is also possible through the structure's skin. Applications, though increasing rapidly, still require working closely with the enclosure manufacturer to achieve proper and integrated results.

Ancillary Spaces

The concourse areas of arenas and stadiums are heavily populated during entrance, exit, and intermission periods. Considerable odor is generated in these areas by food, drink, and smoke, requiring considerable ventilation. If energy conservation is an important factor, consider using carbon filters and controllable recirculation rates. Concourse area air systems should be evaluated for their flexibility in returning or exhausting air, and the economics of this type of flexibility should be evaluated with regard to the associated problem of air balance and freeze-up in cold climates.

Ticket offices, restaurants, and similar facilities are often expected to be open during hours that the main arena is closed; therefore, separate systems should be considered for these areas.

Locker rooms require little treatment other than excellent ventilation, usually not less than 10 to 15 L/s per square metre. To reduce the outdoor air load, excess air from the main arena or stadium may be transferred into the locker rooms. However, reheat or recooling by water or primary air should be considered to maintain the locker room temperature. To maintain proper air balance under all conditions, locker rooms should have separate supply and exhaust systems.

Ice Rinks

See Chapter 44 of the 2018 *ASHRAE Handbook—Refrigeration* for ice sheet design information. When an ice rink is designed into the facility, the concerns of groundwater conditions, site drainage, structural foundations, insulation, and waterproofing become even more important, with the potential of freezing soil or fill under the floor and subsequent expansion. The rink floor may have to be strong enough to support heavy trucks. The floor insulation also must be strong enough to take this load. Ice-melting pits of sufficient size with steam pipes may have to be furnished. If the arena is to be air conditioned, consider combining the air-conditioning system with the ice rink system, although the designer should be aware that both systems operate at vastly different temperatures and have considerably different operation profiles. The radiant effects of the ice on the people and of heat from the roof and lights on the ice must be considered in the system's design and operation. Low air velocities at the ice sheet level help minimize the refrigeration load. Conversely, high air velocities cause the ice to melt or sublimate.

Fog forms when moisture-laden air cools below its dew point. This is most likely to occur close to the ice surface within the boarded area (playing area). Fog can be controlled by reducing the indoor dew point with a dehumidification system or high-latent-capacity air-conditioning system and by delivering appropriate air velocities to bring the air in contact with the ice. Air-conditioning systems have had limited success in reducing the dew-point temperature sufficiently to prevent fog. The section on Ice Rink Dehumidifiers in Chapter 25 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* has more information on fog control.

The type of lighting used over ice rinks must be carefully considered when using precooling before hockey games and between periods. Main lights should be able to be turned off, if feasible. Incandescent lights require no warm-up time and are more applicable than types requiring warm-up. Low-emissivity ceilings with reflective characteristics successfully reduce condensation on roof structures; they also reduce lighting and, consequently, the cooling requirements.

Gymnasiums

Smaller gymnasiums, such as those in schools, are miniature versions of arenas and often have multipurpose features. For further information, see Chapter 8.

Many school gymnasiums are not air conditioned. Low-intensity perimeter radiant heaters with central ventilation supplying four to six air changes per hour are effective and energy efficient. Unit heaters on the ceiling are also effective. Ventilation must be provided because of high activity levels and resulting odors.

Most gymnasiums are located in schools. However, public and private organizations and health centers may also have gymnasiums. During the day, gymnasiums are usually used for physical activities, but in the evening and on weekends, they may be used for sports events, social affairs, or meetings. Thus, their activities fall within the scope of those of a civic center. More gymnasiums are being considered for air conditioning to make them more suitable for civic center activities. Design criteria are similar to arenas and civic centers when used for such activities. However, for schooltime use, space temperatures are often kept between 18 and 20°C during the heating season. Occupancy and the degree of activity during daytime use do not usually require high quantities of outdoor air, but if used for other functions, system flexibility is required.

5. CONVENTION AND EXHIBITION CENTERS

Convention and exhibition centers schedule diverse functions similar to those at arenas and stadiums and present a unique challenge to the designer. The center generally is a high-bay, long-span space, and can change weekly, for example, from an enormous computer room into a gigantic kitchen, large machine shop, department store, automobile showroom, or miniature zoo. They can also be the site of gala banquets or used as major convention meeting rooms.

Income earned by these facilities is directly affected by the time it takes to change from one activity to the next, so highly flexible utility distribution and air-conditioning equipment are needed.

Ancillary facilities include restaurants, bars, concession stands, parking garages, offices, television broadcasting rooms, and multiple meeting rooms varying in capacity from small (10 to 20 people) to large (hundreds or thousands of people). Often, an appropriately sized full-scale auditorium or arena is also incorporated.

By their nature, these facilities are much too large and diverse in their use to be served by a single air-handling system. Multiple air handlers with several chillers can be economical.

Load Characteristics

The main exhibition room is subject to a variety of loads, depending on the type of activity in progress. Industrial shows provide the highest sensible loads, which may have a connected capacity of 215 W/m^2 along with one person per 3.7 to 4.6 m^2. Loads of this magnitude are seldom considered because large power-consuming equipment is rarely in continuous operation at full load. An adequate design accommodates (in addition to lighting load) about 108 W/m^2 and one person per 3.7 to 4.6 m^2 as a maximum continuous load.

Alternative loads of very different character may be encountered. When the main hall is used as a meeting room, the load will be much more latent. Thus, multispeed fans or variable-volume systems may provide a better balance of load during these high-latent, low-sensible periods of use. Accurate occupancy and usage information is critical in any plan to design and operate such a facility efficiently and effectively.

System Applicability

The main exhibition hall is normally handled by one or more all-air systems. This equipment should be able to operate on all outdoor air, because during set-up, the hall may contain highway-size trucks bringing in or removing exhibit materials. There are also occasions when the space is used for equipment that produces an unusual amount of fumes or odors, such as restaurant or printing industry displays. It is helpful to build some flues into the structure to duct fumes directly to the outdoors. Perimeter radiant ceiling heaters have been successfully applied to exhibition halls with large expanses of glass.

Smaller meeting rooms are best conditioned either with individual room air handlers, or with variable-volume central systems, because these rooms have high individual peak loads but are not used frequently. Constant-volume systems of the dual- or single-duct reheat type waste considerable energy when serving empty rooms, unless special design features are incorporated.

Offices and restaurants often operate for many more hours than the meeting areas or exhibition areas and should be served separately. Storage areas can generally be conditioned by exhausting excess air from the main exhibit hall through these spaces.

6. FAIRS AND OTHER TEMPORARY EXHIBITS

Occasionally, large-scale exhibits are constructed to stimulate business, present new ideas, and provide cultural exchanges. Fairs of this type take years to construct, are open from several months to several years, and are sometimes designed considering future use of some buildings. Fairs, carnivals, or exhibits, which may consist of prefabricated shelters and tents that are moved from place to place and remain in a given location for only a few days or weeks, are not covered here because they seldom require the involvement of architects and engineers.

Design Concepts

One consultant or agency should be responsible for setting uniform utility service regulations and practices to ensure proper organization and operation of all exhibits. Exhibits that are open only during spring or fall months require a much smaller heating or cooling plant than those open during peak summer or winter months. This information is required in the earliest planning stages so that system and space requirements can be properly analyzed.

Occupancy

Fair buildings have heavy occupancy during visiting hours, but patrons seldom stay in any one building for a long period. The length of time that patrons stay in a building determines the air-conditioning design. The shorter the anticipated stay, the greater the leeway in designing for less-than-optimum comfort, equipment, and duct layout. Also, whether patrons wear coats and jackets while in the building influences operating design conditions.

Equipment and Maintenance

Heating and cooling equipment used solely for maintaining comfort and not for exhibit purposes may be secondhand, if available and of the proper capacity. Another possibility is to rent the air-conditioning equipment to reduce the capital investment and eliminate disposal problems when the fair is over.

Depending on the size of the fair, length of operation time, types of exhibitors, and fair sponsors' policies, it may be desirable to compare using a centralized heating and cooling plant versus individual plants for each exhibit. The proportionate cost of a central plant to each exhibitor, including utility and maintenance costs, may be considerably less than having to furnish space and plant utility and maintenance costs. The larger the fair, the more savings may result. It may be practical to make the plant a showcase, suitable for exhibit and possibly added revenue. A central plant may also form the nucleus for commercial or industrial development of the area after the fair is over.

If exhibitors furnish their own air-conditioning plants, it is advisable to analyze shortcuts that may be taken to reduce equipment space and maintenance aids. For a 6-month to 2-year maximum operating period, for example, tube pull or equipment removal space is not needed or may be drastically reduced. Higher fan and pump motor power and smaller equipment are permissible to save on initial costs. Ductwork and piping costs should be kept as low as possible because these are usually the most difficult items to salvage; cheaper materials may be substituted wherever possible. The job must be thoroughly analyzed to eliminate all unnecessary items and reduce all others to bare essentials.

The central plant may be designed for short-term use as well. However, if it is to be used after the fair closes, the central plant should be designed in accordance with the best practice for long-life plants. It is difficult to determine how much of the piping distribution system can be used effectively for permanent installations. For that reason, initial piping design should be simple, preferably in a grid, loop, or modular layout, so that future additions can be made easily and economically.

Air Cleanliness

The efficiency of filters needed for each exhibit is determined by the nature of the area served. Because the life of an exhibit is very short, it is desirable to furnish the least expensive filtering system. If possible, one set of filters should be selected to last for the life of the exhibit. In general, filtering efficiencies do not have to exceed 30% (see ASHRAE *Standard* 52.1).

System Applicability

If a central air-conditioning plant is not built, equipment installed in each building should be the least costly to install and operate for the life of the exhibit. These units and systems should be designed and installed to occupy the minimum usable space.

Whenever feasible, heating and cooling should be performed by one medium, preferably air, to avoid running a separate piping and radiation system for heating and a duct system for cooling. Air curtains used on an extensive scale may, on analysis, simplify building structure and lower total costs.

Another possibility when both heating and cooling are required is a heat pump system, which may be less costly than separate heating and cooling plants. Economical operation may be possible, depending on building characteristics, lighting load, and occupant load. If well or other water is available, it may allow a more economical installation than an air-source heat pump.

7. ATRIUMS

Atriums have diverse functions and occupancies. An atrium may (1) connect buildings; (2) serve as an architectural feature, leisure space, greenhouse, and/or smoke reservoir; and (3) afford energy and lighting conservation. The temperature, humidity, and hours of usage of an atrium are directly related to those of the adjacent buildings. Glass window walls and skylights are common. Atriums are generally large in volume with relatively small floor areas. The temperature and humidity conditions, air distribution, impact from adjacent buildings, and fenestration loads to the space must be considered in the design of an atrium.

Perimeter radiant heating (e.g., overhead, wall finned-tube, floor, or combinations thereof) is commonly used for expansive glass windows and skylights. Air-conditioning systems can heat, cool, and control smoke. Distribution of air across windows and skylights can also control heat transfer and condensation. Low supply and high return air distribution can control heat stratification, as well as wind and stack effects. Some atrium designs include a combination of high/low supply and high/low return air distribution to control heat transfer, condensation, stratification, and wind/stack effects.

The energy use of an atrium can be reduced by installing double- and triple-panel glass and mullions with thermal breaks, as well as shading devices such as external, internal, and interior screens, shades, and louvers.

Extensive landscaping is common in atriums. Humidity levels are generally maintained between 10 and 35%. Hot and cold air should not be distributed directly onto plants and trees.

CHAPTER 6

INDOOR SWIMMING POOLS

Design Components 6.1
Design Issues 6.2

INDOOR pools are challenging facilities to get right. When designing a structure to enclose a swimming pool, it is necessary to completely understand what is happening inside the structure to properly control the indoor atmosphere for occupancy comfort, occupancy health, and structure preservation. A holistic, integrated approach to design is needed to ensure a successful outcome.

This chapter addresses the needs of both the architectural design team and the mechanical HVAC design team. Architectural aspects are included because the building envelope must be designed to be suitable for this high-dew-point application. Some aspects of the envelope design must be approached in a certain way because the mechanical system cannot solve the problems they cause.

Many owners, designers, and facility operators are under the misconception that a properly designed HVAC system can clean the air when chloramine odors become an issue and can make condensation issues go away. This is not the case. If chemicals are offgassing, the source of the problem (water chemistry) must be addressed. If the building envelope is not designed correctly and appropriately for this application, there will be condensation and building degradation issues. The HVAC system can influence these issues either positively or negatively, but will not resolve the issues.

The HVAC system and the water treatment system are critical to the success of the facility. These systems must all work together to provide the best indoor air and water quality in the facility. If one of these systems is compromised in any way, the other system will be affected and cannot correct the issue caused by the shortcomings of the other system.

The owner and design team must put occupant health and safety first, and this requires budgeting for a suitable building HVAC system and water treatment system. Compromises directly affect aspects of the facility. Bad air quality, condensation, and building degradation negatively affect the facility's economic viability by increasing operating and maintenance costs while possibly reducing patron memberships. Although most mechanical systems can be applied in any geographic location, some systems or combination of technology may work better than others.

For both engineers and architects, the key to understanding indoor pools is understanding that this is a high-dew-point application. The elevated dew point affects every aspect of this facility. This chapter reviews the implications of this higher dew point, how to calculate loads, and best practices for best possible occupant comfort and satisfaction.

1. DESIGN COMPONENTS

Environmental Control

Like most indoor spaces, a natatorium requires year-round humidity levels between 40 and 60% for comfort, reasonable energy consumption, and building envelope protection. However, space temperatures are generally 5 to 8 K warmer in a natatorium than in a traditional space, and this drives up the dew point. To minimize operating costs, it is recommended the humidity levels be allowed to go to the high end in summer, only trying to keep humidity levels lower in winter. The designer must address humidity control, room pressure control, ventilation requirements for air quality (outdoor and exhaust air), air distribution, duct design, pool water chemistry, and evaporation rates. A humidity control system alone will not provide satisfactory results if any of these items are overlooked. (See Chapter 25 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for dehumidifier application and design information.)

Air Quality Control

Many critical items affect a natatorium's indoor air quality (IAQ). The design team must work with all trades associated with the pool to ensure a complete system design is in place for the best possible air quality. Chloramine reduction and control are critical aspects; source capture exhaust, secondary disinfection, UV, and other technology to reduce or remove chloramines are at least as important as the HVAC aspects of the design. The HVAC system must effectively get air where it is needed. A stratified room or areas that do not get air turnover will suffer.

Humidity Control

When wet, people become more sensitive to relative humidity and experience an evaporative cooling effect on the skin surface. Fluctuations in relative humidity outside the 50 to 60% range are not recommended. Sustained levels above 60% can promote factors that reduce indoor air quality. Relative humidity levels below 50% significantly increase the facility's energy consumption. For swimmers, 50 to 60% rh limits evaporation and corresponding heat loss from the body and is comfortable without being extreme. Higher relative humidity levels can be destructive to building components. Mold and mildew can attack wall, floor, and ceiling coverings, and condensation can degrade many building materials. In the worst case, the roof structure could fail because of corrosion from water condensing on the structure

There are three approaches to humidity control for indoor pools: compressorized, chilled-water coil and ventilation. All are viable options, but must be fully evaluated to understand what they will provide for year-round control. Geography and patron expectations will factor significantly in on whether or not a ventilation only approach might be considered. Ventilation supplemented with a compressor or chilled water coil are also sometimes considered. See Chapter 25 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for details on the compressorized dehumidifiers available.

Temperature Control

The relation between temperature and humidity determines evaporation from the pool water surface and the space's condensation dew point. To minimize evaporation and operating costs, the air temperature should be kept as warm as is practical, ideally at or above the water temperature, with a maximum of 30°C db, which is generally understood to the maximum for human comfort. All surfaces in the space must be maintained above the space dew point to prevent condensation from developing that could damage the building and allow growth of mold and fungi.

The preparation of this chapter is assigned to TC 9.8 Large Building Air-Conditioning Applications.

Vapor Migration

A pool's indoor design dew point typically ranges from 16 to 20°C for ambient conditions of 28 to 29°C and 50 to 60% rh. In comparison, a typical space in winter might be 21°C at 40% rh with a 7°C dew point.

In summer, the 16 to 20°C space dew point is not a condensation concern. The vapor pressure outdoors might be a little higher than it is indoors, but if the vapor migrates through the building envelope, it is too warm for condensation to occur.

The serious concern is in winter, when the indoor vapor pressure is significantly higher than it is outdoors and there is a push from indoors to outdoors to try to equalize pressure. If the vapor is allowed to migrate through the wall, it will encounter a temperature at or below dew point. Condensation or freezing will result, and the structure's integrity will be negatively affected.

Building Pressurization

The balance between ventilation air and exhaust air must be controlled at all times. A pool room space must always be maintained with a negative pressure to prevent moisture and odors from migrating to other parts of the building. A positively pressurized indoor pool can accelerate building damage by pushing the high-moisture-content air into the building envelope. Note that a significant negative space pressure will not reduce or affect vapor migration to the outdoors in winter.

Ventilation Air

Ventilation air should be calculated as the minimum amount recommended in the current ASHRAE *Standard* 62.1. The effect of exceeding these amounts must be reviewed to compensate for any additional moisture being introduced to the space and any effects on increased evaporation, human comfort, and space operating costs.

Exhaust Air

Exhaust air must always be in amounts greater than the ventilation air to maintain negative pressure, but the amount by which exhaust must exceed ventilation depends on building tightness. Strategic exhaust has a positive influence on IAQ. Low exhaust air at or near the surface of the pool water surface should also be evaluated to assist in evacuating any chloramines from the space. This exhaust air is rich in energy, and heat recovery is highly recommended to help reduce operating costs.

Location of Mechanical Equipment

The location of mechanical and electrical equipment rooms affects the degree of sound attenuation treatment required.

2. DESIGN ISSUES

Condensation (water vapor changing from gaseous to liquid state) is the major issue for indoor swimming pools. Both visible and concealed condensation must be prevented. To understand how this happens, a basic familiarity with psychometrics is necessary. The following five terms are commonly encountered when dealing with a psychometric chart (Figure 1):

- **Dry bulb (db) temperature** is the sensible temperature of the air (i.e., what can be read from a common thermometer).
- **Wet-bulb (wb) temperature** is taken by surrounding the sensor with a wet wick and measuring the temperature as the water evaporates from the wick. As the water evaporates from the wick, it draws heat required for evaporation from the thermometer bulb, cooling the thermometer in proportion to the amount of evaporation.
- **Dew-point (dp) temperature** is the temperature at which moisture condenses and forms visible water. The colder the air, the less moisture it can hold.

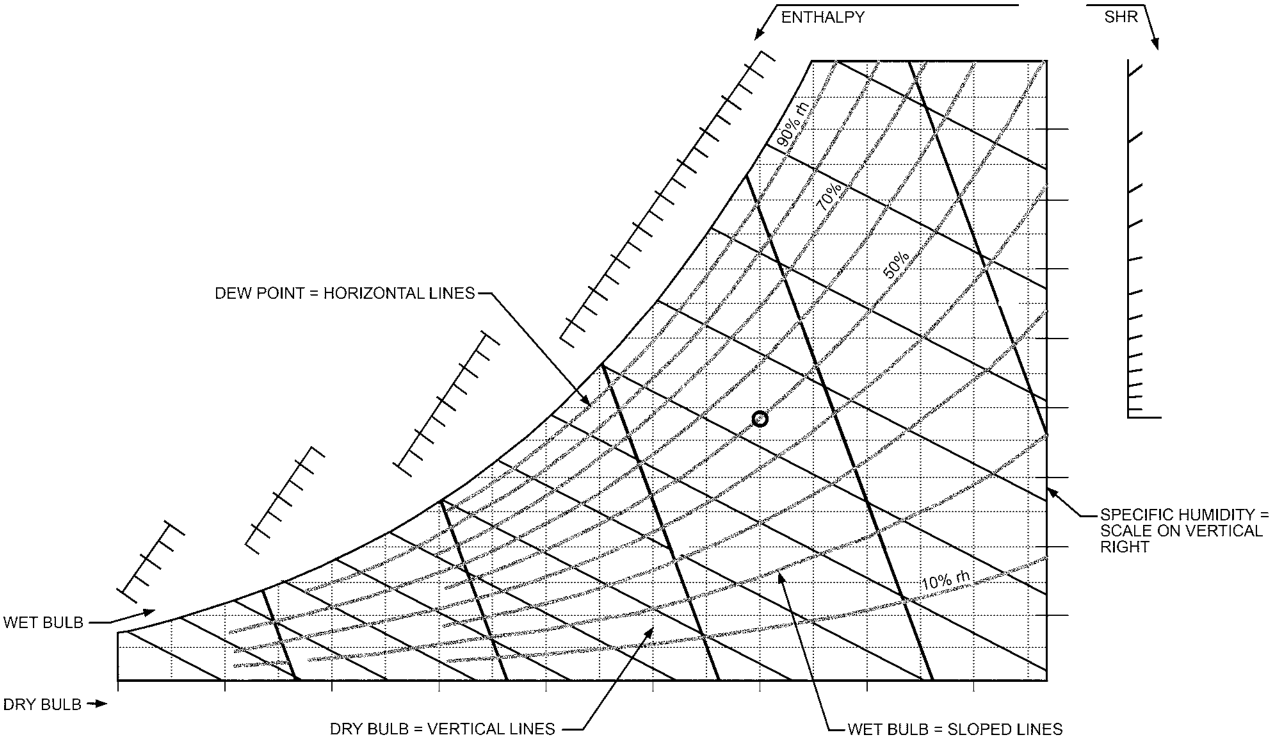

Fig. 1 Example Psychrometric Chart

- **Relative humidity (rh)** expresses the moisture content of air as a percentage of saturation.
- **Specific humidity** is the mass of the moisture in the air compared to the mass of air.

A complete understanding of dew point is important. Figure 2 shows three stages of moisture condensation from the air:

- In Figure 2A, the surface of the glass is clear. This means the glass temperature is above the dew-point temperature.
- In Figure 2B, water is starting to form on the surface of the glass, so the glass temperature is at the dew point.
- In Figure 2C, the glass surface is below the dew point and condensate has formed on the surface.

Without proper understanding and control of dew point and condensation, moisture can form on the indoor and outdoor surfaces of the structure. Figure 3 shows examples of moisture formation and the results.

In a typical indoor pool, indoor temperature ranges from 25.6 to 30°C db. Figure 4 shows three plotted curves with values derived from the psychometric chart. This graph allows plotting the dew-point temperature at indoor temperatures of 28°C db, 29°C db, and 30°C db and relative humidity values from 30 to 60%. An example is shown at 29°C db and 50% rh, showing that the dew point is 18°C.

This example shows that all surfaces inside the pool room must be kept above the dew-point temperature of 18°C to prevent visible condensation. Common design practice adds 3 K to this temperature as a safety factor.

The architect's responsibility is to design wall and ceiling components with this surface temperature in mind, to assist the HVAC design engineer in preventing moisture from forming inside the structure.

Equation (1) calculates the surface temperature of a structural component:

$$T_s = T_i - [K(1/R)(T_i - T_o)] \tag{1}$$

where

T_s = surface temperature
T_i = indoor space temperature
K = indoor air film coefficient; 0.68 for vertical surface, 0.95 for horizontal roof or skylight, 0.76 for 45° roof or skylight
R = total R-value of structural component
T_o = outdoor temperature

Fig. 2 Stages of Moisture Condensation on Glass
(Courtesy Desert-Aire Corp)

Fig. 3 Structural Damage Caused by Condensation
(Courtesy Desert-Aire Corp)

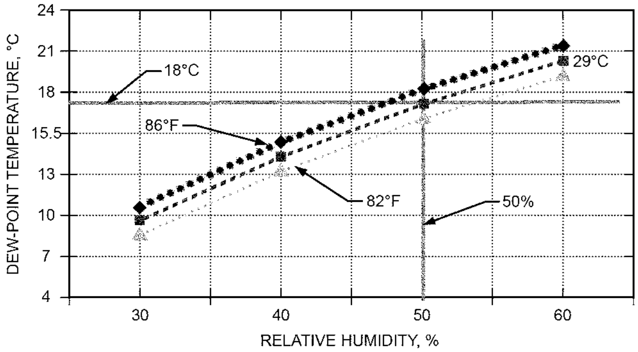

Fig. 4 Condensation Dew Point Chart

Fig. 5 Condensation on Windows: Glass Surface Is below Space Dew Point

To apply Equation (1) to a window, the published window U-factor (see Chapter 15 of the 2017 *ASHRAE Handbook—Fundamentals*) must be converted to the required R-value; for example,

$$R = 1/U = 1/0.4 = 2.5$$

In this example, the indoor temperature is 29°C db and the outdoor temperature is –18°C db. This gives a 16.2°C surface temperature on the window. If the indoor space is at 50% rh, the dew point would be 17.8°C, which would lead to condensation on the glass surface unless the window glass is heated above the dew point (Figure 5).

Figure 6 plots three indoor conditions and several window U-values at different outdoor temperatures: –4°C, –18°C, and –32°C. The left vertical axis shows the relative humidity at which condensation will occur: whenever the indoor relative humidity exceeds these values at the given outdoor condition, condensation will form on the window surface unless the window surface is warmed above the indoor dew point.

Note that, as outdoor conditions get colder, the surface temperature of the glass drops dramatically and eventually attempts to eliminate condensation by reducing the space dew point are not realistic.

Outdoor Air

Outdoor air ventilation rates (as prescribed by ASHRAE *Standard* 62.1) can be a major portion of the total load. The latent load (dehumidification and humidification) and energy used to maintain relative humidity within prescribed limits are also concerns.

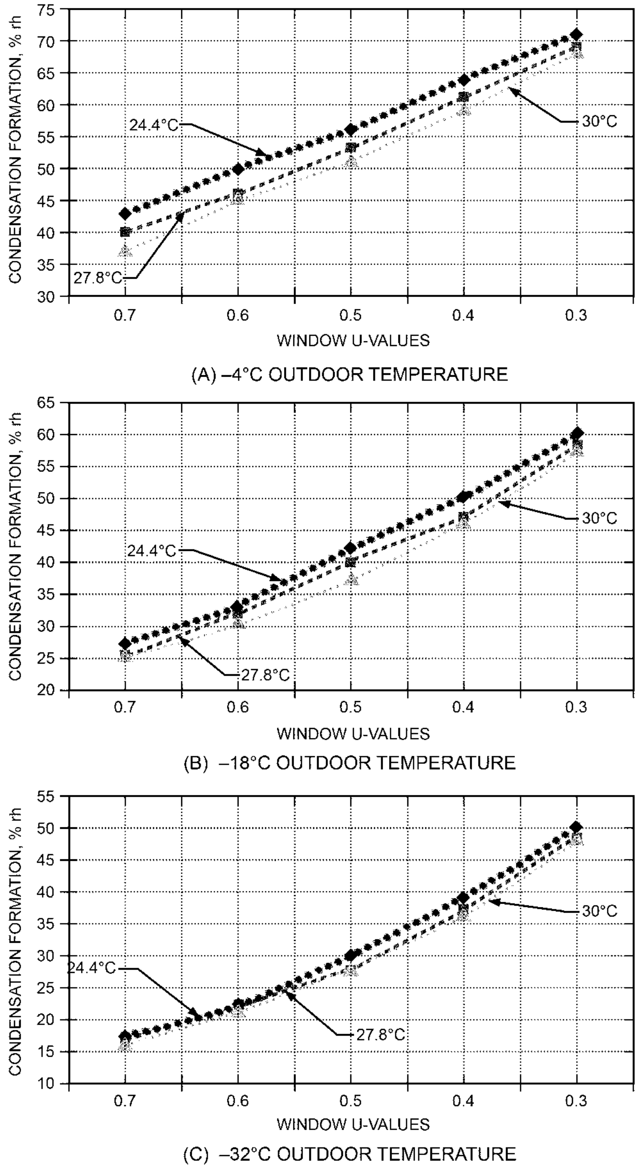

Fig. 6 Effects of U-Values and Indoor and Outdoor Temperatures on Dew Point

Humidity must be maintained at proper levels to prevent mold and mildew growth and for acceptable indoor air quality and comfort.

Load Estimation

Loads for a natatorium include heat gains and losses from outdoor air, lighting, walls, roof, and glass. Internal latent loads are generally from people and evaporation. Evaporation loads in pools and spas are significant relative to other load elements and may vary widely depending on pool features, areas of water and wet deck, water temperature, and activity level in the pool.

Evaporation. The rate of evaporation can be estimated from empirical Equation (2). This equation is valid for pools at normal activity levels, allowing for splashing and a limited area of wetted deck. Other pool uses may have more or less evaporation (Smith et al. 1993).

Table 1 Typical Activity Factors for Various Pool Feature Types

Type of Pool	Typical Activity Factor (F_a)
Baseline (pool unoccupied)	0.5
Residential pool	0.5
Condominium	0.65
Therapy	0.65
Hotel	0.8
Public, schools	1.0
Whirlpools, spas	1.0
Wavepools, water slides	1.5 (minimum)

$$w_p = \frac{A}{Y}(p_w - p_a)(0.089 + 0.0782V) \qquad (2)$$

where

w_p = evaporation of water, kg/s
A = area of pool surface, m^2
Y = latent heat required to change water to vapor at surface water temperature, kJ/kg
p_w = saturation vapor pressure taken at surface water temperature, kPa
p_a = saturation pressure at room air dew point, kPa
V = air velocity over water surface, m/s

Units for the constant 0.089 are W/(m^2·Pa). Units for the constant 0.0782 are (W·s)/(m^3·Pa).

Equation (2) may be modified by multiplying it by an activity factor F_a to alter the estimate of evaporation rate based on the level of activity supported. For Y values of about 2400 kJ/kg and V values ranging from 0.05 to 0.15 m/s, Equation (2) can be reduced to

$$w_p = 4 \times 10^{-5} A(p_w - p_a)F_a \qquad (3)$$

Table 1 lists activity factors that should be applied to the areas of specific features, and not to the entire wetted area.

The effectiveness of controlling the natatorium environment depends on correct estimation of water evaporation rates. Applying the correct activity factors is extremely important in determining water evaporation rates. The difference in peak evaporation rates between private pools and active public pools of comparable size may be more than 100%.

Actual operating temperatures and relative humidity conditions should be established before design. How the area will be used usually dictates design (Table 2).

Air temperatures in public and institutional pools are recommended to be maintained 1 to 2 K above the water temperature (but not above the comfort threshold of 30°C) for energy conservation through reduced evaporation and to avoid chill effects on swimmers.

Competition pools that host swim meets have two distinct operating profiles: (1) swim meets and (2) normal occupancy. It is recommended that both be fully modeled to evaluate the facility's needs. Although swim meets tend to be infrequent, the loads during meets are often considerably higher than during normal operations. To model the swim meet load accurately, it is recommended that the designer know the number of spectators, number of swimmers on the deck, and operating conditions required during the meets. The operator may request a peak relative humidity of 55%, which has a significant effect on total loads. A system designed for swim meet loads should also be designed to operate for considerable portions of the year at part loads. Depending on the layout of the space and location of the spectator gallery, it might be beneficial to provide a separate microclimate to that area, with a separate dedicated unit.

Water parks and water feature (slides, spray cannons, arches, etc.) loads are not fully covered by this chapter. Use caution when evaluating the evaporation from water features/toys installed in natatoriums. Applying higher activity factors when evaluating the evaporation rates at water parks and water features/toys is only one component of accounting for this evaporation. Currently the design professional must rely on experience and professional judgment when calculating the evaporation in water parks and from the water features/toys.

Table 2 Typical Natatorium Design Conditions

Type of Pool	Air Temperature, °C	Water Temperature, °C	Relative Humidity, %
Recreational	24 to 29	24 to 29	50 to 60
Therapeutic	27 to 29	29 to 35	50 to 60
Competition	26 to 29	24 to 28	50 to 60
Diving	27 to 29	27 to 32	50 to 60
Elderly swimmers	29 to 32	29 to 32	50 to 60
Hotel	28 to 29	28 to 30	50 to 60
Whirlpool/spa	27 to 29	36 to 40	50 to 60

It is recommended that the dehumidification load generated by each water feature be calculated individually. The water toys' manufacturers should be contacted to provide specifications related to the pattern and size of the sheet of water that is generated by each water feature/toy to allow for proper load determination. The wet area created by the water toy/feature must be included as wet deck when calculating the ventilation air required for the space as well as the wetted surface for the evaporation load. Because of the concentrated nature of the loads in these facilities, it is recommended that more supply air and outdoor air be used in these facilities compared to what is recommended for traditional pools.

Ventilation Requirements

Air Quality. Outdoor air ventilation rates prescribed by ASHRAE *Standard* 62.1 are intended to provide acceptable air quality conditions for the average pool (where chlorine is used for primary disinfection). The ventilation requirement may be excessive for private pools and installations with low use, and may also prove inadequate for high-occupancy public or water park installations.

Air quality problems in pools and spas are often caused by water quality problems, so simply increasing ventilation rates may prove both expensive and ineffective. Water quality conditions are a direct function of pool use and the type and effectiveness of water disinfection used.

It is recommended that the ASHRAE climate data included with Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* (full data are in the CD and Handbook Online versions of the chapter) be used when calculating the effects of ventilation air on the natatorium's latent load, as mentioned in ASHRAE *Standard* 62.1.

Because indoor pools usually have high ceilings, temperature stratification and stack effect (see Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals*) can have a detrimental effect on indoor air quality. Careful duct layout is necessary to ensure that the space receives proper air changes and homogeneous air quality throughout. Some air movement at the deck and pool water level is essential to ensure acceptable air quality. Complaints from swimmers indicate that the greatest chloramine (see the section on Pool Water Chemistry) concentrations occur at the water surface. Children are especially vulnerable to the ill effects of chloramine inhalation.

Pool and spa areas should be maintained at a negative pressure of 15 to 40 Pa relative to the outdoors and adjacent areas of the building to prevent moisture and chloramine odor migration. Active methods of pressure control may prove more effective than static balancing and may be necessary where outdoor air is used as a part of an active humidity control strategy. Openings from the pool to other areas should be minimized and controlled. Passageways should be equipped with doors with automatic closers and sweeps to inhibit migration of moisture and air.

Exhaust air from pools is rich in moisture and may contain high levels of corrosive chloramine compounds. Exhaust air intake grilles should be located as close as possible to the warmest body of water in the facility. Warmer and more agitated waters offgas chemicals at higher rates compared to traditional pools. This also allows body oils to become airborne. Ideally, these pollutants should be removed from close to the source before they have a chance to diffuse and negatively affect air quality. Installations with intakes directly above whirlpools have resulted in the best air quality.

Air Delivery Rates. Most codes require a minimum of six air changes per hour, except where mechanical cooling is used. This rate may prove inadequate for some occupancy and use.

Where mechanical dehumidification is provided, air delivery rates should be established to maintain appropriate conditions of temperature and humidity. The following rates are typically desired:

Pools areas	4 to 6 air changes per hour
Spectator areas	6 to 8 air changes per hour
Therapeutic pools	4 to 6 air changes per hour

Outdoor air delivery rates may be constant or variable, depending on design. Minimum rates, however, must adequately dilute contaminants generated by pool water and must maintain acceptable ventilation for occupancy.

Where a minimum outdoor air ventilation rate is established to protect against condensation in a building's structural elements, the rates are typically used for 100% outdoor air systems. These rates usually result in excessive humidity levels under most operating conditions and are generally not adequate to produce acceptable indoor air quality, especially in public facilities subject to heavy use. In colder/drier climates, greater amounts of outdoor air may decrease humidity levels below the recommended 40 to 60% range. This increases evaporation, adds to costs for makeup water and chemicals, and may make it difficult to maintain the proper water chemistry.

Air Distribution Effectiveness and Duct Design

Proper duct design and installation in a natatorium is critical. Failure to effectively deliver air where needed will result in air quality problems, condensation, stratification, and poor equipment performance. Ductwork that fails to deliver airflow into the breathing zone at the pool deck level and water surface, for example, will lead to air quality problems in those areas. The following duct construction practices apply to indoor pools:

- Deliver air into the breathing zone at the deck. ASHRAE *Standard* 62.1 defines the breathing zone as the area between 75 and 1800 mm from the floor level. The best quality air in the facility is what is delivered from the supply duct. That air must get to where the patrons are to ensure they are breathing the best possible quality air.
- Supply air should be directed against envelope surfaces prone to condensation (glass and doors). Air movement over the pool water surface must not exceed 15 m/s (as per the evaporation rate w_p in Equation [2]). If air movement over the water surface is increased from the standard 0.15 m/s to 0.6 m/s, the evaporation will increase by approximately 30%. Air that moves across the water surface is best handled by a source-capture-type exhaust system. Evaporation from the water surface should be evaluated using Equation (2).
- Return air inlets should be located to recover warm, humid air and return it to the ventilation system for treatment, to prevent supply air from short-circuiting and to minimize recirculation of chloramines. It is recommended that return air inlets be located both high and low. This helps prevent air stratification and ensure that incoming ventilation air reaches the breathing zone, as recommended in ASHRAE *Standard* 62.1.
- Exhaust air inlets should be located to maximize capture effectiveness and minimize recirculation of chloramines. Exhausting from directly above whirlpools is also desirable. Exhaust air should be taken directly to the outdoors, through heat recovery devices when provided.
- Duct materials and hardware must be resistant to chemical corrosion from the pool atmosphere. Stainless steels, even the 316 series, are readily attacked by chlorides and are prone to pitting. They require treatment to adequately perform in a natatorium environment. Galvanized steel and aluminum sheet metal may be used for exposed duct systems. If galvanized duct is used, steps should be taken to adequately protect the metal from corrosion. It is recommended that, at a minimum, the galvanized ducts be properly prepared and painted with epoxy-based or other durable paint suitable to protect metal surfaces in a pool environment. Note that galvannealed ductwork is easier to weld and paint than hot-dip galvanized, but galvannealed is more susceptible to corrosion if left bare. Certain types of fabric duct (airtight) with appropriate grilles sewn in are also a good choice. Buried ductwork should be constructed from nonmetallic fiberglass-reinforced or PVC materials because of the more demanding environment. Proper means of water drainage in the duct must be considered when ductwork is buried.
- Grilles, registers, and diffusers should be constructed from aluminum. They should be selected for low static pressure loss and for appropriate throws for proper air distribution.
- Filtration should be selected to provide 45 to 65% efficiencies (as defined in ASHRAE *Standard* 52.1) and be installed in locations selected to prevent condensation in the filter bank. Filter media and support materials should be resistant to moisture degradation.
- Fiberglass duct liner should not be used. Where condensation may occur, the insulation must be applied to the duct exterior.
- Air systems should be designed for noise levels listed in Table 1 of Chapter 48 (NC 45 to 50); however the room wall, floor, and ceiling surfaces should be evaluated for their reverberation times and speech intelligibility.

Envelope Design

An indoor pool is a special-application structure and requires care to ensure the entire structure is suitable for a high-dew-point application. There must be

- Enough insulation that no exterior wall or roof surface ever falls below the space dew-point temperature in cold weather.
- Effective vapor migration protections to ensure moisture from the space is prevented from migrating into any build sections (walls, roofs, joints where they meet). A vapor retarder analysis (as in Figure 10 in Chapter 27 of the 2017 *ASHRAE Handbook—Fundamentals*) should be prepared. Failure to install an effective vapor retarder results in condensation forming in the structure, and potentially serious envelope damage.
- Complete elimination of thermal bridging. Window and door frames must be thermally broken.

Figure 7 shows where the vapor retarder should be located in a wall for an indoor pool application. The vapor retarder must be on the warm side of the dew point. The entire pool enclosure (walls and ceilings) must have a vapor retarder in the correct location. Where walls join the roof or floor meet, it is especially vital to ensure there is no breach in the vapor barrier.

A properly located and installed vapor retarder is the only way to protect a structure from vapor migration and the ensuing moisture damage.

Condensation forms on exterior windows when the outdoor temperature drops below the pool room's dew point (typically between 16 and 22°C). The design goal is to keep the surface temperature of the glass and the window frames at least 2 to 3 K above the pool room's dew point. Windows must allow unobstructed air movement on indoor surfaces, and thermal break frames should be used to raise the window's indoor temperature. Avoid recessed windows and protruding window frames. Skylights are especially vulnerable and require attention to control condensation. Wall and roof vapor retarder designs should be carefully reviewed, especially at wall-to-wall and wall-to-roof junctures and at window, door, skylight, and duct penetrations.

Condensation Control

Exterior windows and doors are primary condensation concerns, so it is extremely important that supply air is focused there. Warm air from the dehumidifier keeps the window surface temperature above the dew-point temperature, which ensures that windows and exterior doors remain condensation free.

Exterior windows, exterior surfaces, and other condensation-prone areas should be blanketed with supply air (Figure 8). A good rule of thumb is 15 to 28 L/s per square metre of exterior glass. Select grilles, registers, and diffusers that deliver the required throw distance, and the specified volumetric flow rating.

Pool Water Chemistry

Failure to maintain proper chemistry in the pool water causes serious air quality problems and deterioration of mechanical systems and building components. Water treatment equipment and chemicals should be located in a separate, dedicated, well-ventilated space that is under negative pressure. Pool water treatment consists of primary disinfection, pH control, water filtration and purging, and water heating. For further information, see Kowalsky (1990).

Air quality problems are usually caused by the reaction of chlorine with biological wastes, and particularly with ammonia, which is a by-product of the breakdown of urine and perspiration. Chlorine reacts with these wastes, creating chloramines (monochloramine, dichloramine, and nitrogen trichloride) that are commonly measured as combined chlorine. Adding chemicals to pool water increases total contaminant levels. In high-occupancy pools, water contaminant levels can double in a single day of operation.

Chlorine's efficiency at reducing ammonia is affected by several factors, including water temperature, water pH, total chlorine concentration, and level of dissolved solids in the water. Because of their higher operating temperature and higher ratio of occupancy per unit water volume, spas produce greater quantities of air contaminants than pools.

The following measures have demonstrated a potential to reduce chloramine concentrations in the air and water:

- **Ozonation.** In low concentrations, ozone can substantially reduce the concentration of combined chlorine in the water. In high concentrations, ozone can replace chlorine as the primary disinfection process; however, ozone cannot remain at sufficient residual levels in the water to maintain a latent biocidal effect, so chlorine must be kept as a residual process at concentrations of 0.5 to 1.5 mg/kg.
- **Water exchange rates.** High concentrations of dissolved solids in water directly contribute to high combined chlorine (chloramine) levels. Adequate water exchange rates are necessary to prevent build-up of biological wastes and their oxidized components in pool and spa water. Conductivity measurement is an effective method to control the exchange rate of water in pools and spas to effectively maintain water quality and minimize water use. In high-occupancy pools, heat recovery may prove useful in reducing water heating energy requirements.
- **Medium-pressure UV.** Using medium-pressure UV lamps for water treatment can reduce the amount of chloramines, and should be evaluated during design. Medium-pressure UV can replace chlorine as the primary disinfection process; however, it does not remain at sufficient residual levels in the water to maintain a latent biocidal effect. Consequently, chlorine is required as a residual process at concentrations of 0.5 to 1.5 mg/kg.
- **Swimmer showers.** Requiring each swimmer to shower before entering the water helps reduce the amount of body oils released into the water, thereby reducing the amount of chloramines generated.
- **Bathroom breaks.** Facilities that require all swimmers to exit the pool every hour and visit the restrooms dramatically reduce the amount of urine introduced into the pool.

Energy Considerations

Natatoriums can be a major energy burden on facilities, so they represent a significant opportunity for energy conservation and recovery. ASHRAE *Standard* 90.1 offers some recommendations. Several design solutions are possible using both dehumidification and ventilation strategies. When evaluating a system, the seasonal space conditions and energy consumed by all elements should be considered, including primary heating and cooling systems, fan motors, water heaters, and pumps.

Operating conditions factor significantly in the total energy requirements of a natatorium. Although occupant comfort is a primary concern, the effects of low space temperatures and relative humidity levels below 50% (especially in winter) should be discussed with the owner/operator:

- Lower room air temperature or lower relative humidity increases evaporation from the pools, thus increasing dehumidification requirements and increasing pool water heating costs
- Warmer water temperatures increase evaporation from the pools, thus increasing the dehumidification requirements and increasing pool water heating costs

It is recommended to model the space on both a summer and winter design day to establish whether higher summertime indoor relative humidity level is beneficial to reducing equipment size and operating costs.

Because these facilities require considerable air movement and the supply fans operate 24/7/365, fans and equipment that uses less fan energy lead to considerable energy savings over the equipment life.

These facilities require outdoor and exhaust air. This gives the opportunity for energy recovery from the exhaust air to preheat outdoor air. The economics of a heat recovery decision should be always reviewed, regardless of the facility location: these facilities have warm indoor conditions and show good paybacks for energy recovery, even in warmer climates. A detailed evaluation of the heat exchange process must be done to ensure no condensation develops in the energy recovery device so, in cold climates, ice does not develop and damage equipment or develop an imbalance of airflow.

Compressorized systems can optionally heat pool water with compressor waste heat. The economics of this option should always be reviewed: the heating contributions can be significant and have a dramatic return on investment (ROI).

Natatoriums with fixed outdoor air ventilation rates without dehumidification generally have seasonally fluctuating space temperature and humidity levels. Systems designed to provide minimum ventilation rates without dehumidification are unable to maintain relative humidity conditions within prescribed limits, and may facilitate mold and mildew growth and be unable to provide acceptable IAQ. Peak dehumidification loads vary with activity levels and during the cooling season, when ventilation air becomes an additional dehumidification load to the space.

Design Checklist

The following items should be addressed when evaluating and designing a system for an indoor pool climate control system. This list is a minimum, and additional items can be added by the design team.

- With design team and owner/operators, identify (1) indoor space temperature, (2) water temperature, and (3) design relative humidity levels for both summer and winter.
- Obtain minimum R and U values from architect to determine minimum surface temperature for condensation.
- Include a proper vapor retarder and install it correctly with no breaks.
- Determine correct amount of ventilation air required for proper IAQ and to meet local code requirements.
- Determine correct amount of exhaust air to provide negative building pressure.
- Evaluate whether a source capture exhaust system is needed.
- Evaluate outdoor air/exhaust air energy recovery systems.
- Use correct dehumidification weather data to determine moisture load from the ventilation air.
- Total all moisture/latent loads from (1) people, (2) ventilation air, and (3) water surface.
- Total all sensible loads from (1) building envelope, (2) people, (3) ventilation air, (4) lighting, and (5) other sources.
- Select equipment to meet both sensible and latent peak loads.
- Design air distribution system to deliver air into the breathing zone and prevent air stratification and visible condensation.
- Properly commission equipment and building.
- Include a quarterly equipment maintenance contract as part of operating expense.

CHAPTER 7

HOSPITALITY

Load Characteristics 7.1
Design Concepts and Criteria 7.1
Systems 7.1
Hotels and Motels 7.3
Dormitories 7.8
Multiple-Use Complexes 7.8

HOSPITALITY SPACES, including hotels, motels, assisted living facilities, and dormitories, may be single-room or multi-room, long- or short-term dwelling (or residence) units; they may be stacked sideways and/or vertically. Information in the first three sections of the chapter is general in nature; the last three sections are devoted to the individual types of facilities. Environment and cost considerations require that these type of facilities be energy efficient and sustainable. This chapter provides advice on practices to achieve these aims.

1. LOAD CHARACTERISTICS

- Ideally, each room served by an HVAC unit should be able to be ventilated, cooled, heated, or dehumidified independently of any other room. If not, air conditioning for each room will be compromised, and personalized comfort will not be possible.
- Spaces are typically not occupied at all times. For adequate flexibility, each unit's ventilation and cooling should be able to be shut off (except when humidity control is required), and its heating to be shut off or turned down. This can be achieved by occupant detection, use of door key fobs, controls connected to reservation software, or simple-to-use manual controls such as thermostatic radiator valves (TRVs) on radiators. See Chapter 65 for details on occupant-centric controls.
- Concentrations of lighting and occupancy are variable, ranging from low for units unoccupied during the day, to high and continuous for family homes and residential elderly accommodation; activity is generally sedentary or light.
- Kitchens have the potential for high appliance loads and odor and steam generation, and have large exhaust requirements, with control from low to high, to boost air extraction to suit cooking.
- Rooms generally have an exterior exposure, with good daylight levels and a view to green features; however, kitchens, toilets, and dressing rooms are normally internal and require extract ventilation. The building as a whole usually has multiple exposures, as may many individual dwelling units. Design must optimize passive solar gains while avoiding overheating and glare.
- Toilet, washing, and bathing facilities are almost always incorporated in the dwelling units, and the modern trend is to provide bathrooms en suite for every bedroom. Exhaust air should be incorporated in each toilet and bathroom area, per ASHRAE *Standards* 62.1 and 62.2.
- Hospitality buildings have relatively high hot-water demand; generally demand is concentrated in one to two hour periods, several times a day. Demand timing can vary depending on specific building type, from a fairly moderate and consistent daily load profile in a senior citizens building to sharp, unusually high peaks at about 6:00 PM in dormitories. Hotel peak demand can also vary significantly dependent on the client base; for example, hotels connected to a convention/conference center typically have peaks similar to dormitories, while resort hotels have smaller peaks but more consistent demand for longer periods of time. Chapter 51 includes details on service water heating.
- Load characteristics of rooms, dwelling units, and buildings can be well defined with little need to anticipate future changes to design loads, other than adding a service such as cooling that may not have been incorporated originally.
- The prevalence of shifting, transient interior loads and exterior exposures with glass results in high diversity factors; the long hours of use result in fairly high load factors.

2. DESIGN CONCEPTS AND CRITERIA

Wide load swings and diversity within and between rooms require a flexible system design for 24 h comfort. Besides opening windows, the only way to provide flexible temperature control is having individual room components under individual room control that can cool, heat, and ventilate independent of equipment in other rooms.

In some climates, summer humidity becomes objectionable because of the low internal sensible loads that result when cooling is on/off controlled. Modulated cooling and/or reheat may be required to achieve comfort. Reheat should be avoided unless some sort of heat recovery is involved.

Dehumidification can be achieved by lowering cooling coil temperatures and reducing airflow or by using desiccant dehumidifiers.

Some people have a noise threshold low enough that certain types of equipment disturb their sleep. Higher noise levels may be acceptable in areas where there is little need for air conditioning. Medium- and higher-quality equipment is available with noise criteria (NC) 35 levels at 3 to 4 m in medium to soft rooms and little sound change when the compressor cycles.

Perimeter fan coils are usually more quiet than unitary systems, but unitary systems provide more redundancy in case of failure.

3. SYSTEMS

Energy-Efficient Systems

There is increased impetus to select energy-efficient systems to limit potential climate impact, conserve fossil fuel reserves, and avoid fuel poverty. In Europe, the Energy Performance Directive sets out a strategy for each European country to achieve targets toward this objective. Other countries have similar schemes. In North America, ASHRAE *Standards* 90.1 and 189.1 are setting progressive reductions also aimed zero net energy.

Where natural gas is available, gas-fired condensing boilers are used, with modulating controls linked to load monitoring such as an outdoor temperature detector.

Heating and cooling applications generally include water-source and air-source heat pumps. In areas with ample solar radiation, water-source heat pumps may be solar assisted, and/or solar thermal

The preparation of this chapter is assigned to TC 9.8, Large Building Air-Conditioning Applications.

collectors can be used. Energy-efficient equipment generally has the lowest operating cost and should be kept simple, an important factor where skilled operating personnel are unlikely to be available. Most systems allow individual operation and thermostatic control. The typical system allows individual metering so that most, if not all, of the cooling and heating costs can be metered directly to the occupant (McClelland 1983). Existing buildings can be retrofitted with heat flow meters and timers on fan motors for individual metering, and there is a drive toward providing better real-time energy use data to allow occupants to make changes that reduce their costs at judicious times.

The water-loop heat pump has a lower operating cost than air-cooled unitary equipment and allows a degree of heat recovery because the condenser water loop acts to balance energy use when possible. The lower installed cost encourages its use in mid- and high-rise buildings where individual dwelling units have floor areas of 75 m^2 or larger. Some systems incorporate sprinkler piping as the water loop.

The system has a central plant consisting of circulating pumps, heat rejection when there is surplus heat capacity in the building, and supplementary gas-fired boiler heat input when there is an overall deficit of heat. The water-loop heat pump is predominantly decentralized; individual metering allows most of the operating cost to be paid by the occupant. Its life should be longer than for other unitary systems because most of the mechanical equipment is in the building and not exposed to outdoor conditions. Also, load on the refrigeration circuit is not as severe because water temperature is controlled for optimum operation. Operating costs are low because of the system's inherent energy conservation. Excess heat may be stored during the day for the following night, and heat may be transferred from one part of the building to another.

Although heating is required in many areas during cool weather, cooling could be needed in rooms having high solar loads. This should be avoided by effective solar shading design. On a mild day, surplus heat throughout the building is frequently transferred into the hot-water loop by water-cooled condensers on cooling cycle, so that water temperature rises. The heat remains stored in the water and can be extracted at night; a water heater is therefore avoided. This heat storage is improved by the presence of a greater mass of water in the pipe loop; some systems include a storage tank for this reason, or water tank with phase-change material (PCM) thermal storage. Because the system is designed to operate during the heating season with water supplied at a temperature as low as 15°C, the water-loop heat pump lends itself to solar assist; relatively high solar collector efficiencies result from the low water temperature.

The installed cost of the water-loop heat pump is higher in very small buildings. In severe cold climates with prolonged heating seasons, even where natural gas or fossil fuels are available at reasonable cost, the operating cost advantages of this system may diminish unless heat can be recovered from some another source, such as solar collectors, geothermal, or internal heat from a commercial area served by the same system.

Energy-Neutral Systems

To qualify as energy-neutral, a system must have controls that prevent simultaneous operation of the cooling and heating cycles. Some examples are (1) packaged terminal air conditioners (PTACs) (through-the-wall units), (2) window units or radiant ceiling panels for cooling combined with finned or baseboard radiation for heating, (3) unitary air conditioners with an integrated heating system, (4) fan coils with remote condensing units, (5) variable-air-volume (VAV) systems with either perimeter radiant panel heating or baseboard heating, and (6) variable-refrigerant-flow (VRF) systems. For unitary equipment, control may be as simple as a heat/cool switch. For other types, dead-band thermostatic control may be required.

PTACs are frequently installed to serve one or two rooms in buildings with mostly small, individual units. In a common two-room arrangement, a supply plenum diverts some of the conditioned air serving one room into the second, usually smaller, room. Multiple PTAC units allow additional zoning in dwellings with more rooms. Additional radiation heat is sometimes needed around the perimeter in cold climates.

Heat for a PTAC may be supplied either by electric resistance heaters or by hot-water or steam heating coils. Initial costs are lower for a decentralized system using electric resistance heat. Operating costs are lower for coils heated by combustion fuels. Despite its relatively inefficient refrigeration circuits, a PTAC's operating cost is quite reasonable, mostly because of individual thermostatic control over each machine, which eliminates the use of reheat while preventing the space from being overheated or overcooled. Also, because equipment is located in the space being served, little power is devoted to circulating the room air. Servicing is simple: a defective machine is replaced by a spare chassis and forwarded to a service organization for repair. Thus, building maintenance can be done by relatively unskilled personnel.

Noise levels are generally no higher than NC 40, but some units are noisier than others. Installations near a seacoast should be specially constructed (usually with stainless steel or special coatings) to avoid accelerated corrosion of aluminum and steel components caused by salt. In high-rise buildings of more than 12 stories, special care is required, both in design and construction of outdoor partitions and in installation of air conditioners, to avoid operating problems associated with leakage (caused by stack effect) around and through the machines.

Frequently, the least expensive installation is finned or baseboard radiation for heating and window-type room air conditioners for cooling. The window units are often purchased individually by the building occupants. This choice offers a reasonable operating cost and is relatively simple to maintain. However, window units have the shortest equipment life, highest operating noise level, and poorest distribution of conditioned air of any systems discussed in this section.

Fan-coils with remote condensing units are used in smaller buildings. Fan-coil units are located in closets, and the ductwork distributes air to the rooms in the dwelling. Condensing units may be located on roofs, at ground level, or on balconies.

The heat recovery VRF fan-coil system has one of the lowest operating costs of all dwelling unit temperature control options, but it typically has a higher initial cost. Special design considerations must be made for refrigerant management and piping layout, outdoor air design, and serviceability/maintenance.

Low-capacity residential warm-air furnaces may be used for heating, but with gas- or oil-fired units, combustion products must be vented. In a one- or two-story structure, it is possible to use individual chimneys or flue pipes, but a high-rise structure requires a multiple-vent chimney or a manifold vent. Local codes should be consulted.

Sealed combustion furnaces draw all combustion air from, and discharge flue products through a windproof vent to, the outdoors. The unit must be located near an outer wall, and exhaust gases must be directed away from windows and intakes. In one- or two-story structures, outdoor units mounted on the roof or on a pad at ground level may also be used. All of these heating units can be obtained with cooling coils, either built-in or add-on. Evaporative-type cooling units are popular in motels, low-rise apartments, and residences in mild climates.

Desiccant dehumidification should be considered when independent control of temperature and humidity is required to avoid reheat.

Energy-Inefficient Systems

Energy-inefficient systems allow simultaneous cooling and heating. Examples include two-, three-, and four-pipe fan coil units, terminal reheat systems, and induction systems. Some units, such as the four-pipe fan coil, can be controlled so that they are energy-neutral by ensuring that the two circuits do not simultaneously serve the PTAC. They are primarily used for humidity control.

Four-pipe systems and two-pipe systems with electric heaters can be designed for complete temperature and humidity flexibility during summer and intermediate season weather, although neither provides winter humidity control. Both systems provide full dehumidification and cooling with chilled water, reserving the other two pipes or an electric coil for space heating or reheat. The equipment and necessary controls are expensive, and only the four-pipe system, if equipped with an internal-source heat-recovery design for the warm coil energy, can operate at low cost. When year-round comfort is essential, four-pipe systems or two-pipe systems with electric heat should be considered.

Total Energy Systems

A total energy system is an option for any multiple or large housing facility with high year-round service water heating requirements. Total energy systems are a form of cogeneration in which all or most electrical and thermal energy needs are met by on-site systems, as described in Chapter 7 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. A detailed load profile must be analyzed to determine the merits of using a total energy system. The reliability and safety of the heat-recovery system must also be considered.

Any of the previously described systems can perform the HVAC function of a total energy system. The major considerations, as they apply to total energy in choosing an HVAC system, are as follows:

- Optimum use must be made of thermal energy recoverable from the prime mover during all or most operating modes, not just during conditions of peak HVAC demand.
- Heat recoverable through the heat pump may become less useful because the heat required during many of its potential operating hours will be recovered from the prime mover. The additional investment for heat pump or heat recovery cycles may be more difficult to justify because operating savings are lower.
- The best application for recovered waste heat is for those services that use only heat (i.e., service hot water, laundry facilities, and space heating).

Special Considerations

Local building codes govern ventilation air quantities for most buildings. Where they do not, ASHRAE *Standards* 62.1 and 62.2 should be followed. The quantity of outdoor air introduced into rooms or corridors is usually slightly in excess of the exhaust quantities to pressurize the building. To avoid adding load to individual systems, outdoor air should be treated to conform to indoor air temperature and humidity conditions. In humid climates, special attention must be given to controlling humidity from outdoor air. Otherwise, the outdoor air may reach corridor temperature while still retaining a significant amount of moisture.

In buildings having a centrally controlled exhaust and supply, the system is regulated by a time clock or a central management system for certain periods of the day. In other cases, the outdoor air may be reduced or shut off during extremely cold periods, although this practice is not recommended and may be prohibited by local codes. These factors should be considered when estimating heating load.

For buildings using exhaust and supply air on a 24 h basis, air-to-air heat recovery devices may be merited (see Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment)*. These devices can reduce energy consumption by capturing 60 to 80% of the sensible and latent heat extracted from the air source.

Infiltration loads in high-rise buildings without ventilation openings for perimeter units are not controllable year-round by general building pressurization. When outer walls are pierced to supply outdoor air to unitary or fan-coil equipment, combined wind and thermal stack-effect forces create equipment operating problems. These factors must be considered for high-rise buildings (see Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals*).

Interior public corridors should have tempered supply air with transfer into individual area units, if necessary, to provide kitchen and toilet makeup air requirements. Transfer louvers need to be acoustically lined. Corridors, stairwells, and elevators should be pressurized for fire and smoke control (see Chapter 54).

Kitchen air can be recirculated through hoods with activated charcoal filters rather than exhausted. Toilet exhaust can be VAV with a damper operated by the light switch. A controlled source of supplementary heat in each bathroom is recommended to ensure comfort while bathing.

Air-conditioning equipment must be isolated to reduce noise generation or transmission. The cooling tower or condensing unit must be designed and located to avoid disturbing occupants of the building or of adjacent buildings.

An important but frequently overlooked load is the heat gain from piping for hot-water services. Insulation thickness should conform to the latest local energy codes and standards (at minimum). In large, luxury-type buildings, a central energy or building management system allows supervision of individual air-conditioning units for operation and maintenance.

Some facilities conserve energy by reducing indoor temperature during the heating season. Such a strategy should be pursued with caution because it could affect occupant comfort, and, consequently, the competitiveness of a hotel/motel. Local building codes may also govern occupancy control and thermostat setback requirements for dwelling units.

4. HOTELS AND MOTELS

Hotel and motel accommodations are usually single guest rooms with a toilet and bath adjacent to a corridor, flanked on both sides by other guest rooms. The building may be single-story, low-rise, or high-rise. Multipurpose subsidiary facilities range from stores and offices to ballrooms, dining rooms, kitchens, lounges, auditoriums, and meeting halls. Luxury motels may be built with similar facilities. Occasional variations are seen, such as the inclusion of kitchenettes, multiroom suites, and outer doors to patios and balconies. Hotel classes range from the deluxe hotel to the economy hotel/motel as outlined in Table 1.

A hotel can be divided into three main areas:

1. Guest rooms
2. Public areas
   - Lobby, atrium, and lounges
   - Ballrooms
   - Meeting rooms
   - Restaurants and dining rooms
   - Stores
   - Swimming pools
   - Health clubs
   - Spas
3. Back-of-the-house (BOTH) areas
   - Kitchens
   - Storage areas
   - Laundry
   - Offices
   - Service areas and equipment rooms

The two main areas of use are the guest rooms and the public areas. Maximum comfort in these areas is critical to success of any hotel. Normally the BOTH spaces are less critical than the remainder of the hotel with the exception of a few spaces where a controlled environment is required or recommended.

Table 1 Hotel Classes

Type of Facility	Typical Occupancy, Persons per Room	Characteristics
Deluxe hotel	1.2	Large rooms, suites, specialty restaurants
Luxury/first class, full-service hotel	1.2 to1.3	Large rooms, large public areas, business center, pool and health club, several restaurants
Mid-scale, full-service hotel	1.2 to 1.3	Large public areas, business center, several restaurants
Convention hotel	1.4 to 1.6	Large number of rooms, very large public areas, extensive special areas, rapid shifting of peak loads
Limited-service hotel	1.1	Limited public areas, few restaurants, may have no laundry
Upscale, all-suites hotel	2.0	Rooms are two construction bays, in-room pantries, limited public areas, few restaurants
Economy, all-suites hotel	2.0 to 2.2	Smaller suites, limited public areas and restaurants
Resort hotel	1.9 to 2.4	Extensive public areas, numerous special and sport areas, several restaurants
Conference center	1.3 to 1.4	Numerous special meeting spaces, limited dining options
Casino hotel	1.5 to 1.6	Larger rooms, large gaming spaces, extensive entertainment facilities, numerous restaurants
Economy hotel/motel	1.6 to 1.8	No public areas, little or no dining, usually no laundry

Table 2 Hotel Design Criteria[a,b]

	Indoor Design Conditions							
	Winter		Summer					
Category	Temperature	Relative Humidity[c]	Temperature	Relative Humidity	Ventilation[d]	Exhaust[e]	Filter Efficiency[f]	Noise, RC Level
Guest rooms	23 to 24°C	30 to 35%	23 to 26°C	50 to 60%	varies per room	10 to 25 L/s per room	6 to 8 MERV	25 to 35
Lobbies	20 to 23°C	30 to 35%	23 to 26°C	40 to 60%	5 L/s per person	—	8 MERV or better	35 to 45
Conference/ meeting rooms	20 to 23°C	30 to 35%	23 to 26°C	40 to 60%	3 L/s per person	—	8 MERV or better	25 to 35
Assembly rooms	20 to 23°C	30 to 35%	23 to 26°C	40 to 60%	3 L/s per person	—	8 MERV or better	25 to 35

[a] This table should not be the only source for design criteria. Data contained here can be determined from volumes of the *ASHRAE Handbook*, standards (e.g., ASHRAE *Standard* 55), and governing local codes.
[b] Design criteria for stores, restaurants, and swimming pools are in Chapters 2, 3, and 6, respectively.
[c] Minimum recommended humidity.
[d] Per ASHRAE *Standard* 62.1-2016.
[e] Air exhaust from bath and toilet area.
[f] Per ASHRAE *Standard* 52.2 (MERV = minimum efficiency reporting values).

Guest Rooms

Air conditioning in hotel rooms should be quiet, easily adjustable, and draft free. It must also provide ample outdoor air. Because the hotel business is so competitive and space is at a premium, systems that require little space and have low total owning and operating costs should be selected.

Design Concepts and Criteria. Table 2 lists design criteria for hotel guest rooms. In addition, the design criteria for hotel room HVAC services must consider the following factors:

- Individual and quickly responding temperature control
- Draft-free air distribution
- Toilet room exhaust
- Ventilation (makeup) air supply
- Humidity control
- Acceptable noise level
- Simple controls
- Reliability
- Ease of maintenance
- Operating efficiency
- Use of space

Load Characteristics. The great diversity in the design, purpose, and use of hotels and motels makes analysis and load studies very important. Load diversification is possible because of transient occupancy of guest rooms and the diversity associated with support facility operation.

The envelope cooling and heating load is dominant because the guest rooms normally have exterior exposures. Other load sources such as people, lights, appliances, etc. are a relatively small part of the space sensible and latent loads. The ventilation load can represent up to 15% of the total cooling load.

Because of the nature of the changing envelope sensible load and the transient occupancy of the guest room, large fluctuations in the space sensible load in a one-day cycle are common. The ventilation sensible cooling load can vary from 0 to 100% in a single day, whereas the ventilation latent load can remain almost constant for the entire day. A low sensible heat ratio is common in moderate to very humid climates. Usually, the HVAC equipment must only handle partial or low loads and peak loads rarely occur. For example, in humid climates, introducing untreated outdoor air directly into the guest room or into the return air plenum of the HVAC unit operating at part or low load creates a severe high-humidity problem, which is one of the causes of mold and mildew. The situation is further aggravated when the HVAC unit operates in on/off cycle during part- or low-load conditions.

Applicable Systems. Most hotels use all-water or unitary refrigerant-based equipment for guest rooms. All-water systems include

- Two-pipe fan-coils
- Two-pipe fan-coil with electric heat
- Four-pipe fan-coils

Unitary refrigerant-based systems include

- Packaged terminal air conditioner or packaged terminal heat pump (with electric heat)
- Air-to-air heat pump (ductless, split)
- Water-source heat pump
- Variable-refrigerant-flow system (heat recovery)

Except for the two-pipe fan-coil, all these systems cool, heat, or dehumidify independently of any other room and regardless of the season. A two-pipe fan-coil system should be selected only when economics and design objectives dictate that performance must be compromised. Selection of a particular system should be based on

- First cost

- Economical operation, especially at part load
- Maintainability

Compared to unitary refrigerant-based units, all-water systems offer the following advantages:

- Reduced total installed cooling capacity due to load diversity
- Lower operating cost due to a more efficient central cooling plant
- Lower noise level (compared to PTAC and water-source heat pump)
- Longer service life
- Less equipment to be maintained in the occupied space
- Less water in circulation (compared to water-source heat pump)
- Smaller pipes and pumps (compared to water-source heat pump)

Unitary refrigerant-based systems offer the following advantages:

- Lower first cost (typically)
- Immediate, all year availability of heating and cooling
- No seasonal changeover required
- Cooling available without operating a central refrigeration plant
- Can transfer energy from spaces being cooled to spaces being heated (with water-source heat pump)
- Range of circulated water temperature requires no pipe insulation (for water-source heat pump)
- Less dependence on a central plant for heating and cooling
- Simplicity, which results in lower operating and maintenance staff costs

The type of facility, sophistication, and quality desired by the owner/operator, as well as possible code requirements; typically influence the selection. An economic analysis (life-cycle cost) is particularly important when selecting the most cost-effective system. Chapter 38 has further information on economic analysis techniques. Computer software like the NIST Building Life-Cycle Cost Program (BLCC) performs life-cycle cost analyses quickly and accurately (NIST 2006).

Chapters 2, 5, 13 and 49 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provide additional information about all-water systems and unitary refrigerant-based systems.

Room fan-coils and room unitary refrigerant-based units are available in many configurations, including horizontal, vertical, exposed, and concealed. The unit should be located in the guest room so that it provides excellent air diffusion without creating unpleasant drafts. Air should not discharge directly over the head of the bed, to keep cold air away from a sleeping guest. The fan-coil/heat pump unit is most commonly located

- Above the ceiling in the guest room entry corridor or above the bathroom ceiling (horizontal air discharge),
- On the room's perimeter wall (vertical air discharge), or
- In a floor-to-ceiling enclosed chase (horizontal air discharge).

Locating the unit above the entry corridor is preferred because air can flow directly along the ceiling and the unit is relatively accessible for maintenance (see Figures 1 and 2).

Most units are designed for free-air discharge. The supply air grille should be selected according to the manufacturer's recommendations for noise and air diffusion. Also, airflow should not interfere with the room drapes or other wall treatment.

Other factors that should be considered include

- Sound levels at all operating modes, particularly with units that cycle on and off
- Adequately sized return air grille
- Access for maintenance, repair, and filter replacement

Ventilation (makeup) supply and exhaust rates must meet local code requirements. Ventilation rates vary and the load imposed by ventilation must be considered.

Providing conditioned ventilation air directly to the guest room is the preferred approach. Normally, outdoor air is conditioned in a primary makeup air unit and distributed by a primary air duct to

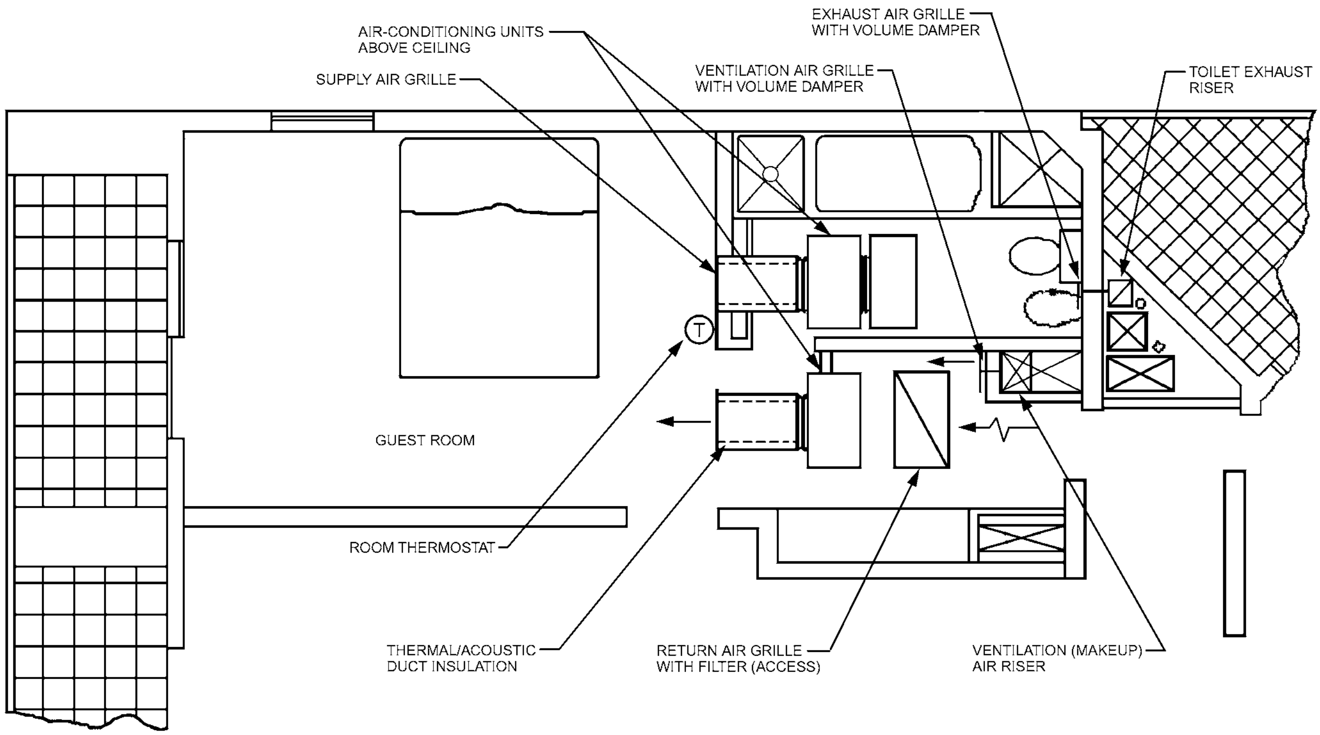

Fig. 1 Alternative Location for Hotel Guest Room Air-Conditioning Unit above Hung Ceiling

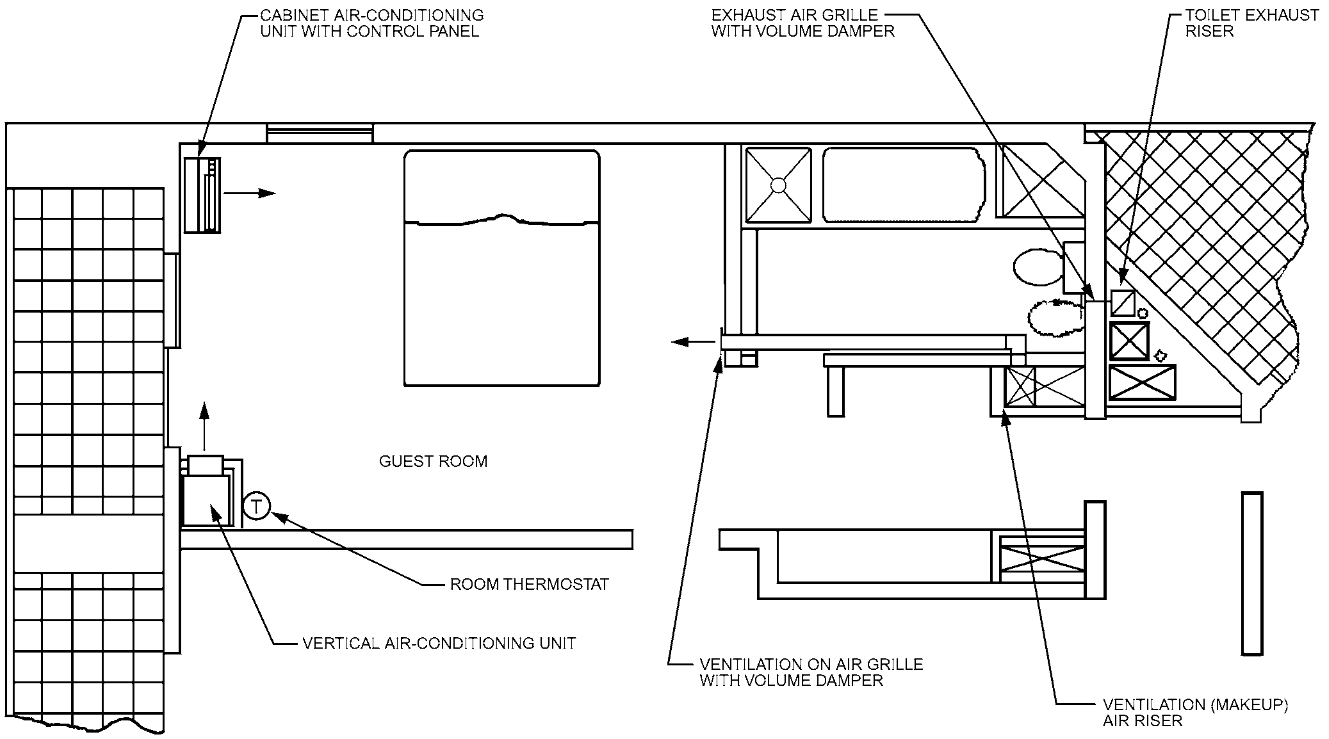

Fig. 2 Alternative Location for Hotel Guest Room Air-Conditioning Unit on Room Perimeter and Chase-Enclosed

every guest room. This approach controls the supply air conditions, ensures satisfactory room conditions and room air balance (room pressurization) even during part- or no-load conditions, and controls mold and mildew.

Other ventilation techniques are to

- Transfer conditioned ventilation air from the corridor to each guest room. This approach controls ventilation air conditions better; however, the air balance (makeup versus exhaust) in the guest room may be compromised. This approach is prohibited under many code jurisdictions.
- Introduce unconditioned outdoor air directly to the air-conditioning unit's return air plenum (perimeter wall installations). This approach can cause mold and mildew and should be avoided. During periods of part or low load, which occur during most of the cooling season, the thermostatically controlled air conditioner does not adequately condition the constant flow of outdoor air because the cooling coil valve closes and/or the compressor cycles off. As a result, humidity in the room increases. Also, when the air conditioner's fan is off, outdoor air infiltrates through the ventilation opening and again elevates the room's humidity level.

Guest-room HVAC units are normally controlled by a room thermostat. Thermostats for fan-coils normally control valves in two-pipe, four-pipe, and two-pipe chilled-water/electric heat systems. Control should include dead-band operation to separate the heating and cooling set points. Two-pipe system control valves are normally equipped with automatic changeover, which senses the water temperature and changes operation from heating to cooling. The thermostat may provide modulation or two-position control of the water control valve. The fan can be adjusted to high, medium, or low speed on most units.

Occupancy sensors, or key-card control, of the HVAC units and partial electrical load are becoming more common, and are required by many code jurisdictions. Special design considerations should be evaluated to maintain ventilation rates and prevent high humidity levels during unoccupied periods.

Typical unitary refrigerant-based units have a push button off/fan/heat/cool selector switch, adjustable thermostat, and fan cycle switch. Heat pumps include a defrost cycle to remove ice from the outdoor coil. Chapter 48 has more information on control for fan coils.

Public Areas

Public areas are generally the showcase of a hotel. Special attention must be paid to incorporating a satisfactory system into the interior design. Locations of supply diffusers, grilles, air outlets, etc. must be coordinated to satisfy the architect. The HVAC designer must pay attention to access doors for servicing fire dampers, smoke dampers, volume dampers, valves, and variable-air-volume (VAV) terminals.

Design Concepts and Criteria. Design criteria for public areas are given in Table 2. In addition, the following design criteria must be considered:

- Year-round availability of heating and cooling
- Independent unit for each main public area
- Economical and satisfactory operation at part- and low-load conditions
- Coordination with adjacent back-of-the-house (BOTH) areas to ensure proper air pressurization (e.g., restaurants, kitchens)

Load Characteristics. The hours of use vary widely with each public area. In many cases, the load is from internal sources from people, lights, and equipment. The main lobby normally is operational 24 hours per day. Areas like restaurants, meeting rooms, and retail areas have intermittent use, so the load changes frequently. HVAC systems that respond effectively and economically must be selected for these areas.

Applicable Systems. All-air systems, single-duct constant-volume, and VAV are most frequently used for public areas. Chapter

Table 3 Design Criteria for Hotel Back-of-the-House Areas[a]

Category	Indoor Design Conditions	Comments
Kitchen, general[b]	28°C	Provide spot cooling
pastry[b]	24°C	
chef's office[b]	23 to 26°C 50 to 60% rh (summer) 30 to 35% rh (winter)	Fully air conditioned
Housekeeper's office	23 to 26°C 50 to 60% rh (summer) 30 to 35% rh (winter)	Fully air conditioned
Electrical equipment room	Per equipment criteria	Stand-alone air conditioner; air conditioned all year
Wine storage	Per food and beverage manager criteria	Air conditioned all year
Laundry		Spot cooling as required at workstations

[a] Governing local codes must be followed for design of the HVAC.
[b] Consult Chapter 34 for details on kitchen ventilation.

4 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* has more information on these systems, and Chapter 48 in this volume covers control for all-air VAV systems.

Back-of-the-House (BOTH) Areas

The BOTH area normally includes service or support areas. Climatic conditions in these areas are typically less critical than in the remainder of the hotel. However, a few spaces require special attention.

Design Concepts and Criteria. Recommended design criteria for several areas in the BOTH are shown in Table 3.

Special Concerns

Humidity, Mildew, Moisture Control, and IAQ. Humidity control is critical to ensure satisfactory air quality and to minimize costly mold and mildew problems in hotels. Moisture can be introduced and infiltrate into the guest rooms in the following ways:

- Unconditioned ventilation air is delivered directly into the guest room through the HVAC unit. At part or low sensible loads or in situations where the unit cycles on and off, the air-conditioning unit will not dehumidify the air adequately to remove the excess moisture.
- Outdoor humid air infiltrates through openings, cracks, gaps. shafts, etc. because of insufficient space pressurization.
- Moisture migrates through external walls and building elements because of a vapor pressure differential.
- An internal latent load or moisture is generated.

Removing water vapor from the air is the most feasible way to control mold and mildew, particularly when the problem spreads to walls and carpeting. Good moisture control can be achieved by applying the following techniques:

- Introduce adequately dried ventilation (makeup) air (i.e., with a dew point of 11°C [8.2 g/kg of dry air] or less) directly to the guest room.
- Maintain slightly positive pressure in the guest room to minimize infiltration of hot and humid air into the room. Before a new HVAC system is accepted by the owner, a certified air balance contractor should be engaged to demonstrate that the volume of dry makeup air exceeds the volume of exhaust air. As the building ages, it is important to maintain this slight positive pressure; otherwise, humid air that infiltrates into the building cavities will be absorbed regardless of how dry the room is maintained (Banks 1992).
- Provide additional dehumidification capability to the ventilation (makeup air) by dehumidifying the air to a lower level than the desired space humidity ratio. For example, introducing 30 L/s of makeup air at 8 g/kg can provide approximately 120 W of internal latent cooling (assuming 9.5 g/kg is a desirable space humidity ratio).
- Allow air conditioning to operate in unoccupied rooms instead of turning the units off, especially in humid areas.
- Improve the room envelope by increasing its vapor and infiltration resistance.

Table 4 Design Criteria for Hotel Guest Room DOAS

Supply Air Conditions				Filter Efficiency (ASHRAE *Standard* 52.2)
Winter		Summer		
Temperature	Relative Humidity	Temperature	Relative Humidity	
20 to 24°C	30 to 45%	23 to 26°C	40 to 50%	6 to 8 MERV

Notes:
1. Follow local codes when applicable.
2. Building location may dictate optimum supply condition in recommended range.
3. MERV = minimum efficiency rating values.

The third method allows ventilation air to handle part of the internal latent load (people, internal moisture generation, and moisture migration from external walls and building elements). In addition, this method can separate the internal sensible cooling, internal latent cooling, and ventilation loads. Independent ventilation/dehumidification allows room pressurization and space humidity control regardless of the mode of operation or magnitude of the air-conditioning load. Desiccant dehumidifiers can be retrofitted to solve existing moisture problems.

Dedicated Outdoor Air Systems (DOAS). DOAS air units are designed to condition ventilation air introduced into a space and to replace air exhausted from the building. The geographic location and class of the hotel dictate the functions of the makeup air units, which may filter, heat, cool, humidify, and/or dehumidify the ventilation air. Makeup air may be treated directly or by air-to-air heat recovery (sensible or combined sensible and latent) and other heat recovery techniques. Equipment to condition the air by air-to-air heat recovery and final heating, cooling, humidification, and/or dehumidification is also available.

Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* provides design weather data for ventilation. Analyzing and selecting the proper makeup unit for the full range of air conditions are critical for efficient and sufficient all-year operation. Air-to-air heat recovery helps stabilize entering conditions, which helps provide efficient and stable operation. However, heat recovery may not always be feasible. Often, exhaust air comes from many individual stacks. In this case, the cost of combining many exhausts for heat recovery may not be warranted.

Typical design criteria for ventilation (makeup) air units are listed in Table 4.

Makeup air units can be stand alone packaged (unitary) or integrated in an air handler. A typical makeup air unit usually has the following features:

- Heating, cooling, and dehumidification
  - Chilled/hot water or steam coils in the air handling unit
  - Unitary refrigerant-based unit (direct-expansion cooling and gas furnace or electric heat)
  - Air-to-air energy recovery combined with mechanical cooling (DX or chilled water) and heating

- Desiccant-based dehumidifier combined with air-to-air energy recovery, indirect/direct evaporative cooling and supplementary mechanical cooling and heating
- Heating only
  - Hot water or steam coils in the air handling unit
  - Stand alone gas-fired or electric makeup units
  - Air-to-air energy recovery with supplement heat

Humidification should be considered for all cold climates. The HVAC designer must also consider avoiding coil freeze up in water based systems. Chapters 26 and 28 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provide information about air-to-air energy recovery and makeup air units, respectively.

Hotel location, environmental quality desired by the owner, and design sophistication determine the system selected. For example, in locations with cool summers, dehumidification with mechanical cooling only is satisfactory. For humid locations or where enhanced dehumidification is required, a desiccant-based unit can provide lower supply air humidity, to help prevent mold and mildew and provide internal latent cooling.

Central Mechanical Plant. Designing a reliable and energy-efficient mechanical plant is essential to ensuring a profitable hotel. The chiller plant must operate efficiently at part-load conditions. Some redundancy should be considered in case of equipment failure. Designs often include spare critical equipment where spare parts and qualified service are not readily available. Chillers with multistage compressors should be considered because they provide partial cooling during failures and enhance part-load operation. When using two chillers, each should provide at least 60% of the total load. Combinations of three chillers providing 40% each or four chillers providing 30% each are better for tracking part-load conditions. Cooling towers, pumps, etc., can be sized in a similar manner.

The heating plant should be designed to accommodate the winter heating load and could provide domestic hot water, swimming pool heating, and service to kitchens and laundries as well. The type of fuel used depends on location, availability, use, and cost.

Multipurpose boiler design for the kitchen and laundry should offer redundancy, effective part-load handling, and efficient operation during summer, when the HVAC heating load does not exist.

In areas with mild winters, a two-pipe system or an air-to-water heat pump chiller/heater can be considered. In any event, the HVAC designer must understand the need for all-year cooling and heating availability in the public areas. In this case, a combination of air-to-water heat pump, chiller/heater for the guest rooms, and independent heat pumps for public areas can be installed.

Acoustics and Noise Control. The sound level in guest room and public areas is a major design element. Both the level and constancy of noise generated by the HVAC are of concern. Normally, packaged terminal air conditioners/heat pumps and water-source heat pumps are noisier due to the compressor. Some equipment, however, has extra sound insulation, which reduces the noise significantly.

Lowering fan speed, which is usually acceptable, can reduce fan noise levels. On/off cycling of the fan and compressor can be objectionable, even if the generated noise is low. Temperature control by cycling the fan only (no flow control valve) should not be used.

Another source of noise is sound that transfers between guest rooms through the toilet exhaust duct. Internal duct lining and sound attenuators are commonly used to minimize this problem.

Noise from equipment located on the roof or in a mechanical room located next to a guest room should be avoided. Proper selection of vibration isolators should prevent vibration transmission. In critical cases, an acoustician must be consulted.

New Technology in Hotels. Modern hotels are implementing techniques to enhance comfort and convenience. For example, the telephone, radio, TV, communications, lighting, and air-conditioning unit can be integrated into one control system. Occupancy sensors conserve energy by resetting the temperature control when the room is occupied or when guests leave. As soon as a new guest checks in at the front desk, the room temperature is automatically reset. But even with this improved technology, it is important to remember that temperature reset may create humidity problems.

5. DORMITORIES

Dormitory buildings frequently have large commercial dining and kitchen facilities, laundering facilities, and common areas for indoor recreation and bathing. These ancillary loads may make heat pump or total energy systems appropriate, economical alternatives, especially on campuses with year-round activity.

When dormitories are shut down during cold weather, the heating system must supply enough heat to prevent freezing. If the dormitory contains nondwelling areas such as administrative offices or eating facilities, these facilities should be designed as a separate zone or with a separate system for flexibility, economy, and odor control.

Subsidiary facilities should be controlled separately for flexibility and shutoff capability, but they may share common refrigeration and heating plants. With internal-source heat pumps, this interdependence of unitary systems allows reclamation of all internal heat usable for building heating, domestic water preheating, and snow melting. It is easier and less expensive to place heat reclaim coils in the building's exhaust than to use air-to-air heat recovery devices. Heat reclaim can easily be sequence controlled to add heat to the building's chilled-water system when required.

6. MULTIPLE-USE COMPLEXES

Multiple-use complexes combine retail, office, hotel, residential, and/or other commercial spaces into a single site. Peak HVAC demands of the various facilities may occur at different times of the day and year. Loads should be determined independently for each occupancy. Where a central plant is considered, a block load should also be determined.

Separate air handling and distribution should serve separate facilities. However, heating and cooling units can be combined economically into a central plant. A central plant provides good opportunities for heat recovery, thermal storage, and other techniques that may not be economical in a single-use facility. A multiple-use complex is a good candidate for central fire and smoke control, security, remote monitoring, billing for central facility use, maintenance control, building operations control, and energy management.

THIS chapter contains technical, environmental, and design considerations to assist the design engineer in the proper application of heating, ventilation, and air-conditioning systems and equipment for educational facilities.

1. PRESCHOOLS

General Design Considerations

Commercially operated preschools are generally provided with standard architectural layouts based on owner-furnished designs. A typical preschool facility provides programs for infants (1 to 2 years old), toddlers (2 years old), and preschoolers (3 to 4 years old). Larger facilities also offer programs for older children, such as kindergarten programs (5 years old). Areas such as lobbies, libraries, and kitchens are also included to support the variety of programs. Given this range of age, special attention for the design of the HVAC systems is required to meet the needs of every age group.

All preschool facilities require quiet and economical systems. The equipment should be easy to operate and maintain, and the design should provide warm floors and no drafts. These facilities have two distinct occupant zones: (1) the floor level, where younger children play, and (2) normal adult height, for the teachers. The teacher also requires a place for a desk; consider treating this area as a separate zone.

Preschool facilities generally operate on weekdays from early in the morning to evening (6:00 or 7:00 PM). This schedule usually coincides with the normal working hours of the children's parents, plus one hour for drop-off and pick-up. The HVAC systems therefore operate 12 to 14 h per workday, and may be off or on at night and weekends, depending on whether setback is applied.

Supply air outlets should be positioned so that the floor area is maintained at about 24°C without introducing drafts. Both supply and return air outlets should be placed where they will not be blocked by furniture positioned along the walls or within reach of children. Coordination with the architect on location of these outlets is essential. Proper ventilation is crucial for controlling odors and helping prevent the spread of diseases among the children.

Floor-mounted heating equipment, such as electric baseboards heaters, should be avoided because children must be prevented from coming in contact with hot surfaces or electrical devices. However, radiant-floor systems can be used safely and effectively.

Design Criteria

Table 1 provides typical indoor design conditions for preschools. Table 2 provides typical ventilation and exhaust design criteria using the ventilation rate procedure of ASHRAE *Standard* 62.1-2016. Table 3 lists design criteria for acceptable noise in preschool facilities.

The preparation of this chapter is assigned to TC 9.7, Educational Facilities.

Table 1 Recommended Temperature and Humidity Design Criteria for Various Spaces in Preschools

	Indoor Design Conditions, °C	
Category/Humidity Criteria	**Winter**	**Summer**
Infant, toddler, and preschooler classrooms and daycare sickroom[a]		
30% rh	22.3 to 26.2	24.5 to 27.5
40% rh	22.3 to 25.8	24.3 to 27.2
50% rh	22.1 to 25.6	24.1 to 26.9
60% rh	21.87 to 25.3	23.8 to 26.7
Administrative, offices, lobby, kitchen		
30 to 60% rh	22.3 to 25.3	24.5 to 26.7
Storage		
No humidity control	17.8	
Mechanical rooms[b]		
No humidity control	16.1	

Notes:
[a]Based on *ASHRAE Thermal Comfort Tool* (ASHRAE 2010) v. 2.0.03, for people wearing typical summer and winter clothing, 0.6 and 0.9 clo, respectively, at sedentary activity (1.0 met). Air speed assumed at 0.1 m/s and mean radiant temperature (MRT) assumed equal to air temperature. Temperature range is within acceptable ASHRAE *Standard* 55 range (–0.5 < Predicted mean vote (PMV) < +0.5) using the analytical comfort zone method, section 5.3.2 of ASHRAE *Standard* 55-2017.
[b]Usually not conditioned.

Load Characteristics

Preschool cooling and heating loads depend heavily on ambient conditions, because the rooms typically have exterior exposures (walls, windows, and roofs) and relatively higher needs for ventilation. Although preschool facilities are relatively small, the design engineer must pay special attention to properly calculate the cooling, heating, dehumidification, and humidification loads. Sizing and applying the HVAC equipment is critical for handling the loads and the large amounts of outdoor air from a capacity and occurrence standpoint (peak sensible and latent loads do not always coincide).

Humidity Control

Preschool classrooms require humidity control to provide comfort and prevent health problems. Maintaining humidity levels between –1 and 15.5°C dew point satisfies nearly all people nearly all the time. However, the designer should discuss comfort expectations with the owner, to avoid misunderstandings.

In hot and humid climates, it is recommended that air conditioning and/or dehumidification be operated year-round to prevent growth of mold and mildew. Dehumidification can be improved by adding optional condenser heat/reheat coils, heat pipes, or air-to-air heat exchangers in conjunction with humidity sensors in the conditioned space or return air.

Additional information on humidity control is in the section on K-12 Schools.

Table 2 Typical Recommended Design Criteria for Ventilation and Filtration for Preschools

Category	Ventilation and Exhaust[a, g, j] Outdoor Air, L/s per Person	Occupant Density[k] per 100 m²	Outdoor Air L/(s·m²)	Outdoor Air L/s per Unit	Minimum Filtration Efficiency, MERV[h]
Infant, toddler, and preschooler classrooms and daycare sickroom[b]	8.6	25			8 to 13[l]
Administrative and office space[c]	8.5	5			6 to 8
Kitchen[d]			1.5 (exhaust)		i
Toilets[e]				25 (exhaust)	NA
Storage[f]			0.6		1 to 4

Notes:
[a]Based on ASHRAE *Standard* 62.1-2016, Table 6-2.2.1, default values for ventilation, and Table 6-5 for exhaust rates.
[b]Based on ASHRAE *Standard* 62.1-2016, Table 6-2.2.1, default values for educational facilities-daycare.
[c]Based on ASHRAE *Standard* 62.1-2016, Table 6-2.2.1, default values for office buildings/ office spaces.
[d]Based on ASHRAE *Standard* 62.1-2016, Table 6-5, for kitchenettes.
[e]Based on ASHRAE *Standard* 62.1-2016, Table 6-5, for private toilets (rate is for toilet room intended to be occupied by one person).
[f]Based on ASHRAE *Standard* 62.1-2016, Table 6-2.2.1, for storage rooms.
[g]This table should not be used as the only source for design criteria. Governing local codes, design guidelines, and ASHRAE *Standard* 62.1-2016 with current addenda *must* be consulted.
[h]MERV = minimum efficiency reporting values, based on ASHRAE *Standard* 52.2-2017.
[i]See Chapter 31 for additional information on kitchen ventilation.
[j]Consult local codes for exhaust requirements.
[k]Use default occupancy density when actual occupant density is not known.
[l]NAFA 2012

Systems and Equipment Selection

HVAC systems for preschools are typically decentralized, using either self-contained or split air-conditioners or heat pumps (typically air- or water-source). When the preschool is part of a larger facility, utilities such as chilled water, hot water, or steam from a central plant can be used. When natural gas is available, the heating system can be a gas-fired furnace, or, when economically justifiable, electric heat can be used.

The type of HVAC equipment selected also depends on the climate and the months of operation. In hot and dry climates, for instance, the primary type of cooling may be evaporative. In colder climates, heating can also be provided by a hot-water hydronic system originating from a boiler plant in conjunction with radiant floor or hot-water coils. For small, decentralized systems without central building control, a zone-level programmable temperature control is recommended (and sometimes required by local code).

Decentralized systems are dedicated systems serving a single zone, and typically include the following:

- Direct-expansion (DX) split systems and variable refrigerant flow (VRF) systems
- Rooftop packaged air conditioners or heat pumps with or without optional enhanced dehumidification (condenser reheat coil)
- Rooftop packaged air conditioners or heat pumps integrated with an energy recovery module, with optional enhanced dehumidification (condenser reheat coil; see Figure 5). Consult ANSI/ASHRAE/IESNA *Standard* 90.1-2016, section 6.5.6.1, for cases with a high percentage of outdoor air.
- Water-source heat pumps (with cooling tower and supplementary boiler)

Table 3 Typical Recommended Design Guidelines for HVAC-Related Background Sound for Preschool Facilities

Category	Sound Criteria[a, b] NC/RC	Comments
Infant, toddler, and preschooler classrooms	30	
Administrative/office areas	40	For open-plan office
Service/support areas	35 to 45

Table 4 Applicability of Systems to Typical Areas[d]

Typical Area	Decentralized Cooling/Heating Systems[c] PSZ/SZ Split/VRF[e]	PSZ with Energy Recovery and Dehumidification	WSHP	Geothermal Heat Pump	Heating Only Radiant Floor[b]
Classrooms	X[a]	X[a]	X	X	X
Administrative areas, lobby	X		X	X	
Kitchen	X		X	X	
Ventilation (outdoor air)	DOAS		DOAS	DOAS	DOAS

SZ = single zone
PSZ = packaged single zone
DOAS = dedicated outdoor air system
VRF = variable refrigerant flow
WSHP = water-source heat pump

Notes:
[a]PSZ for classrooms requires individual thermostatic control.
[b]Typically with cooling system such as PSZ/SZ split.
[c]Heating system for PSZ/SZ split can be gas furnace, hot-water coil, or electric.
[d]See Table 10 for additional systems if preschool is not a stand-alone facility.
[e]Special consideration required for risk associated with refrigerant leaks. ASHRAE *Standards* 15 and 34 should be consulted.

- Geothermal heat pumps (ground-coupled, ground-water-source, surface-water-source)
- Packaged dedicated outdoor air systems with DX system for cooling and gas-fired furnace, electric heating, or part of water-source and geothermal heat pump system

Information about decentralized systems can be found in Chapters 5, 18, 49, and 50 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Additional information on geothermal heat pumps can be found in Kavanaugh and Rafferty (1997) and Chapter 35 of this volume. Chapter 6 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides information on radiant heating.

Note that some decentralized systems may need additional acoustical modifications to meet the design criteria in Table 3. Therefore, it is strongly recommended to carefully check the acoustical implications of applying these systems.

Dedicated Outdoor Air Systems (DOASs). Specialized DOASs should be used to treat outdoor air before it is introduced into classrooms or other areas. DOAS units can bring 100% outdoor air to at least space conditions, which allows the individual space units to handle only the space cooling and heating loads. A detailed description of DOAS is provided in the K-12 Schools section of this chapter. Additional information can be found in Chapter 25 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Systems Selection by Application. Table 4 shows the applicability of systems to areas in preschool facilities.

2. K-12 SCHOOLS

General and Design Considerations

K (kindergarten)-12 schools typically include elementary, middle (junior high), and high schools. These facilities are typically one- to three-story buildings.

Elementary schools are generally comprised of 10 to 15 classrooms plus cafeteria, administration, gymnasium, and library areas. Elementary schools are usually used during the school season (late August to June); during summer, they are usually closed or have minimal activity. Current trends include science classrooms and a preschool facility. Typical elementary schools operate between 7:00 AM and 4:00 PM.

Middle schools are larger than elementary schools and include additional computer classrooms and locker rooms. A recent trend toward eliminating middle schools (retaining traditional K-8 elementary and 9-12 high schools) (Wright 2003) may require that elementary school designs incorporate some middle school features.

High schools also include a cafeteria and auditorium, and may include a natatorium, ice-skating rink, etc. High schools operate longer hours and are often open during the summer, either as a summer school or to use special facilities such as gymnasiums, natatoriums, etc.

Typical areas found in K-12 schools are shown in Table 5.

K-12 schools require an efficiently controlled atmosphere to ensure a proper learning environment. This involves the selection of HVAC systems, equipment, and controls to provide adequate ventilation and indoor air quality (IAQ), comfort, and a quiet atmosphere. The system must also be easily maintained by the facility's maintenance staff.

The following are general design considerations for each of the areas typically found in K-12 schools:

Classrooms. Classrooms typically range between 80 and 100 m^2, and are typically designed for 20 to 30 students. Each classroom should be, at a minimum, heated and ventilated. Air conditioning should be seriously considered for school districts that have year-round classes in warm, humid climates. In humid climates, seriously consider providing dehumidification during summer, even if the school is unoccupied, to prevent mold and mildew.

Science Classrooms. Science rooms are now being provided for elementary schools. Although the children do not usually perform experiments, odors may be generated if the teacher demonstrates an experiment or if animals are kept in the classroom. Under these conditions, adequate ventilation is essential along with an exhaust fan with a local, timer-based (e.g., 0 to 60 min) on/off switch for occasional removal of excessive odors.

Computer Classrooms. These rooms have a high sensible heat load because of the computer equipment. They may require additional cooling equipment such as small spot-cooling units to offset the additional load. Humidification may also be required. See Chapter 20 for additional information.

Educational Laboratories. Middle and high school laboratories and science facilities may require fume hoods with special exhaust systems. A makeup air system may be required if there are several fume hoods in a room. If there are no fume hoods, a room exhaust system is recommended for odor removal, depending on the type of experiments conducted in the room and whether animals are kept there; when applicable, a local exhaust with on/off switch and a timer can be considered. Associated storage and preparation rooms are generally exhausted continuously to remove odors and vapors emanating from stored materials. The amount of exhaust and location of exhaust grilles may be dictated by local codes or National Fire Protection Association (NFPA) standards. See Chapter 17 for further information. Additional information on laboratories can be found in ANSI/AIHA *Standard* Z9.5-2012 and McIntosh et al. (2001).

Administrative Areas. The office area should be set up for individual control because it is usually occupied during and after school hours. Because offices are also occupied before school starts in the fall, air conditioning for the area should be considered or provisions should be allowed for future upgrades.

Gymnasiums. Gyms may be used after regular school hours for evening classes, meetings, and other functions. The gym may also be used on weekends for group activities. Loads for these occasional uses should be considered when selecting and sizing the systems and equipment. Independent gymnasium HVAC systems with control capability allow for flexibility with smaller part-load conditions. If a wooden floor is installed, humidity control should be considered to avoid costly damage.

Libraries. Libraries should be air conditioned to preserve the books and materials stored in them. See Chapters 3 and 24 for additional information.

Auditoriums. These facilities require a quiet atmosphere as well as heating, ventilation, and, in some cases, air conditioning. Auditoriums are not often used, except for assemblies, practice for programs, and special events. For other considerations, see Chapter 5.

Home Economics Rooms. These rooms usually have a high sensible heat load from appliances such as washing machines, dryers, stoves, ovens, and sewing machines. Different options should be considered for exhaust of stoves and dryers. If local codes allow, residential-style range hoods may be installed over the stoves. A central exhaust system could be applied to the dryers as well as to the stoves. If enough appliances are located within the room, a makeup air system may be required. These areas should be maintained at negative pressure in relation to adjacent classrooms and administrative areas. See Chapter 34 for more information.

Cafeteria and Kitchen. Typical schools require space for preparation and serving of meals. A well-designed school cafeteria includes the following areas: loading/receiving, storage, kitchen, serving area, dining area, dishwashing, office, and staff facilities (lockers, lavatories, and toilets). Chapter 34 provides detailed information on design criteria, load characteristics, and design concepts for these facilities.

Auto Repair Shops. These facilities require outdoor air ventilation to remove odors and fumes and to provide makeup air for exhaust systems. The shop is usually heated and ventilated but not air conditioned. To contain odors and fumes, return air should not be

Table 5 Typical Spaces in K-12 Schools

supplied to other spaces, and the shop should be kept at a negative pressure relative to surrounding spaces. Special exhaust systems such as welding exhaust or direct-connected carbon monoxide exhaust systems may be required. See Chapter 33 for more information.

Industrial Shops. These facilities are similar to auto repair shops and have special exhaust requirements for welding, soldering, and paint booths. In addition, a dust collection system is sometimes provided, and the collected air is returned to the space. Industrial shops have a high sensible load from operation of the shop equipment. When calculating loads, the design engineer should consult the teacher about shop operation, and, where possible, diversity factors should be applied. See Chapter 33 for more information.

Locker Rooms. Building codes in the United States require that these facilities be exhausted directly to the outside when they contain toilets and/or showers. They are usually heated and ventilated only. These areas typically require makeup air and exhaust systems that should operate only when required. Where applicable, energy recovery systems can be considered.

Ice Rinks. These facilities require special HVAC and dehumidification systems to keep spectators comfortable, and to prevent roof condensation and fog formation at the surface. Where applicable, energy recovery systems can be considered. See Chapter 5 of this volume, Chapter 44 of the 2018 *ASHRAE Handbook—Refrigeration*, and Harriman et al. (2001) for more on these systems.

Natatoriums. These facilities, like ice rinks, require special humidity control systems. In addition, special construction materials are required. Where applicable, energy recovery systems can be considered. See Chapter 5 and Harriman et al. (2001) for more on these systems.

School Stores. These facilities contain school supplies and paraphernalia and are usually open for short periods. The heating and air-conditioning systems serving these areas should be able to be shut off when the store is closed to save energy.

Design Criteria

A typical HVAC design criteria covers parameters required for thermal comfort, indoor air quality (IAQ), and sound. Thermal comfort parameters (temperature and humidity) are covered by ASHRAE *Standard* 55-2017 and Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*. Ventilation and IAQ are covered by ANSI/ASHRAE *Standard* 62.1-2016 and Chapter 16 of the 2017 *ASHRAE Handbook—Fundamentals*. Sound and vibration are discussed in Chapter 49 of this volume and Chapter 8 of the 2017 *ASHRAE Handbook—Fundamentals.*

Thermal comfort is affected by air temperature, humidity, air velocity, and mean radiant temperature (MRT). In addition, nonenvironmental factors (clothing, gender, age, and physical activity) affect thermal comfort. These variables and their correlation with thermal comfort can be evaluated by the *Thermal Comfort Tool CD* (ASHRAE 2010) in conjunction with ASHRAE *Standard* 55-2017. Note that, in addition to thermal comfort criteria, several zones in schools (libraries, gymnasiums, locker rooms, natatoriums, ice rinks, etc.) require additional considerations to account for issues such as mold prevention, condensation, corrosion, etc., as discussed in more detail in the section on Humidity Control. General guidelines for temperature and humidity applicable for K-12 schools are shown in Table 6.

All schools need outdoor air for ventilation. Outdoor air is introduced to occupied areas and then exhausted by fans or exhaust openings, removing indoor air pollutants generated by occupants and any other building-related sources. ASHRAE *Standard* 62.1 is used as the basis for many building codes. To define the ventilation and exhaust design criteria, consult local applicable ventilation and exhaust standards. Table 7 provides recommendations for ventilation design based on the ventilation rate procedure method of ASHRAE *Standard* 62.1-2016 and filtration criteria for K-12 educational facilities.

Table 6 Typical Recommended Temperature and Humidity Ranges for K-12 Schools

Category/ Humidity Criteria	Indoor Design Conditions: Temperature, °C Winter	Summer	Comments
Classrooms, laboratories, libraries, auditoriums, offices[a, e]			
30% rh	22.3 to 26.2	24.5 to 27.5	
40% rh	22.3 to 25.8	24.3 to 27.2	
50% rh	22.1 to 25.6	24.1 to 26.9	
60% rh	21.87 to 25.3	23.8 to 26.7	
Gymnasiums			
30 to 60% rh	20.3 to 23.3	23.3 to 25.8	For gym with wooden floor, 35 to 50% humidity recommended at all times
Shops			
20 to 60% rh	20.3 to 23.3	23.3 to 25.8	
Cafeteria[b]			
20 to 30% (winter), 50% (summer) rh	21.1 to 23.3	25.8	
Kitchen[b]			
No humidity control	21.1 to 23.3	28.9 to 31.1	
Locker/shower rooms			
No humidity control	26.7		Usually not conditioned
Toilets			
No humidity control	22.2		Usually not conditioned
Storage			
No humidity control	17.8		
Mechanical rooms			
No humidity control	16.1		Usually not conditioned
Corridors			
No humidity control	20.0		Frequently not conditioned
Natatorium[c]			
50 to 60% rh	26.7 to 28.9	26.7 to 28.9	Based on recreational pool
Ice rink[d]			
1.7 to 7.2°C dp (maximum)	10.0 (minimum)	18.3 (maximum)	Minimum 5.5 K temperature difference between dew point and dry bulb to prevent fog and condensation

Notes:
[a]Based on *ASHRAE Thermal Comfort Tool* v. 2.0.03, for people wearing typical summer and winter clothing, 0.6 and 0.9 clo respectively, at sedentary activity (1.0 met). Air speed assumed at 0.1 m/s and MRT assumed equal to air temperature. The temperature range is within acceptable ASHRAE *Standard* 55 range (–0.5< PMV<+0.5) using the analytical comfort zone method, section 5.3.2 of ASHRAE *Standard* 55-2017.
[b]Based on Chapter 3.
[c]Based on Chapter 5.
[d]Based on Harriman et al. (2001).
[e]For libraries, keep minimum humidity of –1.1°C dp and maximum of 55% rh.

Additional information on IAQ for educational facilities can be found in EPA (2000).

Acceptable noise levels in classrooms are critical for a proper learning environment. High noise levels reduce speech intelligibility and student's learning capability. Although Chapter 49 provides information on design noise criteria, additional sources, such as local

Table 7 Typical Recommended Design Criteria for Ventilation and Filtration for K-12 Schools

[b]RC (Room Criterion), from Chapter 7 of the 2017 *ASHRAE Handbook—Fundamentals*.

codes and ANSI *Standard* S12.60-2010 Part 1, should be consulted for adequate design criteria.

Table 8 summarizes applicable noise criteria for K-12 schools.

Load Characteristics

Proper cooling, heating, dehumidification, and humidification load calculations and properly sized equipment are critical to both energy efficiency and cost effectiveness. Many computer programs and calculation methodologies, as described in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*, can be used for these tasks. Assumptions and data used for infiltration, lighting, equipment loads, occupancy, etc., are critical for proper load calculations. Although equipment is sized by peak cooling and heating, it is extremely important to analyze the occurrences of the peak sensible and latent cooling loads. In many instances, peak sensible cooling load does not coincide with peak latent cooling load. Ignoring this phenomenon can result in unacceptable indoor humidity. By carefully analyzing and understanding the peak loads and the load profiles, the designer can properly apply and size the most suitable equipment to meet the sensible and the latent cooling loads efficiently. Elementary schools are generally occupied from about 7:00 AM to about 3:00 PM; occupation is longer for middle and high schools. Peak cooling loads usually occur at the end of the school day. Peak heating usually occurs early in the day, when classrooms begin to be occupied and outdoor air is introduced into the facility. Although K-12 schools are dominated by perimeter zones (and zones exposed to the roof), careful attention should be given to components of the loads. Typical breakdowns of moisture loads are shown in Table 9.

Table 9 Typical Classroom Summer Latent (Moisture) Loads

Category	Moisture Loads, kg/h	Moisture Loads, %
People	3.3	22.5
Permeance	0.09	0.6
Ventilation	9.2	62.5
Infiltration	2.1	14.4
Doors	0	0
Wet surfaces	0	0
Humid materials	0	0
Domestic loads	0	0

Note: Based on Harriman et al. (2001), Chapter 18, Figure 18.2.

Typically, the dominant cooling loads in classrooms are occupants and ventilation, and ventilation and roof for heating. Given the dominance of ventilation loads, special effort should be made to effectively treat outdoor air before its introduction to the space, as discussed in more detail in the section on Systems and Equipment Selection.

Humidity Control

School buildings host many activities that require special humidity control. Harriman et al. (2001) provide detailed information on the basics of design and equipment selection for proper humidity control for several applications; Chapter 18 of that volume is dedicated to schools.

Classrooms require humidity control to provide comfort and prevent humidity-related problems (e.g., growth of dust mites and fungus, which produce allergens and even toxic by-products). Low humidity, on the other hand, favors longevity of infectious viruses, and therefore their transmission between occupants. Maintaining dew-point levels between –1 and 15.5°C satisfies nearly all people nearly all the time. However, the designer should discuss comfort expectations with the owner, to avoid misunderstandings.

Libraries require humidity control to provide comfort to the occupants and also to protect books and electronic records. Maintaining dew-point levels between –1 and 15.5°C provides a comfortable environment for the library occupants. However, controlling humidity at this range does not prevent books from absorbing excess moisture. Typically, books take up moisture quickly but lose it slowly. To avoid growth of mold and mildew, a dew point above –1°C and maximum of 55% rh are recommended. As with classrooms, the principal moisture loads for the library are ventilation (the major load) and infiltration.

Gymnasiums with wooden floors require special attention; failure to control humidity in gyms with wooden floors may have costly consequences. The Maple Flooring Manufacturers Association (MFMA 2005) specifies a floor-level humidity between 35 and 50% rh.

Showers and locker rooms require humidity control to prevent corrosion and growth of bacteria and fungus. Therefore, special attention is required to exhaust air quantities and placement of supply and exhaust air registers.

Natatoriums and ice rinks are typically isolated areas with more specialized HVAC equipment specifically designed to address ventilation and humidity control. Chapters 27 and 28 of Harriman et al. (2001) provide detailed information on humidity control for natatoriums and ice rinks, respectively.

Systems and Equipment Selection

Selection of HVAC equipment and systems depends on whether the facility is new or existing, and (in the latter case) whether it is to be totally or partially renovated. For minor renovations, existing HVAC systems are often expanded in compliance with current codes and standards with equipment that matches the existing types. For major renovations or new construction, new HVAC systems and equipment should be installed. When applicable, the remaining useful life of existing equipment and distribution systems should be considered.

HVAC systems and equipment energy use and associated life-cycle costs should be evaluated. Energy analysis may justify new HVAC equipment and systems when an acceptable return on investment can be shown. The engineer must review all the assumptions in the energy analysis with the school administration. Assumptions, especially about hard-to-measure items such as infiltration and part-load factors, can significantly affect the energy use calculated.

Other considerations for existing facilities are (1) whether the central plant is of adequate capacity to handle additional loads from new or renovated facilities; (2) the age and condition of the existing equipment, pipes, and controls; and (3) the capital and operating costs of new equipment. Schools usually have very limited budgets. Any savings in capital expenditures and energy costs may be available for the maintenance and upkeep of the HVAC systems and equipment and for other facility needs.

The type of HVAC equipment selected also depends on the climate and months of operations. In hot, dry climates, for instance, evaporative cooling may be the primary approach. Some school districts may choose not to provide air conditioning. However, in hot, humid climates, it is recommended that air conditioning or dehumidification be operated year-round to prevent growth of mold or mildew.

Chapter 1 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides general guidelines on HVAC systems analysis and selection procedures. Although in many cases system selection is based solely on the lowest first cost, it is suggested that the engineer propose a system with the lowest life-cycle cost (LCC). LCC analysis typically requires hour-by-hour building energy simulation for annual energy cost estimation. Detailed first and maintenance cost estimates of proposed design alternatives, using sources such as R.S. Means (2018a, 2018b), can also be used for the LCC analysis along with software such as BLCC 5.1 (FEMP 2010). Refer to Chapters 38 and 59, and the Value Engineering (VE) and Life-Cycle Cost Analysis (LCCA) section of this chapter, for additional information.

System Types. HVAC systems for K-12 schools may be centralized, decentralized, or a combination of both. Centralized systems typically incorporate secondary systems to treat the air and distribute it. The cooling and heating medium is typically water or brine that is cooled and/or heated in a primary system and distributed to the secondary systems. Centralized systems comprise the following systems:

Secondary Systems

- Air handling and distribution (see Chapter 4 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)
- In-room terminal systems (see Chapter 5 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)
- DOAS with chilled water for cooling and hot water, steam, or electric heat for heating

Primary Systems

- Central cooling and heating plant (see Chapter 3 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*)

Typical decentralized systems (dedicated systems serving a single zone, or packaged systems such as packaged variable-air-volume) are

- Water-source heat pumps (WSHPs), also known as water-loop heat pumps (WLHPs)
- Geothermal heat pumps (groundwater heat pumps, ground-coupled heat pumps)
- Hybrid geothermal heat pumps (combination of groundwater heat pumps, ground-coupled heat pumps, and an additional heat

rejection device), for cases with limited area for the ground-coupled heat exchanger or where it is economically justified

- Packaged single-zone and variable-volume units
- Light commercial split systems
- Minisplit and variable-refrigerant-flow (VRF) units

Chapters 2, 9, 18, 49, and 50 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provide additional information on decentralized HVAC systems. Additional information on geothermal energy can be found in Chapter 35 of this volume.

It is important to note that, to meet the acoustical design criteria in Table 8, designers should avoid locating HVAC equipment in classrooms, and that some centralized and decentralized systems located close to classrooms might need additional sound-attenuating features. Coordination between the HVAC designer, architect, and acoustical consultant is critical for meeting the desired noise criteria. Siebein and Likendey (2004) provide information on the applicability of systems to classrooms with regard to acoustical criteria. Additional information on how HVAC&R manufacturers' acoustical data and application information can be best used can be found in Ebbing and Blazier (1998). Schaffer (1993) provides a practical guide to noise and vibration control for HVAC systems. Commercial acoustics analysis software can also be helpful.

Dedicated Outdoor Air Systems. Although most centralized and decentralized systems are very effective at handling the space sensible cooling and heating loads, they are less effective (or ineffective) at handling ventilation air and the latent loads. As a result, a DOAS should be used. DOAS units bring 100% outdoor air to at least space conditions, which allows individual space units to handle only the space loads. It is preferable, however, to introduce the outdoor air at a lower humidity ratio than the desired space humidity ratio, to allow the zone HVAC unit to handle only the space sensible cooling load. This approach can be easily implemented in a classroom where a significant amount of outdoor air is required for ventilation.

Example. In a typical classroom with 30 students, the ventilation requirements are 222 L/s. If the outdoor air can be introduced at a humidity ratio of 6.9 g/kg and the space is designed to be maintained at 10 g/kg, the space dehumidification capability of the pre-dehumidified outdoor air is the following:

$$\begin{matrix}\text{Space dehumidification}\\ \text{capability, W}\end{matrix} = \begin{matrix}\text{Latent load}\\ \text{factor,}\\ \text{W/(L·s)}\end{matrix} \times \begin{matrix}\text{Flow}\\ \text{rate,}\\ \text{L/s}\end{matrix} \times \left(\begin{matrix}\text{Space humidity ratio} -\\ \text{Supply humidity ratio}\end{matrix}\right)$$

Then,

$$\begin{matrix}\text{Dehumidification}\\ \text{capability, W}\end{matrix} = 3010 \times 222\left[\frac{(10 - 6.9)}{1000}\right] = 2071 \text{ W} = 2.07 \text{ kW}$$

where 3010 is the air latent factor (see Chapter 18 of the 2013 *ASHRAE Handbook—Fundamentals*), in W/(L·s).

The 2.07 kW of space latent load is equivalent to the latent load of 30 occupants (seated, very light work, 0.045 kW per occupant) and the additional space latent load (e.g., infiltration latent load).

$$\text{Occupant latent load} = 30 \times 0.045 = 1.35 \text{ kW}$$

$$\text{Remainder of total dehumidification capability} = 2.07 - 1.35 = 0.72$$

This additional dehumidification capability can help in handling infiltration latent load and others.

This simple example demonstrates the ability of pre-dehumidified outdoor air to handle the space latent load, resulting in almost full separation of the space latent cooling load treatment from the space sensible cooling load. This approach allows only thermostatic control without losing humidity control in conditioned classrooms.

Typical DOAS units are air-handling units that cool, dehumidify, heat, humidify, and filter the outdoor air before it is introduced to the conditioned space. Typical DOASs include the following major components:

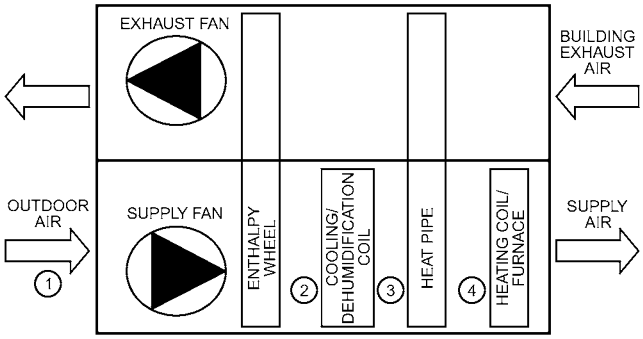

Fig. 1 Typical Configuration of DOAS Air-Handling Unit: Enthalpy Wheel with Heat Pipe for Reheat

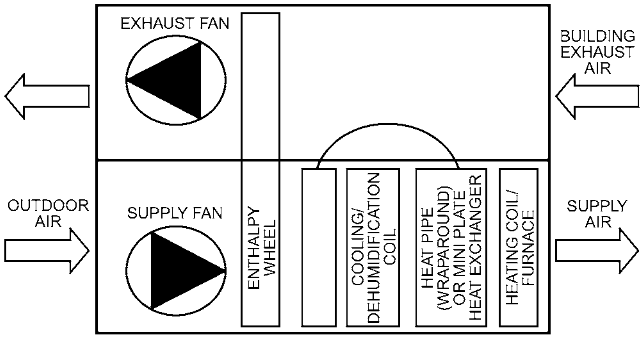

Fig. 2 Typical Configuration of DOAS Air-Handling Unit: Enthalpy Wheel with Wraparound Heat Pipe for Reheat

- Mechanical cooling/dehumidification
  - DX coil
  - Chilled-water coil
- Desiccant-based cooling/dehumidification
  - Desiccant (dehumidification) and direct-expansion (DX) coil (post sensible cooling)
  - Desiccant (dehumidification) and chilled-water coil (post sensible cooling)
- Heating
  - Coils (hot-water, steam, electric, heat pump)
  - Gas-fired furnace
- Humidification
  - Passive (in conjunction with enthalpy wheel heat recovery)
  - Active (steam, electric-to-steam, gas-to-steam)
- Exhaust air recovery: air-to-air heat recovery
  - Rotary (enthalpy wheel, sensible wheel)
  - Fixed (heat pipe, plate heat exchanger, runaround coils)
- Dehumidification enhancements for air-to-air heat recovery
  - Heat pipe based (wraparound coil)
  - Mini plate heat exchanger based

Which DOAS configuration is most cost effective depends on variables such as availability of utilities (chilled water, gas, steam), space constraints, climatic data, utility cost, and budget. DOAS can be configured easily by using modular components that meet the design criteria. Selection and analysis software of these systems is readily available from DOAS manufacturers, which simplifies configuration and analysis of the most cost-effective system. Typical configurations of DOAS are shown in Figures 1 and 2. A cooling/dehumidification psychrometrics process of DOAS is shown in Figure 3.

Air-to-air energy recovery is an important element in a DOAS. In addition to recovering energy from the exhaust air, a well-designed energy recovery module, such as an enthalpy wheel, can enhance and stabilize operation of the cooling and heating elements in the DOAS unit. As shown in Figure 3, the process of bringing outside air from point 1 to point 2 can be defined as "compressing" the outdoor air conditions to almost return air conditions. Additional information about DOAS systems can be found in ASHRAE (2017).

Given the need for more stringent and complex control schemes for outdoor air preconditioning, DOAS typically incorporate, direct digital control (DDC) systems, either stand-alone microprocessor-based or with the ability to communicate with central energy management system. The control system can be purchased as an option or installed in the field by the controls vendor. Typical supply air conditions for a DOAS air-handling unit are shown in Table 10.

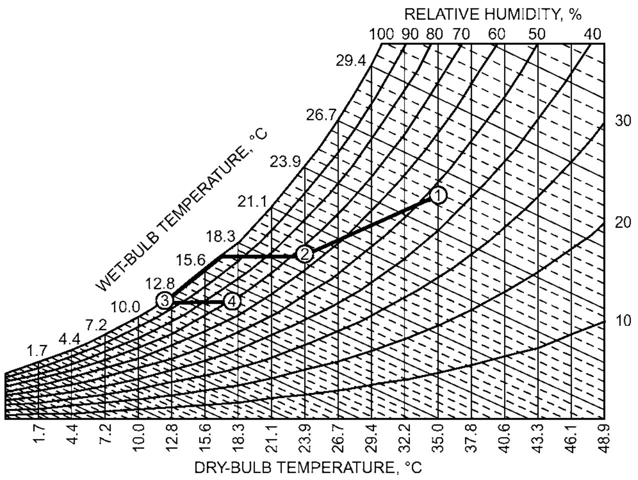

Fig. 3 Cooling/Dehumidification Psychrometric Process of Typical DOAS Air-Handling Unit in Figure 1

Typical arrangements of DOAS integrated with local cooling and heating systems are shown in Figure 4. Additional information on DOAS systems can be found in Chapter 25 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Systems with High Percentage of Outdoor Air. Air-handling systems with a high percentage of outdoor air (above 30%) can be found in several areas in educational facilities. To prevent indoor air quality problems and conserve energy, an energy recovery module can be added to pretreat the outdoor air before it is mixed with return air. Figure 5 shows a typical rooftop packaged AC unit with energy recovery module. See Chapter 26 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on energy recovery equipment and systems.

The addition of an energy recovery module is dependent on the percentage of outdoor air and the geographic location. See ANSI/ASHRAE/IES *Standard* 90.1-2016, section 6.5.6.1, for the correlation between geographic location and percentage of outdoor air (OA). Checking the exceptions provided in that section is strongly recommended.

Systems Selection by Application. Table 11 shows the applicability of systems to areas in K-12 school facilities.

Displacement Ventilation and Active/Induction Chilled Beams

Displacement Ventilation. The use of displacement ventilation (as opposed to the more traditional mixing ventilation) for classrooms has been extended for enhanced IAQ and thermal comfort. In displacement ventilation, fresh air at colder temperature than the room air is discharged close to the floor level, and warm air is exhausted at or close to the ceiling. After being discharged at a low level, the colder supply air rises as it is heated by heat sources (e.g., people, computers), also allowing effective removal of containments generated in the room.

Guidelines and procedures for designing displacement ventilation systems can be found in California Energy Commission (2006), Chen and Glicksman (2003), Skistad et al. (2002), Chapter 20 of the

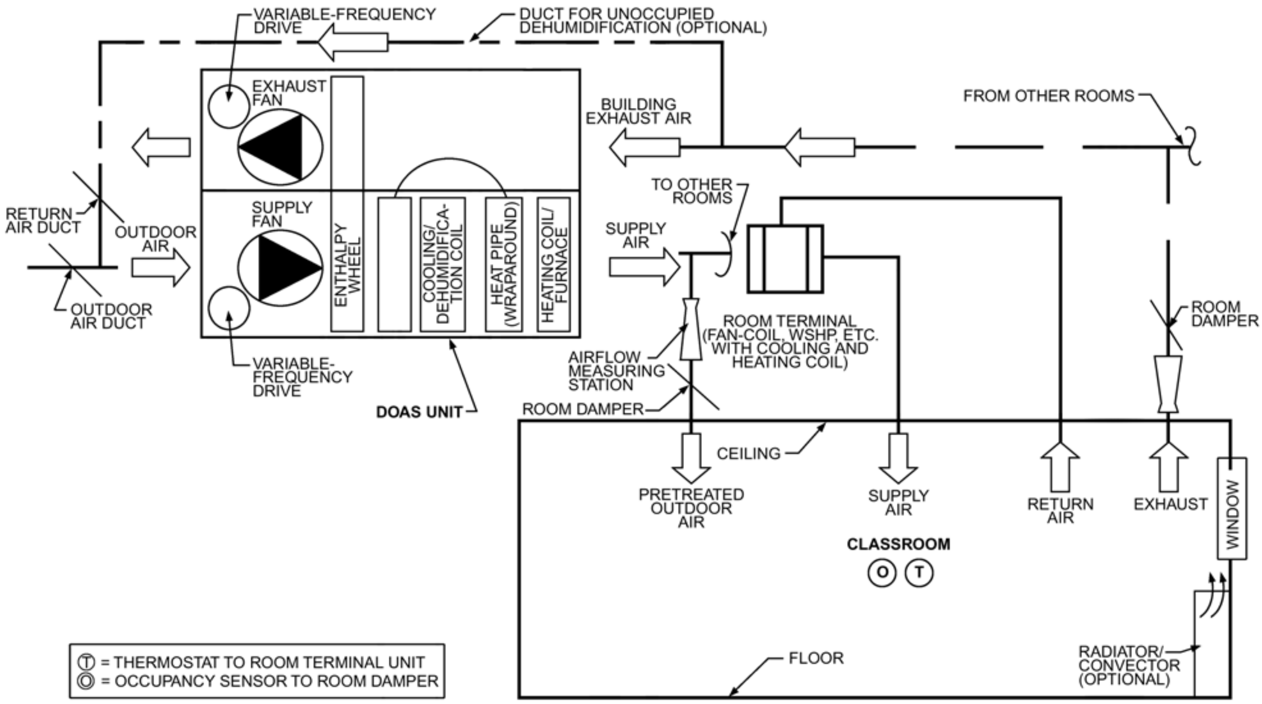

Fig. 4 Typical Schematic of DOAS with Local Classroom Cooling/Heating Terminal

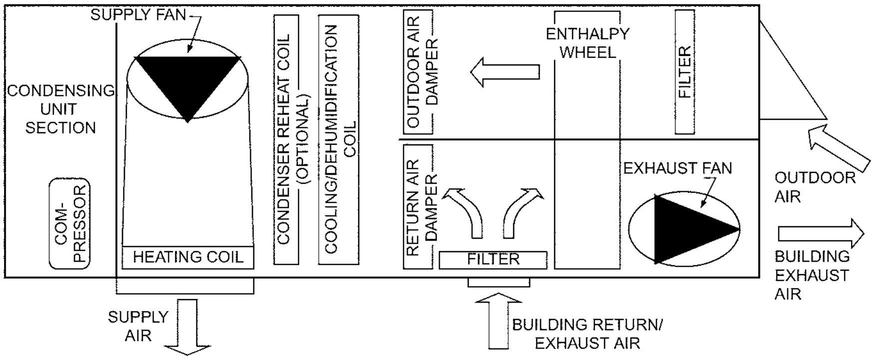

Fig. 5 Typical Configuration of Rooftop Packaged Air Conditioners with Energy Recovery Module and Enhanced Dehumidification (Condenser Reheat Coil)

Table 10 Typical Design Criteria for DOAS Air-Handling Unit

	Supply Air Conditions[a]		Minimum Air Filtration Efficiency, MERV[b]
	Temperature, °C	Humidity Ratio, g/kg	
Winter	18 to 20	4 to 6	8 to 13[c]
Summer	15[d] to 18	6 to 9	8 to 13[c]

Notes:
[a]Building location may dictate optimum supply condition in recommended range.
[b]Filter efficiency definition per ASHRAE Standard 52.2-2017.
MERV = minimum efficiency reporting values
[c]NAFA 2012
[d]Refer to ASHRAE *Standard* 90.1-2016, section 6.5.2.6. This standard restricts the supply air temperature to 15°C; when required by the standard, this criterion should be used.

2016 *ASHRAE Handbook—HVAC Systems and Equipment,* and Chapter 58 of this volume.

Typical displacement ventilation systems for classrooms include the following main subsystems (Figure 6):

- DOAS air-handling unit that can cool and dehumidify outdoor air to 15 to 17°C and 5 to 7 g/kg for summer, and heat air to 18 to 20°C for winter
- Zone fan-powered terminal with sensible cooling capability (located outside the conditioned zone)
- Special displacement ventilation diffusers
- Heating radiators or convectors placed below windows in perimeter zones
- Control systems (thermostats and occupancy sensors)

In addition to the traditional displacement ventilation system described previously, displacement ventilation with induction can also be considered for classrooms. A displacement ventilation system with induction uses special terminals to provide additional cooling and heating with the displacement ventilation effect. These terminals are not equipped with fans, resulting in lower noise levels as required by more stringent noise criteria.

A displacement ventilation system with induction includes the following main subsystems:

- DOAS air-handling unit that can cool and dehumidify outdoor air to 12 to 14°C and 5 to 7 g/kg for summer, and heat air to 18 to 20°C for winter
- Zone displacement ventilation with induction terminal, equipped with two- or four-pipe cooling and heating coil mounted along perimeter walls and windows
- Control systems (thermostats and occupancy sensors)

Active (Induction) Chilled Beams. Recently, the use of active/induction chilled beams for classrooms and other areas in educational facilities has been extended for enhanced IAQ, thermal comfort, and energy conservation. As with displacement ventilation with induction, an active/induction chilled beam terminal includes special small air jets that induce room air to flow through cooling or heating coils, depending on the system (two- or four-pipe). The primary air is outdoor air pretreated in a DOAS unit, as described previously. Figure 7 shows the principle of active/induction chilled-beam terminals.

Although more room space is required for chilled-beam induction, these systems allow significant size and capacity reductions in air-handling systems, and decouple sensible cooling and heating from ventilation and humidity control. Temperatures of chilled water distributed to the chilled-beam terminals are typically elevated to around 13°C, which can reduce energy consumption. Hot water can be provided from a standard hot-water boiler at 66 to 82°C, or lower if condensing boilers applied.

An active/induction chilled-beam system typically includes the following main subsystems:

- DOAS unit that can cool and dehumidify outdoor air to 12 to 14°C and 5 to 7 g/kg for summer, and heat air to 18 to 20°C for winter
- Zone active/induction chilled-beam terminal, equipped with two- or four-pipe cooling and heating
- Control systems (thermostats and occupancy sensors)

Specialized Equipment. Areas such as natatoriums and ice rinks need specialized equipment to address the unique design requirements and the cooling, dehumidification, and heating characteristics. Natatoriums typically use special units that can introduce large quantities of outdoor air and allow active humidity control (mainly dehumidification). This equipment is similar to DOAS, and typically uses chilled water or a DX system for dehumidification. For systems with air-cooled condensers, condenser heat can be recovered to heat the swimming pool. See Chapter 5 of this volume for more information on natatoriums. Similarly, an ice rink requires special equipment; selection depends heavily on the school's location and seasonal use. Ice rink HVAC and dehumidification equipment can be desiccant-based or self-contained mechanical refrigeration. See Chapter 5 of this volume and Chapter 44 of the 2018 *ASHRAE Handbook—Refrigeration* for more information on ice rinks.

Chapters 27 and 28 of Harriman et al. (2001) also provide detailed information on humidity control for natatoriums and ice rinks, respectively.

Demand Control Ventilation (DCV). Demand control ventilation can reduce the cost of operating the HVAC systems. To ensure proper IAQ and comply with ASHRAE *Standard* 62.1-2016 and local codes that allow DCV, the designer must carefully follow

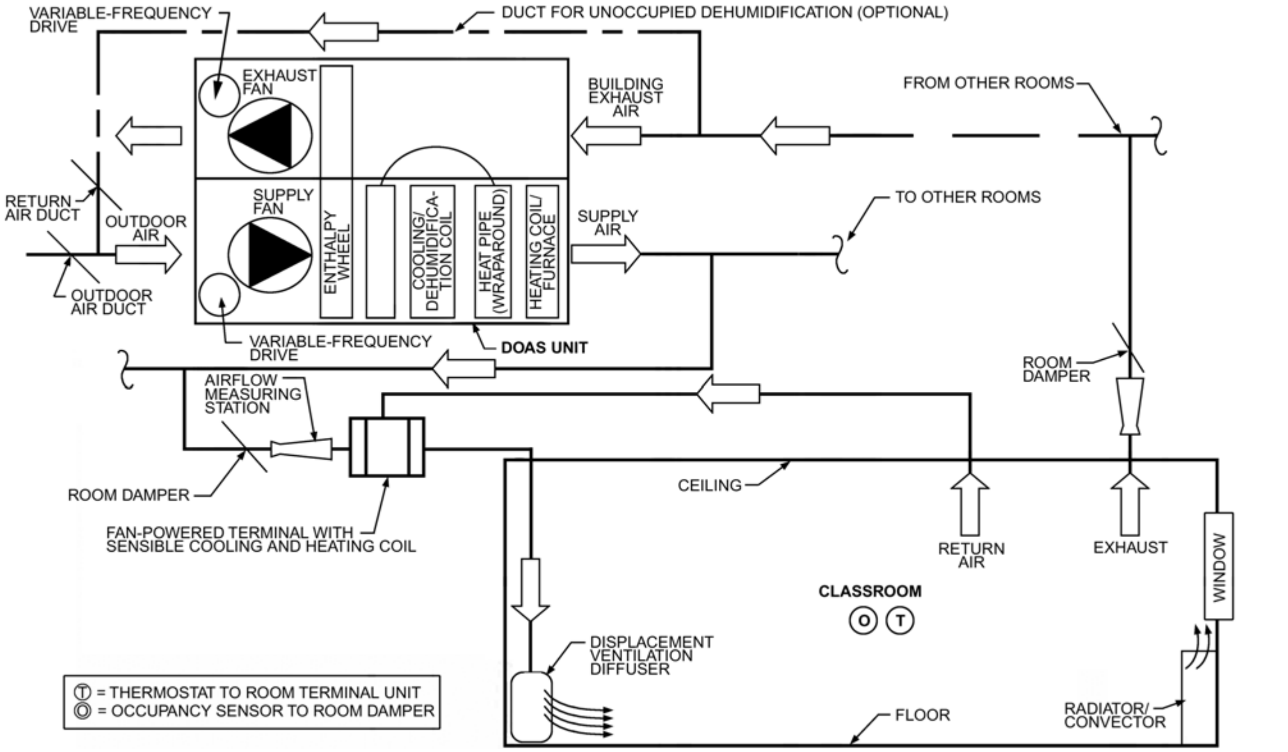

Fig. 6 Typical Displacement Ventilation System Layout

Table 11 Applicability of Systems to Typical Areas

	Cooling/Heating Systems								
	Centralized			Decentralized				Heating Only	
Typical Area[c]	SZ[a]	VAV/ Reheat	Fan Coil (Two- and Four-Pipe)	PSZ/ SZ[a] Split/ VRF[g]	PVAV/ Reheat	WSHP	Geothermal Heat Pump and Hybrid Geothermal Heat Pump	Baseboard/ Radiators	Unit Heaters

Auto Repair Shop									X
Industrial Shop									X
Locker Rooms								X	X
Ventilation (Outdoor Air)	DOAS	d	DOAS	DOAS[f]	d	DOAS	DOAS	DOAS	DOAS

SZ = single zone
PVAV = packaged variable air volume
VRF = variable refrigerant flow
VAV = variable air volume
WSHP = water-source heat pump
PSZ = packaged single zone
DOAS = dedicated outdoor air system

Notes:
[a]SZ and PSZ/SZ split for classrooms requires individual thermostatic control.
[b]Systems for laboratories must comply with local codes and be in accordance with current practices for laboratories.
[c]Systems and equipment for ice rinks and natatoriums not shown; refer to specialized equipment section.
[d]Special attention should be given for adequate OA supply in VAV applications without DOAS; consult ASHRAE *Standard* 62.1-2016 Section 6.2.5.
[e]In some cases, these areas can be served by SZ, WSHP, and geothermal HP systems without OA from DOAS.
[f]When percentage of outdoor air dictates use of energy recovery in SZ or PSZ unit, OA for DOAS may not be required.
[g]Special consideration is required for risk associated with refrigerant leaks. ASHRAE *Standards* 15 and 34 should be consulted.

section 6.2.7 (Dynamic Reset) of the standard. *Standard* 62.1-2016 explicitly allows use of CO_2 levels or occupancy to reset intake airflow in response to space occupancy levels. Pay special attention to the area served by the HVAC system and the system type. Areas such as gymnasiums and auditoriums can benefit from CO_2-based DCV, commonly used in single-zone systems without DOAS,

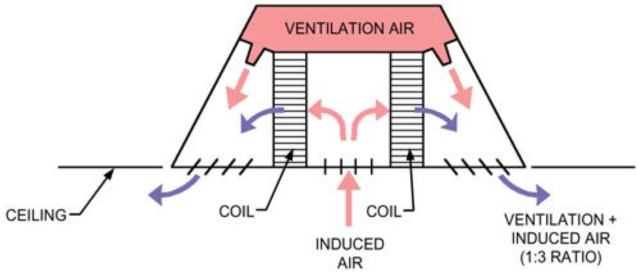

Fig. 7 Typical Active/Induction Chilled-Beam Terminal
(Rumsey and Weale 2006)

serving one space with varying occupancy. In these cases, DCV control is simple, reliable, and cost-effective. Systems such as multizone VAV with recirculated air without DOAS require special attention to ensure adequate OA supply to multiple zones under varying loads (such as classrooms). This problem complicates the design, operation, and maintenance of DCV control systems and also adds the cost of additional sensors.

A simpler approach for DCV is in systems that use DOAS: the OA supply to each individual space can be controlled independently by occupancy sensors that can reduce the OA to a preset value (and also turn off the lights), or by CO_2 sensors (see Figure 4).

3. COLLEGES AND UNIVERSITIES

General and Design Considerations

College and university facilities can be comprised of a campus, cluster of buildings, or a single isolated building. Some colleges and universities have satellite campuses scattered throughout a city or a state. The design criterion for each building is established by the requirements of its users. The following are major facilities commonly found on college and university campuses.

Libraries/Learning Centers. Libraries and learning centers are central to the purpose of modern college and university. A library can be a collection of printed and electronic material and/or a place where individuals or groups of students gather for study or other academic activities. A typical library includes the following areas:

- Collection/stacks
- Library staff and services
- Main reading room
- Specialty areas (special collections, music and audiovisual resources, computer areas, etc.)
- Support areas

Temperature and humidity control is needed for maintaining the printed materials and the collections. Proper air distribution can be challenging because of different ceiling heights, stacks, mezzanines, etc. Reading rooms require air supply without draft, and special collections or rare books areas need a dedicated air-handling system. Noise is also critical in libraries; an acoustic consultant must review or be part of the mechanical design. See Chapter 24 for specifics on HVAC design for libraries.

Academic Buildings and Professional Schools. These buildings accommodate classrooms, which are the core of the university teaching and learning experience. There are two main categories of classrooms, with several subcategories (Neumann 2003):

Flat-floor classrooms are typically rectangular, basic, and easily reconfigurable for different teaching needs. In most cases, the number of students is relatively low. Sometimes, a larger flat-floor room can be subdivided to smaller rooms by folding or sliding partitions.

Sloped-floor classrooms are used when the class size exceeds that at which all students can see each other clearly in a flat-floor classroom. Sloped-floor classrooms typically have more than 40 students. Those with a capacity of 250 students or more are generally referred as auditoriums, which require theater design consideration.

Academic buildings also have faculty offices and auxiliary areas to support teaching activities. Professional schools are typically allocated to a specific academic discipline. Each of these schools has specific needs, depending on the academic requirements. The HVAC design and systems for classrooms and other administrative areas are similar to classrooms in high schools (see Table 11).

Science Teaching and Research Facilities. College and university science facilities accommodate highly specialized areas for teaching and research in several disciplines (e.g., chemistry, biology, physics). Teaching facilities are designed mainly for group instruction, typically with one or more instructors and 12 to 32 students; an average-sized teaching lab can accommodate 24 students. The laboratory should be designed to support a range of activities for various courses: for example, a chemistry lab should be able to handle introductory chemistry, organic chemistry, etc.

Research facilities can be part of a science teaching building or grouped in a stand-alone research facility. Research facilities are customized and designed for graduate and postgraduate students, typically under the direction and supervision of several principal investigators (PIs). Unlike teaching labs, which are designed for large group instruction, research labs should be designed to accommodate the activities of individuals or small groups. Given potentially hazardous activities in teaching and research labs, the most critical factor in designing systems for labs is safety; this concern has major implications on the design of HVAC and mechanical systems.

Teaching and research labs may contain fume hoods, machinery, lasers, vivariums, areas with controlled environments, and departmental offices. The HVAC systems and controls must be able to accommodate diverse functions of the facility, which may have 24 h, year-round operation, and yet be easy to service and quick to repair. Variable-air-volume (VAV) systems can be used. Proper control systems should be applied to introduce and extract the required quantities of supply and exhaust air. Maintaining the required space pressure differential to adjacent spaces and the minimum airflow under all circumstances is extremely critical for safe laboratory operation. Energy can be saved by recovering energy from exhaust air and tempering outdoor makeup air. Pay special attention to containment in the exhaust air stream. Examine potential carryover of air from exhaust to supply, and interaction with the energy recovery device adsorbent for cases with total (sensible and latent) energy recovery. In general, air exhausted from fume hoods should not be used for energy recovery. Where heat recovery from fume hoods exhaust is considered, careful coordination with the site health and safety (H&S) officer is required. Other energy-saving systems used for laboratory buildings include (1) active chilled beams (Rumsey and Weale 2006), (2) ice storage, (3) heat reclaim chillers to produce hot water for domestic use or for booster coils in the summer, and (4) cooling tower free cooling.

The design engineer should discuss expected contaminants and concentrations with the owner to determine construction materials for fume hoods and fume exhaust systems. Close coordination with H&S personnel is vital for safe laboratory building operation. Backup or standby systems for emergency use should be considered, such as alarms on critical systems. Maintenance staff should be thoroughly trained in upkeep and repair of all systems, components, and controls. For design criteria and other design information on laboratories and vivariums, see Chapter 17, ANSI/AIHA *Standard* Z9.5-2012, DiBerardinis et al. (2013), and McIntosh et al. (2001). Additional information on energy conservation in labs can be found on the Labs 21 web site (labs21benchmarking.lbl.gov/).

Table 12 Housing Rooms Design Criteria[a]

Category	Inside Design Conditions: Winter Temperature	Winter Relative Humidity[b]	Summer Temperature	Summer Relative Humidity	Combined Outdoor Air Rate[c]	Exhaust[d]	Filter Efficiency[e]	Noise, RC (N);QAI < 5 dB Level[f]
Dorm, suite rooms	21 to 23°C	30 to 35%	23 to 26°C	50 to 60%	11 L/s	NR	6 to 8 MERV	30
Apartments and studio rooms	21 to 23°C	30 to 35%	23 to 26°C	50 to 60%	42.5 L/s	37.5 L/s	6 to 8 MERV	30
Couple and faculty housing	21 to 23°C	30 to 35%	23 to 26°C	50 to 60%	42.5 L/s	37.5 L/s	6 to 8 MERV	30

NR = not required.
[a]This table should not be used as the only source for design criteria. The data contained here can be determined from ASHRAE handbooks, standards, and governing local codes.
[b]Minimum recommended humidity.
[c]Per ASHRAE *Standard* 62.1-2016, based on two occupants for room. For areas with exhaust, ventilation is based on exhaust requirements.
[d]Air exhaust from bathroom, toilet, and kitchen areas.
[e]Per ASHRAE *Standard* 52.2-2017.
[f]Based on Chapter 49.

Some research facilities include vivariums (animal facilities). These spaces are commonly associated with laboratories, but usually have their own separate areas. Additional areas that can found in vivariums are necropsy rooms, surgery suites, and other specialty areas. Animal facilities need close temperature control and require a significant amount of outdoor ventilation to control odors and prevent the spread of diseases among the animals. Animal facilities are discussed in Chapters 17 and 25, and by the National Research Council (NRC 1996).

Housing

Student Housing. Housing is an integral part of student's academic and social life. Student housing of the past had few amenities, and for years the emphasis was on economy and reduced construction cost. Today, more housing administrators are changing this philosophy by providing an enhanced, rich on-campus residential life. Student and staff housing facilities include the following:

- Dormitories (residence halls)
- Suites
- Apartments and studios
- Couples housing

Dormitories (residence halls) are typically for freshman students. Student living units are generally single- or double-occupancy rooms that open directly to a corridor. The building can be a high rise or low rise, depending on the setting or the location of the campus. Typically, there are two students per room, with one single-occupancy room reserved for the resident assistant. On the ground floor are public facilities, which may include a living room, reception desk, kitchen/lounge, and cafeteria. Dorm rooms often do not have individual kitchens or bathrooms; communal bathrooms usually serve one floor.

Suites are typically occupied by older undergraduate students. The suite plan typically connects four to six double-occupancy sleeping room rooms with a shared bathroom and living room.

Apartments and **studios** are often occupied by upper-division and graduate students, and are basically suites with kitchens and private bathrooms. Apartments and studios are the most desirable housing and are the most expensive because of their additional plumbing and electrical systems.

Couples housing generally consists of one-, two-, or three-bedroom apartments in separated complexes. A couples housing facility may have a section for married couples, who often have young children whose safety and security needs must be considered. These facilities may have outdoor play areas and child care facilities.

Faculty Housing. Faculty members typically find housing outside the campus, but the high cost of local living has convinced many universities that offering on-campus housing will attract the best candidates to their academic institution. This type of housing is similar to typical residential housing and can include duplexes, apartments, townhouses, and single-family homes.

Air conditioning in campus housing for students and faculty should be quiet, easily adjustable, and draft free. Systems that require little space and have low total owning and operating costs should be selected. Table 12 lists design criteria for housing facilities.

Typically, decentralized systems with DOAS or air-to-air energy recovery should be used for these applications:

- Water-source heat pumps (WSHPs), also known as water-loop heat pumps (WLHPs)
- Geothermal heat pumps (groundwater heat pumps, ground-coupled heat pumps)
- Hybrid geothermal heat pumps (combination of groundwater heat pumps, ground-coupled heat pumps, and an additional heat rejection device), where there is limited area for the ground-coupled heat exchanger or where it is economically justified
- Light commercial split systems
- Minisplit and variable-refrigerant-flow (VRF) units
- Fan-coil units

When dormitories are closed during winter breaks, the heating system must supply sufficient heat to prevent freeze-up. If the dormitory contains non-dwelling areas, such as administrative offices or eating facilities, these facilities should be designed as a separate zone or with a separate system for flexibility, economy, and odor control. Solar energy can be considered for domestic hot water (DHW).

Athletics and Recreational Facilities

College and university sports facilities ranging from large arenas for ice hockey, basketball, and other spectator sports, to small gymnasiums and fitness centers. College sports activities are heavily influenced by intercollegiate sports, which are governed by extensive standards and regulations of the National Collegiate Athletic Association (NCAA). A university's participation in intercollegiate sports is well known to be an important revenue source and is often critical in prospective students' decision-making processes. Typical sports facilities that can be found in universities campuses are

- Collegiate arenas (indoor sport arenas dedicated to a particular sport, or multipurpose)
- Gymnasiums (for activities such as physical education)
- Field houses (for outdoor activities to be played indoors during bad weather)
- Natatoriums
- Recreation centers (multipurpose activity courts, fitness/weight room)

Chapter 5 of this volume covers design practices for several of these facilities. For ice rinks and arenas, consult Chapter 44 of the 2018 *ASHRAE Handbook—Refrigeration* and Chapter 27 of Harriman et al. (2001) (which covers natatoriums, as well).

Social and Support Facilities

Social and support facilities and campus centers include common areas designed to improve and expand student services: for example, auditoriums, lounges, lobbies, dining and food services, offices and administration, libraries, cafés and snack bars, classrooms, meeting rooms, bookstores and other retail areas, banks, printing shops, etc. Given this variety of applications, the reader should refer to Chapters 2, 3, 5, 24, and 34 of this volume and other application-specific sources for the design of HVAC&R systems for these areas.

Cultural Centers

Universities and colleges with cultural facilities and academic programs such as music, theater, dance, and visual arts enhance the cultural and artistic lives of students. The two main cultural facilities are performing arts and visual arts centers. Several areas are common for both these areas are

- **Public support areas,** which include lobby, student common, café, gift shop, box office, coat room, and restroom facilities
- **Administration/faculty areas,** including offices, administration areas, and conference rooms
- **Back of the house,** such as loading docks, shipping and receiving, maintenance and building operation, mechanical rooms, and control rooms

Unique areas for **performing arts** are

- **Performance spaces,** including seating areas, stage, orchestra pit, dimmer room, audio rack room, and lighting and sound control
- **Backstage/performer support,** such as the green room, dressing rooms, wardrobe, laundry, and storage
- **Theater, music, and dance instruction areas,** which include rehearsal rooms, dance studios, instrumental rehearsal rooms, listening labs, and music and instrument storage

Unique areas for **visual arts** are

- **Museums,** which include art galleries, workrooms, art storage, and conservation areas
- **Fine arts instruction rooms,** comprising design, drawing, painting, print making studios, photographic darkrooms, and library
- **General arts instruction,** such as lecture halls, classrooms, seminar rooms, and computer labs

Cultural centers encompass a large number of specialty areas, and careful attention required when designing, constructing, and maintaining the HVAC&R systems. Consult Chapters 2, 3, 5, and 24 for details.

Central Utility Plants

Universities and college campuses typically have large central utility plants or smaller mechanical rooms serving an individual building or cluster of buildings. The central utility plants can supply chilled water, steam, and electrical power or only steam or chilled water. In these cases, chilled water, steam, or hot water is generated at a building level or in one smaller utility plant serving a cluster of buildings. The setup depends heavily on site constraints, including geographic location. The central utility plant comprises chillers, boilers, steam specialties, primary and secondary pumps, cooling towers, heat exchangers, combined heat and power (CHP) prime movers, and CHP auxiliary equipment, electrical power transformers, switchgears, control systems, etc. In the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, see Chapter 3 for design of central heating and cooling plants, Chapter 7 for CHP, Chapter 11 for steam systems, and Chapter 12 for district heating and cooling.

In addition to accommodating the mechanical and electrical equipment, central utility plants also house engineering, operation, and maintenance personnel. Central plants are not conditioned but generally are heated and ventilated; storage areas, shops, and other support areas are heated, ventilated, or cooled, depending on the use. Offices, administration areas, and control rooms are typically fully conditioned.

Where economically justifiable, chilled water and steam can be purchased from an independent operator.

Central plant optimization tools have been gaining momentum for large campuses, allowing optimal operation of central utility plants containing on-site power generation, chiller plants, heating plants, and storage systems. The section on Selected Topics on Energy and Design provides information on these systems.

4. SUSTAINABILITY AND ENERGY EFFICIENCY

Embrace of the principles of sustainable design on the part of the educational community has increased in recent years. Begun as a means to educate the students in conserving earth resources, this approach also provides benefits such as enhanced IAQ and lower operating costs.

There are several definitions of sustainability, green buildings, and high-performance buildings. In the context of this chapter, these terms refer to a building that minimizes the use of energy, water, and other natural resources and provides a healthy and productive indoor environment (e.g., IAQ, lighting, noise). The HVAC&R designer plays a major role in supporting the design team in designing, demonstrating, and verifying these goals, particularly in the areas of energy efficiency and indoor environmental quality. Because energy efficiency is the area of expertise of the HVAC&R designer, this section covers these topics in more detail.

Several tools and mechanisms are available to assist the HVAC&R designer in designing sustainable educational facilities; the following are the most common tools:

Advanced Energy Design Guide (AEDG) for K-12 Schools

The *Advanced Energy Design Guide for K-12 Schools* (ASHRAE 2008) was developed to help designers of K-12 facilities achieve energy savings of at least 30% compared to ANSI/ASHRAE/IESNA *Standard* 90.1-1999.

An updated version of the *Advanced Energy Design Guide for K-12 Schools* (ASHRAE 2011) is also available to help designers of K-12 facilities achieve energy savings of at least 50% compared to ANSI/ASHRAE/IESNA *Standard* 90.1-2004. Most recently, *Advanced Energy Design Guide for K-12 School Buildings—Achieving Zero Energy* (ASHRAE 2018) is available to help designers to achieve net zero energy.

These guides provide recommendations for energy-efficient design based on geographic location, covering issues such as envelope, lighting, HVAC, and service water heating (SWH), and can be found online through the ASHRAE Bookstore.

ASHRAE/USGBC/IES *Standard* 189.1-2014

This standard provides minimum requirements for the siting, design, construction, and plan for operation of high-performance green buildings to

- Balance environmental responsibility, resource efficiency, occupant comfort and well-being, and community sensitivity
- Support the goal of development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

This standard provides minimum criteria that apply to the following elements of building projects:

- New buildings and their systems
- New portions of buildings and their systems
- New systems and equipment in existing buildings

The standard addresses site sustainability, water use efficiency, energy efficiency, indoor environmental quality (IEQ), and the building's impact on the atmosphere, materials, and resources.

Leadership in Energy and Environmental Design (LEED®)

Many schools are seeking LEED certification from the U.S. Green Building Council (USGBC). The LEED for Schools (USGBC 2009a) rating system is unique to the design and construction of K-12 schools.

The system awards credits in seven categories:

1. Sustainable sites (SS)
2. Water efficiency (WE)
3. Energy and atmosphere (EA)
4. Materials and resources (MR)
5. Indoor environmental quality (IEQ)
6. Innovation and design process (ID)
7. Regional priority (RP)

Categories 1 to 5 include prerequisites, which are mandatory for certification, and credits. The last two categories are credits only.

Typically, the HVAC&R designer is heavily involved in the (1) energy and atmosphere and (2) indoor environmental quality categories. In the EA category, the HVAC&R designer, along with the architect, electrical engineers, and plumbing engineers, demonstrates compliance with prerequisite EA 2 by using the following procedures:

- Option 1: Whole-building energy simulation, by demonstrating 10% improvement (for new construction) or a 5% improvement in the proposed building performance rating for major renovations to existing buildings over ANSI/ASHRAE/IESNA *Standard* 90.1-2007, appendix G. Projects registered after April 7, 2016, are subject to the four-point mandatory minimum, and must demonstrate an 18% improvement in the proposed building performance rating for new building or 14% improvement in the proposed building performance for major renovation to existing buildings compared to the baseline building performance rating.
- Option 2: Prescriptive compliance path, for less than 18 600 m^2, using *Advanced Energy Design Guide for K-12 Schools* (ASHRAE 2008). With this option, the project needs to comply with all the prescriptive measured identified in ASHRAE (2008) and also comply with all applicable criteria as established in the guide for the climate zone in which the building is located. Projects outside the United States may use ASHRAE/ASHRAE/IESNA *Standard* 90.1-2007, Appendices B and D, to determine the appropriate climate zone. This option is not available for projects registered after April 7, 2016, to meet the four-point mandatory minimum.
- Option 3: Prescriptive compliance path: *Advanced Buildings™ Core Performance™ Guide*, developed by the New Buildings Institute (2007). This option is applicable for buildings less than 9300 m^2.

Additional EA credits can be obtained by demonstrating additional energy cost savings compared to the ANSI/ASHRAE/IESNA *Standard* 90.1-2007's Appendix G and from other sections of the EA group, such as on-site renewable energy, enhanced commissioning, measurement and verification, and green power. In addition, the HVAC&R designer is involved in issues of indoor environmental quality; these issues are typically associated with minimum and enhanced ventilation, acoustics, thermal comfort, controls, daylighting, mold prevention, etc.

Details and additional information on new construction and major renovations of K-12 facilities or previous editions of LEED for schools can be found on the USGBC web site at new.usgbc.org/leed.

For existing schools, the LEED rating system for existing buildings can be applied (see USGBC web site).

ENERGY STAR for K-12 Facilities

Similarly to appliances, a building or manufacturing plant can earn the ENERGY STAR label. An ENERGY STAR-qualified facility meets strict energy performance standards set by the U.S. EPA and uses less energy, is less expensive to operate, and causes fewer greenhouse gas emissions than its peers. To qualify, a building must score in the top 25% based on the EPA's National Energy Performance Rating System, which considers energy use among other, similar types of facilities (including K-12 educational facilities) on a scale of 1 to 100. This rating system accounts for differences in operating conditions, regional weather data, and other important considerations.

To determine eligibility for the ENERGY STAR label, as well as LEED-EB certification, the EPA's free online tool, Portfolio Manager, can be used (www.energystar.gov/benchmark). If the school facility scores 75 or higher (of a maximum of 100) using Portfolio Manager, a professional engineer will verify and approve the analysis. Detailed procedures for earning the ENERGY STAR labels can be found at www.energystar.gov, including case studies, useful information for educational facilities, and a list of professional engineers who provide free verification services. A database of ENERGY STAR labeled K-12 schools can be found online as well.

Collaborative for High Performance Schools (CHPS)

CHPS (www.chps.net) is leading a national movement to improve student performance and the entire educational experience by building the best possible schools. CHPS provides useful information for designing and maintaining high-performance schools. The following is a list of best practices and information available from CHPS:

- Planning for high-performance schools
- Design for high-performance schools
- Maintenance and operations of high-performance schools
- Commissioning of high-performance schools
- High-performance relocatable classrooms

In addition, lists of CHPS criteria for several states are available.

Laboratories for the 21st Century (Labs21)

Laboratories for the 21st Century (Labs21; EPA [2010]) is designed to meet the needs of facility designers, engineers, owners, and facility managers of laboratory and similar high-performance facilities. Cosponsored by the EPA and DOE, Labs21 offers the opportunity for worldwide information exchange and education.

The primary guiding principle of the Labs21 approach is that improving a facility's energy efficiency and environmental performance requires examining the entire facility from a whole-building perspective. This perspective allows owners to improve the efficiency of the entire facility, rather than focusing on specific building components. The Labs21 program provides excellent information for laboratory design, energy conservation, best practices, and tools, such as the following:

- Introduction to low-energy design
- Design guide for energy-efficient research labs
- Best practice guides
- Case studies
- Energy benchmarking
- Laboratory equipment efficiency wiki
- Environmental performance criteria

Table 13 Examples of Domestic and International Rating Systems

Rating System	Country
BRE Environmental Assessment Method (BREEAM)	U.K.
Comprehensive Assessment System for Building Environmental Efficiency (CASBEE)	Japan
Germany Sustainable Building Certificate (DGNB)	Germany
Green Building Evaluation Standard (Three-Star System)	China
Green Globes System	Canada
Green Star	Australia
Hong Kong Building Environmental Assessment Method (HK-BEAM)	China (Hong Kong only)
National Green Building Standard	United States

- Design intent tool
- Labs21 design process manual

Additional information can be found at lbt.i2sl.org.

EnergySmart Schools

The EnergySmart Schools (U.S. DOE 2009) program provides energy efficiency information on planning, financing, design build and operation and maintenance of schools at www.energy.gov/sites/prod/files/2013/11/f5/ess_o-and-m-guide.pdf.

Other Domestic and International Rating Systems

Additional domestic and international systems are shown in Table 13.

5. ENERGY CONSIDERATIONS

Energy standards such as ANSI/ASHRAE/IESNA *Standard* 90.1-2016 and local energy codes should be followed for minimum energy conservation criteria. Because the HVAC&R designer deals mostly with the mechanical systems, Table 14 presents a list of selected energy conservation measures. Note that additional measures such as modifications to lighting, motors/drives, building envelope, and electrical services should be considered for energy reduction. Energy procurement or supply-side opportunities should also be investigated for energy cost reduction.

6. ENERGY MEASUREMENT AND VERIFICATION (M&V)

Energy measurement and verification (M&V) is the process of measuring and verifying both energy and cost savings resulting from implementation of an energy conservation measure. An energy conservation measure is defined as the installation or modification of energy-using equipment, or systems, for the purpose of reducing energy use and/or costs.

M&V should be used by anyone wishing to prove the achievement of savings in utility resources (e.g., energy, water) delivered through any type of savings project or program. This typically includes

- Building owners and managers
- Facility managers, plant and process engineers,
- Energy service companies (ESCO) and other energy services professionals, such as energy auditors and energy management consultants, who provide advice or deliver energy savings through an energy performance (EPC), or other contracting arrangements

Energy M&V essentially compares energy use before and after an energy retrofit, taking into account and adjusting for non-retrofit changes (e.g., weather, occupancy schedules) that affect energy use. These variables must be removed to objectively calculate the energy savings from the energy conservation measure. Chapter 42 provides additional information on M&V.

The following is a short overview of M&V methodologies from the two major authorities. Other sources for M&V include DOE (2015) and EVO (2018).

ASHRAE *Guideline* 14-2014

ASHRAE *Guideline* 14-2014 is a reference for calculating energy and demand savings associated with performance contracts. In addition, it sets forth instrumentation and data management guidelines and describes methods for accounting for uncertainty associated with models and measurements; for compliance, the overall uncertainty of savings estimates must be below prescribed thresholds. It does not discuss other issues related to performance contracting. *Guideline* 14 describes three M&V procedures. The three approaches are closely related to and support the options provided in the *International Performance Measurement and Verification Protocol* (IPMVP) (EVO 2018):

- **Whole-building approach.** This approach uses a main meter to measure energy flow to the whole building, a group of buildings, or separate sections of a building. Energy flow is usually electric, gas, oil, and thermal. One or more of the systems served by the meter may have energy conservation measures (ECMs) applied. This approach may involve using monthly utility bill data, or data gathered more frequently from a main meter.
- **Retrofit isolation approach.** This approach uses meters to isolate energy use and/or demand of ECM-controlled subsystems (e.g., lighting, chiller, boiler) from that of the rest of the facility. These measurements may be made once before and once after the retrofit, periodically, or continuously. Savings derived from isolated and metered systems may be used as a basis for determining savings in similar but unmetered systems in the same facility, if they are subjected to similar operating conditions throughout the baseline and post-retrofit periods.
- **Whole-building calibrated simulation approach.** This approach involves using a computer simulation tool to create a model of the facility's energy use and demand. The model, which is typically of pre-retrofit conditions, is calibrated or checked against actual measured energy use and demand data, and possibly other operating data. The calibrated model is then used to predict energy use and demand under post-retrofit conditions. Savings are derived by comparing modeled results under the two sets of conditions, or by comparing modeled and actual metered results.

International Performance Measurement and Verification Protocol (IPMVP; 2007)

The IPMVP groups M&V methodologies into four general categories (Table 15).

The options are generic M&V approaches for energy and water saving projects. As in ASHRAE *Guideline* 14, the IPMVP M&V approaches are divided into two general types: retrofit isolation and whole facility. Retrofit isolation methods look only at the affected equipment or system independent of the rest of the facility; whole-facility methods consider the total energy use and deemphasize specific equipment performance.

7. SELECTED TOPICS IN ENERGY AND DESIGN

Energy Efficiency and Integrated Design Process (IDP)

An integrated design process (IDP) is vital for the design of high-performance educational facilities. Chapter 60 covers the concept of integrated building design (IBD) and IDP in detail, and additional information can be found on the Northwest Energy Efficiency Alliance's BetterBricks web site (www.betterbricks.com/solutions/integrated-design).

Table 14 Selected Potential Energy Conservation Measures

Category	Description
HVAC air side	DDC systems upgrade
	Variable-speed drives on fan motors
	Conversion from constant volume (CV) to variable air volume (VAV)
	Air-side economizer
	Temperature set point adjustments
	Exhaust fume hood controls modifications
	Reheat minimization
	DOAS and air-to-air energy recovery
	Destratification fans
	Airflow reduction and air-side retrocommissioning in laboratories
	Active chilled beams (classrooms, laboratories, etc.)
	Natural ventilation (where applicable)
	Evaporative cooling (where applicable)
Chiller plants	Chiller plant operation optimization (hydronic system)
	Chiller(s) replacement
	Chiller energy source switching
	Heat recovery (from CHP) driven chiller
	Cooling tower repair, optimization, replacement
	Cooling tower water treatment optimization
	Cooling tower fans conversion to variable speed
	Water-side free cooling
	Conversion of DX system to chilled water
	Offline chiller isolation
	Chilled/condenser water temperature reset
	Thermal storage
Boiler plants	Boiler optimization/replacement
	Burner optimization/replacements
	Oxygen and excess air trim controls
	Conversion of linkage-based burner control to parallel positioning (servo motors)
	Dual-fuel switching/capability
	Boiler heat recovery (stack economizer)
	Condensing boilers
	Boiler temperature reset
	Offline boiler isolation
	Automatic blowdown control
	Blowdown heat recovery
	Condensate systems upgrade and optimization
	Feed water delivery improvements
	Water treatment optimization
Steam and chilled-water distribution	Steam distribution pressure control
	Steam trap repair/replacement/program
	Insulation repairs/upgrade
	Piping balancing
	Variable-speed pumping
	Primary/secondary piping
	Conversion from constant flow to variable flow
Energy management and control systems	LAN systems/network interfacing
	Equipment sequencing
	Conversion to DDC system
	Space temperature setback and setup
	Demand control ventilation (DCV)
	Chiller plant efficiency monitoring (see ASHRAE *Guideline* 22-2008)
	Boiler plant efficiency monitoring (steam flow and gas flow)
	Duty cycling
	Chiller plant control optimization
	Boilers sequencing optimization
	Load shedding
	Remote communications
	Equipment performance and energy use monitoring
	Preventive/predictive maintenance
	Automated/web-based fault detection and diagnostics (FDD)
	Airflow and water flow measurements
	Energy metering and submetering
	Emissions and/or CO_2 tracking
Central plant supply side and renewable energy	Combined heat and power (CHP)
	Solar energy (thermal)
	Photovoltaic applications
	Wind energy
	Geothermal energy and hybrid geothermal systems
Domestic hot water	Condensing water heaters
	Demand (tankless or instantaneous) water heaters
	Heat pump water heaters
	Solar domestic water heater and pool water heating

Source: Adapted from Petchers (2002).

Unlike the sequential design process (SDP), in which the elements of the built solution are defined and developed in a systematic and sequential manner, the integrated design process (IDP) encourages holistic collaboration of the project team during all phases of the project, resulting in cost-effective and environmentally friendly design. IDP is accomplished by responding to the project objectives, typically established by the owner before team selection. A typical IDP approach includes the following elements:

- Owner planning
- Predesign
- Schematic design
- Design development
- Construction documents
- Procurement
- Construction
- Operation

Detailed information on each element can be found in Chapter 60.

In high-performance buildings, the objectives are typically related to site sustainability, water efficiency, energy and atmosphere, materials and resources, and indoor environmental quality. These objectives are in fact the main components of several rating systems. As indicated previously, the HVAC&R designer is heavily involved in meeting energy efficiency objectives. Energy use objectives are typically the following:

- Meeting minimum prescriptive compliance (mainly local energy codes, ANSI/ASHRAE/IESNA *Standard* 90.1, etc.)
- Improving energy performance by an owner-defined percentage beyond the applicable code benchmark
- Demonstrating minimum energy performance (or prerequisite) and enhanced energy efficiency (for credit points) for sustainable design rating (e.g., USGBC; LEED®; energy and atmosphere using ANSI/ASHRAE/IESNA *Standard* 90.1, Appendix G)
- Providing a facility/building site energy density (e.g., energy utilization index [EUI]) less than an owner-defined target (e.g., EPA, ENERGY STAR’s Portfolio Manager)

Table 15 IPMVP M&V Options

M&V Option	Performance[a] and Usage[b] Factors	Savings Calculation
Option A: Retrofit isolation with key parameter measurement	Based on combination of measured and estimated factors when variations in factors are not expected. Measurements are spot or short-term and taken at component or system level, in both baseline and postinstallation cases. Measurements should include key performance parameter(s) that define ECM's energy use. Estimated factors are supported by historical or manufacturer's data. Savings determined by engineering calculations of baseline and postinstallation energy use based on measured and estimated values.	Direct measurements and estimated values, engineering calculations and/or component or system models often developed through regression analysis. Adjustments to models are not typically required.
Option B: Retrofit isolation with all-parameter measurement	Based on periodic or continuous measurements of energy use taken at the component or system level when variations in factors are expected. Energy or proxies of energy use are measured continuously. Periodic spot or short-term measurements may suffice when variations in factors are not expected. Savings determined from analysis of baseline and reporting period energy use or proxies of energy use.	Direct measurements, engineering calculations, and/or component or system models often developed through regression analysis. Adjustments to models may be required.
Option C: Utility data analysis (whole facility)	Based on long-term, continuous, whole-building utility meter, facility level, or submeter energy (or water) data. Savings determined from analysis of baseline and reporting-period energy data. Typically, regression analysis is conducted to correlate with and adjust energy use to independent variables such as weather, but simple comparisons may also be used.	Based on regression analysis of utility meter data to account for factors that drive energy use. Adjustments to models are typically required.
Option D: Calibrated computer simulation (retrofit isolation or whole facility)	Computer simulation software is used to model energy performance of a whole facility (or subfacility). Models must be calibrated with actual hourly or monthly billing data from the facility. Implementation of simulation modeling requires engineering expertise. Inputs to the model include facility characteristics; performance specifications of new and existing equipment or systems; engineering estimates, spot-, short-term, or long-term measurements of system components; and long-term whole-building utility meter data. After the model has been calibrated, savings are determined by comparing a simulation of the baseline with either a simulation of the performance period or actual utility data.	Based on computer simulation model (e.g., eQUEST) calibrated with whole-building, end-use metered data, or both. Adjustments to models are required.

Source: FEMP (2008).
[a]Performance factors indicate equipment or system performance characteristics, such as kW for a chiller or watts/fixture for lighting.
[b]Operating factors indicate equipment or system operating characteristics such as annual cooling ton-hours for chillers or operating hours for lighting.

- Providing a facility/building source energy density less than an owner-defined target
- Deriving an owner-defined percentage of facility source energy from renewable energy

Building Energy Modeling

Building energy modeling has been one of the most important tools in the process of IDP and sustainable design. Building energy modeling uses sophisticated methods and tools to estimate the energy consumption and behavior of buildings and building systems. To better clarify the concept of energy modeling, the difference between HVAC sizing and selection programs and energy modeling tools will be described.

Design, sizing selection, and equipment sizing tools are typically used for design and sizing of HVAC&R systems normally at the design point. Examples include the following:

- Cooling/heating loads calculations tools
- Ductwork design
- Piping design
- Acoustics
- Equipment selection programs for air-handling units, packaged rooftop units, fans, chillers, pumps, diffusers, etc.

These tools are used to specify cooling and heating capacities, airflow, water flow, equipment size, etc., at a design point as defined and agreed by the client.

Energy modeling (or building modeling and simulation) is used to model the building's thermal behavior and the performance of building energy systems. Unlike design tools, which are used for one design point or for sizing, the building energy simulation analyzes the building and its systems up to 8760 times (or hour-by-hour, or in some cases in smaller time intervals).

A building energy simulation tool is a computer program consisting of mathematical models of building elements and HVAC&R equipment. To run a building energy simulation, the user must define the building elements, equipment variables, energy cost, and so on. After these variables are defined, the simulation engine solves mathematical models of the building elements, equipment, etc., typically through a sequential process, 8760 times (one for every hour). Results include annual energy consumption, annual energy cost, hourly profiles of cooling loads, and hourly energy consumption. Chapter 19 of the 2017 *ASHRAE Handbook—Fundamentals* provides detailed information on energy modeling techniques.

Typically, energy modeling tools (or building energy simulation programs) have to meet minimum requirements to be accepted by rating authorities such as the USGBC and local building codes. The following is a typical minimum modeling capabilities for building energy simulation program:

- 8760 h per year
- Hourly variations in occupancy, lighting power, miscellaneous equipment power, thermostat set points, and HVAC system operation are defined separately for each day of the week and holidays
- Thermal mass effects
- Ten or more thermal zones
- Part-load performance curves for mechanical equipment
- Capacity and efficiency correction curves for mechanical heating and cooling equipment
- Air-side economizers with integrated control
- Capable of performing design load calculations to determine required HVAC equipment capacities and air and water flow rates in accordance with generally accepted engineering standards and handbooks (e.g., *ASHRAE Handbook—Fundamentals*)
- Testing according to ASHRAE *Standard* 140

Energy modeling is typically used for the following applications:

- As a decision support tool to analyze several design alternatives and select the optimal solution for a given set of criteria for energy systems in new construction and retrofit projects.
- To provide vital information to the engineer about the building behavior and systems performance during the design stage
- To demonstrate compliance with energy standards such as ASHRAE *Standard* 90.1, section 11 (energy cost budget method)
- To support LEED certification in the energy and atmosphere (EA) section
- To model existing buildings and systems and analyze proposed energy conservation measures (ECMs) by performing calibrated simulation
- To demonstrate energy cost savings as part of measurements and verification (M&V) protocol by using calibrated simulation procedures

Energy modeling is used intensively in LEED for Schools (USGBC 2009a), energy and atmosphere (EA), prerequisite 2 (minimum energy performance), and for EA credit 1 (optimize energy performance). An energy simulation program meeting the preceding requirements and those of ASHRAE *Standard* 90.1, Appendix G, is used to perform whole-building energy simulation to demonstrate energy cost savings. The number of credits awarded is in correlation to the energy cost reduction. ASHRAE *Standard* 90.1-2016 added another simulation-based compliance path based on Appendix G (Performance Rating Method).

Energy Benchmarking and Benchmarking Tools

Energy benchmarking is an important element of energy use evaluation and tracking, comparing a building's normalized energy consumption to that of other similar buildings. The most common normalization factor is gross floor area. Energy benchmarking is less accurate than other energy analysis methods, but can provide a good overall picture of relative energy use.

Relative energy use is commonly expressed by an energy utilization index (EUI), which is the energy use per unit area per year. Typically EUI is defined in terms of MJ/m^2 per year. In some cases, the user is interested in energy cost benchmarking, which is known as the cost utilization index (CUI), with units of \$/m^2 per year. It is important to differentiate between *site* EUI and *source* EUI. Building energy use can be reported as the actual energy used on site (i.e., site EUI), or as energy used at the energy source (i.e., source EUI). About two-thirds of the primary energy that goes into an electric power plant is lost in the process as waste heat.

One of the most important sources of energy benchmarking data is the U.S. DOE Energy Information Administration's (DOE/EIA) Commercial Building Energy Consumption Survey (CBECS). Table 2 of Chapter 37 shows an example of EUI calculated based on DOE/EIA 2003 CBECS. As shown in that table, the mean site EUI for high schools is 765 MJ/yr per square meter.

The following is a list of common energy benchmarking tools:

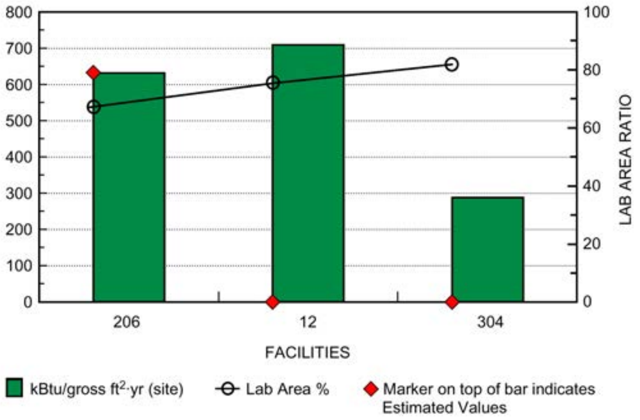
- U.S. EPA ENERGY STAR Portfolio Manager (www.energystar.gov/benchmark)
- Labs 21 for laboratory energy benchmarking (lbt.i2sl.org)

An example of laboratory energy benchmarking (in I-P units) is shown in Figure 8.

Comprehensive information on energy benchmarking and available benchmarking tools can be found in Glazer (2006) and Chapter 37.

Combined Heat and Power in Educational Facilities

Combined heat and power (CHP) plants and building cooling, heating, and power (BCHP) can be considered for large facilities when economically justifiable. Chapter 7 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and other sources such as Meckler and Hyman (2010), Orlando (1996), Petchers (2002), and ASHRAE's *Combined Heat and Power Design Guide* (2015) provide information on CHP systems. Additional Internet-based sources for CHP include the following:



METRIC	MINIMUM	AVERAGE	MAXIMUM	COUNT
TOTAL BUILDING kBtu/gross $ft^2 \cdot yr$ (SITE)	285.78	542.37	708.61	3

FACILITY	LAB TYPE	YEAR	kBtu/gross $ft^2 \cdot yr$ (site)	LAB AREA RATIO	OCCUPANCY HOURS PER WEEK	CLIMATE
206	Biological	2007	632.73	67%	108	5A
12	Biological	2001	708.61	75%	144	5A
304	Biological	2008	285.78	82%	100	5A

Fig. 8 Example of Laboratory Building Energy Benchmarking (Labs 21)

- U.S. EPA Combined Heat and Power (CHP) Partnership, at www.epa.gov/chp/
- U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, at www.energy.gov/eere/
- The U.S. DOE Midwest CHP Technical Assistance Partnership, at www.midwestchptap.org

A market analysis report by Ryan (2004) clearly suggests that secondary schools (9-12) are more suitable for BCHP than primary schools, because secondary schools

- Are more likely to operate 12 months a year
- Are more likely to contain an indoor swimming pool facility
- Are more likely to operate into the evenings and weekends, allowing longer period of BCHP operation
- Typically contain gymnasiums with shower facilities

The EPA's Combined Heat and Power (CHP) Partnership web site can be consulted for procedures of conducting feasibility studies and evaluations for CHP integration.

Maor and Reddy (2008) describe a procedure to optimally size the prime mover and thermally operated chiller for a large school by combining a building energy simulation program and a CHP optimization tool.

A database of CHP installations is available at doe.icfwebservices.com/chpdb/.

CHP is more common for large colleges and universities than for primary or secondary schools, given their larger scale and ability to use waste heat efficiently. Because many large colleges and universities are equipped with large district cooling and heating facilities, the integration of CHP can be very cost effective.

The type of prime mover depends heavily on the electrical and thermal loads, ability to use the waste heat efficiently, and utility rates. Typically, schools are good candidates for gas-fired reciprocating engine prime movers or microturbine-based systems. Large universities can use reciprocating engine prime movers or gas-fired combustion turbines. Table 1 in Chapter 7 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* provides information on the applicability of CHP.

Renewable Energy

The U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy (EERE) (U.S. DOE 2014; www.energy.gov/eere) discusses several renewable energy (RE) options for schools, including solar, wind, and biomass.

Renewable energy utilization can add credits for USGBC LEED for Schools (USGBC 2009a), energy and atmosphere (credit 2) by awarding credits depending on the percentage of renewable energy used.

Given the increased number and popularity of solar systems in educational facilities, only these systems will be discussed in this chapter. Geothermal energy is also considered renewable; these systems are discussed earlier in this chapter and in Chapter 35.

Solar: Photovoltaic. Photovoltaic (PV) technology is the direct conversion of sunlight to electricity using semiconductor devices called solar cells. Photovoltaics are almost maintenance-free and seem to have a long lifespan. Their longevity, lack of pollution, simplicity, and minimal resource requirements make this technology highly sustainable, and, along with the proper financing mechanisms (as explained later), these systems can be economically justifiable.

Educational facilities are excellent candidate for PV technology due to the following reasons:

- Availability of large roof area or (in some cases) areas suitable for PV canopies
- Hours and seasons of operation
- Educational as a showcase of renewable energy technologies

The most common PV cell technology in use today is crystalline silicon, which uses silicon wafers wired together and attached to a module substrate. Crystalline silicon cells may be monocrystalline or polycrystalline, with the monocrystalline cells typically having a higher efficiency and correspondingly higher cost. Thin-film PV technologies, such as amorphous silicon and cadmium-telluride, are based on depositing chemicals directly onto a substrate (e.g., glass or flexible stainless steel). The cost of producing crystalline silicon PV modules has dropped dramatically in recent years, and as a result, crystalline silicon technology currently accounts for over 90% of PV module production worldwide.

PV modules produce direct current (DC), not the alternating current (AC) used to power most building equipment. Thus, an inverter is required to transform the DC power to grid-quality AC power. The simplest type of PV installation is a grid-connected system that operates when the utility grid is operating and shuts down in the event of a utility grid outage. Adding storage batteries to the system increases cost but can also add functionality, such as the ability to operate the PV/storage during a grid outage to provide back-up power, or the ability to deploy energy storage to reduce peak customer demand at a facility. Design and installation of PV systems require careful evaluation and engineering expertise to accommodate issues such as availability of spaces, installation type (roof, parking canopy, or ground mount), site constraints, etc., which impact the cost and the economics of the installation.

The ability to transfer excess electricity generated by a photovoltaic system back into the utility grid can be advantageous for schools. Most utilities are required to buy excess site-generated electricity back from the customer. In many states, public utility commissions or state legislatures have mandated net metering: utilities pay and charge equal rates regardless of which way the electricity flows. School districts in these states will find PV more economically attractive. A good source of information on rebates and incentives for solar systems and other renewable technologies is the Database of State Incentives for Renewables & Efficiency (DSIRE [NCSU 2018], www.dsireusa.org), which is a comprehensive source of information on state, local, utility, and federal incentives and policies that promote renewable energy and energy efficiency.

PV systems should be integrated during the early stages of the design. In existing facilities, a licensed contractor can be employed for a turnkey project, which should include sizing, analysis, economic analysis, design documents, specifications, permits, documentation for incentives, etc. The DSIRE database also provides state requirements for licensed solar contractors.

RETScreen® (Renewable Energy and Energy-Efficient Technologies) is a free decision support tool at www.retscreen.net, developed to assist in evaluation of energy production and savings, costs, emission reductions, financial viability, and risk for various types of renewable energy technologies (RETScreen 2018). The program is available in 35 languages.

In addition, several commercial tools are available for analysis of PV systems.

Financing PV projects in the educational sector can be more complex because of tax exemptions and questions of how to most efficiently allocate public funds and leverage incentives; detailed information can be found in Bolinger (2009) and Cory et al. (2008). The primary mechanism that has emerged to finance public-sector PV projects is a third-party ownership model. This model allows the public sector take advantage of all the federal tax and other incentives without large up-front outlay of capital. The public sector does not own the solar PV, but only hosts it in its property. The cost of the electrical power generated is then secured at a fixed rate, which is lower than the retail price for 15 to 25 years.

Figures 9 and 10 show examples of educational facilities' PV projects.

Solar: Thermal. Educational facilities can be good candidates for active thermal solar heating systems. In most cases, a solar hot-water system can reduce the energy required for service hot water and pool heating. Solar heating design and installation information can be found in ASHRAE (1988, 1991). Chapter 37 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and Krieth and Goswami (2007) are good sources of information for design and installation of active solar systems. Online sources include the U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy's site at www.energy.gov/eere.

Fig. 9 Example of PV Installation at Ohlone College, Newark Center, Newark, CA: 450 kW, 3530 m^2
(Esberg 2010)

Value Engineering (VE) and Life-Cycle Cost Analysis (LCCA)

The use of value engineering (VE) and life-cycle cost analysis (LCCA) is growing in all types of construction and as part of the integrated design process (IDP) concept. In some cases, public facilities such as schools are required to use these procedures. Both VE and LCCA are logical, structured, systematic processes used with decision support tools to achieve overall cost reduction, but there are some distinctions between them (Anderson et al. 2004).

In value engineering, the project team examines the proposed design components in relation to the project objectives and requirements. The intent is to provide essential functions while exploring cost savings opportunities by modifying or eliminating nonessential design elements. Examples are using alternative systems or substituting equipment.

Life-cycle cost analysis is used to evaluate design alternatives (or alternative systems, equipment substitutions, etc., as part of VE) that meet the facility's design criteria with reduced cost or increased value over the life of the facility or system.

The combination of VE and LCCA is suitable for schools, because they are often government funded and intended for longer lifespans than commercial facilities. Unfortunately, VE and LCCA often are not included in the early design stages, which results in a last-minute effort to reduce cost and stay within the budget, compromising issues such as energy efficiency and overall value of the facility. Therefore, VE and LCCA should be deployed in the early stages of the project. VE and LCCA programs for large schools can add 0.1 to 0.5% in initial cost, but can save 5 to 10% of initial costs and 0.5 to 10% of operation and maintenance costs (Dell'Isola 1997).

LCCA is recommended for economic evaluation as part of any school construction. Chapters 38 and 60 discuss LCCA in detail. Other methodologies such as simple payback should be avoided because of inaccuracies and the need to take in account the time value of money. LCCA is more accurate: it captures all the major initial costs associated with each item, the costs occurring during the life of the system, and the value of money for the entire life of the system.

Chapter 38 provides details, tools, and examples of LCCA (see Table 7 in that chapter). Anderson et al. (2004) provides detailed information on all the aspects of design, construction management, cost control, and other resources for building and renovating schools.

The School as a Learning Tool for Energy Conservation and Sustainability

Schools are excellent for enhancing students' interest in energy efficiency and sustainable design from a young age. USGBC (2009a)'s LEED® for Schools awards one point for integrating high-performance features in the school curriculum (ID section, credit 3). Sources for this integration include the following:

- National Energy Education Development (NEED) project (www.need.org)
- Alliance to Save Energy's PowerSave Schools Program (ase.org/projects/powersave-schools)
- National Energy Foundation educational resources (nef1.org/)
- Energy Information Administration's Energy Kids web site (www.eia.gov/kids/index.cfm)

In addition, real-time feedback on how systems such as photovoltaic electrical generation, geothermal heat pumps, and water conservation save energy and operating costs is recommended. Seibert (2010) shows these features, as illustrated in Figure 11.

Fig. 10 Example of PV Installation at Twenhofel Middle School, Independence, KY: 22 kW
(Seibert 2010)

8. ENERGY DASHBOARDS

Energy dashboards provide information such as energy consumption, energy cost, EUI, CO_2 levels, or Energy Star rating. In some cases, the energy dashboard is part of an enterprise that incorporates features such as fault detection and diagnostics (FDD) tools, tracking of energy conservation projects, information-sharing tools, and other analytical features to enhance energy conservation. Educational facilities are good candidates for this system: for example, a school district can monitor and track the energy consumption of every school in the district in nearly real time. One good example is the Build Smart DC program (www.buildsmartdc.com/buildings/).

Features of Build Smart DC include the following:

- Tens of thousands of data points (15 min electricity data) delivered daily: annual energy consumption, annual energy cost, EUI, and Energy Star score
- Descriptions of energy efficiency projects ranging from low-cost building management system updates to full-scale school systems upgrades

Figure 12 depicts an example of the Build Smart DC energy dashboard for elementary and middle schools in Washington, D.C.

Figure 13 shows an example of higher education energy dashboard for a campus-scale facility with multiple buildings, where each individual building can be tracked, as shown in Figure 14.

Remember, however, that regardless of its sophistication, an energy dashboard will not save energy without action by site personnel (e.g., adjusting schedules or set points, fixing equipment malfunction).

Central Plant Optimization for Higher Education Facilities

Higher education facilities where numerous individual buildings are combined in a campus setting often use large central plants to provide cooling, heating, and/or power. These applications are ideal for central plant optimization, to improve operations and lower operating costs. Given the complexity of such large central plants, which use multiple types of equipment, an optimization solution can help to ensure efficient operation.

Common components in large central plants include the following:

Central Cooling Plants

- Multiple **chillers** of different types (e.g., electric cooling only, electric heat pump or heat recovery, thermally operated [steam and hot-water absorption or gas-fired absorption], steam-driven electric chillers). Each type has unique characteristics with respect to operating, efficiency at full- and part-load conditions, and controls (e.g., variable-speed drive, slide valves, inlet guide vanes).
- Multiple **cooling towers** of various types, different efficiencies, a wide range of operation (in range and approach), and different fan controls (e.g., variable speed, staging of cells, fan motor stages).

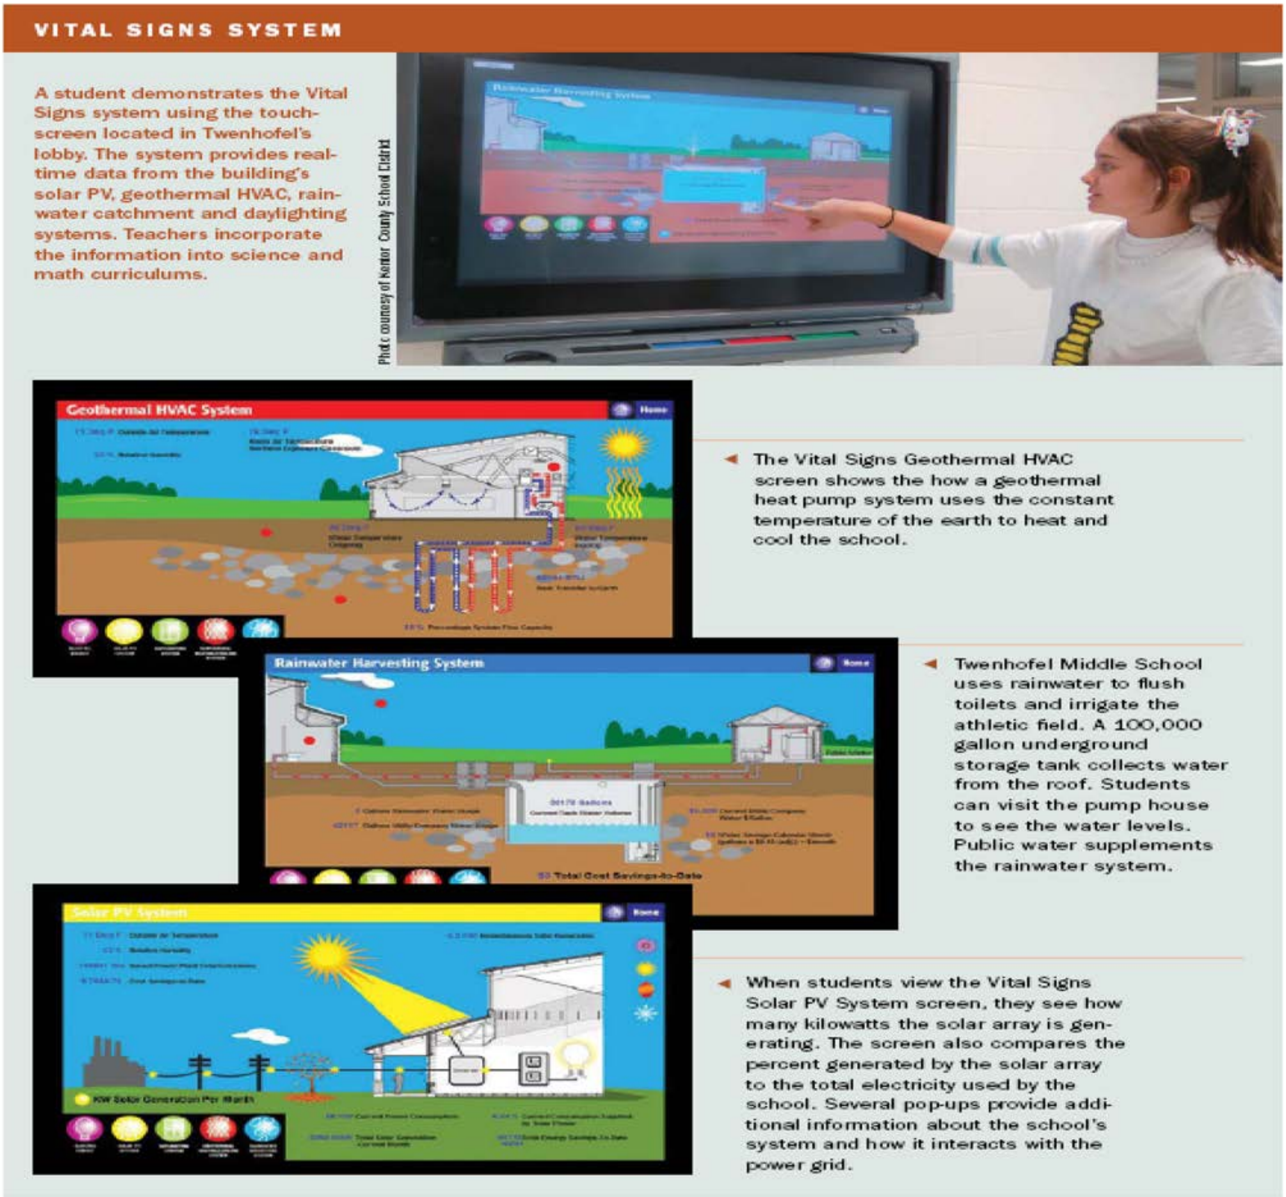


Fig. 11 Integration of Sustainability Features for Educational Purposes, Twenhofel Middle School, Independence, KY
(Seibert 2010)

- **Cold storage** (chilled water or ice).
- **Water-side economizer.**
- Multiple chilled- and condenser-water **pumps** of different sizes.
- Different **chilled-water distribution** arrangements such as primary/secondary (e.g., constant-flow primary and variable-flow secondary), variable-flow primary, etc.
- Different **condenser water distribution** arrangements such as headered layout, dedicated pump for each chiller, etc.

Central Heating Plants

- Multiple **steam boilers** with different fuel types (e.g., gas powered, dual fuel).
- Multiple **hot-water boilers** with different fuel types (e.g., gas powered, dual fuel).
- **Heat pump chillers.**
- **Hot-water storage.**
- **Waste heat heat exchangers.**
- **Hot-water pumps.**
- **Hot-water distribution systems.**

On-Site Power Generation and Storage

- **Power generating prime movers** (e.g., reciprocating engines, gas turbines, micro turbines, steam turbines, fuel cells).
- **Battery storage.**
- **Solar photovoltaics.**

In addition to having to properly operate and maintain various equipment, the operation of central plants is further complicated by variables such as

- **Weather.** Changes in ambient conditions affect campus cooling, heating, and electrical loads that must be met by the central plant. Ambient conditions also affect the operation and efficiency of the plant equipment (e.g., impact of wet-bulb temperature on cooling tower operation).

Fig. 12 Building Smart DC Example for Whittier Elementary School, Washington D.C. (ENERGYSTAR Score: 76)
(www.buildsmartdc.com/buildings/270/)

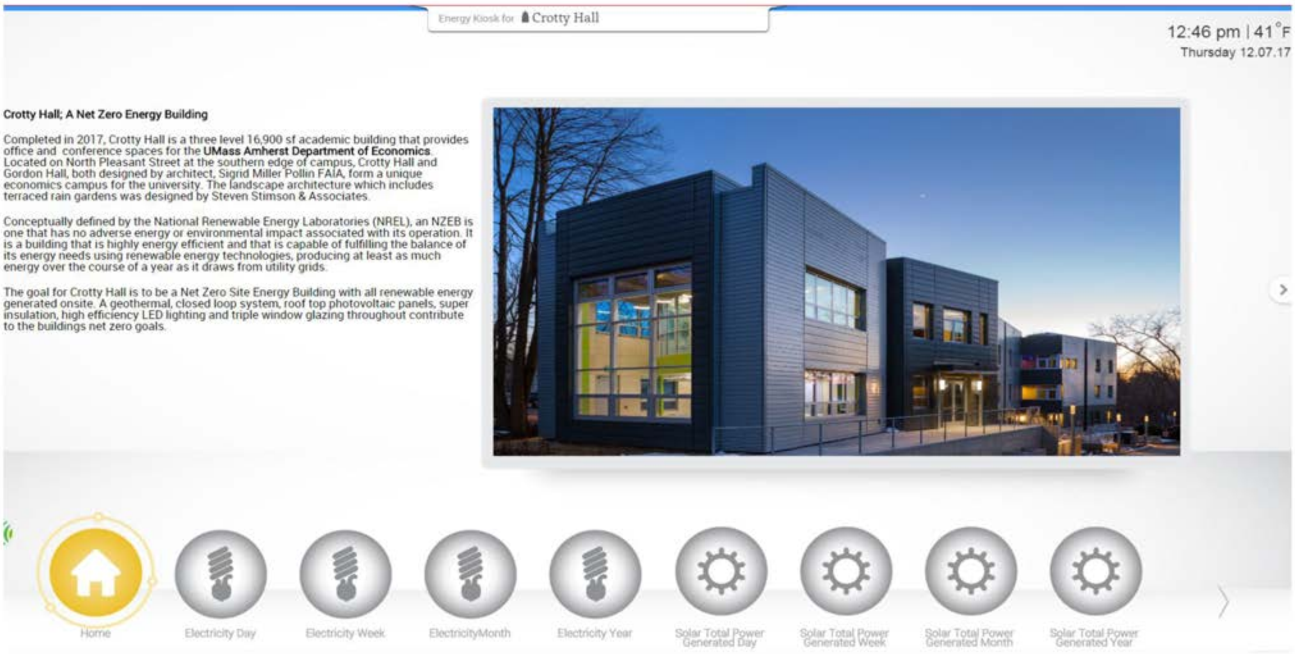

Fig. 13 Energy Kiosk Example for University of Massachusetts Amherst MA
(bedashboard.com/Kiosk/Home/index/20/5359)

- **Load profiles.** The cooling, heating, and electrical loads of the campus, on an hourly or sub-hourly basis, determine what central plant equipment needs to operate and at what capacities and combinations. Campus load profiles are typically an aggregation of a large number of buildings, each with different individual load patterns (e.g., classrooms, lecture halls, laboratories, dormitories, dining facilities, recreational facilities, office/administration).
- **Utility rates.** Utility rate structures (for electricity, fossil fuels, and water) can vary significantly depending on the application and location. To minimize operating cost, knowledge of the rate structures is critical (e.g., time-of-use charges, demand ratchets, real time pricing).

Central plant optimization solutions typically attempt to minimize the plant's energy consumption by altering variables and making decisions related to the following:

- Chilled-water temperature set points
- Condenser-water temperature set points
- Chilled-water differential pressure set points
- Staging of chillers, water-side economizers, and cold storage systems

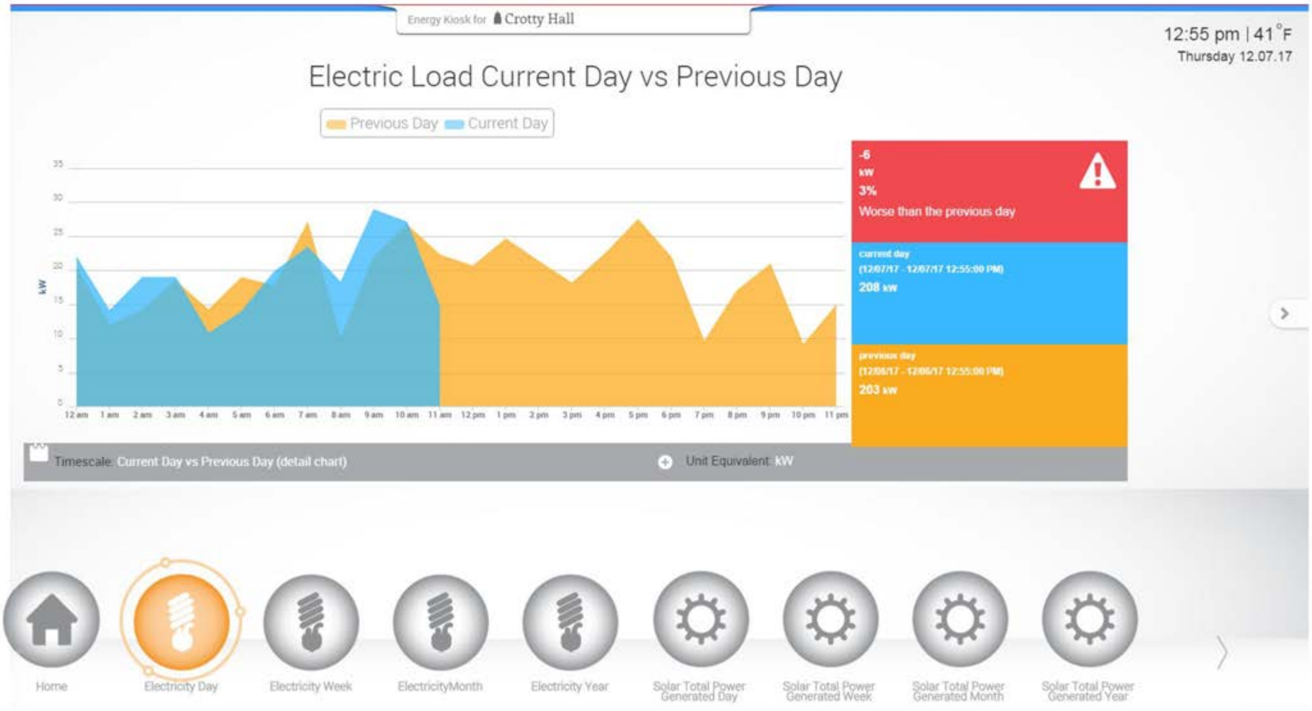

Fig. 14 Energy Kiosk Example for University of Massachusetts Amherst Tracking Specific Building on Campus
(bedashboard.com/Kiosk/Home/index/20/5359)

- Sequencing and speed control of chilled-water and condenser pumps
- Sequencing of cooling towers and cooling tower fan speed control
- Hot-water temperature set points
- Boiler, heat recovery heat exchangers, hot-water storage staging
- Heat pump and heat recovery chillers/heater
- Staging of on-site electrical power prime mover generators (e.g., reciprocating engines, gas turbine) and electrical storage

Given this complexity, and with so many decisions to make, a single control sequence or manual operation without the aid of more sophisticated tools cannot maximize operating efficiency or minimize operating cost of all plant equipment, under all weather conditions, load conditions, and utility rate structure scenarios. In addition, at any given moment in time, there may be multiple ways to meet a cooling, heating, and electrical load by the different types of plant equipment. For example, in a large central plant, the current cooling load could be met by an electric centrifugal chiller, heat pump chiller, water-side economizer, thermally operated chillers, or cold water storage tank. Similarly, for cases that have on-site power generation equipment, electrical power can be generated at the site, purchased from the local utility, or discharged from electrical storage; furthermore, waste heat from the power generation can be used to provide heat or heat for thermally operated chillers, and the optimal approach at any moment may not be intuitively obvious.

Chapter 43 provides information on optimization theory, methods, and procedures for central plants. Typical central plant optimization involves determining the control sequence and parameters (i.e., set points) that minimize total operating costs or total energy consumption. In Chapter 43, two broad classifications of optimization procedures are discussed: static optimization and dynamic optimization. **Static optimization** addresses the problem of optimizing the operation of a system at a given instant by operating each component of the system at conditions that achieve an optimal result. Typically, energy cost minimization involves using an objective function that is the sum of the operating costs of each component (e.g., chillers, pumps, cooling towers, boilers) with respect to all discrete and continuous controls and subject to both equality and inequality constraints (imposed by the physical realities of the system).

Dynamic optimization addresses control of the system over time. Therefore, it must account for the possibility that future conditions (e.g., weather, loads, utility prices) may impact the optimal control decisions in a given moment. In addition, present control decisions may impact operating conditions and optimal control decisions in the future. Methods such as model-predictive control (MPC) have been established to implement dynamic optimization of building systems. Figure 15 shows an example of a dynamic central plant optimization framework suitable for the operation of a higher education campus.

Central plant optimization solutions are typically integrated with site controls so that optimal operation of the plant occurs automatically. Some systems may also be able to run in an advisory mode, wherein the system provides recommendations to facilities personnel on how to optimize plant operating but does not directly control. Another common feature is real-time tracking of the plant's current operating conditions and efficiency, as shown in Figure 16.

Educational Facilities for Students with Disabilities

Although a large number of papers exist on students with disabilities, no clear HVAC system design guidelines or criteria were found to address the special requirements of these educational facilities. The intent of this section is to make the designer aware of the special considerations required to address accessibility issues during design, construction, and operation. Close coordination with the architect and other professionals is critical in addressing these requirements.

Students' disabilities can be classified by referring to the Individuals with Disabilities Education Act (IDEA), which covers 13 conditions (Understood.org 2019):

- **Specific learning disability (SLD).** Conditions in this group affect a child's ability to read, write, listen, speak, reason, or do math. Issues in this category include
  - Dyslexia

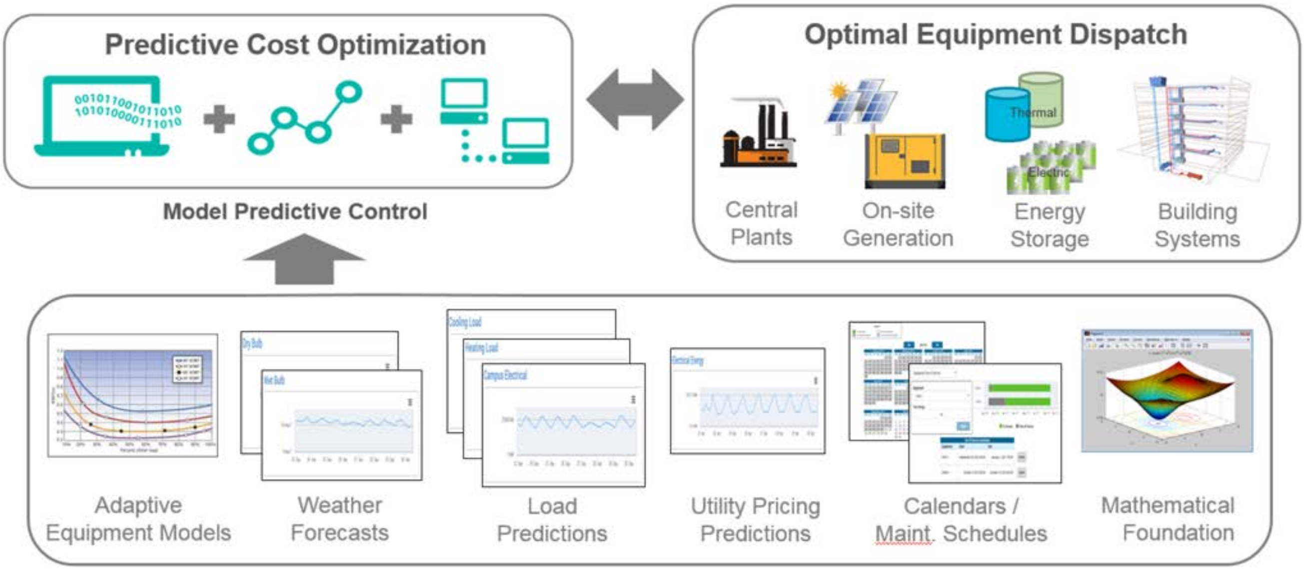

Fig. 15 Example of Dynamic Central Plant Optimization Framework for Higher Education Campus
(courtesy of Johnson Controls)

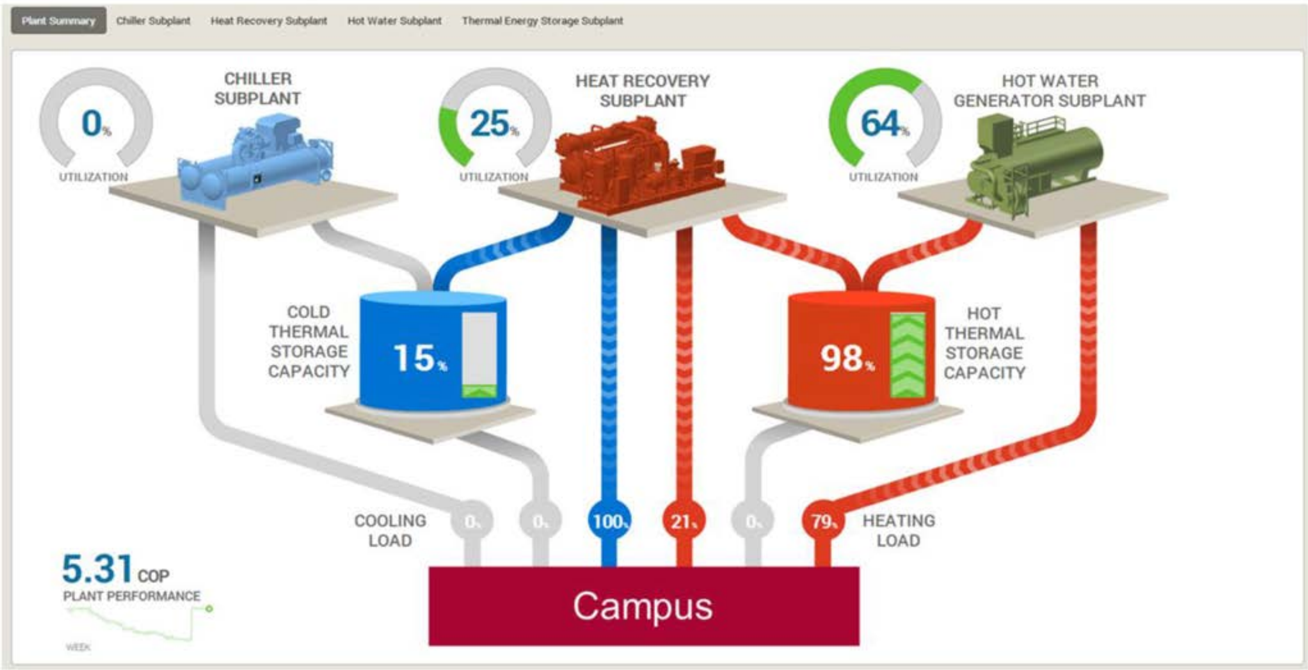

Fig. 16 Example of Central Plant Optimization System Operator Dashboard
(courtesy of Johnson Controls)

- Dysgraphia
- Dyscalculia
- Auditory processing disorder
- Nonverbal learning disability

- **Other health impairment.** These conditions limit a child's strength, energy, or alertness. ADHD is one example.
- **Autism spectrum disorder (ASD).** ASD is a developmental disability. It covers a wide range of symptoms and skills, but mainly affects a child's social and communication skills. It can also impact behavior.
- **Emotional disturbance.** Children covered under the term "emotional disturbance" can have a number of mental disorders. These include anxiety disorder, schizophrenia, bipolar disorder, obsessive-compulsive disorder, and depression.
- **Speech or language impairment.** The umbrella term "speech or language impairment" covers a number of communication problems, including stuttering, impaired articulation, language impairment, or voice impairment.
- **Visual impairment, including blindness.** A child who has vision problems is considered to have a visual impairment. This condition includes both partial sight and blindness. If a vision problem can be corrected with eyewear, it does not qualify.
- **Deafness.** Children with a diagnosis of deafness have a severe hearing impairment. They are unable to process language through hearing.

- **Hearing impairment.** This is a hearing loss not covered by the definition of deafness, and can change or fluctuate over time. There is a distinction between being hard of hearing and having auditory processing disorder.
- **Deaf-blindness.** Children with a diagnosis of deaf-blindness have both hearing and visual impairments. Their combined needs exceed those met by programs for the deaf or blind.
- **Orthopedic impairment.** Any impairment to a child's body, no matter the cause, is considered an orthopedic impairment. Cerebral palsy, caused by damage to areas of the brain that control the body, is one example.
- **Intellectual disability.** Children with this type of disability have below-average intellectual ability. They may also have poor communication, self-care, or social skills. Down syndrome is one example of an intellectual disability.
- **Traumatic brain injury.** This is a brain injury caused by an accident or some kind of physical force.
- **Multiple disabilities.** A child with multiple disabilities has more than one condition covered by IDEA. Having multiple issues creates educational needs that cannot be met in a program for any one condition.

Given the varied nature these disabilities, it is difficult to establish a set of HVAC design criteria that will be simultaneously acceptable for each disability. For HVAC system design, each disability may entail specific requirements for thermal comfort design criteria, ventilation and IAQ design criteria, and noise criteria.

Thermal comfort design criteria covering variables such as space temperature, humidity, thermal comfort, etc. for the disabilities described was not found. ASHRAE *Standard* 55 does not provide sufficient information to allow specification of these conditions. Webb and Parsons (1998) investigated thermal comfort levels of people with disabilities, and one of the conclusions (with the subjects tested) was that people with physical disabilities had widely varying responses, making it is necessary to evaluate the needs of people with physical disabilities on an individual or case-by-case basis.

Similarly, ventilation standards for acceptable indoor air quality (e.g., ASHRAE *Standard* 62.1) are not covering these cases, whereas "standard" educational facilities are well covered.

Noise criteria for educational facilities for students with disabilities are mentioned in ANSI *Standard* S.12.60-2010, suggesting that young children and persons with hearing, language, speech, attention deficit, or learning disabilities will benefit from the application of this standard.

More research is required to address educational facilities for students with disabilities.

9. COMMISSIONING

Commissioning (Cx) is a quality assurance process for buildings from predesign through design, construction, and operations. The commissioning process involves achieving, verifying, and documenting the performance of each system to meet the building's operational needs. Given the criticality of issues such as indoor air quality, thermal comfort, noise, etc., in educational facilities and the application of equipment and systems such as DOAS, EMS, and occupancy sensors, it is important to follow the commissioning process as described in Chapter 44 and ASHRAE *Guideline* 0-2013. Technical requirements for the commissioning process are described in detail in ASHRAE *Guideline* 1.1-2007; another useful source is from the AABC Commissioning Group (ACG 2005). Proper commissioning ensures that fully functional systems can be operated and maintained properly throughout the life of the building. Although commissioning activities should be implemented by a qualified commissioning professional or commissioning authority (CA), it is important for other professionals to understand the basic definitions and processes in commissioning.

The following are basic terms used in commissioning:

- **Owner's project requirements (OPR):** a written document that details the functional requirements of the project and the expectations of how it will be used and operated.
- **Commissioning process:** refers to a quality-focused process for enhancing the delivery of a project. The process focuses upon verifying and documenting that the facility and all its systems and assemblies are planned, installed, tested and maintained to meet the OPR
- **Recommissioning:** an application of the commissioning process to a project that has been delivered using the commissioning process.
- **Retrocommissioning** (also called **existing building commissioning**): applied to an existing facility that was not previously commissioned.
- **Ongoing commissioning:** an extension of the commissioning process well into the occupancy and operation phase.

Commissioning: New Construction

Table 16 shows the phases of commissioning, as defined in ASHRAE *Guideline* 1.1-2007.

ACG (2005) refers to the following HVAC commissioning processes for new construction:

- Comprehensive (starts at the inception of a building project from the predesign phase till postacceptance)
- Construction (takes place during construction, acceptance, and postacceptance; predesign and design phases are not included in this process)

Table 16 Key Commissioning Activities for New Building

Phase	Key Commissioning Activities
Predesign	Preparatory phase in which OPR is developed and defined.
Design	OPR is translated into construction documents, and basis of design (BOD) document is created to clearly convey assumptions and data used to develop the design solution. See Informative Annex K of ASHRAE *Guideline* 1.1-2007 for detailed structure and an example of a typical BOD.
Construction	The commissioning team is involved to ensure that systems and assemblies installed and placed into service meet the OPR.
Occupancy and operation*	The commissioning team is involved to verify ongoing compliance with the OPR.

*Also known as acceptance and post-acceptance in ACG (2005).

Table 17 Key Commissioning Activities for Existing Building

Phase	Key Commissioning Activities
Planning	Define HVAC goals
	Select a commissioning team
	Finalize recommissioning scope
	Documentation and site reviews
	Site survey
	Preparation of recommissioning plan
Implementation	Hire testing and balancing (TAB) agency and automatic temperature control (ATC) contractor
	Document and verify TAB and controls results
	Functional performance tests
	Analyze results
	Review operation and maintenance (O&M) practices
	Operation and maintenance (O&M) instruction and documentation
	Complete commissioning report

Source: Adapted from ACG (2005).

Commissioning is an important element in new construction. LEED® for Schools (USGBC 2009a) requires as a prerequisite (Energy and Atmosphere, prerequisite 1) verification that the project's energy-related systems are installed and calibrated and perform according to the OPR, BOD, and construction document. Additional credits (Energy & Atmosphere, and Enhanced Commissioning) can be obtained by applying the entire commissioning process (or comprehensive HVAC commissioning), as described previously.

Commissioning Existing Buildings

HVAC commissioning in existing buildings covers the following:

- Recommissioning
- Retrocommissioning (RCx)
- HVAC systems modifications

Although recommissioning and retrocommissioning differ, the methodology for both is identical. Retrocommissioning applies to buildings that were not previously commissioned. Recommissioning is initiated by the owner of a previously commissioned building, and seeks to resolve ongoing problems or to ensure that the systems continue to meet the facility's requirements. There also could have been changes in the building's occupancy, design strategies, equipment or equipment efficiency, occupant comfort, or IAQ that can initiate the need for recommissioning. Typical recommissioning activities are shown in Table 17.

Table 18 Selected Case Studies from *ASHRAE Journal*

Project Name	Facility Type	Location	Description	Publ. Date
University of California, Merced, Sierra Terraces	Higher ed.	Merced, California	Dormitory	May-10
De Anza College, Kirsch Center for Environmental Studies	Higher ed.	Cupertino, California	Classrooms, labs, open study stations	May-10
The Kahnawake Survival School (KSS)	K-12	Kahnawake, Québec, Canada	High school, community center, public assembly	May-10
Whitmore Lake High School	K-12	Whitmore Lake, Michigan	Gymnasium, cafeteria, natatorium, media center, commons area, and classrooms	May-10
Ann Arbor Skyline High School	K-12	Ann Arbor, Michigan	Classrooms, learning communities, gymnasiums, cafeteria/commons, lab spaces, decentralized administration, auditorium, black-box theater, and natatorium	May-11

Université de Sherbrooke, Campus Longueuil	Higher ed.	Longueuil, Québec, Canada	Classrooms, offices, labs, gathering areas, etc.	May-12
Maple School District, Northwestern High School	K-12	Maple, Wisconsin	Classrooms, labs, auditorium, gymnasium, and district offices	May-12
St. Clair County Community College: North Building	Higher ed.	Port Huron, Michigan	Faculty offices and instructional classrooms.	Sep-12
Jarvis Hall, The University of Wisconsin-Stout (UW-Stout)	Higher ed.	Menonomie, Wisconsin	Labs, vivarium, clean rooms, classrooms, offices, and greenhouse	Oct-12
Hamilton Heights Elementary School	K-12	Arcadia, Indiana	Elementary school (grades 3-6). Includes classrooms and administrative offices.	Mar-13
University of California, Davis	Higher ed.	Davis, California	Student services. Academic advising center, computer center, recreation room, laundry room, service desk, mail center, and convenience store.	Apr-13
The Segundo Services Center (SSC) at University of California, Davis (UCD)	Higher ed.	Davis, California	Student service center	Apr-13
Portland State University Academic and Student Recreation Center,	Higher ed.	Portland, Oregon	Academic and student recreation center	May-13
City College of San Francisco	Higher ed.	San Francisco, California	Classrooms, administrative offices, specialized laboratories, computer lab, study spaces, childcare/family training center, meeting rooms, and a café,	May-13
McGill University McIntyre Pavilion	Higher ed.	Montreal, Québec, Canada	Research and teaching facility. Includes laboratories, library, and classrooms.	Aug-13
Vancouver Island University (VIU)	Higher ed.	Duncan, British Columbia, Canada	Classrooms, science labs, offices, meeting rooms, and a cafeteria	Dec-13
Davis Building University of Findlay	Higher ed.	Findlay, Ohio	University level science education. Includes 19 science laboratories, a 112-seat lecture hall, one computer lab, 15 faculty offices, one conference room, and one student lounge.	May-14
Energy Environment Experiential Learning University of Calgary	Higher ed.	Calgary, Alberta, Canada	Post-secondary classroom and laboratory building. Includes classrooms, offices, teaching and research labs for biology, chemistry, earth sciences, chemical, civil, and mechanical engineering students.	Sep-14
Otto Maass Laboratory Building	Higher ed.	Montreal, Québec, Canada	Education and research in chemistry. Includes teaching and research laboratories, classrooms, lounge, and large lecture hall.	Nov-14
Valley View Middle School	K-12	Snohomish, Washington	Public middle school (grades 7 and 8)	May-15
Discovery Elementary School	K-12	Arlington, Virginia	Public middle school (grades K-5)	May-18

*All articles are available from technologyportal.ashrae.org; ASHRAE members have free access (must be logged in).

Commissioning is also an important element in existing buildings. USGBC (2009b) *LEED® for Existing Buildings & Operation Maintenance* awards up to six credits for commissioning systems in existing buildings in the Energy and Atmosphere (EA) section.

HVAC systems modifications can vary from minor modifications up to complete reconstruction of all or part of building's HVAC system. The process for this type of project should follow the process described previously for new construction.

10. SEISMIC- AND WIND-RESTRAINT CONSIDERATIONS

Seismic bracing of HVAC equipment should be considered. Wind restraint codes may also apply in areas where tornados and hurricanes necessitate additional bracing. This consideration is especially important if there is an agreement with local officials to use the facility as a disaster relief shelter. See Chapter 56 for further information.

11. SELECTED CASE STUDIES

Tables 18 and 19 list selected case studies of educational facilities as published in *ASHRAE Journal* and *High Performance Building* Magazine respectively.

CHAPTER 9

HEALTH CARE FACILITIES

REGULATION AND RESOURCES 9.1
Air Conditioning in Disease Prevention and Treatment 9.2
Sustainability 9.3
HOSPITAL FACILITIES 9.3
Air Quality 9.3
Facility Design and Operation 9.6
Specific Design Criteria 9.7
OUTPATIENT HEALTH CARE FACILITIES 9.16
Dental Care Facilities 9.17
Continuity of Service and Energy Concepts 9.17
RESIDENTIAL HEALTH, CARE, AND SUPPORT FACILITIES 9.17

CONTINUAL advances in medicine and technology necessitate constant reevaluation of the air-conditioning needs of hospitals and medical facilities. Medical evidence shows that air conditioning can affect certain clinical outcomes, and ventilation requirements exist to protect against harmful occupational exposures. Although the need for clean and conditioned air in health care facilities is high, the relatively high cost of air conditioning demands efficient design and operation to ensure economical energy management. It is a challenge to establish a balance between patient outcomes, safety, and higher operating costs. Often, there is little research or data to quantify the effect of the HVAC system on patient outcomes; whereas energy costs are relatively easy to quantify. The following is a suggested prioritization of the HVAC system design characteristics for a healthcare facility (Turpin 2013):

1. Performance (infection control, comfort, patient outcome)
2. Safety (fire, life safety, potential injuries)
3. Reliability
4. Maintenance cost
5. Energy cost
6. Adaptability

Health care occupancy classification, based on the latest occupancy guidelines from the National Fire Protection Association's (NFPA) *Life Safety Code*® and applicable building codes, should be considered early in project design. Health care facilities are unique in that there may be multiple, differing authorities having jurisdiction (AHJs) overseeing the design, construction, and operation of the facility. These different AHJs may use different standards or different versions of the same standards. Health care occupancy classification is important to determine for fire protection (smoke zones, smoke control) and for future adaptability of the HVAC system for a more restrictive occupancy.

Health care facilities are increasingly diversifying in response to a trend toward outpatient services. The term *clinic* may refer to any building from a residential doctor's office to a specialized cancer treatment center. Integrated regional health care organizations are becoming the model for medical care delivery as outpatient facilities take on more advanced care and increasingly serve as the entryway to the acute care hospital. These organizations, as well as long-established hospitals, are sometimes constructing buildings that look less like hospitals and more like luxury hotels and office buildings. However, when specific health care treatments in these facilities are medically consistent with hospital-based treatment activity, then the environmental design guidance applicable to the hospital-based treatment should also apply to the clinic's treatment environment.

For the purpose of this chapter, health care facilities are divided into the following categories:

- Hospital facilities
- Outpatient health care facilities
- Residential health care and support facilities

The general hospital provides a variety of services; its environmental conditions and design criteria apply to comparable areas in other health care facilities. The general acute care hospital has a core of patient care spaces, including rooms for operations, emergency treatment, delivery, patients, and a nursery. Usually, the functions of radiology, laboratory, central sterile, and pharmacy are located close to the critical care space. Inpatient nursing, including intensive care nursing, is also within the complex. The facility also incorporates a kitchen, dining and food service, morgue, and central housekeeping support.

Outpatient surgery is performed with the anticipation that the patient will not stay overnight. An outpatient facility may be part of an acute care facility, a freestanding unit, or part of another medical facility such as a medical office building.

Nursing facilities are addressed separately, because their fundamental requirements differ greatly from those of other medical facilities in regards to odor control and the average stay of patients.

Dental facilities are briefly discussed. Requirements for these facilities differ from those of other health care facilities because many procedures generate aerosols, dusts, and particulates.

1. REGULATION AND RESOURCES

The specific environmental conditions required by a particular medical facility may vary from those in this chapter, depending on the agency responsible for the environmental standard. ANSI/ASHRAE/ASHE *Standard* 170 represents the minimum design standard for these facilities, and gives specific minimum requirements for space design temperatures and humidities as well as ventilation recommendations for comfort, asepsis, and odor control in spaces that directly affect patient care.

Standard 170 is in continuous maintenance by ASHRAE, with proposed addenda available for public review/comment and published addenda available for free download from www.ashrae.org. It is republished in whole approximately every four years with all published addenda incorporated. See Table 1 for an excerpt of requirements found in ASHRAE *Standard* 170.

Standard 170 is also included in its entirety in the Facility Guidelines Institute's *Guidelines for Design and Construction of Hospitals and Outpatient Facilities* and *Guidelines for Design and Construction of Residential Health, Care, and Support Facilities* (FGI 2014a, 2014b). The FGI Guidelines are adopted in more than 42 U.S. states by AHJs overseeing the planning, construction, and operation of health care facilities in those states.

Many outpatient facilities are B-occupancy, and may require compliance to ASHRAE/ANSI *Standard* 90.1 or other energy regulations, which may also cover ventilation. ASHRAE *Guidelines* 10

The preparation of this chapter is assigned to TC 9.6, Healthcare Facilities.

Table 1 Sample of ASHRAE *Standard* 170 Design Parameters

Function of Space	Pressure Relationship to Adjacent Areas	Minimum Outdoor ach*	Minimum Total ach*	All Room Air Exhausted Directly to Outdoors	Air Recirculated by Room Units	Design Relative Humidity,%	Design Temp. °C
Operating room	Positive	4	20	NR*	No	20 to 60	20 to 24
Emergency department public waiting area	Negative	2	12	Yes	NR*	max. 65	21 to 24
AII rooms	Negative	2	12	Yes	No	max. 60	21 to 24
Patient room	NR*	2	4	NR*	NR*	max. 60	21 to 24

*ach = air changes per hour, NR = no requirement.

and 29 may be especially applicable to the design of health care facilities. The *HVAC Design Manual for Hospitals and Clinics* (ASHRAE 2013) presents enhanced design practice approaches to health care facility design and greatly supplements the information in this chapter. The ASHRAE Learning Institute (ALI) provides many applicable courses, including Designing High Performing Health Care HVAC Systems and Health Care Facilities: Best Practice Design and Applications.

ASHRAE *Standard* 188-2015 requires health care buildings to establish a water management program to control growth of *Legionella*. The program must include a systematic analysis of building water systems, including the locations of end-point uses of potable and nonpotable water systems; the location of water processing equipment and components, and how water is received and processed, including how it is conditioned, stored, heated, cooled, recirculated, and delivered to end-point uses. A process flow diagram is required to graphically describe the step-by-step detail of where building water systems are at risk of harboring or promoting *Legionella* growth and dissemination. Those areas so identified must have control measures and limits established to allow monitoring of conditions and corrective actions to ensure the system is operating as designed.

NFPA *Standard* 99, which has been adopted by many jurisdictions, provides requirements for ventilation of medical gas storage and transfilling spaces. It also has requirements for heating, cooling, and ventilating the emergency power system room.

American Society for Healthcare Engineering's (ASHE) monographs and interpretation tools are an important resource to help integrate facility management considerations into the built environment. The American Conference of Governmental Industrial Hygienists' (ACGIH 2013) *Industrial Ventilation: A Manual of Recommended Practice for Design* includes guidance on source control of contaminants.

Agencies that may have standards and guidelines applicable to medical facilities include state and local health agencies, the U.S. Department of Health and Human Services (including the Centers for Disease Control and Prevention [CDC], Indian Health Service, Food and Drug Administration [FDA], U.S. Public Health Service, and Medicare/Medicaid), U.S. Department of Defense, U.S. Department of Veterans Affairs, and The Joint Commission's Hospital Accreditation Program.

Other medically concerned organizations with design and/or operational standards and guidelines that may be applicable to health care facility design include the United States Pharmacopeia (USP), American Association of Operating Room Nurses (AAORN), and Association for the Advancement of Medical Instrumentation (AAMI).

FGI (2014a, 2014b) requires the owner to provide an infection control risk assessment (ICRA) and prepare infection control risk mitigation recommendations (ICRMR) that are intended to pre-identify and control infection risks arising from facility construction activities. The ICRMR and ICRA are then to be incorporated in the contract documents by the design professional. Therefore, it is essential to discuss infection control objectives with the hospital's infection control committee.

International standards for health care ventilation sometimes contain suggestions that differ significantly from those in this chapter. International standards include the following:

- Canada's CSA Group's *Standard* Z317.2
- Australasian Health Facility Guidelines (AusHFG), available at www.healthfacilityguidelines.com.au
- U.K. Department of Health and Social Care's *Healthcare Technical Memorandum* 03-01 *premises*
- German Institute for Standardization's (DIN) *Standard* 1946-4 *Ventilation and air conditioning—Part 4*
- Spain's AENOR/UNE *Standard* 100713:2005
- Department of Health–Abu Dhabi (HAAD) *Health Facility Guidelines,* available at www.healthdesign.com.au/haad.hfg/
- World Health Organization's (WHO) *Natural Ventilation for Infection Control in Health-Care Settings*

ASHRAE international associate societies (e.g., India's ISHRAE) may have health care resources specific to the local culture and climate; see www.ashraeasa.org/members.html for a list of associate organizations.

Along with HVAC requirements for normal operation, many health care facilities are considered essential facilities and have programmatic requirements to remain operational after earthquakes or other naturally occurring events. Building code importance factor designation and application can require structural and restraint features not normally included in other types of facilities. Many health care facilities have on-site diesel engine generated electric power, which can necessitate EPA fuel storage permitting, security requirements, and potentially air permitting issues.

1.1 AIR CONDITIONING IN DISEASE PREVENTION AND TREATMENT

In hospitals, air conditioning can play a role beyond the promotion of comfort. In many cases, proper air conditioning is a factor in patient therapy. Patients in well-controlled environments generally show more rapid physical improvement than those in poorly controlled environments. Examples of HVAC considerations for various patients include the following:

- Patients exhibiting thyrotoxicosis (related to hyperthyroidism) may be more sensitive to hot, humid conditions or heat waves (Pearce 2006).
- Extreme ambient heat is a public health threat, especially for the elderly and persons with preexisting health conditions (Richard et al. 2011).
- Cardiac patients are often unable to maintain the circulation necessary to ensure normal heat loss. Air conditioning cardiac wards and rooms of cardiac patients, particularly those with congestive heart failure, is necessary and considered therapeutic (Burch and Pasquale1962).
- Individuals subjected to operations and those with barbiturate poisoning may be susceptible to hypothermia (Belani et al. 2013). HVAC systems may reduce this risk.

- Symptoms of rheumatoid arthritis are correlated to humidity of the environment (Patberg and Rasker 2004). Some have suggested the benefit of dry environments (less than 35% rh).
- Dry air increases the difficulty in terminally cleaning spaces and causes particles to remain airborne for longer periods of time. Pathogen transmission through the air is greater when the air is dry, and infectious particles travel deeper into the lungs when they are small. Cilia in the respiratory system, which are responsible for clearing particulates out of the bronchial tubes, have reduced function in dry conditions. Dry air also leads to cracks in the skin and increased cortisol production.
- Clinical areas devoted to upper respiratory disease treatment and acute care are often maintained at a minimum of 30% rh. The foundation and associated clinical benefit of this practice have recently come under question, so the designer is encouraged to closely consult the latest design guidance and the facility owner when establishing this design criterion.
- Exposure to dry environments may have a negative impact. Taylor (2016) found an increase in the number of healthcare associated infections in patients in a medical-surgery wing and in an oncology wing when the relative humidity dropped below 40% rh.
- Patients with chronic pulmonary disease often have viscous respiratory tract secretions. As these secretions accumulate and increase in viscosity, the patient's exchange of heat and water dwindles. Under these circumstances, inspiration of warm, humidified air is essential to prevent dehydration (Walker and Wells 1961).
- Patients needing oxygen therapy, those with tracheotomies, and other mechanically ventilated patients require warm, humidified air (Jackson 1996). Cold, dry oxygen or bypassing the nasopharyngeal mucosa presents an extreme situation. Rebreathing techniques for anesthesia and enclosure in an incubator are special means of addressing impaired heat loss in therapeutic environments.
- Warm, moist air has been shown to be beneficial in treatment of burn patients (Liljedahl et al. 1979; Zhou et al. 1998). A ward for severe burn victims should have temperature controls (and compatible architectural design and construction) that allow room temperatures up to 32°C db and relative humidity up to 95%.

Reducing **hospital-acquired infections (HAIs**; also called **nosocomial infections**) is a focus of the health care industry. It is difficult to draw any general conclusions about HVAC's contributions or ability to affect infections (DeRoos et al. 1978; Jacob et al. 2013). True airborne infection is somewhat rare (5 to 15%), compared to the direct route of infection (Short and Al-Maiyah 2009),although there is evidence that too little ventilation increases risk of infection (Atkinson 2009). The exact ventilation rates needed to control infectious agents in hospitals are not known (Li et al. 2007; Memarzadeh 2013). It was previously believed that 100% exhaust or 100% outdoor air was necessary. ASHRAE research project RP-312 found that recirculation of most hospital air is appropriate (Chaddock 1983).

HVAC engineering controls, such as required differential pressure relationships between spaces, directional airflow, methods of air delivery, air filtration, overall building pressurization, etc., directly contribute to maintaining asepsis. Well-designed HVAC systems also affect indoor environmental quality and asepsis integrity through specifically HVAC related factors (e.g., thermal comfort, acoustics, odor control). Therefore, HVAC system effectiveness can also lead to an improved healing environment for the patient, contributing to shorter patient stays and thereby minimizing the risk of HAIs. ASHE (2011) provides an engineering perspective on the topic with many additional references.

1.2 SUSTAINABILITY

Health care is an energy intensive, energy-dependent enterprise. Hospital facilities are different from other structures in that they operate 24 hours a day and year round, require sophisticated back up systems in case of utility shutdowns, use large quantities of outdoor air to combat odors and to dilute microorganisms, and must deal with problems of infection and solid waste disposal. Similarly, large quantities of energy are required to power diagnostic, therapeutic, and monitoring equipment, and to support services such as food storage, preparation, and service and laundry facilities. Control strategies such as supply air temperature reset on variable-air-volume systems and hydronic reheat supply water temperature reset on variable pumping systems can often be applied with good results, but should be applied with care: undesired impacts on temperature and (especially) humidity can result. Resources to help ensure efficient, economical energy management and reduce energy consumption in hospital facilities include ASHRAE *Standard* 90.1 and the *Advanced Energy Design Guides* on hospitals (ASHRAE 2009, 2012). ASHRAE *Standard* 189.3 provides guidance for design, construction, and operation of high-performance, green health care facilities.

Hospitals can conserve energy in various ways, such as using individual zoning control with advanced control strategies and energy conversion devices that transfer energy from building exhaust air to incoming outdoor air. The critical nature of the health care environment requires design and operational precautions to minimize the chances of heat exchangers becoming a source of contaminants in the supply air stream. Use of heat pipes, runaround loops, enthalpy wheels, and other forms of heat recovery is increasing; ASHRAE *Standard* 170 addresses their use. Large health care campuses use central plant systems, which may include thermal storage, hydronic economizers, primary/secondary pumping, cogeneration, heat recovery boilers, and heat recovery incinerators. Integrating building waste heat into systems and using renewable energy sources (e.g., solar under some climatic conditions) provide substantial savings (Setty 1976).

Selecting building and system components for cost effective energy measures requires careful planning and design. Life-cycle cost analysis can show the full effect of design decisions, considering fuel and labor costs, maintenance costs, desired performance (comfort and air quality), replacement costs, cost of downtime, and the value of investment dollars over time.

2. HOSPITAL FACILITIES

Although proper air conditioning is helpful in preventing and treating disease, application of air conditioning to health care facilities presents many problems not encountered in usual comfort conditioning design.

The basic differences between air conditioning for hospitals (and related health care facilities) and that for other building types stem from the (1) need to restrict air movement in and between departments; (2) specific requirements for ventilation and filtration to dilute and remove contamination (odor, airborne microorganisms and viruses, hazardous chemicals, and radioactive substances); (3) different temperature and humidity requirements for various areas; and (4) design sophistication needed for accurate control of environmental conditions.

2.1 AIR QUALITY

Systems should provide air virtually free of dust, dirt, odor, and chemical and radioactive pollutants. In some cases, untreated outdoor air is hazardous to patients suffering from cardiopulmonary, respiratory, or pulmonary conditions. In such instances, consider treatment of outdoor air as discussed in ASHRAE *Standard* 62.1.

Infection Sources

Bacterial Infection. *Mycobacterium tuberculosis* and *Legionella pneumophila* (Legionnaires' disease) are examples of bacteria that are highly infectious and transported in air (or air and water mixtures). Wells (1934) showed that droplets or infectious agents of 5 μm or less in size can remain airborne indefinitely.

Viral Infection. Examples of viruses that are transported by, and virulent within, air are *Varicella* (chicken pox/shingles), *Rubella* (German measles), and Rubeola (regular measles). Research indicates that many airborne viruses that transmit infection are originally submicron in size, though in air they are often attached to larger aerosol and/or as conglomerates of multiple viruses, which may be more easily filtered from the airstream.

Molds. Evidence indicates that some molds such as *Aspergillis* can be fatal to advanced leukemia, bone marrow transplant, and other immunocompromised patients.

Chemicals. Hospitals use various chemicals as disinfectants, which may require control measures for worker or patient safety. Many pharmaceuticals are powerful chemical agents.

Control Measures

Outdoor Air Ventilation. If outdoor air intakes are properly located and areas adjacent to the intakes are properly maintained, outdoor air is virtually free of infectious bacteria and viruses compared to room air. Infection control problems frequently involve a bacterial or viral source within the hospital. Ventilation air dilutes indoor viral and bacterial contamination. If ventilation systems are properly designed, constructed, and maintained to preserve correct pressure relations between functional areas, they control the between-area spread of airborne infectious agents and enable proper containment and removal of pathogens from the hospital environment.

Filtration. Some authorities recommend using high-efficiency particulate air (HEPA) filters with test filtering efficiencies of 99.97% in certain areas. Although there is no known method to effectively eliminate 100% of the viable particles, HEPA and/or ultralow-penetration (ULPA) filters provide the greatest air-cleaning efficiency currently available.

Pressure Differential. Directional airflow created by differential pressures, which result from controlling the HVAC system in a particular manner, is a common control measure to help prevent dispersal of contaminants between adjoining spaces.

Anterooms. Isolation rooms and isolation anterooms with appropriate ventilation/pressure relationships are a primary means used to prevent the spread of airborne contaminants from space to space in the health care environment. The addition of the anteroom allows for the dilution and control of air that passes from one space to another every time a door is opened and closed.

Contaminant Source Control. Certain aerosol-generating activities may also benefit from local control techniques to minimize virus dissemination and other contaminants. Exhausted enclosures (e.g., biological safety cabinets, chemical fume hoods, benchtop enclosures) and localized collection methods (e.g., snorkels, direct equipment connections) are typical control measures. Physical locations of supply air diffusers and return/exhaust grilles in a space can be designed to help control contaminant dispersal within the room.

Temperature and Humidity. These conditions can inhibit or promote the growth of bacteria, and activate or deactivate viruses. Some bacteria, such as *Legionella pneumophila*, are basically waterborne and survive more readily in a humid environment. Codes and guidelines specify temperature and humidity range criteria in some hospital areas for infection control as well as comfort. Historical use of flammable anesthetics also influenced the minimum relative humidity requirements of various governing documents. Where flammable anesthetics have been phased out, there is considerable interest in lowering minimum humidity requirements because of the humidification systems' increased energy usage and operational and maintenance challenges. Medical equipment static electricity concerns and transmission and growth of various potential contaminants in differing humidity environments have also been examined, and led to a relaxation of some minimum relative humidity requirements in ASHRAE *Standard* 170. Specialized patient care areas, including organ transplant and burn units, should have additional ventilation provisions for air quality control as may be appropriate.

Ultraviolet Light, Ionization and Chemicals. ASHRAE guidance on the use of ultraviolet energy as an adjunct infection control measure may be found in Chapter 60 of the 2015 *ASHRAE Handbook—HVAC Applications* and Chapter 17 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Current guidance from the U.S. Centers for Disease Control and Prevention can be found in CDC (2005) and NIOSH (2009). Ionization devices and/or chemical fogging/mists are not recommended in occupied environments and should only be considered for terminal cleaning applications in unoccupied spaces.

Increasing Air Changes. Whether achieved by introducing clean fresh air or filtration, increasing a room's air change rate reduces its airborne burden of microorganisms, thus reducing opportunities for airborne exposures. Table 2 notes the theoretical time to remove particles from a room being flushed with clean, filtered air, assuming perfect mixing/perfect ventilation effectiveness in the space (ASHRAE 2013).

Outdoor Air Intakes. These intakes should be located as far as is practical (on directionally different [i.e., compass directions] exposures whenever possible), but not less than 7.6 m, from combustion equipment stack exhaust outlets, ventilation exhaust outlets from the hospital or adjoining buildings, medical/surgical vacuum systems, cooling towers, plumbing vent stacks, smoke control exhaust outlets, and areas that may collect vehicular exhaust and other noxious fumes. Air intakes should be located at least 9 m from any Class 4 air exhaust discharges as defined in *Standard* 62.1-2010. The bottom of outdoor air intakes serving central systems should be located as high as practical (minimum of 3.7 m recommended) but not less than 1.8 m above ground level or, if installed above the roof, 1 m above the roof level.

Exhaust Air Outlets. These exhausts should be located a minimum of 3 m above ground level and away from doors, occupied areas, and operable windows. Preferred location for exhaust outlets is at roof level projecting upward or horizontally away from outdoor air intakes. Care must be taken in locating highly contaminated exhausts (e.g., from engines, fume hoods, biological safety cabinets, kitchen hoods, paint booths). Prevailing winds, adjacent buildings, and discharge velocities must be taken into account (see Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*). In critical or complicated applications, wind tunnel studies or computer modeling may be appropriate. ASHRAE *Standard* 170 contains additional minimum requirements for certain exhaust discharges.

Air Filters. The purpose of filters is to remove contaminants from the air. While there is no generally accepted ratio of organic to

Table 2 Effect of Air Change Rates on Particle Removal

Air Changes per Hour, ach	Time Required for Removal Efficiency of 99%, min	Time Required for Removal Efficiency of 99.9%, min

20	14	21
50	6	8

Source: CDC (2003).

inorganic particles, it is generally accepted that the presence of more airborne particles correlates to a greater number of airborne microorganisms that cause surgical site infections (Birgand et al. 2015). As with most HVAC design considerations, the engineer must guide the owner to make the best choice of filters, considering life cycle cost and efficacy for each air handler and space.

As described in 2017 *ASHRAE Handbook—Fundamentals* Chapter 11, air contaminants are generally classified as

- Particles: These may be aerosols or particulate matter. Particles may be organic, inorganic, viable, or non-viable. Particles of interest are often 0.1 to 10 μm.
- Gases: These include gases and vapors considered at the molecular level. Chapters 10 and 12 in the 2017 *ASHRAE Handbook—Fundamentals* discuss techniques to manage odors.

HVAC filters, which may include prefilters, second-stage filters, and final-stage filters, should be tested in accordance with ASHRAE *Standard* 52.2. This standard is written for testing filters under controlled conditions (laboratory environment) and establishes the minimum efficiency reporting value (MERV) of an air filter. Filters are classified as MERV 1 to 16. Tests are based on removal efficiency (%) in three particle size ranges: 0.3 to 1 μm, 1 to 3 μm, and 3 to 10 μm. The higher the MERV rating, the better the overall removal. ASHRAE *Standard* 145.2 is written for testing gaseous air contaminant filters under controlled conditions (laboratory environment) and establishes efficiency ratings for contaminants that represent broad classes of organic chemicals and ozone.

Air filters necessitate a comprehensive management program, including installation, monitoring, replacement, and disposal. Typically, the priorities for selecting an air filter are

1. Contaminant removal efficiency (MERV, MERV-A)
2. Initial and operating cost (Total cost of ownership)
3. Structural integrity

Some filters exhibit different behavior under field conditions. ISO *Standard* 29462 describes testing of HVAC filters for removal efficiency in field conditions. See Chapter 29 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. All central ventilation or air-conditioning systems should be equipped with filters having efficiencies no lower than those indicated in ASHRAE *Standard* 170. Appropriate precautions should be observed to prevent wetting the filter media by uncontrolled condensation or free moisture from humidifiers. The filter system should be designed and equipped to allow safe removal, disposal, and replacement of contaminated filters.

Guidelines for filter installations are as follows:

- HEPA filters are required by *Standard* 170 only for protective-environment rooms. These rooms are used for patients with a high susceptibility to infection due to leukemia, burns, bone marrow transplant, chemotherapy, organ transplant, or human immunodeficiency virus (HIV). HEPA filters should also be considered for discharge air from fume hoods or biological safety cabinets in which infectious, highly toxic, or radioactive materials are processed. Some hospitals choose to use HEPA filters on exhaust originating from airborne infectious isolation rooms and on supply air to very sensitive patients, such as those in orthopedic surgery. Filter seals or gaskets should be installed to prevent leakage between filter segments and between the filter bed and its supporting frame. A small leak that allows any contaminated air to escape through the filter significantly reduces performance. Leakage can occur due to poor gaskets, warping of the rack, or holes in the rack. Ensure that the rack is designed to withstand high lateral pressure. Diagonal supports may be necessary to maintain the integrity of the filter rack. Maintaining the rated filtration efficiency over the entire installed service life of the filter should be considered, particularly if the initial removal efficiency is based on an electrostatic charge on the filter.
- High-efficiency filters should be installed in the system, with adequate facilities provided for maintenance and in situ performance testing without introducing contamination into the delivery system or the area served. Also keep in mind maintenance workers' safety. High-efficiency filters are expensive. Energy costs associated with the pressure drop can be 70% of the total cost of ownership. Consider filter life, first cost, energy cost, and maintenance (installation, removal, and disposal). Provide a local manometer to measure pressure drop across each filter bank. Be sure the gauge range is appropriate (usually 0 to 500 Pa). Mark the gage with the manufacture's recommended initial and final pressure drops. In addition, BAS control sequences to monitor and alarm, including ability to normalize or benchmark pressure drops and associated airflows, indicate when replacement is necessary even when air handlers operate at less than full flow. Filter system life-cycle costs can be calculated and various scenarios compared for overall optimization (Eurovent/CECOMAF 2005). Installing a lower-efficiency prefilter upstream of the high-efficiency filter keeps coils cleaner and extend the life of the high-efficiency final filter.
- During construction, openings in ductwork and diffusers should be sealed in accordance with ASHRAE *Standard* 170 to prevent intrusion of dust, dirt, and hazardous materials. Such contamination is often permanent and provides a medium for growth of infectious agents. Existing or new filters as well as coils may rapidly become contaminated by construction dust. The final filter should be installed downstream of all the chilled-water coil.

Air Movement

Table 3 illustrates the degree to which contamination can be dispersed into the air by routine patient care activities. The bacterial counts in the hallway clearly indicate the spread of this contamination.

Because of the bacteria dispersal from such necessary activities, air-handling systems should provide air movement patterns that minimize spread of contamination. Undesirable airflow between rooms and floors is often difficult to control because of open doors, movement of staff and patients, temperature differentials, and stack effect, which is accentuated by vertical openings such as chutes, elevator shafts, stairwells, and mechanical shafts. Although some of these factors are beyond practical control, the effect of others may be minimized by terminating shaft openings in enclosed rooms and by designing and balancing air systems to create positive or negative air pressure in certain rooms and areas.

Pressure differential causes air to flow in or out of a room through various leakage areas (e.g., perimeter of doors and windows, utility/fixture penetrations, cracks). A level of differential air pressure (2.5 Pa) can be efficiently maintained only in a tightly sealed room. Therefore, it is important to obtain a reasonably close fit of all doors

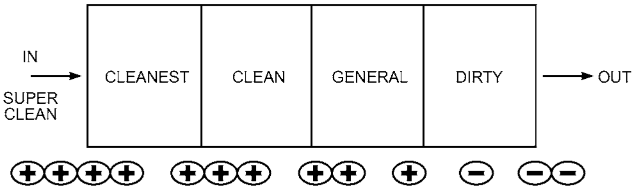

Fig. 1 Controlling Air Movement through Pressurization
(ASHRAE 2013)

and seal all walls and floors, including penetrations between pressurized areas. Opening a door between two areas immediately reduces any existing pressure differential between them, effectively nullifying the pressure difference. When such openings occur, a natural interchange of air takes place between the two rooms because of turbulence created by the door opening and closing and personnel ingress/egress. For critical areas requiring both maintenance of pressure differentials to adjacent spaces and personnel movement between the critical and adjacent areas, consider using anterooms. The purpose of differential pressurization is to inhibit movement of potentially infectious particles from dirty areas to clean ones. Figure 1 illustrates controlling airflow through pressurization. More air is supplied to the cleanest areas, with less air supplied to less clean areas, and air is exhausted from dirty areas.

In general, outlets supplying air to sensitive ultraclean areas should be located on the ceiling, and several perimeter exhaust outlets should be near the floor. This arrangement provides downward movement of clean air through the breathing and working zones to the floor area for exhaust.

Airborne infectious isolation (AII) rooms should locate the exhaust outlets over the patient bed or on the wall behind the bed. Supply air may be located above and near the doorway and/or near the exterior window with ceiling-mounted supply outlets. This arrangement controls the flow of clean air first to parts of the room where workers or visitors are likely to be, and then across the infected source into the exhaust. Because of the relatively low air exchange rates and minimal influence of the exhaust outlet, this arrangement's ability to achieve directional airflow is limited. The supply diffusers must be carefully selected and located such that primary air throw does not induce bedroom air to enter the corridor or anteroom (if provided) or overly disturb the function of the exhaust to remove contaminants (Memarzadeh and Xu 2011).

The laminar airflow concepts developed for industrial cleanroom and pharmaceutical use have applications in **surgical suites**. There are advocates of both vertical and horizontal laminar airflow systems, with and without fixed or movable walls around the surgical team (Pfost 1981), as well as air curtain concepts. Vertical laminar airflow in surgical operating rooms is predominantly unidirectional where not obstructed by extensive quantities of ceiling-mounted swing-arm booms.

Ventilation system design must, as much as possible, provide air movement from clean to less clean areas. In critical-care areas, use constant-volume systems to ensure proper pressure relationships and ventilation. In noncritical patient care areas and staff rooms, variable-air-volume (VAV) systems may be considered for energy conservation; if VAV is used, take special care to ensure that minimum ventilation rates as required by codes are maintained, and that pressure relationships between various spaces are maintained. With VAV systems, a method such as air volume tracking between supply, return, and exhaust could be used to control pressure relationships (Lewis 1988).

Smoke Control

As the ventilation design is developed, a proper smoke control strategy must be considered. Both passive and active smoke control systems are in use. Passive systems rely on fan shutdown, smoke and fire barriers, and proper treatment of duct penetrations. Active smoke control systems use the ventilation system to create areas of positive and negative pressures that, along with fire and smoke partitions, limit the spread of smoke. The ventilation system may be used in a smoke removal mode in which combustion products are exhausted by mechanical means. NFPA *Standard* 99 has specific guidance on smoke control and other safety provisions, which have changed in each edition. The engineer and code authority should carefully plan system operation and configuration with regards to smoke control. Refer to Chapter 53 and NFPA *Standards* 90A, 92A, and 101 as enforced by the AHJ.

2.2 FACILITY DESIGN AND OPERATION

Zoning

Zoning (using separate air systems for different departments) may be indicated to (1) compensate for exposures caused by orientation or for other conditions imposed by a particular building configuration, (2) minimize recirculation between departments, (3) provide flexibility of operation, (4) simplify provisions for operation on emergency power, and (5) conserve energy.

Ducting the air supply from several air-handling units into a manifold gives central systems some standby capacity. When one unit is shut down, air is diverted from noncritical or intermittently operated areas to accommodate critical areas, which must operate continuously. This, or another means of standby protection, is essential if the air supply is not to be interrupted by routine maintenance or component failure.

Separating supply, return, and exhaust systems by department is often desirable, particularly for surgical, obstetrical, pathological, and laboratory departments. The desired relative balance in critical areas should be maintained by interlocking supply and exhaust fans. Thus, exhaust should cease when supply airflow is stopped in areas otherwise maintained at positive or neutral pressure relative to adjacent spaces. Likewise, supply air should be deactivated when exhaust airflow is stopped in spaces maintained at a negative pressure.

Heating and Hot Water Standby Service

When one boiler breaks down or is temporarily taken out of service for routine maintenance, the remaining boilers should still be able to provide hot water for clinical, dietary, and patient use; steam for sterilization and dietary purposes; and heating for operating, delivery, birthing, labor, recovery, intensive care, nursery, and general inpatient rooms. Some codes or authorities do not require reserve capacity in climates where a design dry-bulb temperature of –4°C is equaled or exceeded for 99.6% of the total hours in any one heating period, as noted in the tables in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*.

Boiler feed, heat circulation, condensate return, and fuel oil pumps should be connected and installed to provide both normal and standby service. Supply and return mains and risers for cooling, heating, and process steam systems should be valved to isolate the various sections. Each piece of equipment should be valved at the supply and return ends.

Some supply and exhaust systems for delivery and operating room suites should be designed to be independent of other fan systems and to operate from the hospital emergency power system in the event of power failure. Operating and delivery room suites should be ventilated such that the hospital retains some surgical and delivery capability in cases of ventilating system failure.

Boiler steam is often treated with chemicals that may be released into the air-handling systems serving critical areas where patients may be more susceptible to respiratory irritation and its complications. In this case, a clean steam system could be considered for humidification. ASHRAE *Standard* 170 provides minimum requirements for steam treatment additives where direct injection steam is used.

Mechanical Cooling

Carefully consider the source of mechanical cooling for clinical and patient areas. The preferred method is to use an indirect refrigerating system using chilled water. When using direct refrigerating systems, consult codes for specific limitations and prohibitions, and refer to ASHRAE *Standard* 15. Until recently, it has been difficult to maintain desired temperatures and humidity with direct expansion (DX) systems. Newer technology has provided additional means of maintaining temperature and humidity in spaces. Use care when selecting DX equipment.

Insulation

Linings in air ducts and equipment must meet the erosion test method described in Underwriters Laboratories *Standard* 181. These linings (including coatings, adhesives, and insulation on exterior surfaces of pipes and ducts in building spaces used as air supply plenums) should have a flame spread rating of 25 or less and a smoke developed rating of 50 or less, as determined by an independent testing laboratory, per ASTM *Standard* E84.

ASHRAE *Standard* 170 does not allow duct lining to be used downstream of the second filter bank (final filter). Duct lining with an impervious cover may be allowed in terminal units, sound attenuators, and air distribution devices downstream of the second filter bank. This lining and cover will be factory installed. Internal insulation of terminal units may be encapsulated with approved materials, but metal lining is preferable. Duct lining should be avoided except where necessary for acoustical improvement; for thermal purposes, external insulation should be used. The use of acoustical materials as duct interior linings, exposed to air movement, should be carefully reviewed for the application and regulatory standards in effect. Duct-mounted sound traps, where necessary, should be of the packless type or have polymer film linings over acoustical fill.

Testing, Adjusting, and Balancing (TAB) and Commissioning

For existing systems, testing before beginning remodeling construction (preferably before design completion) is usually a good investment. This early effort provides the designer with information on actual system performance and whether components are suitable for intended modifications, as well as discloses additional necessary modifications.

The importance of TAB for modified and new systems before patient occupancy cannot be overemphasized. Health care facilities require validation and documentation of system performance characteristics. Often, combining TAB with commissioning satisfies this requirement. See Chapters 39 and 44 for information on TAB and commissioning.

Operations and Maintenance

Without routine inspection and maintenance of HVAC system components, systems might operate outside of their optimum performance parameters. This variance can affect delivered system performance. Often, manufacturers' maintenance information applies only to their components, not the entire system. ASHRAE *Standard* 180 addresses the often inconsistent practices for inspecting and maintaining HVAC systems in health care buildings where the public may be exposed to the indoor environment. The standard establishes minimum HVAC inspection and maintenance requirements to preserve a system's ability to achieve acceptable thermal comfort, energy efficiency, and indoor air quality.

The American Society for Healthcare Engineering (ASHE) (of the American Hospital Association [AHA]) and the International Facility Management Association (IFMA) jointly published *O&M Benchmarks for Health Care Facilities* (ASHE/IFMA 2000). Health care facility management professionals at 150 different health care facilities, representing a broad cross section of the field, were surveyed for the report, which discusses facility age and location, utility costs and practices, maintenance costs and staffing, environmental services, waste streams, linen services, and operational costs. In addition to common facility benchmarks (e.g., cost per area, cost per worker), the report's analysis also includes metrics that hospital leaders recognize, such as adjusted patient days and adjusted discharges.

ASHRAE *Standard* 170 provides recommended operations and maintenance procedures for certain health care specific rooms in its Informative Appendix A. Chapter 40 of this volume also discussed operation and maintenance.

A common cause of operational problems is the control system. Often, sensors are out of calibration. Maintenance and/or controls personnel often alter set points and sequences to provide short-term fixes. Training and persistent commissioning are necessary to keep the systems operating correctly.

Planning. *Standard* 170 requires that an operational facility plan be established to ensure that the number and arrangements of system components can best support the owner's operational goals. The plan should take into account the age and reliability of the HVAC equipment, capabilities of different areas of the facility and their criticality to the facility mission, and available personnel resources. This plan typically examines loss of normal power scenarios, loss of certain pieces of HVAC equipment, back-up fuel sources, redundant systems, temporary measures, and abnormal events. In the event of power loss, inpatient areas should allow for potential 24 h operation and nonambulatory patients who may not be able to be relocated. The capital outlay for imaging and treatment equipment and their associated operating personnel can be balanced against additional potential outlays for redundant cooling or other features as adjusted for the risk of failure.

2.3 SPECIFIC DESIGN CRITERIA

There are seven principal divisions of an acute care general hospital: (1) surgery and critical care, (2) nursing, (3) ancillary, (4) administration, (5) diagnostic and treatment, (6) sterilizing and supply, and (7) service. Environmental requirements of each department/space in these divisions differ according to their function and procedures carried out in them. This section describes the functions of these departments/spaces. ASHRAE *Standard* 170 provides details of HVAC design requirements for spaces in the hospital that directly affect patient care. If additional regulatory or organizational criteria must be met, refer to those criteria for specific space requirements. Close coordination with health care planners and medical equipment specialists in mechanical design and construction of health facilities is essential to achieve the desired conditions.

Surgery and Critical Care

No area of the hospital requires more careful control of aseptic environmental conditions than the surgical suite. Systems serving operating rooms, including cystoscopy and fracture rooms, require careful design to minimize concentrations of airborne organisms.

The greatest amount of bacteria found in the operating room comes from the surgical team and is a result of their activities during surgery. During an operation, most members of the surgical team are near the operating table, creating the undesirable situation of concentrating contamination in this highly sensitive area.

Operating Rooms. Past studies of operating room air distribution devices (e.g., Memarzadeh and Manning [2002]) and observation of installations in industrial cleanrooms indicate that delivering air from the ceiling, with a downward movement to several exhaust/return openings located low on opposite walls, is the

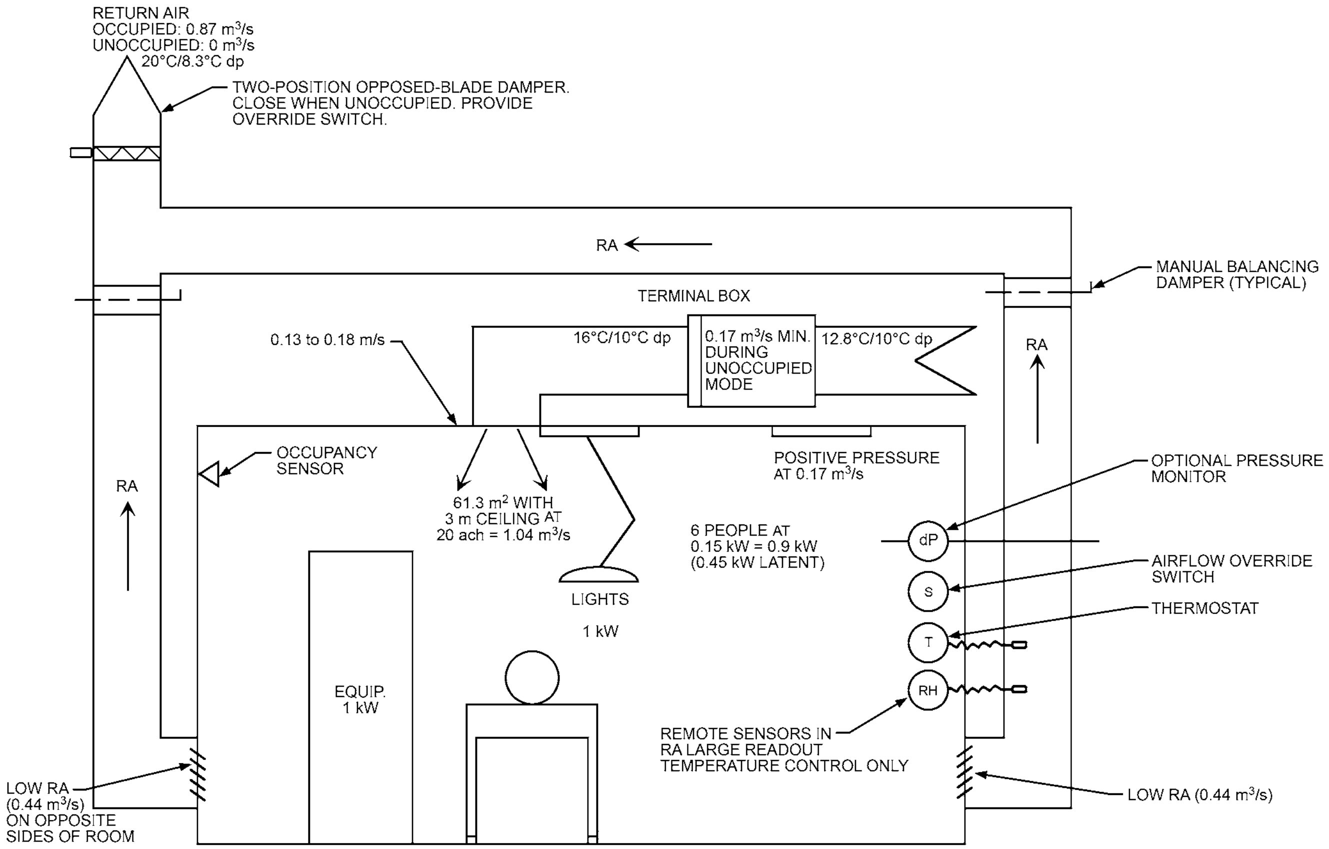

Fig. 2 Operating Room Layout
(ASHRAE 2013)

most effective (and current code requirement for) air movement pattern to minimize contamination of the surgical field. Completely perforated ceilings, partially perforated ceilings, and ceiling-mounted diffusers have been applied successfully (Pfost 1981). Memarzadeh and Manning (2002) found that a mixture of low and high exhaust opening locations may work slightly better than either all-low or all-high locations, with supply air furnished at average velocities of0.13 to 1.8 m/s from a unidirectional laminar-flow ceiling array. It appears that the main factor in the design of the ventilation system is the control of the central region of the operating room (surgical or sterile field). The laminar flow concept generally represents the best option for an operating room in terms of contamination control, as it results in the smallest percentage of particles impacting the surgical site. Figure 6 shows a typical operating room layout.

Operating room setback (night setback or unoccupied setback) is a proven energy saving strategy in all climates. Love (2011) details these strategies. Operating room suites are typically used no more than 8 to 12 h per day (except trauma centers and emergency departments). Temperature is typically allowed to drift during setback. Lowering the set point during unoccupied times reduces reheat energy; however, positive space pressure must be maintained. Design of the setback solution should consider local climate, facility type, user needs, existing conditions (where applicable), relevant code requirements, and cost. There are several approaches to setback. Each has trade-offs between the level of control, complexity, and cost. Common approaches include

- Two-position supply with shutoff dampers in return/exhaust
- Pressure-independent valves on supply and return
- Modulating control damper or terminal box on return

If a return terminal box is used, consider adding a filter upstream of the terminal box to protect the airflow sensor.

A separate anesthesia waste gas disposal vacuum system should be provided for removal of trace gases (NFPA *Standard* 99). One or more outlets may be located in each operating room to connect the anesthetic machine scavenger hose.

Although good results have been reported from air disinfection of operating rooms by irradiation, this method is seldom used. The reluctance to use irradiation may be attributed to the need for special designs for installation, protective measures for patients and personnel, constant monitoring of lamp efficiency, and maintenance. Ultraviolet germicidal irradiation (UVGI) air and surface treatments have emerging applications in health care facilities; see Chapter 60 for general information on their application.

The following conditions are recommended for operating, catheterization, and cystoscopy rooms:

- Temperature set points should be adjustable to suit the surgical staff, and relative humidity should be maintained within the required range. Systems should be able to maintain the programmed space temperature and temperature rates of change for specialized procedures such as cardiac surgery. Tolerable temperature ranges are not intended to be dynamic control ranges. Special or supplemental cooling equipment should be considered if this lower temperature negatively affects energy use for surrounding areas.
- Air pressure should be kept positive with respect to any adjoining rooms. A differential-pressure-indicating device should be installed to help monitor air pressure readings in the rooms.

Thorough sealing of all wall, ceiling, and floor penetrations are essential to maintaining pressure differential.
- Humidity and temperature indicators should be located for easy observation. Occupant control of temperature may result in an unintended change in relative humidity.
- Filter efficiencies should be in accordance with ASHRAE *Standard* 170 and the user's requirements. Supply air HEPA filtration has been applied for some orthopedic surgical suites where long procedures with large open wound sites and significant generation of aerosols caused by use of surgical tools may occur. HEPA filtration has also been applied for high-air-change-rate recirculation systems where required by the surgical team.
- Air should be supplied at the ceiling with exhaust/return from at least two locations near the floor spaced approximately half of the room apart. Endoscopic, laparoscopic, or thoracoscopic surgery procedures aided by camera, and robotic or robot-assisted surgery procedures, require heat-producing equipment in the operating room. Exhaust/return openings located above this equipment can capture the more buoyant heated air and prevent it from being reentrained in the ceiling supply airstream. The bottom of low openings should be at least 75 mm above the floor. Supply diffusers should be unidirectional (laminar-flow), located over the patient and the surgical team. High-induction ceiling or sidewall diffusers should be avoided.
- Total air exchange rates should address lights and equipment (e.g., blanket and blood warmers, fiber-optic equipment, robotic consoles) as well as the peak occupancy of the space and the potentially lower temperature required.
- Generally, all humidification should be done at the air handler. Where there is an unusual requirement for different humidity levels in different ORs, then sufficient lengths of straight, watertight, drained stainless steel or aluminum duct should be installed downstream of humidification equipment to ensure complete evaporation of water vapor before air is discharged into the room. Consider also providing a viewing window in the ductwork to allow easy verification of system performance.

Obstetrical Areas. The pressure in the obstetrical department should be positive or equal to that in other areas.

Delivery (Caesarean) Rooms. The delivery room design should conform to the requirements of operating rooms.

Recovery Rooms. Because the smell of residual anesthesia sometimes creates odor problems in recovery rooms, ventilation is important, and a balanced air pressure relative to that of adjoining areas should be provided.

Intensive Care Units. These units serve seriously ill patients, such as postoperative and coronary patients. HVAC is similar to general inpatient rooms unless used for wound (burn) intensive care.

Nursery Suites. Air movement patterns in nurseries should be carefully designed to reduce the possibility of drafts. Some codes or jurisdictions require that air be removed near floor level, with the bottoms of exhaust openings at least 75 mm above the floor; the relative efficacy of this exhaust arrangement has been questioned by some experts, because exhaust air outlets have a minimal effect on room air movement at the relatively low air exchange rates involved. Finned-tube radiation and other forms of convection heating should not be used in nurseries.

Full-Term Nurseries. The nursery should have a positive air pressure relative to the work space and examination room, and any rooms located between the nurseries and the corridor should be similarly pressurized relative to the corridor.

Special-Care Nurseries. This type of nursery is usually equipped with individual incubators to regulate temperature and humidity. It is desirable to maintain these same conditions in the nursery proper to accommodate both infants removed from the incubators and those not placed in incubators. Pressurization of special-care nurseries should correspond to that of full-term nurseries.

Observation Nurseries. Temperature and humidity requirements for observation nurseries are similar to those for full-term nurseries. Because infants in these nurseries have unusual clinical symptoms, air from this area should not enter other nurseries. A negative air pressure relative to that of the workroom should be maintained in the nursery. The workroom, usually located between the nursery and the corridor, should be pressurized relative to the corridor.

Emergency Rooms. Emergency rooms are typically the most highly contaminated areas in the hospital because of the condition of many arriving patients and the large number of persons accompanying them. Waiting rooms and triage areas require special consideration due to the potential to house undiagnosed patients with communicable airborne infectious diseases. Clean-to-dirty directional airflow and zone pressurization techniques should be maintained, to reduce the potential of airborne exposure for health care personnel assigned to the emergency room reception stations.

Trauma Rooms. Emergency trauma rooms located with the emergency department should have the same temperature, humidity, and ventilation requirements as those of other applicable operating rooms.

Anesthesia Storage Rooms. Anesthesia storage rooms must be mechanically ventilated in conformance with several detailed requirements in NFPA *Standard* 99. Building codes may impose additional requirements on the storage of compressed gases.

Nursing

Patient Rooms. Each patient room should have individual temperature control. Air pressure in general patient suites can be neutral in relation to other areas. Most governmental design criteria and codes require that all air from toilet rooms be exhausted directly outdoors. The requirement appears to be based on odor control, though recent research has documented the ability of toilets to generate droplets and aerosols (Johnson et al. 2013). Where recirculating room unit systems are used within patient rooms, it is common practice to exhaust through the adjoining toilet room an amount of air equal to the amount of outdoor air brought in for ventilation. Ventilation of toilets, bedpan closets, bathrooms, and all interior rooms should conform to applicable codes.

HVAC energy consumption by patient rooms can be a major contributor to a hospital's overall HVAC energy usage because they are constantly occupied. This high occupancy rate, along with the space's minimum air change requirements, should be a focus of methods to minimize energy use. Design requirements for minimum air changes may result in excessive reheating of supply air from central air-handling units in certain climate zones and building exposures.

Protective Environment Isolation Units. Immunosuppressed patients (including bone marrow or organ transplant, leukemia, burn, and AIDS patients) are highly susceptible to diseases. Some physicians prefer an isolated laminar airflow unit to protect the patient; others feel that the conditions of the laminar cell have a psychologically harmful effect on the patient and prefer flushing out the room and reducing pathogens in the air. An air distribution of 12 air changes per hour (ach) supplied through a nonaspirating diffuser is often recommended. With this arrangement, the clean air is drawn across the patient and removed at or near the door to the room. Protective environment rooms are sometimes treated as clean spaces with design considerations such as an anteroom, supply air HEPA filtration, and particle count testing evaluated during design.

In cases where the patient is immunosuppressed but not contagious, positive pressure must be maintained between the patient room and adjacent area. Some jurisdictions may require an anteroom, maintenance of differential pressure, and local pressure monitoring or alarming. Exam and treatment rooms for these patients should be controlled in the same manner. Positive pressure should also be maintained between the entire unit and adjacent areas to preserve clean conditions.

Exceptions to normally established negative and positive pressure conditions include operating rooms where highly infectious patients may be treated (e.g., operating rooms in which bronchoscopy or lung surgery is performed) and infectious isolation rooms that house immunosuppressed patients with airborne infectious diseases such as tuberculosis (TB). When a patient is both immunosuppressed and potentially contagious, **combination airborne infectious isolation/protective environment (combination AII/PE)** rooms are provided. These rooms require an anteroom, which must be either positive or negative to both the AII/PE room and the corridor or common space. Either of these anteroom pressurization techniques minimizes cross contamination between the patient area and surrounding areas, and may be used depending on local fire smoke management regulations. Pressure controls in the adjacent area or anteroom must maintain the correct pressure relationship relative to the other adjacent room(s) and areas. A separate, dedicated air-handling system to serve the protective isolation unit simplifies pressure control and air quality (Murray et al. 1988). Figure 3 shows a typical protective environment room arrangement. The differential pressure (DP) sensor measures the differential pressure between the patient room and the corridor. If the patient room becomes negative with respect to the corridor, alarm lights are triggered to alert staff of the change in pressurization.

Airborne Infection Isolation Unit. The airborne infection isolation (AII) room protects the rest of the hospital from patients' airborne infectious diseases. Multidrug-resistant strains of tuberculosis have increased the importance of pressurization, air change rates, filtration, and air distribution design in these rooms (Rousseau and Rhodes 1993). Temperatures and humidities should correspond to those specified for patient rooms.

The designer should work closely with health care planners and the code authority to determine the appropriate isolation room design. It may be desirable to provide more complete control, with a separate anteroom used as an air lock to minimize the potential that aerosol from the patients' area reach adjacent areas. Design approaches to airborne infection isolation may also be found in CDC (2005). AII room exhaust may include HEPA filtration where there is a concern over recirculation of the exhaust air into nearby building air intakes or due to concern of the location of where maintenance workers may be working. Figure 4 shows a typical AII room arrangement with an anteroom. The differential pressure (DP) sensor measures the differential pressure between the patient room and the corridor. If the AII patient room becomes positive with respect to the corridor, alarm lights are triggered to alert staff.

Some facilities have switchable isolation rooms (rooms that can be set to function with either positive or negative pressure). CDC (2005) and FGI (2014a) have, respectively, recommended against and prohibited this approach. The two drawbacks of this approach are that (1) it is difficult to maintain the mechanical dampers and controls required to accurately provide the required pressures, and (2) it provides a false sense of security to staff who think that this provision is all that is required to change a room between protective isolation and infectious isolation, to the exclusion of other sanitizing procedures.

Biocontainment Treatment Areas (BTAs). These patient treatment areas (also called biocontainment patient care units) are of increasing interest and should possibly adopt the previously discussed clean-to-dirty zoning and airflow paradigm. BTAs are special and often isolated clinical and supporting areas specifically designed to minimize nosocomial transmission during treatment of patients with suspected or confirmed highly contagious and hazardous illnesses. The design focus for these areas is to protect both the hospital and attending healthcare workers, while providing an environment conducive to patient treatment and recovery. This is partially achieved by following protective engineering and design principles similar to those used in biosafety level 3 and 4 laboratory facilities (Smith et al. 2006). Exact design features for BTAs can vary depending on illness, modes of disease transmission, and available resources, and BTAs may be designed as disease-specific treatment (or triage) areas or for an all-hazards infectious disease approach. The spectrum of care may be very broad, ranging from basic medical observation to intensive clinical care. The most protective BTA design features include a clean-to-dirty single-pass airflow design that augments an established clean-to-dirty human and material workflow. This approach often incorporates separate entry and exit points from the patient room. Anterooms at the entry point can be used for donning personal protective equipment (PPE) as well as clean observation areas for use by unexposed observers. Patient rooms within the BTA should be under negative pressure and may benefit from being AII rooms. Key system redundancies (i.e., power, HVAC, exhaust) should be considered and incorporated if integral to the effectiveness of the BTA's functional intent. Due to the significant PPE requirements and their corresponding influence on worker heat stress, the patient room conditioning capacity should allow for room temperatures below those commonly used for inpatient treatment.

BTA patient rooms should ideally have private bathrooms with self-closing doors, toilets with fully closing toilet lids (as allowed by local code and the AHJ), and hands-free electronic faucets. Negative

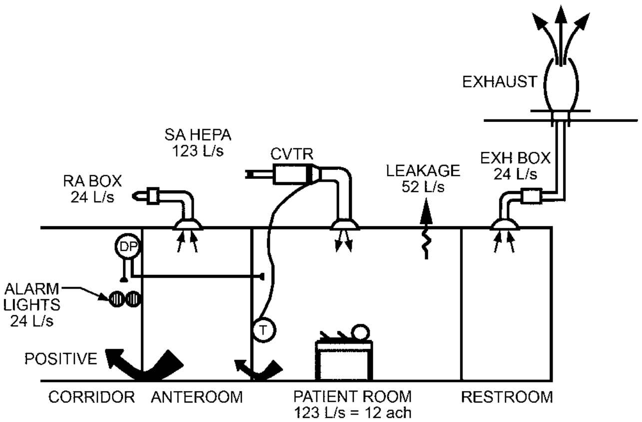

Fig. 3 Protective Environment Room Arrangement
(ASHRAE 2013)

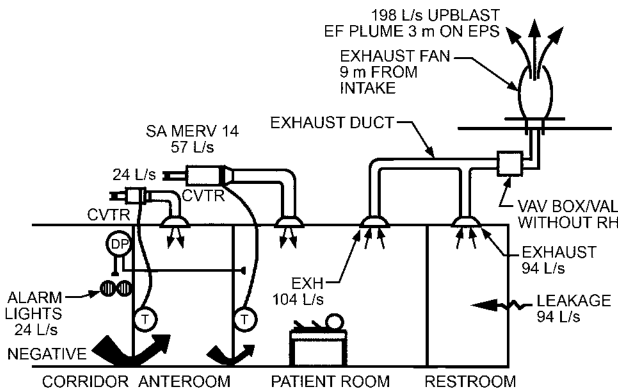

Fig. 4 Airborne Infection Isolation Room
(ASHRAE 2013)

air pressure, enhanced exhaust airflow volumes, and strategic exhaust louver placement to facilitate capture and removal of toilet plume aerosols are appropriate considerations for such patient bathrooms. Exit points and pathways from the patient room should consider issues such as worker/material decontamination and PPE doffing, sufficient temporary storage for hazardous medical waste, and exit path routing of wastes and laboratory samples.

A dedicated laboratory capacity may also be incorporated into the BTA and should be placed in a location that is compatible with the clean-to-dirty paradigm. Facilities considering more than one patient room in their BTA may want to consider incorporating a shared exit-path anteroom to accommodate many of these functions while optimizing usage of space. Depending on the scope, size, and capacity of the BTA, dedicated BTA worker restrooms, decontamination showers, changing rooms, PPE storage, and break areas may be appropriate. Facilities that specialize in pediatric patients may also consider special observation and/or interactive capabilities (e.g., specialized glove ports built into wall of clean observation area) that allow for safe familial interaction with pediatric patients. Figure 5 contains a sample layout of a biocontainment unit.

Floor Pantry. Ventilation requirements for this area depend upon the type of food service used by the hospital. Where bulk food is dispensed and dishwashing facilities are provided in the pantry, using hoods above equipment with exhaust to the outdoors is recommended. Small pantries used for between-meal feedings require no special ventilation. Air pressure of the pantry should be in balance with that of adjoining areas to reduce air movement in either direction.

Labor/Delivery/Recovery/Postpartum (LDRP). The procedures for normal childbirth are considered noninvasive, and rooms are controlled similarly to patient rooms. Some jurisdictions may require higher air change rates than in a typical patient room. It is expected that invasive procedures such as cesarean section are performed in a nearby operating room.

Ancillary

Radiology Department. Factors affecting ventilation system design in these areas include odors from certain clinical treatments and the special construction designed to prevent radiation leakage. Fluoroscopic, radiographic, therapy, and darkroom areas require special attention.

Fluoroscopic, Radiographic, and Deep Therapy Rooms. These rooms may require a temperature from 25.5 to 26.7°C and a relative humidity from 40 to 50%. This relative humidity range control often requires dedicated room equipment and control. Depending on the location of air supply outlets and exhaust intakes, lead lining may be required in supply and return ducts at points of entry to various clinical areas to prevent radiation leakage to other occupied areas.

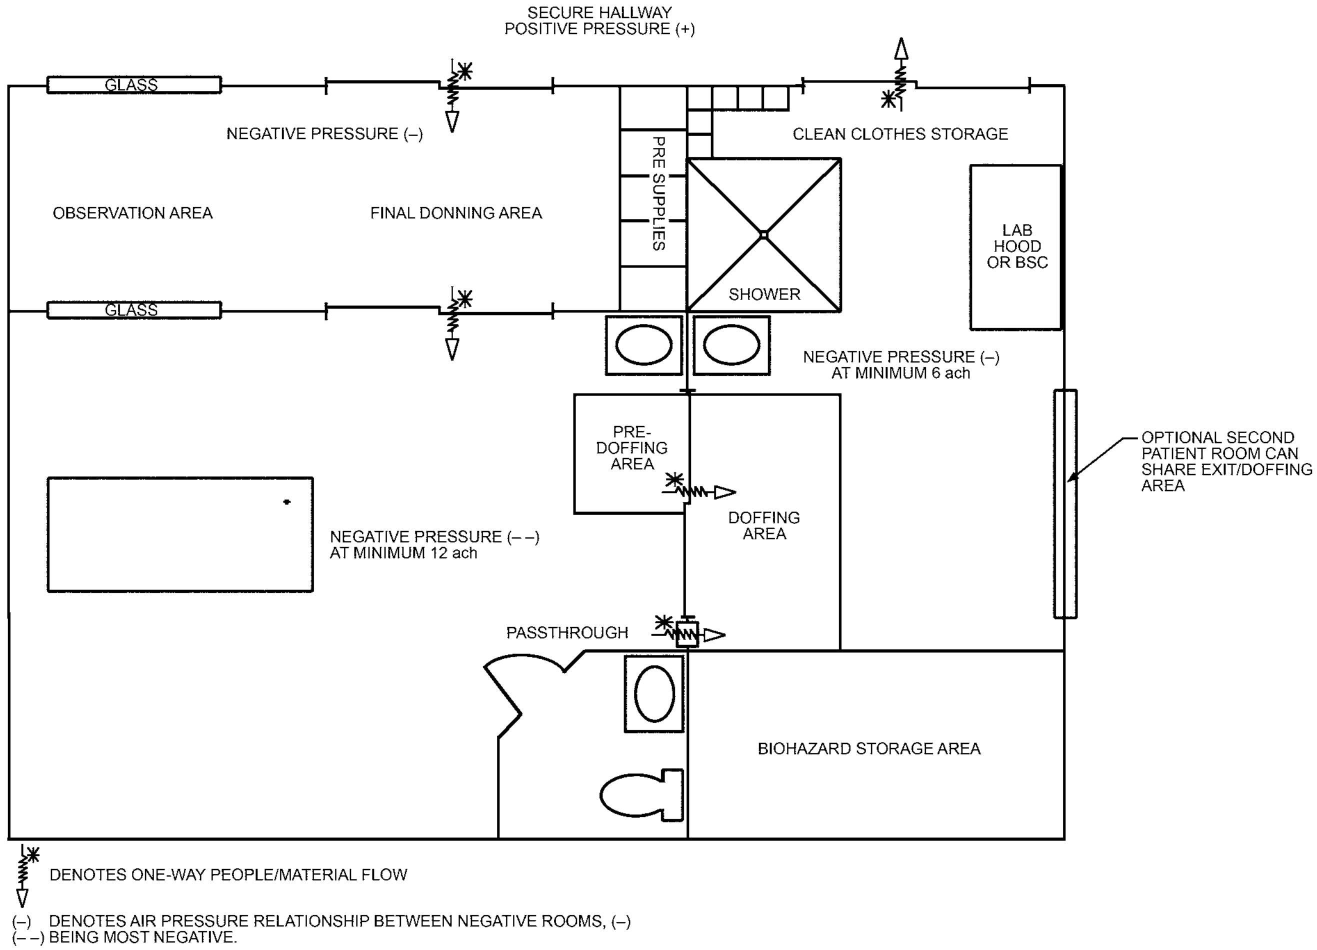

Fig. 5 Biocontainment Treatment Areas
(ASHRAE 2013)

Darkroom. The darkroom is normally in use for longer periods than x-ray rooms and should have an exhaust system to discharge air to the outdoors. Exhaust from the film processor should be connected into the darkroom exhaust system.

Laboratories. Air conditioning is necessary in laboratories for the comfort and safety of the technicians (Degenhardt and Pfost 1983). Chemical fumes, odors, vapors, heat from equipment, and the undesirability of open windows all contribute to this need. Pay particular attention to the size and type of equipment used in the various laboratories, because equipment heat gain usually constitutes a major portion of the cooling load; see Table 7 in Chapter 18 of the 2013 *ASHRAE Handbook—Fundamentals* for examples.

The general air distribution and exhaust systems should be constructed of conventional materials following standard designs for the type of systems used. Exhaust systems serving hoods in which radioactive materials, volatile solvents, and strong oxidizing agents (e.g., perchloric acid) are used should be made of stainless steel. Washdown facilities and dedicated exhaust fans should be provided for hoods and ducts handling perchloric acid.

Hood use may dictate other duct materials. Hoods in which radioactive, carcinogenic, or infectious materials are to be used should be equipped with high-efficiency (HEPA) filters for the exhaust and have a procedure and equipment for safe removal and replacement of contaminated filters. Exhaust duct routing should be as short as possible with minimal horizontal offsets and, when possible, duct portions with contaminated air should be maintained under negative pressure (e.g., locate fan on clean side of filter). This applies especially to perchloric acid hoods because of the extremely hazardous, explosive nature of this material. Hood exhaust fans should be located at the discharge end of the duct system to prevent exhaust products entering the building. The hood exhaust system should not shut off if the supply air system fails. Chemical storage rooms must have a constantly operating exhaust air system. For further information on laboratory air conditioning and hood exhaust systems, see AIHA *Standard* Z9.5, Hagopian and Hoyle (1984), NFPA *Standard* 45, and Chapter 16 of this volume.

Exhaust air from hoods in biochemistry, histology, cytology, pathology, glass washing/sterilizing, and serology-bacteriology units should be discharged to the outdoors with no recirculation. Use care in designing the exhaust outlet locations and arrangements: exhaust should not be reentrained in the building through outdoor air intakes or other building openings. Separation from outdoor air intake sources, wind direction and velocity, building geometry, and exhaust outlet height and velocity are important. In many laboratory exhaust systems, exhaust fans discharge vertically at a minimum of 3 m above the roof at velocities up to 20 m/s. The entire laboratory area should be under slight negative pressure to reduce the spread of odors or contamination to other hospital areas. Temperatures and humidities should be within the comfort range.

Bacteriology Laboratories. These units should not have undue air movement; limit air velocities to a minimum. The sterile transfer room, which may be within or adjoining the bacteriology laboratory, is where sterile media are distributed and where specimens are transferred to culture media. To maintain a sterile environment, a HEPA filter should be installed in the supply air duct near the point of entry to the room. The media room should be ventilated to remove odors and steam.

Infectious Disease and Virus Laboratories. These laboratories, found only in large hospitals, require special treatment. A minimum ventilation rate of 6 ach or makeup approximately equal to hood exhaust volume is recommended for these laboratories, which should have a negative air pressure relative to adjacent areas to help prevent exfiltration of airborne contaminants. Exhaust air from fume hoods or safety cabinets must be sterilized before being exhausted to the outdoors. This may be accomplished by using electric or gas-fired heaters placed in series in the exhaust systems and designed to heat the exhaust air to 315°C. A more common and less expensive method of sterilizing the exhaust is to use HEPA filters in the system.

Nuclear Medicine Laboratories. Such laboratories administer radioisotopes to patients orally, intravenously, or by inhalation to facilitate diagnosis and treatment of disease. There is little opportunity in most cases for airborne contamination of the internal environment, but exceptions warrant special consideration. One important exception involves the use of iodine-131 solution in capsules or vials to diagnose thyroid disorders. Another involves use of xenon-133 gas via inhalation to study patients with reduced lung function.

Capsules of iodine-131 occasionally leak part of their contents before use. Vials emit airborne contaminants when opened for preparation of a dose. It is common practice for vials to be opened and handled in a standard laboratory fume hood; a minimum face velocity of 0.5 m/s should be adequate for this purpose. This recommendation applies only where small quantities are handled in simple operations. Other circumstances may warrant use of a glove box or similar confinement. Diagnostic use of xenon-133 involves a special instrument that allows the patient to inhale the gas and to exhale back into the instrument. The exhaled gas is passed through a charcoal trap mounted in lead, and is often vented outdoors. The process suggests some potential for escape of the gas into the internal environment.

Because of the specialized nature of these operations and of the equipment involved, it is recommended that system designers determine the specific instrument to be used and contact the manufacturer for guidance. Other guidance is available in U.S. Nuclear Regulatory Commission *Regulatory Guide* 10.8 (NRC 1980). In particular, emergency procedures in case of accidental release of xenon-133 should include temporary evacuation of the area and/or increasing the ventilation rate of the area. Recommendations for pressure relationships, supply air filtration, supply air volume, airborne particle counts, recirculation, and other attributes of supply and discharge systems for histology, pathology, pharmacy, and cytology laboratories are also relevant to nuclear medicine laboratories. The NRC does, however, impose some special ventilation system requirements where radioactive materials are used. For example, NRC (1980) provides a computational procedure to estimate the airflow necessary to maintain xenon-133 gas concentration at or below specified levels. It also contains specific requirements as to the amount of radioactivity that may be vented to the atmosphere; the disposal method of choice is adsorption onto charcoal traps.

Autopsy Rooms. Susceptible to heavy bacterial contamination (e.g., tuberculosis) and odor, autopsy rooms must maintain a negative air pressure relative to adjoining rooms or the corridor to help prevent the spread of contamination (Murray et al. 1988). Autopsy rooms are part of the hospital's pathology department and require special attention (CDC 2005). Exhaust intakes should be located both at the ceiling and in the low sidewall. Where large quantities of formaldehyde are used, special exhaust systems can effectively control concentrations below legal exposure limits. A combination of localized exhaust and ventilation systems with downdraft or sidedraft tables has been shown to effectively control concentrations while using smaller exhaust volumes than those required by dilution ventilation (Gressel and Hughes 1992). In smaller hospitals where the autopsy room is used infrequently, local control of the ventilation system and an odor control system with either activated charcoal or potassium permanganate-impregnated activated alumina may be sufficient.

Animal Quarters. Principally because of odor, animal quarters (found only in larger research hospitals) require a mechanical exhaust system that discharges contaminated air above the hospital roof and maintains a negative air pressure relative to adjoining areas to help prevent the spread of odor, allergens, or other contaminants. Chapter 16 has further information on animal room air conditioning.

Pharmacies. Design and ventilation requirements for pharmacies can vary greatly according to the type of compounding performed within the space. Pharmacies handling hazardous drugs and/or involved in sterile compounding activities have special requirements for incorporating primary engineering controls (PECs) such as horizontal or vertical laminar-airflow workbenches (LAFW), biological safety cabinets (BSC), and compounding (barrier) isolators. Room air distribution and filtration must be coordinated with any PECs that may be needed. See Chapters 16 and 18 for more information.

Sterile Compounding. Sterile pharmaceutical compounding requirements are prescribed by USP (2008). USP Chapter 797 is enforceable under the U.S. Food and Drug Administration, is adopted in whole or in part by many state boards of pharmacy, and may be incorporated into the inspection programs of health care accreditation organizations. The Joint Commission recognized USP 797 as a consensus-based safe practice guideline for sterile compounding; however, they do not require its direct implementation as a condition of accreditation. End users, owners, architects, and engineers should consult the most recent release of USP 797, which is under continuous maintenance, as well as applicable sterile compounding design guidance adopted by their state boards of pharmacy.

USP 797 prescribes that all sterile pharmaceutical preparations to be administered more than 1 h after preparation must be compounded entirely within a critical work zone protected by a unidirectional, HEPA-filtered airflow of ISO class 5 (former class 100 under withdrawn *Federal Standard* 209E; see Chapter 18 for class definitions) or better air quality. This ISO class 5 environment is generally provided using a primary engineering control (PEC) such as a LAFW, BSC, or compounding isolator. USP 797 also requires that the ISO class 5 critical work zone be placed within a buffer area (also called a buffer room or cleanroom) (the air quality of which must meet a minimum of ISO class 7) and contain air-conditioning and humidity controls. Adjacent to the buffer area, the sterile compounding pharmacy design must incorporate an ante area for storage, hand washing, nonsterile preparation activities, donning and doffing of protective overgarments, etc. The air cleanliness in the ante area must be a minimum of ISO class 8 (exception: see the following Hazardous Drugs section). The ante area and buffer area constitute secondary engineering controls. Low-risk preparations that are nonhazardous and destined for administration within 12 h of compounding are granted an exemption from these secondary engineering controls if they are prepared within an ISO class 5 PEC and the compounding area is segregated from noncompounding areas. Pharmacy designers should note that the ISO class 5, 7, and 8 air cleanliness requirements are specified for dynamic conditions (USP 2008). Although ASHRAE *Standard* 170 does not prescribe a design temperature for health care pharmacies, USP 797 recommends a maximum temperature of 20°C because of the increased thermal insulation that results from wearing protective clothing and the adverse sterility conditions that could arise from uncomfortably warm and/or sweaty pharmacy workers.

Beyond air quality requirements, the physical design features separating the buffer area from the ante area are based on the pharmacy's **compounded sterile preparation (CSP)** risk level (low, medium, or high) for microbial, chemical, and physical contamination. USP 797 instructs pharmacy professionals on how to determine their pharmacy's CSP risk level based on purity and packaging of source materials, quantity and type of pharmaceuticals, time until its administration, and various other factors. The desired CSP risk level capability should be identified before designing the pharmacy design layout. Pharmacies intended for compounding high-risk-level CSPs require a physical barrier with a door to separate the buffer room from the anteroom, and the buffer room must be maintained at a minimum positive pressure differential of 5 Pa. For medium- and low-risk level CSPs, the buffer area and ante area can be in the same room, with an obvious line of demarcation separating the two areas and with the demonstrable use of displacement airflow, flowing from the buffer area towards the ante area. Depending on the affected cross-sectional area and the moderately high velocity required to maintain the displacement uniformity (typically 0.2 m/s or greater), designers may find the physical barrier design to be a more energy friendly approach. USP further prescribes areas to receive a minimum of 30 ach (with up to 15 of these provided by the PEC) if the area is designated to be ISO class 7. There is no minimum ventilation requirement prescribed for ISO class 8 ante areas (USP 2008).

Selecting pharmacy PECs can be a delicate task. Class II BSCs are currently certified following the construction and performance guidelines developed by the National Sanitation Foundation (NSF) and adopted by the American National Standards Institute (ANSI/NSF *Standard* 49-2014). However, no such national certification program exists for compounding isolators. USP 797 addresses this shortcoming by referencing isolator testing and performance guidelines developed by the Controlled Environment Testing Association (CETA 2006).

Hazardous Drugs. Compounding hazardous drugs is another pharmaceutical operation that requires special design considerations. NIOSH (2004) warned of the dangers of occupational exposures to hazardous drugs, over 130 of which were defined and identified; roughly 90 of these drugs were antineoplastic agents primarily used during cancer treatments. Several of NIOSH's recommended protective measures can affect a pharmacy's ventilation design and physical layout. These recommendations include the following:

- Prepare hazardous drugs in an area devoted to that purpose alone and restricted to authorized personnel.
- Prepare hazardous drugs inside a ventilated cabinet designed to prevent hazardous drugs from being released into the work environment.
- Use a high-efficiency particulate air (HEPA) filter for exhaust from ventilated cabinets and, where feasible, exhaust 100% of the filtered air to the outdoors, away from outdoor air intakes or other points of entry.
- Place fans downstream of HEPA filters so that contaminated ducts and plenums are maintained under negative pressure.
- Design the exhaust system such that negative pressure is maintained in the cabinet in the event of fan failure.
- Do not use ventilated cabinets (BSCs or compounding aseptic containment isolators [CACIs]) that recirculate air inside the cabinet or that exhaust air back into the pharmacy unless the hazardous drug(s) in use will not volatilize (evaporate or sublimate) while they are being handled or after they are captured by the HEPA filter. (*Note*: This recommendation is a shift from traditional pharmacy design practice and involves knowledge of the physical properties of drugs within the current drug formulary as well as future new drugs that might be compounded within the cabinet. Within-cabinet recirculation [e.g., BSC class II Type A2 or B1] is allowed when airstream has zero or only minute vapor drug contaminant.)
- Store hazardous drugs separately from other drugs, in an area with sufficient general exhaust ventilation to dilute and remove any airborne contaminants. Depending on the physical nature and quantity of the stored drugs, consider installing a separate, high-volume, emergency exhaust fan capable of quickly purging airborne contaminants from the storage room in the event of a spill, to prevent airborne migration into adjacent areas.

The American Society of Health Systems Pharmacists' *Guidelines on Handling Hazardous Drugs* (ASHP 2006) adopted NIOSH's (2004) protective equipment recommendations, and added the specification that hazardous drug compounding should be done in a contained, negative-pressure environment or one that is protected by an airlock or anteroom.

Often, hazardous drugs also require sterile compounding. If so, pharmacies must have an environment suitable for both product sterility and worker protection. ASHP (2006), NIOSH (2004), and USP (2008) all address these dual objectives by recommending the use of BSCs or compounding aseptic containment isolators. The precautionary recommendations regarding in-cabinet recirculation and cabinet-to-room recirculation of air potentially contaminated with hazardous drugs still apply. In addition, USP 797 requires hazardous drug sterile compounding to be conducted in a negative-pressure compounding area and to be stored in dedicated storage areas with a minimum of 12 ach of general exhaust. When CACIs are used outside of an ISO 7 buffer area, the compounding area must maintain a negative pressure of 2.5 Pa and also have a minimum of 12 ach. Anterooms adjacent to an ISO 7 buffer area must also be ISO 7, since there will be air leakage from the anteroom into the negative pressure hazardous drug buffer area.

Table 4 provides a matrix of design and equipment decision logic based on USP 797 and NIOSH (2004).

In February 2016, USP published a new pharmaceutical standard identified as general chapter 800: Hazardous Drugs—Handling in Healthcare Settings. The new chapter applies to all hazardous drug compounding, whereas the previously published guidance in USP 797 was only applicable to sterile compounding. As a USP chapter numbered less than 1000, it is federally enforceable, as well as adoptable (in whole or in part) by individual state boards of pharmacy. Although published in 2016, USP 800 has an official implementation date of December 1, 2019 to allow health care facilities sufficient time to implement necessary engineering design requirements. The USP 800 chapter applies to all health care facilities (including veterinary facilities) where hazardous drugs are handled, manipulated, stored, or distributed. Most of the guidance for hazardous drug sterile compounding carries over from USP 797, but there are two major changes: (1) the low-volume exemption mentioned in Table 3 no longer applies, and (2) USP 800 allows low-to-medium risk sterile compounding to occur in an ISO 5 PEC placed in a nonclassified area (segregated compounding area) in accordance with USP 797 use limitations. The USP 800 chapter adopts a reception-through-administration approach to protecting health care workers from hazardous drug exposures and provides specified requirements for receiving, storing, mixing, preparing, compounding, dispensing, and administering hazardous drugs. Most of these requirements include an engineering and/or architectural design component are summarized in Table 5.

Administration

This department includes the main lobby and admitting, medical records, and business offices. Admissions and waiting rooms may harbor patients with undiagnosed airborne infectious diseases, so consider using local exhaust systems that move air toward the admitting patient. A separate air-handling system is considered desirable to segregate this area from the hospital proper, because it is usually unoccupied at night and thus a good candidate for energy savings control solutions. Open-water features are strongly discouraged inside health care occupancies; if closed water features are proposed, provide water treatment and other administrative and engineering controls to protect occupants from infectious or irritating aerosols. Refer to ASHRAE *Standard* 188-2015 and *Guideline* 12 for further guidance.

Diagnostic and Treatment

Bronchoscopy, Sputum Collection, and Pentamidine Administration Procedures. These procedures have a high potential for discharges of potentially infectious droplet nuclei into the room air via coughing. Bronchoscopy procedures can release airborne aerosols into the room from a patient who could possibly be diagnosed with tuberculosis, and nontherapeutic exposures to pentamidine are an additional exposure concern. The procedures and patient recovery period (when excessive coughing may occur) are best suited for an **airborne infectious isolation (AII)** room. ASHRAE *Standard* 170 requires local capture exhaust (enclosed administration booth, enclosing hood or tent) near the bronchoscopy procedure site along with exhaust and pressurization similar to an AII room.

Magnetic Resonance Imaging (MRI) Rooms. These rooms should be treated as exam rooms in terms of temperature, humidity, and ventilation. However, special attention is required in the control room because of the high heat release of computer equipment, and in the exam room because of the cryogens used to cool the magnet. Nonferrous material requirements and shielding penetrations should be in accordance with the specific manufacturer's requirements.

Heat Gains from Medical Equipment. Table 6 in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals* tabulates typical heat gain from many types of smaller mobile medical equipment. ASHRAE research project RP-1343 (Koenigshofer et al. 2009) developed methods to test heat gain from large, fixed medical imaging equipment systems at both idle and peak outputs during operational cycles. Tables 6 and 7 present results for some of the equipment tested in RP-1343. Medical equipment heat outputs can vary widely among different manufacturers, even for equipment that performs a similar function, and the medical equipment field is rapidly advancing. The functional program should identify specific manufacturers and models for the HVAC designer's use early in the design process.

Treatment Rooms. Patients are brought to these rooms for special treatments (e.g., hyperbaric oxygen therapy) that cannot be conveniently administered in patient rooms. To accommodate the patient, the rooms should have independent temperature and humidity control. Temperatures and humidities should correspond to those specified for patients' rooms.

Table 4 Minimum Environmental Control Guidance for Pharmacies

Compounding Scenario	Hazardous Drug (HD) (Requires separate area)	Nonhazardous Drug
Sterile compounding to be administered within 12 h	ISO 5 CACI or BSC within negative-pressure ISO 7 buffer + ISO 7 ante areas	If immediate use and low risk: no environmental requirements if administered <12 h + ISO 5 PEC within segregated compounding area
Sterile compounding to be administered after 12 h or more	ISO 5 CACI or BSC within negative-pressure ISO 7 buffer + ISO 7 ante areas	ISO 5 PEC + ISO 7 buffer + ISO 8 ante areas - High-risk compounding requires physical barrier with min. positive pressure (5 Pa) in buffer room relative to anteroom - Medium- and low-risk compounding may use physical barrier (as per high risk) or a clearly identified line of demarcation between buffer and ante areas with uniform displacement airflow (min. of 0.2 m/s recommended) in direction of buffer to ante areas
Nonsterile compounding	Needs compounding containment isolator or BSC	No sterility or occupational exposure controls required

*For facilities that prepare a low volume of hazardous drugs and use two tiers of containment (e.g., CSTD within CACI or BSC), a negative-pressure buffer area is not required.

Table 5 Engineering Requirements for Receiving, Storing, and Manipulating Hazardous Drugs

Activity	Minimum Engineering Requirements
Hazardous drug receipt/unpacking	Segregated area at negative or neutral pressure to surrounding areas
Hazardous drug storage*	Segregated area, externally vented, (2.5 Pa) negative pressure, 12 ach
Nonsterile HD compounding	Containment, primary engineering control (C-PEC): externally vented (preferred) or redundant HEPA filtered. Containment, secondary engineering control (C-SEC): externally vented, (2.5 Pa) negative pressure, 12 ach
Sterile HD compounding (two allowable configurations):	
Buffer room configuration	C-PEC: ISO 5 direct compounding area, externally vented [e.g. Class II (Types A2, B1 or B2), Class III BSC or CACI] C-SEC: externally vented, ISO 7 buffer area, (2.5 Pa) negative pressure, 30 ach plus ISO 7 anteroom, (5 Pa) positive pressure relative to all adjacent unclassified areas, 30 ach
Segregated compounding area configuration (for low- and medium-risk compounding use only; see USP 797 for compounding risk determinations)	Nonclassified air cleanliness, 12 ach, 2.5 Pa negative pressure

*Non-antineoplastic-reproductive risk only, and final dosage forms of antineoplastic HDs may be stored with other inventory if permitted by entity policy.

Table 6 Summary of Heat Gain to Air from Imaging Systems

System	Maximum 60 min Time-Weighted Average, kW	Calculated Idle, kW	Manufacturer's Design Information, kW
MRI #1	24.42	22.23	—
MRI #2	23.58	19.14	—
X-ray	1.25	1.08	1.35
Fluoroscopy #1	12.13	9.18	7.31
Fluoroscopy #2	5.01	4.43	5.90
CT–64 slice	7.06	6.57	19.18
PET/CT	12.60	9.80	—
Nuclear camera	1.11	1.06	—
Linear accelerator	32.59	19.87	9.16
Ultrasound (portable)	0.86	0.50	—
Cyberknife	13.40	10.38	—

Physical Therapy Department. The cooling load of the electrotherapy section is affected by the shortwave diathermy, infrared, and ultraviolet equipment used in this area.

Hydrotherapy Section. This section, with its various water treatment baths, is generally maintained at temperatures up to 26.5°C. The potential latent heat load in this area should not be overlooked. The exercise section requires no special treatment; temperatures and humidities should be within the comfort zone. Air may be recirculated within the areas, and an odor control system is suggested.

Occupational Therapy Department. In this department, spaces for activities such as weaving, braiding, artwork, and sewing require no special ventilation treatment. Air recirculation in these areas using medium-grade filters in the system is permissible. Larger hospitals and those specializing in rehabilitation may offer patients a greater diversity of skills to learn and craft activities, including carpentry, metalwork, plastics, photography, ceramics, and painting. The air-conditioning and ventilation requirements of the various sections should conform to normal practice for such areas and to the codes relating to them. Temperatures and humidities should be maintained within comfort levels.

Inhalation Therapy Department. This department treats pulmonary and other respiratory disorders. The air must be very clean, and the area should have a positive pressure relative to adjacent areas, except when the patient may also be airborne infectious or when the treatment regimen uses hazardous drug therapies. Local exhaust ventilation controls (e.g., administration booth, enclosing hood or tent) should be provided to control exposure of staff to hazardous drug therapies.

Table 7 Summary of Heat Gain to Air

Equipment	Calculated Idle, kW	High, kW
Dialysis machine	0.40	0.69
Film processor	0.40	0.42
Pharmacy freezer	0.73	0.82
Pharmacy refrigerator	0.48	0.59

Workrooms. Clean workrooms serve as storage and distribution centers for clean supplies and should be maintained at a positive pressure relative to the corridor. Soiled workrooms serve primarily as collection points for soiled utensils and materials. They are considered contaminated rooms and should have a negative air pressure relative to adjoining areas. Temperatures and humidities should be in the comfort range and account for protective clothing requirements required for the room occupants.

Decontamination, High-Level Disinfection, Sterilization and Supply

Used and contaminated utensils, instruments, and equipment are brought to this unit for decontamination and high level disinfection or sterilization before reuse. The central sterile processing unit usually consists of a decontamination area, a sterile prep area, a sterilizing area, and a sterile storage area where supplies are kept until requisitioned. The decontamination area must be physically separated from the sterile prep and sterilization areas. A dedicated endoscope reprocessing area may support the inpatient endoscopy suite. Although AAMI allows for decontamination and high level disinfection to be located in the same space, a clear line of demarcation between soiled cleaning activities and the clean manual or automated disinfection activities. Air should flow from the clean disinfection area toward the contaminated cleaning area (ANSI/AAMI *Standard* 58:2013). Air pressure relationships should conform to those indicated in ASHRAE *Standard* 170. Temperature and humidity should be within the comfort range. Pay special attention to equipment used in these areas (gaps in disinfection/cleaning equipment and piping penetrations between decontamination and clean rooms) to maintain pressurization requirements.

The following guidelines are important in the central sterilizing and supply unit:

- Insulate sterilizers to reduce heat load.
- Amply ventilate sterilizer equipment closets to remove excess heat.
- Where ethylene oxide (ETO) gas sterilizers are used, provide a separate exhaust system with terminal fan (Samuals and Eastin

1980). Provide adequate exhaust capture velocity in the vicinity of sources of ETO leakage. Install an exhaust at sterilizer doors and over the sterilizer drain, and exhaust flammable storage cabinets and sterilant cylinder supply cabinets. Exhaust aerator and service rooms. Sterilizers should be equipped with automatic aeration functionality. Audible and visual ETO alarm sensors and exhaust flow sensors should also be provided and monitored. ETO sterilizers should be located in dedicated unoccupied rooms that have a highly negative pressure relative to adjacent spaces and 10 ach. Many jurisdictions require that ETO exhaust systems have equipment to remove ETO from exhaust air (see OSHA *Standard* 29 CFR 1910.1047).

- Similar provisions for monitoring and alarms should be considered for hydrogen peroxide sterilizers.
- Maintain storage areas for sterile supplies at a relative humidity of no more than 50%.

Service

Service areas include dietary, housekeeping, biohazardous waste storage, mechanical, and employee facilities. Whether these areas are conditioned or not, adequate ventilation is important to provide sanitation and a wholesome environment. Ventilation of these areas cannot be limited to exhaust systems only; provision for supply air must be incorporated into the design. Such air must be filtered and delivered at controlled temperatures. The best designed exhaust system may prove ineffective without an adequate air supply. Experience shows that relying on open windows results only in dissatisfaction, particularly during the heating season. Air-to-air heat exchangers in the general ventilation system offer possibilities for sustainable operation in these areas.

Dietary Facilities. These areas usually include the main kitchen, bakery, dietitian's office, dishwashing room, and dining space. Because of the various conditions encountered (i.e., high heat and moisture production, cooking odors), special attention in design is needed to provide an acceptable environment. See Chapter 34 for information on kitchen facilities.

The dietitian's office is often located within the main kitchen or immediately adjacent to it. It is usually completely enclosed for privacy and noise reduction. Air conditioning is recommended for maintaining normal comfort conditions.

The dishwashing room should be enclosed and minimally ventilated to equal the dishwasher hood exhaust. It is not uncommon for the dishwashing area to be divided into a soiled area and a clean area. In such cases, the soiled area should be kept at a negative pressure relative to the clean area.

Ventilation of the dining space should conform to local codes. The reuse of dining space air for ventilation and cooling of food preparation areas in the hospital is suggested, provided the reused air is passed through filters with a filtration efficiency of MERV 13 or better. Where cafeteria service is provided, serving areas and steam tables are usually hooded. The air-handling capacities of these hoods should be sized to accommodate exhaust flow rates (see Table 6 in Chapter 34). Ventilation systems for food preparation and adjacent areas should include an interface with hood exhaust controls to assist in maintaining pressure relationships.

Kitchen Compressor/Condenser Spaces. Ventilation of these spaces should conform to all codes, with the following additional considerations: (1) 165 L/s of ventilating air per compressor kilowatt should be used for units located in the kitchen; (2) condensing units should operate optimally at 32°C maximum ambient temperature; and (3) where air temperature or air circulation is marginal, specify combination air- and water-cooled condensing units. It is often worthwhile to use condenser water coolers or remote condensers. Consider using heat recovery from water-cooled condensers.

Laundry and Linen Facilities. Of these facilities, only the soiled linen storage room, soiled linen sorting room, soiled utility room, and laundry processing area require special attention. The room for storing soiled linen before pickup by commercial laundry is odorous and contaminated, and should be well ventilated, exhausted, and maintained at a negative air pressure. The soiled utility room is provided for inpatient services and is normally contaminated with noxious odors. This room should be mechanically exhausted directly outdoors.

In the laundry processing area, equipment such as washers, flatwork ironers, and tumblers should have direct overhead exhaust to reduce humidity. Such equipment should be insulated or shielded whenever possible to reduce the high radiant heat effects. A canopy over the flatwork ironer and exhaust air outlets near other heat-producing equipment capture and remove heat best. Air supply inlets should be located to move air through the processing area toward the heat-producing equipment. The exhaust system from flatwork ironers and tumblers should be independent of the general exhaust system and equipped with lint filters. Air should exhaust above the roof or where it will not be obnoxious to occupants of other areas. Heat reclamation from the laundry exhaust air may be desirable and practicable.

Where air conditioning is contemplated, a separate supplementary air supply, similar to that recommended for kitchen hoods, may be located near the exhaust canopy over the ironer. Alternatively, consider spot cooling for personnel confined to specific areas.

Mechanical Facilities. The air supply to boiler rooms should provide both comfortable working conditions and the air quantities required for maximum combustion of the particular fuel used. Boiler and burner ratings establish maximum combustion rates, so the air quantities can be computed according to the type of fuel. Sufficient air must be supplied to the boiler room to supply the exhaust fans as well as the boilers.

At workstations, the ventilation system should limit temperatures to32°C effective temperature. When ambient outdoor air temperature is higher, indoor temperature may be that of the outdoor air up to a maximum of36°C to protect motors from excessive heat.

Maintenance Shops. Carpentry, machine, electrical, and plumbing shops present no unusual ventilation requirements. Proper ventilation of paint shops and paint storage areas is important because of fire hazard and should conform to all applicable codes. Maintenance shops where welding occurs should have exhaust ventilation.

3. OUTPATIENT HEALTH CARE FACILITIES

An outpatient health care facility may be a free-standing unit, part of an acute care facility, or part of a medical facility such as a medical office building (clinic). Any outpatient surgery is performed without anticipation of overnight stay by patients (i.e., the facility operates 8 to 10 h per day).

If physically connected to a hospital and served by the hospital's HVAC systems, spaces within the outpatient health care facility should conform to requirements in the section on Hospital Facilities. Outpatient health care facilities that are totally detached and have their own HVAC systems may be categorized as diagnostic clinics, treatment clinics, or both. Many types of outpatient health care facilities have been built with many combinations of different programmed uses occurring in a single building structure. Some of the more common types include primary care facilities, freestanding emergency facilities, freestanding outpatient diagnostic and treatment facilities, freestanding urgent care facilities, freestanding cancer treatment facilities, outpatient surgical facilities, gastrointestinal endoscopy facilities, renal dialysis centers, outpatient psychiatric centers, outpatient rehabilitation facilities, freestanding birth centers, and dental centers.

When specific treatments in these outpatient facilities are medically consistent with hospital-based treatments, then environmental design guidance for hospitals should also apply to the outpatient treatment location. Information under the Hospital Facilities part of this chapter may also be applicable to outpatient occupancies performing a similar activity. Outpatient and clinic facilities should generally be designed according to criteria shown in ASHRAE *Standard* 170, unless those criteria conflict with local or state requirements.

3.1 DIAGNOSTIC AND TREATMENT CLINICS

A diagnostic clinic is a facility where ambulatory patients are regularly seen for diagnostic services or minor treatment, but where major treatment requiring general anesthesia or surgery is not performed. Diagnostic clinics may use specialized medical imaging equipment, which may be portable cart-mounted items or large permanently mounted pieces with adjoining control rooms and equipment rooms. The equipment may require a minimum relative humidity for proper operation. Heat gains from equipment can be large; see Table 5 and the equipment manufacturer's recommendations.

A treatment clinic is a facility where major or minor procedures are performed on an outpatient basis. These procedures may render patients temporarily incapable of taking action for self-preservation under emergency conditions without assistance from others (NFPA *Code* 101).

Design Criteria

See the following subsections under Hospital Facilities:

- Infection Sources
- Control Measures
- Air Quality
- Air Movement
- Temperature and Humidity
- Smoke Control

An outpatient recovery area may not need to be considered a sensitive area, depending on the patients' treatments. Infection control concerns are the same as in an acute care hospital. Minimum ventilation rates, desired pressure relationships and relative humidity, and design temperature ranges are similar to the requirements for hospitals in ASHRAE *Standard* 170.

The following departments in an outpatient treatment clinic have design criteria similar to those in hospitals:

- Surgical: operating, recovery, and anesthesia storage rooms
- Ancillary
- Diagnostic and treatment
- Decontamination, high-level disinfection, sterilization, and supply
- Service: soiled workrooms, mechanical facilities, and locker rooms

3.2 DENTAL CARE FACILITIES

Institutional dental facilities include reception and waiting areas, treatment rooms (called operatories), and workrooms where supplies are stored and instruments are cleaned and sterilized; they may include laboratories where restorations are fabricated or repaired.

Many common dental procedures generate aerosols, dusts, and particulates (Ninomura and Byrns 1998). The aerosols/dusts may contain microorganisms (both pathogenic and benign), metals (e.g., mercury fumes), and other substances (e.g., silicone dusts, latex allergens). Some measurements indicate that levels of bioaerosols during and immediately following a procedure can be extremely high (Earnest and Loesche 1991). Lab procedures have been shown to generate dusts and aerosols containing metals. At this time, only limited information and research are available on the level, nature, or persistence of bioaerosol and particulate contamination in dental facilities. Consider using local exhaust ventilation (possibly recirculating with HEPA filtration) to help capture and control these aerosols, because dental care providers and patients are often close together.

Nitrous oxide is used as an analgesic/anesthetic gas in many facilities. The design for controlling nitrous oxide should consider that nitrous oxide (1) is heavier than air and may accumulate near the floor if air mixing is inefficient, and (2) should be exhausted directly outdoors. Use active waste gas scavenging to prevent accumulation of waste gases during dental procedures; passive scavenging through an open window or a vent in the wall should not be used.

3.3 CONTINUITY OF SERVICE AND ENERGY CONCEPTS

Some owners may desire standby or emergency service capability for the heating, air-conditioning, and service hot-water systems and that these systems be able to function after a natural disaster.

To reduce utility costs, use energy-conserving measures such as recovery devices, variable air volume, load shedding, or devices to shut down or reduce ventilation of certain areas when unoccupied. Mechanical ventilation should take advantage of outdoor air by using an economizer cycle (when appropriate) to reduce heating and cooling loads.

The section on Facility Design and Operation includes information on zoning and insulation that applies to outpatient facilities as well.

4. RESIDENTIAL HEALTH, CARE, AND SUPPORT FACILITIES

FGI's (2014b) *Guidelines for Design and Construction of Residential Health, Care, and Support Facilities* discusses requirements for nursing homes, hospice facilities, assisted living facilities, independent living settings, adult day care facilities, wellness centers, and outpatient rehabilitation centers. HVAC design requirements for these spaces, and consequently applicability of ASHRAE standards to their design, can vary greatly. ASHRAE *Standard* 170 addresses assisted living, hospice, and nursing facilities. ASHRAE *Standard* 62.1 or 62.2 may be applicable to other types of commercial space design, if they are nontransient and residential in nature.

Nursing Facilities

Nursing facilities may be classified as follows:

Extended care facilities are for recuperation by hospital patients who no longer require hospital facilities but do require the therapeutic and rehabilitative services of skilled nurses. This type of facility is either a direct hospital adjunct or a separate facility with close ties with the hospital. Clientele may be of any age, usually stay from 35 to 40 days, and usually have only one diagnostic problem.

Skilled nursing homes care for people who require assistance in daily activities; many of them are incontinent and nonambulatory, and some are disoriented. Residents may come directly from their homes or from residential care homes, are generally elderly (with an average age of 80), stay an average of 47 months, and frequently have multiple diagnostic problems.

Residential care homes are generally for elderly people who are unable to cope with regular housekeeping chores but have no acute ailments and are able to care for all their personal needs, lead normal lives, and move freely in and out of the home and the community. These homes may or may not offer skilled nursing care. The average length of stay is four years or more.

Functionally, these buildings have five types of areas that are of concern to the HVAC designer: (1) administrative and support areas inhabited by staff, (2) patient areas that provide direct normal daily services, (3) treatment areas that provide special medical services, (4) clean workrooms for storing and distributing clean supplies, and (5) soiled workrooms for collecting soiled and contaminated supplies and for sanitizing nonlaundry items.

4.1 DESIGN CONCEPTS AND CRITERIA

Nursing homes occupants are usually frail, and many are incontinent. Though some occupants are ambulatory, others are bedridden, suffering from advanced illnesses. The selected HVAC and air distribution system must dilute and control odors and should not cause drafts. Local climatic conditions, costs, and designer judgment determine the extent and degree of air conditioning and humidification. Odor may be controlled with large volumes of outdoor air and heat recovery. To conserve energy, odor may be controlled with activated carbon or potassium permanganate-impregnated activated alumina filters instead.

Temperature control should be on an individual room basis. In geographical areas with severe climates, patient rooms may have supplementary heat along exposed walls. In moderate climates (i.e., where outdoor winter design conditions are–1°C or above), overhead heating may be used.

Controlling airborne pathogen levels in nursing homes is not as critical as it is in acute care hospitals. Nevertheless, the designer should be aware of the necessity for odor control, filtration, and airflow control between certain areas.

ASHRAE *Standard* 170 lists recommended filter efficiencies for air systems serving specific nursing home areas, as well as recommended minimum ventilation rates and desired pressure relationships. Recommended interior winter design temperature is24°C for areas occupied by patients and21°C for nonpatient areas. Provisions for maintenance of minimum humidity levels in winter depend on the severity of the climate and are best left to the designer's judgment. Where air conditioning is provided, the recommended interior summer design temperature and humidity is 24°C, and a maximum of 60% rh.

The general design criteria in the hospital sections on Heating and Hot Water Standby Service, Insulation, and Sustainability apply to nursing home facilities as well.

STANDARDS

AENOR/UNE
Standard 100713:2005 — Air Conditioning in Hospitals

ANSI/AAMI
Standard 58:2013 — Chemical Sterilization and High-level Disinfection in Health Care Facilities

CHAPTER 10

JUSTICE FACILITIES

Terminology 10.1
General System Requirements 10.1
Jails, Prisons, and Family Courts 10.4
Courthouses 10.5
Forensic Labs 10.6
Indoor Shooting Ranges 10. 8

TECHNICAL and environmental factors and considerations for HVAC systems that serve justice facilities are presented in this chapter. Most of the information provided is specific to facilities in the United States; regulations in other parts of the world differ significantly, and the authorities governing these facilities should be consulted directly. Refer to the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for further information on HVAC systems and equipment mentioned herein, and to other chapters of this volume for various space applications and design considerations.

1. TERMINOLOGY

The following terms are used throughout this chapter:

Justice Facility. Any building designated for purposes of detention, law enforcement, or rendering a legal judgment.

Cell. A room for confining one or more persons; it may contain a bed for each occupant and a toilet and wash basin.

Holding Cell. A room designed to confine a person for a short period of time; it may or may not contain a bed.

Small Jail. A facility consisting of up to 100 rooms and ancillary areas, designed for confining people.

Large Jail. A facility consisting of more than 100 rooms and ancillary areas, designed for confining people.

Prison. A facility consisting of one or several buildings and ancillary areas surrounded by high walls and/or fences, designed to confine a minimum of 500 people.

Minimum Security. A facility or area within a jail or prison that allows confined people to mix together with little supervision for periods of time during the day.

Medium Security. A facility or area within a jail or prison that allows confined people to mix together with some or total supervision for periods of time during the day.

Maximum Security. A facility or an area within a jail or prison that confines people to their cells with total supervision.

Work Release. A program that allows minimum-security occupants freedom during the day to work outside the facility, but requires them to return for the night.

Courthouse. A facility consisting of courtrooms, judges' chambers/offices, jury rooms, jury assembly rooms, attorney interview rooms, libraries, holding cells, and other support areas.

Police Stations. Facilities housing the various functions of local police departments. These may contain holding cells, evidence storage rooms, weapons storage, locker rooms, offices, conference rooms, interview rooms, and parking garages.

Juvenile Facilities. Also known as **family court** facilities, these facilities are for young offenders. Usually kept separate from adult facilities, they house their own court or hearing rooms, judges' chambers, offices for social workers and parole officers, conference rooms, waiting areas, classrooms, sleeping rooms, intake areas, libraries, exercise rooms/areas, kitchens, dining areas, and laundry.

Inmate. A person confined to a cell, jail, prison, or juvenile facility.

Correctional Officer. A trained law officer who supervises inmates.

Correctional Officer Facilities. Areas designated for use only by correctional officers, including control rooms, break rooms, locker rooms, and storage rooms.

Inmate Areas. Areas that inmates have access to, with or without supervision, including cells, day rooms, exercise areas, outside areas, and certain ancillary areas.

Day Rooms. A room where confined people can congregate for periods of time outside of their cells during the day under supervision. The room usually contains chairs, tables, TVs, and reading and game materials.

Exercise Areas. Gymnasiums or rooms used for exercise by staff members, and areas designated for use by inmates where they can mix and exercise for short time periods during the day. This inmate area is usually outdoors or has at least one wall or the roof exposed to the outdoors.

Ancillary Areas. Support areas, including offices, kitchens, laundry, mechanical rooms/plants, electrical rooms/plants, libraries, classrooms, and rooms for exercise, health care, visitation, interviews, records, evidence, storage, fingerprinting, lineups, inmate intake, etc.

Control Room. A room that allows viewing or monitoring of various areas of the facility by correctional officers and/or houses electronic or pneumatic controls for door locks, lights, and other functions.

Sally Port. A room or space that encloses occupants or vehicles and allows only one door at a time to open.

Forensic Lab. Laboratory where human remains and physical evidence are examined and tested to determine whether a crime has been committed, and to identify bodies and people.

2. GENERAL SYSTEM REQUIREMENTS

Outdoor Air. All areas require outdoor air for ventilation to provide good air quality and makeup air for exhaust systems, and to control pressures within facilities. Minimum outdoor air requirements for various areas in justice (correctional) facilities can be found in ASHRAE *Standard* 62.1.

Equipment Locations. Access to mechanical equipment and controls must be kept secure from inmates at all times, and equipment rooms should be located where inmates do not have access to them. Where inmates do have access, security ceilings with lockable access panels must be used for mechanical equipment, and components should be located in ceiling plenums. Equipment serving areas not accessible to inmates can be located as in other facilities, unless the owner has other specific requirements. Equipment near noise-sensitive areas (e.g., courtrooms, jury rooms, attorney interview rooms) should be isolated with vibration isolators and have sound

The preparation of this chapter is assigned to TC 9.4, Justice Facilities.

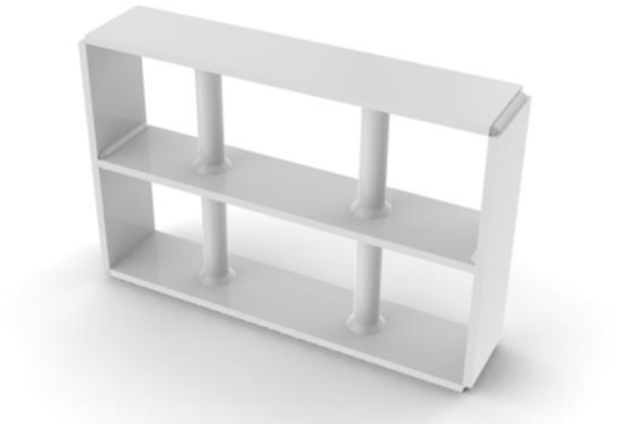

Fig. 1 Typical Security Barrier

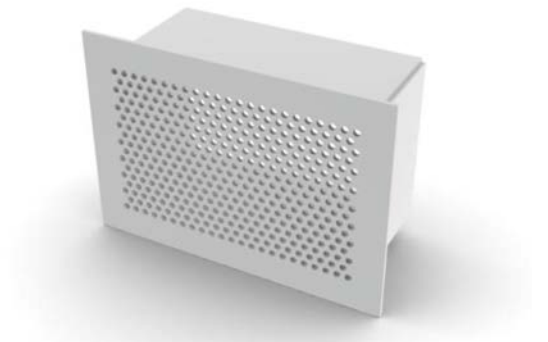

Fig. 2 Typical Air Grille

attenuation devices on supply, return, and exhaust ducts; penetrations for ducts and pipes to those areas and out of mechanical areas should be sealed for sound as well as fire protection.

Security Barriers. Where ducts or openings pass into or out of secure areas, and at exterior intakes and exhausts, security barrier bars are usually installed in ducts or openings that are at least 100 mm high and 150 mm wide. Barrier bars (Figure 1) are usually solid steel bars or heavy-gage tubes mounted in a heavy-gage steel frame to match the duct or opening size. Space between bars or tubing must not exceed 125 mm. They must be installed as an assembly in a structural wall compartment whenever possible, much like a fire damper. Barrier locations should be coordinated with the facility's owner. Include the bars in static pressure calculations for airflow systems.

Air Devices. Grilles and registers are usually security-type devices constructed of heavy-gage steel and welded or built in place in the walls or ceilings of secure areas accessible to inmates, and are designed to reduce entry of obstacles into the grilles (Figure 2). Locations of these devices in secure areas should be coordinated with the facility's owner. Air devices serving areas not accessible to inmates may be standard grilles, registers, and diffusers. Standard diffusers may also be installed in secure areas with ceilings over 4.5 m above the floor.

Outdoor Air Intakes and Exhausts. Louvers and grilles associated with intake and exhaust air should be located at or above the roof level, and/or (1) where inmates do not have access to them and (2) where substances cannot be discharged into them to harm or disrupt services and personnel in the facility. Barrier bars are usually installed at these devices.

Filtration and Ultraviolet (UV) Lights. Most areas in justice facilities use pleated throwaway filters with a minimum efficiency reporting value (MERV; see ASHRAE *Standard* 52.2) of at least 8. Higher-efficiency filters, such as HEPA or MERV 14 filters, may be required for clinic areas and isolation cells, and UV lights may also be installed to reduce bacteria and the spread of disease. Grease filters must be installed in kitchen exhaust hoods over cooking surfaces. In lieu of bringing large amounts of outdoor air into the facility, normal outdoor air quantities may be used by installing gas-phase or carbon filters in recirculated air streams. Discuss filter applications with the owner and authorities having jurisdiction (AHJ). For more information on filters, see Chapter 29 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Energy Considerations

Some areas of justice facilities (e.g., cells, day rooms) are occupied 24 h/day year-round and require a large amount of outdoor air that is subsequently exhausted. Methods to recover exhausted tempered air and reduce the energy needed to cool and heat the outdoor intake air include the following:

- Total energy recovery wheels for sensible and latent heat recovery or heat exchangers may be used in air-handling systems with high ventilation loads, or as required by ASHRAE *Standard* 90.1.
- Runaround heat recovery coil loops may be used when exhaust and supply airstreams are separated.
- Thermal storage is available for heating and cooling.
- Variable-speed drives may be used on cooling towers, fans, pumps, supply and exhaust fans, and chillers.
- Variable-air-volume systems may be used in office spaces and other areas not requiring constant airflow.
- Supply temperature reset based on outdoor air temperatures may be used on heating and cooling systems.
- Air- or water-side economizer cycles may be used per ASHRAE *Standard* 90.1 and current codes.
- Heat captured from boiler stacks can preheat combustion air or makeup water.
- Free-cooling heat exchangers provide cooling water by using cooling towers in lieu of the chiller when outdoor air conditions allow.
- Where reheat is required, water rejected from mechanical cooling or recaptured heat sources (e.g., from laundries) may offer economical paybacks.
- Smaller local systems may be installed to serve areas that are occupied at all times or operate seasonally, so that larger equipment may be shut off at certain times. Modular systems allow various modules to be staged on and off as needed to serve the same purpose.
- Night and holiday setback temperatures at least 3 K above or below the normal occupied settings, with morning warm-up or cooldown, should be used wherever possible for areas that are not always occupied or have varying occupancies.
- Evaporative cooling systems may be used in arid climates to replace water chillers and/or cooling towers. They may also be used in other regions to provide makeup air for some facilities, such as kitchens and laundries.
- Heat pumps may be used wherever possible. See Chapter 9 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for a discussion of these systems.
- Combined heat and power (CHP) systems may be used in larger facilities. See Chapter 7 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for a discussion of these systems.
- Laundry water recycling to reduce water consumption by 50% and save energy by reusing laundry hot water.
- Geothermal loop for remote buildings on prison campus.
- Heat recovery chillers able to capture heat from chiller for reheating or boiler water preheating.

- An intelligent hood exhaust control system for kitchen makeup air units and exhaust fans.

Whatever form of energy recovery is used, all systems should be examined for the rates of return on the cost of implementing and operating the systems.

Heating and Cooling Plants and Mechanical Rooms

Most larger justice facilities have central heating and cooling plants, with mechanical rooms located throughout the facility. Smaller facilities generally use local systems, with mechanical rooms located throughout the facility or with a combination of rooftop units or split systems. For larger facilities, central plants with water chillers, cooling towers, and fuel- or dual-fuel-fired steam or hot-water boilers are normally used to serve air-handling units, fan-coil units, reheat coils, and other equipment in mechanical rooms throughout the complex. Primary/secondary or primary variable-speed hydronic pumping systems should also be considered.

The heating and cooling requirements are for continuous operation while there are occupants. Essential equipment should be backed up with standby units for use during maintenance or equipment failure. In addition, major components may need to be braced for seismic and/or wind restraint to ensure continuous service. For seismic design, HVAC systems and components need to be braced in accordance with local codes and the AHJ; see Chapter 56 and the *ASHRAE Practical Guide for Seismic Restraint* for details. Zoning of various areas for occupancy times and seasonal changes should be factored into system arrangements and types.

It is preferable for plants and mechanical rooms to be accessed from the outdoors and located in areas not accessible to inmates, unless supervised maintenance and/or operation is performed by inmates. Central utility plants (CUPs) serving very large facilities may be located away from the complex (outside the secure fences or walls). Some of these plants use underground distribution tunnels from the plant to the various buildings in lieu of direct burial of the piping. Access to these tunnels must be kept secure from inmates. Vertical duct and pipe chases in facilities are usually located adjacent to cell areas, incorporated in plumbing chases, and stacked to connect to the heating, cooling, and ventilating or exhaust equipment. Service to these chases must be from outside the cell areas.

Consider maintenance personnel's abilities and training in selecting the types of systems and equipment to be used in the design. Consult the owner and/or maintenance personnel to determine the best combination of components, systems, and location of the plants and mechanical rooms for the facility.

Mechanical equipment in central plants and mechanical rooms must have the proper vibration isolation, flexible pipe and duct connections, and duct-mounted sound attenuators (where needed) to prevent transmission of vibration and noise to sensitive spaces, such as inmate housing day rooms, where it is essential to meet American Correctional Association (ACA) acoustical requirements. Mechanical rooms may have to be sound treated with acoustical materials to prevent transmission of room noise to adjacent spaces. Equipment (e.g., fan types) may also have to be modified to reduce noise transmission. See Chapter 49 for vibration and noise applications.

Controls

Controls serving HVAC systems for small facilities can be local and consist of electric, electronic, pneumatic, or a combination of all of these, and may need to be located in lockable control boxes. Controls for larger facilities are usually direct digital control (DDC) or a combination of electronic/electric and pneumatic, and are connected to a central, computerized system or building automation system (BAS) so that operators can remotely manage and monitor systems more efficiently. Thermostats and other sensors in or near inmate areas should be inaccessible to inmates (e.g., located in return or exhaust ducts) and/or located with secure covers. Control panels are usually located in the locked mechanical rooms or should be located within secure areas. Conceal and secure all interconnecting wiring and pneumatic tubing from inmates.

Fire/Smoke Management

All confined occupants of justice facilities need to be kept safe from fire and smoke. Consider smoke purge in holding areas, dayrooms, cells, and any other areas of confinement. Outdoor recreation and other areas that are open to the outdoors are not considered for smoke purge. Early detection of fires should be accounted for in all facilities. Discuss installation of fire and smoke detectors with the owner: detectors must be installed in secure areas or in the air-conditioning units or ducts, and inaccessible to inmates. Quite often, smoke detection occurs in the ductwork, behind secure air devices. Typically, the fire alarm system notifies the building management system (BMS), which initiates the proper sequence of operation for smoke removal. In addition to automatic operation of the smoke purge system, most codes require a smoke management panel that provides ultimate override control by the fire department. Coordinate with the jail commission (if applicable) or the authorities having jurisdiction on whether this panel is required and where it should be located.

Smoke purge systems should be designed in accordance with all applicable standards, preferably federal design guidelines or a state jail standard. If there is no adopted state jail standard or jail commission to consult, good practice is considered to be 10 air changes per hour (ach) for the area where smoke has been detected. Some state jail standards require as many as 15 ach; it is important to research standards applicable to the project and jurisdiction carefully. In smoke purge applications, use high-temperature fans that are intended for smoke removal.

Smoke purge systems should also be considered to facilitate evacuation of inmates to safe areas during an emergency, especially if the facility has no other means to evacuate the inmates to secure areas outside the buildings. The owner should be aware of the costs and complexity of smoke management before implementation. See Chapter 54 for information on fire and smoke management.

Tear Gas and Pepper Spray Storage and Exhaust

Tear gas and pepper spray are used to control people during riots and other uprisings by discharging an incapacitating gas that causes tear ducts to generate tears, blinding those exposed. (For details on how these agents work, see the section on Irritants in Chapter 61.) Tear gas is usually in grenade form or in canisters fired from shotguns (with the canisters exploding on impact). Pepper spray can be contained in the same forms as tear gas, or in spray containers for use in close quarters. Once discharged, the gas must be evacuated from any enclosed space. Unlike smoke, both tear gas and pepper spray are heavier than air. The smoke purge system is often used to help evacuate the chemical agent from the space. Another alternative is to use separate, portable exhaust systems to direct the air outdoors (e.g., to an outdoor recreation space). The designer must consider the space geometry, openings to the outdoors, the staff emergency action plan, and any other relevant details. It is also common to tie the chemical agent purge into the electronic security control panel or touch screen in direct supervision facilities. The sequence of operations in a gas/spray event differ from smoke purging: in the former, the HVAC systems are temporarily shut down and isolated with dampers while the agent is dispersed and the inmates are brought under control; then the agent is exhausted out. Without this delay, the gas/spray could be exhausted before it can work effectively. An automated purge through the smoke purge fans is usually preferred because it does not require other equipment to be brought in from outside the perimeter, has fewer disruptions to the pod where the incident occurred, and requires little or no staff to implement. The system should also have a manual on/off switch in the mechanical room to ensure that the gases are exhausted after the event. No internal duct lining should be used in these types of exhaust systems.

Storage of tear gas and pepper spray containers must follow HAZMAT requirements: the chemicals must be stored for rotation from date of purchase and removed after about three years. Shelving should be ventilated and away from walls. All persons dealing with the chemicals should have immediate access to protective masks. The storage room should be secured and located away from occupied buildings, and exhaust a minimum of 12 ach from the floor. The room should be kept at negative pressure, and at about 21°C and 50% rh year-round. Supply air should be from the ceiling near the center of the room.

Health Issues

Large prison health facilities, health care areas in large facilities, and some cells or rooms used for isolation in small facilities should be designed for negative pressurization to provide isolation from other spaces for inmates with communicable diseases such as tuberculosis (TB). These spaces should have separate, dedicated exhaust systems, alarms, and controls. Application and component requirements should be discussed with the owner. See Chapter 9 for discussions of health care systems and applications.

3. JAILS, PRISONS, AND FAMILY COURTS

Jails may be a stand-alone structure or part of a larger facility that confines inmates. Some are totally self supported and have their own kitchen, laundry, intake room, fingerprinting, storage for personal belongings, sally ports, parking garage, central plants, and other support areas. Security may be anything from minimum to maximum, and may include a work release area, as well. Jails may be located within the city limits or outside of the city.

Prisons are large facilities that confine inmates for longer periods of time than jails, and may have all levels of security and fences or walls with guard towers. Prisons are usually totally self supported and have every facility required to serve their needs in one large or several small buildings, including laundries, kitchens, dining halls, library, gyms, auditoriums, cell blocks, health clinics, offices, interview rooms, visiting areas, storage rooms for personal belongings, sally ports, intake and release areas, isolation cells or areas, central heating and cooling plants, and correctional officer facilities. Prisons are generally located outside of cities and towns.

Family courts or **juvenile detention centers** are similar to jails but house young offenders up to the age of 18. These facilities include courtrooms, judges' chambers and offices, interview rooms, exercise areas, lockable sleeping areas, classrooms, offices for social workers, kitchens, laundries, and other support facilities. Generally, offices, courtrooms, judges' chambers, interview rooms, exercise areas, classrooms, kitchens, and laundry are unoccupied after working hours, so the mechanical systems for these facilities must be able to respond to various occupied hours of operation.

HVAC Design Criteria

- Use outdoor **summer temperature conditions** equal to ASHRAE 1% design dry bulb and mean coincident wet bulb. For outdoor **winter temperature conditions**, use ASHRAE 99% design dry bulb.
- **Indoor air** should be at 23 to 25°C and maximum 50% rh for summer conditions and occupancy, and 22°C ± 2 K and 20 to 35% rh for winter, unless otherwise noted.
- For noise levels in **cells** or **sleeping rooms**, use a maximum of 70 dBA (day) and 45 dBA (night), with minimum constant-volume airflows and outdoor airflow in accordance with ASHRAE *Standard* 62.1. Maintain negative room pressure and negative air pressures in accordance with that standard, especially when the room or cell contains a toilet.
- Room criterion (RC) defines the limits that the octave-band spectrum of noise sources must not exceed. For **classrooms**, use noise levels between 25 and 30 RC, and airflows in accordance with ASHRAE *Standard* 62.1. See Chapter 8 for discussion of educational facilities.
- **Interview rooms** should have the same noise levels as for classrooms, with minimum airflows of 6 ach of supply air with a minimum of 0.3 L/(s·m^2) of outdoor air through low-noise diffusers and grilles.
- When **guard stations** are separate rooms for observing inmates, minimum airflow must be in accordance with ASHRAE *Standard* 62.1. Airflows should be constant volume, and noise levels should be 35 to 45 RC. This room may be occupied 24 h a day.
- **Control rooms** should be treated as guard stations. Room loads include computer equipment and video monitors, where required. This room is occupied 24 h a day. Provide a back-up direct-expansion (DX) system to maintain constant required temperature and humidity.
- **Laundries** are usually heated in winter when not used, and well ventilated to remove generated heat but not air conditioned when in use. All air supplied should be exhausted and the room kept at a negative pressure during operating hours. Maximum noise levels are about 45 to 50 RC. Energy conservation measures may involve evaporative cooling if tempered air is supplied to the space, and discharged warm laundry water may be recovered for preheating makeup water. See ASHRAE *Standard* 62.1 for ventilation and minimum airflow requirements.
- **Libraries** require close space temperature and humidity control, with 24°C db year-round and 40% (winter) to 50% (summer) humidity. Constant-volume airflow meeting ASHRAE *Standard* 62.1 is required. See Chapter 24 for details on libraries.

System Requirements

HVAC equipment is generally either a triple-deck multizone, constant-volume, or variable-air-volume (VAV) system. Constant-volume and triple-deck multizone systems are usually used in dayrooms, cells or sleeping quarters, and storage areas. VAV systems may be used in administrative offices, health services, factories, interview rooms, and visitor areas. Cells and sleeping areas are usually exhausted to comply with codes and ASHRAE *Standard* 62.1, and to help control odors. Intake rooms are also exhausted, with supply and exhaust air outlets located both high and low to sweep the room and help control odors. Systems must be able to adjust to variable loads and occupancy times, and be zoned to meet the requirements of ASHRAE *Standard* 62.1. Back-up equipment should be provided to serve dayrooms, cells, and critical spaces.

Mechanical equipment must be located in perimeter mechanical rooms outside of areas occupied by inmates, but must be accessible for maintenance. Cells, sleeping quarters, and dayrooms are usually provided with maximum-security-type grilles for supply, return, or exhaust.

Jails, family courts, and prisons located within city limits or near neighborhoods need to be concerned about noise from mechanical equipment and inmates transmitted to the outdoors. Louvers for equipment, indoor exercise rooms, or windows where inmates congregate need noise abatement. Equipment needs to be examined not only for noise transmitting into the facility but transmitted to the outdoors. See Chapter 49 for information on noise and vibration control.

Dining Halls

Dining halls are usually located in large facilities. Space loads vary, depending on occupancy schedules for food preparation and eating. Food-warming station loads also need to be included in the space loads. Smaller facilities use a central kitchen to prepare the food, which is then delivered to inmates on trays in warming carts and may then be reheated in ovens just before serving. If ovens are used, they must be included in the local space loads. Latent loads for eating must also be allowed for.

Kitchens

Kitchens are either centrally located with the prepared food then transferred to the inmates, or they are associated with the dining halls. Kitchens are full service and include pantry, freezers, coolers, ovens, stoves, kettles, fryers, grilles, dishwashers, and exhaust hoods. In many justice facilities, inmates prepare food, so the kitchen should be designed as a secure area. See Chapter 34 and ASHRAE *Standard* 154 for information and requirements on kitchen ventilation.

Guard Stations

Guard stations are located within the cell and dayroom area, where guards mingle with inmates, or they are remote and enclosed, where guards can observe cells and dayrooms through secure glass windows. Guard stations are staffed while inmates are awake and not in their cells, and may also be staffed during the night if the owner requires it.

Control Rooms

Control rooms use cameras to remotely monitor inmates, and regulate doors into and around inmate and other secure areas. These rooms are occupied at all times; room loads should include the control panels and video monitors.

Laundries

Laundries are usually located in their own building or separate rooms and contain washing machines, dryers, and pressing machines. The laundries are very warm places and may be tempered with evaporative cooling and outdoor air economizer cycles with full room exhaust. Spot cooling is recommended for personnel at work stations. Warm water discharged from the washing machines may be reused through laundry water recycling systems to reduce water and energy. Laundries usually have steam supplied from the central plant or their own boilers for heating the wash and rinse water and the pressing machines. Laundry service space should be designed as a secure area because of inmate movement.

4. COURTHOUSES

This section covers courtrooms in civil, bankruptcy, and criminal courthouses, as well as support divisions for judges' chambers, clerk of court, jury rooms, library, fitness center, marshal areas, jail cells, and administrative areas. Courtrooms generally do not have a clear schedule of operation; however, they generally operate between 9:00 AM until approximately noon. Support staff generally work between 8:00 AM and 5:00 PM, except in constant-occupancy spaces such as marshal areas, jail cells, and other administration areas. Jury areas are generally 9:00 AM to 5:00 PM, but may be occupied much longer, depending on the type of trial.

Courthouses (state, federal, and county) should be designed to suit operational hours and fluctuating visitors and staff occupancies for maximum energy conservation and optimum controls. Architectural features in courtrooms are generally above standard conventional design, and often include wood and ornate ceilings, which require both temperature and humidity control.

HVAC Design Criteria

- Use outdoor **summer temperature conditions** equal to ASHRAE 1% design dry bulb and mean coincident wet bulb. For outdoor **winter temperature conditions**, use ASHRAE 99% design dry bulb and mean coincident wet bulb.
- **Indoor air** should be at 23°C and 50% rh for summer conditions and occupancy, and 22°C and 20 to 35% rh for winter.
- If provided, the **smoke purge system** in the courtroom should be activated manually as well as automatically.
- All **openings** carrying piping through the slab or through partitions must be sealed with appropriate fire/smoke-resistive material. All air ducts leading to and from sensitive spaces must be acoustically treated with 50 mm thick, 48 kg/m^3 density duct lining for at least 3.5 m from the supply diffusers or return air intake.
- Design HVAC systems for **optimum flexibility in scheduling** use of courtrooms, chambers, and jury areas.
- All **fresh and exhaust air locations** should be at least 12 m above grade (or as high as possible) to protect against terrorist attack (see Chapter 61 for more information).

System Requirements

HVAC equipment generally consists of either constant- or variable-volume air systems. The same independent system should be used for courtrooms, judges' chambers, and jury suites. Every courtroom should have an independent system that can maintain the required temperature and humidity set points in the space, using a thermostat and a humidistat designed to precool before scheduled occupancy. Controls for jury deliberation rooms and judges' chambers should be placed in the conditioned space and be adjustable for variable occupancy.

HVAC systems for courthouses should be zoned to meet the fresh-air requirements of ASHRAE *Standard* 62.1. Central plant systems (including chillers, boilers, and air-handling units) should be designed for 24 h operation, intermittent occupancy, and after-hours activity. All VAV terminal units and reheat coils should be located outside courtrooms and deliberation rooms, and should be accessible for maintenance.

Courtrooms/Chambers

The HVAC system serving judges' chambers, courtrooms, and trial jury suites should provide an average occupied temperature of 23°C. The courtroom system zone should allow temperature sensors to be reset from the building automation system to precool to 21°C before scheduled occupancy. Humidity sensors should maintain minimum relative humidity at 20% (winter) to 50% rh (summer).

Provide a minimum of 6 ach for rooms with ceiling heights up to 4.5 m, and 8 ach for rooms with higher ceilings. Systems should be designed to meet these requirements when spaces are fully occupied. These airflows should be reduced during long unoccupied hours, at night, and on weekends and holidays.

Each courtroom should be served by a dedicated fan system, and return air from each courtroom and associated areas (jury rooms, judge's chambers, etc.) must be ducted directly back to the unit or system.

Jury Facilities

Trial jury suites should be served from the same system as the associated courtrooms. (A separate temperature and humidity control for each trial jury room is desirable.)

Air distribution systems must provide separate temperature control and a high degree of acoustical isolation, particularly in grand jury and trial jury rooms. Return air must be ducted directly back to the unit or exhaust air riser. Ductwork must be treated to meet the acoustical deliberation room design criterion of a maximum of 25 to 35 RC. Before recommending underfloor air distribution, filtration, temperature, distribution, air balancing, and commissioning method should be considered.

In the jury assembly room, deliberation room, and associated toilet rooms, the system must provide 10 ach with 80 to 85% return and exhaust.

Libraries

See the discussion of libraries in the section on Jails, Prisons, and Family Courts.

Jail Cells and U.S. Marshal Spaces (24 h Spaces)

A separate air-handling system tied to the main HVAC system should be able to operate independently after hours. A separate 100% fresh and exhaust air system should be provided to jail cells; it should have security grilles and barrier bars, and should maintain negative pressure.

Marshal spaces should be treated as normal office areas, except for cell areas and exercise rooms. Contents usually include computer and radio equipment, cells, exercise rooms, gun vaults, and perhaps sleeping rooms, and may be occupied 24 h a day. HVAC systems serving these areas should be separate from other systems.

Fitness Facilities

These facilities should be tied to the 24 h system and have a separate 100% fresh air unit able to dehumidify air to 10°C dp. Provide exhaust air and heat recovery systems, and maintain the space under negative pressure. See Chapter 5 for more information on gymnasiums.

Acoustic Performance

Acoustic performance should be a major consideration when selecting HVAC equipment. Systems serving courtrooms and auxiliary spaces should be designed with sound attenuation to provide consistent and acceptable sound levels (25 to 40 RC). This is particularly critical in court facilities that require extensive use of sound and audio/visual (A/V) equipment for recording and presentations. Vibration and acoustic performance should be in accordance with guidance in Chapter 49.

To control noise during all modes of operation and for all load conditions, HVAC systems should be provided with one or more of the following:

- Sound traps and acoustic lining in supply and return or exhaust ductwork
- Low-velocity, low-static-pressure fan systems (pay special attention to fan types for noise levels)
- Special low-noise diffusers

Return air should be ducted, especially in courtrooms and jury rooms. Special attention should be given to location of any partitions extending to the floor above and the acoustical treatment around the penetrations of these partitions.

HVAC equipment, including air-handling units (AHUs) and VAV boxes, should not be located close to courtrooms, jury rooms, or chambers. The minimum distance between a space and these units should be 7.5 m. General system design needs to provide appropriate treatment of mechanical supply/return ducts to minimize sound and voice transmission to surrounding areas.

For court and jury facilities, RC should range from 25 to 40. For sound level maintenance, the courtroom should be served by constant-volume air supply. The system must also support variable outdoor air requirements and variable cooling loads. Air ducts serving trial and grand jury suites must be lined with 50 mm thick, 48 kg/m^3 density acoustical absorption material for at least 3.5 m from the diffuser or return air intake.

5. FORENSIC LABS

In forensic labs, physical evidence is examined, autopsies may be performed, human remains are tested and identified, firearms are tested, evidence is stored, all aspects of suspected criminal activity are reviewed to determine whether a crime has been committed, and people are identified from evidence taken at crime scenes.

The labs contain many chemicals, fume hoods, ovens, centrifuges, microscopes, x-ray units, and other laboratory equipment that need to be considered in space loads and ventilation requirements. Some lab equipment is sensitive to changes in temperature and humidity. See Chapter 17 for more information on laboratories.

Forensic labs may be stand-alone facilities or part of other facilities, or specific departments may be separated and located in other facilities. Components may include offices, data rooms, storage rooms, laboratories, autopsy rooms, interview rooms, inspectors' offices, mechanical and electrical rooms or central plants, firearms rooms, x-ray rooms, photo developing rooms, and body or evidence drying rooms.

HVAC Design Criteria

- Use outdoor **summer temperature conditions** equal to ASHRAE 1% design dry bulb and mean coincident wet bulb. For outdoor **winter temperature conditions**, use ASHRAE 99% design dry bulb and mean coincident wet bulb.
- For **indoor air**, 23°C and 50% rh for summer conditions and occupancy, and 22°C and 20 to 35% rh for winter, depending on user requirements.
- **Nonhospital autopsy rooms** may require room temperatures as low as 16°C and airflows as high as 15 ach when the medical examiners are suited in heavy or rubber garments during an autopsy, or when odors are especially noticeable. Autopsy rooms must be kept under negative pressure at all times. Air should be exhausted high and low in the space when autopsies are being performed. Specific autopsy sinks may include their own exhaust grilles and need to be exhausted when they are in use. All outdoor air may be required for odor control when autopsies are being performed and for at least 30 min after autopsies are completed. Noise levels of 20 to 35 RC may be required, because of recordings made during autopsies.
- **Laboratories** should be kept at 21 to 22°C and at least 20 to 30% rh in winter, and 21 to 23°C and 50% rh in summer. These rooms often contain fume hoods and the supply, room exhaust, and hood exhaust airflows must all be controlled together to keep the space under a negative pressure, although some laboratory operations may require positive pressure. All room air must be exhausted and not recirculated. These spaces contain large equipment loads that produce high sensible and latent heat gains at various times. Systems serving these rooms must be flexible enough to react to these load changes and maintain their room sensor set points. Most labs require year-round cooling and dehumidification with reheat to prevent build-up of excessive humidity under some weather conditions. Clean steam may be required for the fume hoods and humidifiers serving the labs; fume hoods and lab benches may also require specially treated water (e.g., deionized [DI)] water), inert gases, and natural gas supplies.
- **Microscope tables** need to be isolated from vibrations from mechanical equipment and from building vibrations; information on vibration isolation can be found in Chapter 49.
- Usually, **forensic labs** are occupied 24 h a day, with a small number of rooms that may only be occupied during normal business hours; equipment should be selected, zoned, and controlled to allow for these various occupancies.

System Requirements

Offices and general storage in forensic laboratories are served by normal air-handling systems and should maintain normal room airflows and temperature and humidity set points. Return air may be recirculated. Offices should be kept at positive pressure to keep odors out and to allow use as makeup air for negative-pressure spaces (e.g., storage areas for formaldehyde, which should be exhausted to the outdoors). Systems serving the offices may be required to have their own independent heating and cooling units or terminal units, because their occupancy schedules may differ from those of the labs and other areas.

HVAC systems in cold climates that use 100% outdoor air may experience maintenance problems with frozen hydronic coils unless glycol is used in the water system or the cooling coils are drained in the winter. If internal face-and-bypass dampers are used, cold air can become stratified and freeze portions of the coils. External or integral coil face-and-bypass dampers often are a better application, because they allow cold air to move around the coil or pass through a tempered coil, which reduces the freezing potential.

Ducted supply and exhaust air systems should be used for labs and autopsy rooms. The amount of negative pressure should be maintained carefully in these rooms, so that doors open without excessive door-opening force, as required for smoke control systems (see Chapter 54).

Variable-volume control of supply and exhaust fans may be provided with variable-frequency drives (VFDs). Control of the VFDs should allow for offset of supply and exhaust airflows and to adjust for variances within the systems, such as for dirty filters.

Fume hood exhaust fans should be located on the roof at least 7.5 m from any outdoor air intakes, so they will discharge a vertical plume above and away from the roof. Exhaust fans should not be located inside the occupied space; this can produce a positive air pressure in the exhaust duct downstream of the fan, causing leakage back into the space. Consider using redundant exhaust fans or an $N + 1$ exhaust fan system for critical areas.

Exhaust duct and fan materials need to be checked for corrosion resistance against chemicals from fume hoods and laboratories. Coordinate with laboratory personnel regarding these fumes. Fiberglass, plastic, stainless steel, or coated galvanized duct materials should all be considered. Internal duct lining should never be used in exhaust ducts. Also, consider requiring the exhaust fan to be explosion-proof and spark-resistant if materials exhausted may be explosive.

Use care in locating supply air diffusers in relation to the fume hoods, so that exhaust air flowing into the fume hood is not disturbed and does not create turbulence in front of the hood. Supply air should be introduced slowly in a semilaminar flow pattern away from the hoods.

Intake Air Quality

The quality of outdoor air brought into forensic laboratories should be carefully controlled. Usually, these labs are in urban environments close to traffic, parking garages, industrial areas, emergency generator exhausts, restaurant exhausts, and other contaminants. Also, risks from bioterrorism should be addressed by locating outdoor air intakes where they are inaccessible to the public (see Chapter 61). MERV 13 or 14 final filters may be required for critical lab areas, such as DNA extraction labs, autopsy rooms, and toxicology labs, to prevent cross contamination from other processes in the facility or from other outdoor air influences.

Firearms Testing Laboratories

Firearms testing labs often contain microscope rooms, firearms and ammunition storage rooms, bullet traps, workbench tool rooms, catalog reference rooms, and researcher offices.

Ballistic shooting trap areas are usually kept under negative pressures because of smoke emissions. These rooms should be treated for noise attenuation to prevent noise being transmitted to other spaces or reverberating within the room. Air should be supplied near the shooter's breathing zone and exhausted at or near the bullet trap and downstream of the muzzle of the firearm. Using two-speed supply and exhaust fans or fans with VFDs is recommended, so that fan speed is lower when no shooting is occurring. All exhaust systems should be ducted to roof-mounted fans.

Catalog reference rooms and all offices may operate at different hours than the labs, and may be served by their own HVAC systems or systems with equivalent occupancy schedules. Room temperature and pressures should be the same as for general offices, and return air can be recirculated back to the air-handling system.

Acoustic Performance

Acoustic performance should be a major consideration in selecting HVAC equipment. Systems serving laboratory and autopsy spaces should be designed with sound attenuation to provide consistent and acceptable sound levels (25 to 40 RC). This is particularly critical for autopsy rooms that require extensive use of sound and A/V equipment for recordings. Vibration and acoustic performance should be in accordance with Chapter 49.

To control noise during all modes of operation and for all load conditions, the HVAC systems should be provided with one or more of the following:

- Sound traps and acoustic lining in supply and return ductwork
- Sound trap in exhaust ductwork
- Low-velocity, low-static-pressure fan systems (pay special attention to fan types for noise levels)
- Special low-noise diffusers

Pay special attention to location of any partitions extending to the floor structure above and the acoustical treatment at penetrations of these partitions to provide sound attenuation around the perimeter of ducts and pipes to prevent noise transmissions.

Critical Spaces

Rooms containing freezers or coolers and critical computer rooms should be served by their own independent cooling systems with emergency power back-up, to ensure operation in the event of an extended power outage.

Room pressure controls and monitors should be provided in critical laboratory areas, autopsy rooms, firearms testing rooms, storage rooms that contain hazardous materials, DNA rooms, evidence vaults, trace evidence rooms, drying rooms, photo developing rooms (darkrooms), and other areas deemed necessary by the owner. Room pressures should be continually maintained by measuring supply and exhaust airflows to the room and varying the supply air rate to maintain a differential from the exhaust airflow rate.

Evidence Vaults. Humidity control and cross-contamination prevention are critical, as is exhausting odors from drugs stored in the vault. The room must be kept under negative pressure at 22 to 23°C and 30% rh in the winter and no more than 50% rh in the summer. Barrier bars must be installed on any duct penetrations for these rooms. Firestopping and combination smoke/fire dampers should be installed at duct penetrations.

Photo Developing. Photographic darkrooms must be kept under negative pressure and exhausted to the outdoors, because of the chemicals stored and used within the room. Exhaust should be located behind developing sinks and counters. Outdoor air should be supplied at a minimum of 2.5 $L/(s \cdot m^2)$, from low-velocity diffusers behind lab personnel. Exhaust ducts and fans must be corrosion resistant and contain combination fire/smoke dampers and firestopping at the penetrations. Exhaust fans should also be explosionproof and spark resistant. See Chapter 23 for information on temperatures and humidity levels.

Photo Studios. Photo studios have high heat loads because of their excessive lighting requirements. Systems serving these spaces should be designed to minimize noise and air motion and handle variable loads, because of the occupancy schedule and lighting levels.

Trace Rooms. Trace rooms are laboratories where very small amounts of evidence are examined and tested. Consequently, supply airflows need to be low, laminar flow away from the work surfaces to prevent any disturbance of materials. These rooms should be treated as any other lab for temperature, humidity, pressurization, and airflows.

Drying Rooms. Some forensic labs have rooms where evidence must be dried very slowly, to preserve it. HVAC systems serving these rooms should be separate from other systems to prevent cross contamination; temperatures should be maintained between 24 and 27°C, pressure should be negative, and all air exhausted to the outdoors. Laminar air supply should be introduced into the room and high and low exhaust inlets should be installed. Supply air should receive final HEPA filtration.

Laboratory Information Management Systems (LIMS)

Many labs use a separate laboratory information management system to document temperature, pressure, and humidity levels in critical laboratory spaces for validation and certification purposes. System requirements need to be coordinated with the owner.

Historical data storage and retrieval of selected processes and system events, system documentation, and data should be required. This function should allow report formatting and generation from archived historical data. Typical reports consist of alarm summaries, limit summaries, report time reports, all-points logs, trend listing, time of day start/stop schedules, message summaries, energy logs, and maintenance reports.

An independent commissioning agent should be retained at the beginning of system design and should perform complete, detailed commissioning services, including system start-up services, operation and maintenance training and documentation, control of shop drawings, and operation and maintenance manuals. A validation procedure may also be required to ensure the system's operational effectiveness meets both the design intent and operator's requirements.

6. INDOOR SHOOTING RANGES

Indoor shooting ranges are used by law enforcement and the military for practice and to maintain accuracy and proficiency with their weapons.

These ranges must be well ventilated to remove gases and lead dust, at a low enough velocity so as not to disturb suspended targets. The range also must be soundproofed from adjoining or neighboring facilities.

Indoor ranges consist of shooting booths, shooting lanes, bullet trap area, range officer position area, weapon storage, ammunition storage, weapon cleaning, restrooms, classroom/lobby, and HVAC systems. The ventilation system must be in operation during all shooting times, cleanup time, and for at least 30 min after shooting times.

Shooting booths are usually 1.1 to 1.2 m wide, 2.7 m high, and 1.8 m deep. Shooting booths are separated by soundproof partitions.

The shooting lanes are usually 1.1 to 1.2 m wide, 4.0 m high and 22.9 m long, with mechanical target moving systems. At the end of each shooting lane is a bullet trap.

The shooting range should have its own ventilation system. Some indoor ranges have entering outdoor air tempered for occupant comfort. If so, air delivered should be at least 18.3°C in winter and maximum of 26.7°C in the summer.

The total amount of outdoor air to be delivered depends on the number of shooting lanes installed. Typical airflows are based on 0.38 m/s at each firing lane, with some air exhausted at the ceiling 6.1 to 7.6 m from the booth and the remaining air exhausted at the bullet traps, or a minimum of 0.25 m/s at each firing lane and all air exhausted at the bullet traps. Supply air should be evenly distributed at the firing line about 4.6 m behind the shooters on the back wall in a laminar-flow plenum wall fashion, or along the ceiling above and behind the shooters. The range must be kept at a negative pressure at all times when in use and for at least 30 min after use, with supply and exhaust fans interlocked. The minimum exhaust rate must be about 10% above supply rates.

Exhaust ducts must be located behind and at the apex of bullet traps, or along the sides of the trap and slightly in front of the trap apex. Exhaust air must be filtered with HEPA filters.

Outdoor and exhaust air inlets and outlets must have sound traps to reduce any shooting noise emitted to the outdoors. Acoustical material must be applied to the exterior of the HVAC ducts. The maximum noise levels are about 165 dBA within the range.

If heat recovery from the exhaust is to be used, it must be carefully planned to avoid reintroducing lead fumes and toxic gases into the facility. Inorganic lead exposures are about 50 mg/m^3 based on an 8 h time-weighted average. Again, at least 10% more air must be exhausted than supplied.

Use MERV 7 prefilters on once-through systems. Use MERV 14 prefilters and HEPA filters (bag-out removal) for recirculated air systems. On exhaust air, use MERV 6 prefilters and HEPA filters (bag-out removal). Check with local authorities about safe disposal of lead-contaminated filters.

The weapon cleaning and ammunition storage areas must be exhausted and kept at negative pressures. The other areas of the facility should be maintained at positive pressure to the shooting range, and the toilets at negative pressure to the classroom/lobby area.

The mechanical room or equipment should be accessible without going into the shooting range.

CHAPTER 11

AUTOMOBILES

Design Factors 11.1
Air-Handling Subsystem 11.3
Heating Subsystem 11.7
Refrigeration Subsystem 11.8

THERMAL systems in automobiles (HVAC, engine cooling, transmission, power steering) have significant energy requirements that can adversely affect vehicle performance. New and innovative approaches are required to provide the desired comfort in an energy-efficient way. In recent years, efficiency of the thermal systems has increased significantly (compared to systems used in the early to mid-1990s). Providing thermal comfort in an energy-efficient way has challenged the automotive industry to search for innovative approaches to thermal management. Hence, managing flows of heat, refrigerant, coolant, oil, and air is extremely important because it directly affects system performance under the full range of operating conditions. This creates significant engineering challenges in cabin and underhood thermal management. Optimization of the components and the system is required to fully understand the components' effects on the system. Thus, modeling the components and the system is essential for performance predictions. Simulation of thermal systems is becoming an essential tool in the development phase of projects. Durability and reliability are also important factors in design of these systems.

Environmental control in modern automobiles usually consists of one (or two for large cars, trucks, and sport utility vehicles) in-cabin air-handling unit that performs the following functions: (1) heating, (2) defrosting, (3) ventilation, and (4) cooling and dehumidifying (air conditioning). This unit is accompanied by an underhood vapor cycle compressor, condenser, and expansion device. The basic system can be divided into three subsystems: air handling, heating, and refrigeration (cooling). All passenger cars sold in the United States must meet defroster requirements of the U.S. Department of Transportation (DOT) Federal Motor Vehicle Safety *Standard* 103 (FMVSS), so ventilation systems and heaters are included in the basic vehicle design. The most common system today integrates the defroster, heater, and ventilation system. In the United States, the vast majority of vehicles sold today are equipped with air conditioning as original equipment.

1. DESIGN FACTORS

General considerations for design include cabin indoor air quality (IAQ) and thermal comfort, ambient temperatures and humidity, operational environment of components, airborne contaminants, vehicle and engine concessions, physical parameters, durability, electrical power consumption, cooling capacity, occupants, infiltration, insulation, solar effect, vehicle usage profile, noise, and vibration, as described in the following sections.

Thermal Comfort and Indoor Air Quality (IAQ)

ASHRAE *Standard* 55 provides information on the airflow velocities and relative humidity required to provide thermal comfort. Effective comfort cooling system design in cars must create air movement in the vehicle, to remove heat and occupants' body effluents and to control moisture build-up. Assuming an effective temperature of 22°C with no solar load at 24°C, 98% of people are comfortable with zero air velocity over their body. If the temperature increases to 27°C, the same number of people are comfortable with an air velocity of 2.5 m/s. If panel vent outlets can deliver sufficient air velocity to the occupants, comfort can be reached at a higher in-vehicle temperature than with low airflow (Figure 1).

Several modeling manikins for predicting human physiological behavior are described in Guan et al. (2003a, 2003b, 2003c), Jones (2002a, 2002b), and Rough et al. (2005).

During the increasingly common gridlock or stop-and-go conditions, **tailpipe emissions** can make outdoor air (OA) extremely polluted, and it is important to ensure that passengers' exposures to these gases do not exceed American Conference of Governmental Industrial Hygienists (ACGIH 2014) short- or long-term exposure limits.

Tailpipe emissions include

- Nitrogen oxides (NO_x), which include both nitric oxide (NO) and nitrogen dioxide (NO_2), which always occur together (Pearson 2001)
- Carbon monoxide (CO), which forms in the combustion chamber when oxygen supply is insufficient
- Hydrocarbons (HCs) from unburnt fuel due to incomplete combustion
- Volatile organic compounds (VOCs) emitted from plastic parts, carpet, seats, headliner, door panels, etc.

Diesel engines emit mainly NO_x and HC, and gasoline engines emit mainly CO and HC. Worldwide, road transportation accounts for approximately 50% of NO_x emissions, and gasoline-powered vehicles alone account for 32% of HC emissions in the United States (Pearson 2001).

In winter, the HVAC unit is typically operated in outdoor air mode. Hence, there is a possibility of tailpipe emission entering the cabin in all heating modes (defrost, defrost-foot, and foot). To limit

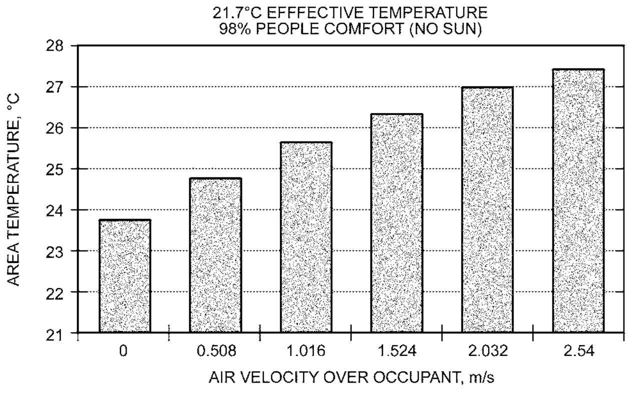

Fig. 1 Comfort as Function of Air Velocity

The preparation of this chapter is assigned to TC 9.3, Transportation Air Conditioning.

passengers' exposure to tailpipe emissions, the blower unit's air intake door can be switched from outdoor air mode to recirculation mode during times of traffic congestion and potential poor OA quality (Mathur 2006, 2018a). Once the vehicle is out of the traffic jam, the mode door can be switched back to outdoor air mode (Mathur 2007a).

Carbon dioxide (CO_2) from passenger exhalations can also build up in the cabin, especially in low-body-leakage or new vehicles, so the vehicle's A/C system should not be operated in recirculation mode for extended periods. This issue becomes critical when several occupants are in a vehicle that has 100% return air in recirculation mode. A timed strategy is recommended for recirculation; after the set time (e.g., 30 min) elapses, the mode automatically changes to outdoor to reduce CO_2 levels in the cabin. A CO_2 sensor can be installed to monitor levels in the cabin, and automatically switch to OA mode when set levels are exceeded (Mathur 2007b, 2008, 2009a, 2009b). Informative Appendix D of ASHRAE *Standard* 62.1-2016 specifies the suggested levels of carbon dioxide in conditioned space: no more than 700 ppm over the ambient conditions for an extended period (for satisfaction of visitors entering a space, with respect to human bioeffluents [body odor]). Current global average ambient concentration level of CO_2, as of April 2018, is approximately 411 ppm (NOAA 2018). Hence, if the CO_2 concentration exceeds approximately 1100 ppm inside a vehicle cabin, then outdoor air must be introduced into the cabin to reduce the CO_2 concentration. This is especially crucial given that driver alertness and fatigue are impacted by CO_2 build-up (Mathur 2016b).

Relative humidity also affects cabin IAQ. Too high a level affects occupant comfort and can lead to condensation and fogging on windows. A relative humidity sensor can detect excessive humidity and intervene.

See the section on Controls under Air-Handling Subsystem for more information on cabin IAQ.

Cooling Load Factors

Occupancy. Occupancy per unit volume is high in automotive applications. The air conditioner (and auxiliary evaporators and systems) must be matched to the intended vehicle occupancy.

Infiltration. Like buildings, automobiles are not completely sealed: wiring harnesses, fasteners, and many other items must penetrate the cabin. Infiltration varies with relative wind/vehicle velocity. Unlike buildings, automobiles are intended to create a relative wind speed, and engines may emit gases other than air. Body sealing and body relief vents (also known as the drafter) are part of air-conditioning design for automobiles. Occasionally, sealing beyond that required for dust, noise, and draft control is necessary.

By design, vehicles are allowed to have controlled body leakage that allows air movement in the vehicle to provide comfort to the passengers. This also helps control moisture build-up and the occupants' perceived comfort level. However, excessive body leakage results in loss of heating and cooling performance. Vehicle body leakage characteristics typically are significantly different in dynamic conditions compared to static conditions. Air can leak from the vehicle's doors, windows, door handles, and trunk seals (uncontrolled exit points); drafters allow a controlled exit for air from the cabin, and should be self-closing to prevent inflow when the body pressure is negative with respect to the exterior pressure. According to the Society of Automotive Engineers (SAE) *Standard* J638, infiltration of untreated air into the passenger compartment through all controlled and uncontrolled exit points should not exceed 0.165 m^3/s at a cabin pressure of 0.25 kPa (Atkinson 2000). However, each vehicle has different body leakage characteristics. Some vehicles have two drafters inside the trunk on either side, and some have only one.

Insulation. Because of cost and mass considerations, insulation is seldom added to reduce thermal load; insulation for sound control is generally considered adequate. Additional dashboard and floor thermal insulation helps reduce cooling load. Some new vehicles have insulated HVAC ducts to reduce heat gain during cooling and heat loss during heating. Typical interior maximum temperatures are 93°C above mufflers and catalytic converters, 50°C for other floor areas, 63°C for dash and toe board, and 43°C for sides and top.

Solar Effects. The following four solar effects add to the cooling load:

- **Vertical.** Maximum intensity occurs at or near noon. Solar heat gain through all glass surface area normal to the incident light is a substantial fraction of the cooling load.
- **Horizontal and reflected radiation.** Intensity is significantly less, but the glass area is large enough to merit consideration.
- **Surface heating.** Surface temperature is a function of the solar energy absorbed, the vehicle's interior and exterior colors, interior and ambient temperatures, and the automobile's velocity.
- **Vehicle colors and glazing.** The vehicle's interior and exterior colors, along with the window glazing surfaces (clear or tinted), strongly affect vehicle soak temperature. Breathing-level temperatures after a 1 h soak can be 22 to 33 K higher than ambient, with internal surfaces being 28 to 55 K above ambient (Atkinson 2000).

Ambient Temperatures and Humidity. Several ambient temperatures need to be considered. Heaters are evaluated for performance at temperatures from –40 to 21°C. Air-conditioning systems are evaluated from 4 to 45°C, although ambient temperatures above 52°C are occasionally encountered. The load on the air-conditioning system is also a function of ambient humidity (at most test conditions, this latent load is around 30% of the total). Typical design points follow the combinations of ambient temperature and humidities of higher probability, starting at around 90% rh at 32°C and with decreasing humidity as temperature increases.

Because the system is an integral part of the vehicle, the effects of vehicle-generated local heating must be considered. For interior components, the design high temperature is usually encountered during unoccupied times when the vehicle is soaked in the sun. Interior temperatures as high as 90°C are regularly recorded after soaks in the desert of the southwestern United States. Achieving a comfortable interior temperature after a hot soak is usually one of the design conditions for most vehicle manufacturers.

Operational Environment of Components

Underhood components may be exposed to very severe environments. Typical maximum temperatures can reach 120°C. The drive to achieve more fuel-efficient automobiles has reduced available space under the vehicle hood to a minimum. This crowding exposes many components to temperatures approaching that of exhaust system components. Heat from the vehicle also adds to the cooling loads that the air-conditioning system must handle. During idle, heat convected off the hood can raise the temperature of air entering the air inlet plenum by as much as 6 to 14 K (Mathur 2005a). A similar effect is found during idle when air from the engine compartment is reentrained into the air flowing through the condenser (Mathur 2005b). Air temperatures as high as 70°C have been encountered on parts of a vehicle's condenser during operation with a tailwind in ambient temperatures as low as 38°C. Typically, front air management is improved by using air guides and seals to prevent air bypassing either the condenser or radiator at idle. Significant improvements in vent outlet temperatures (a maximum of 4 K and cabin temperatures of 1 to 3 K) and a reduction in head pressures (200 to 530 kPa) have been obtained. Recirculation of hot engine compartment air was reduced from 29 K over ambient (base case) to approximately 15 K over ambient. Further details are provided in the section on Vehicle Front-End Design.

Airborne Contaminants and Ventilation

Normal airborne contaminants include bacteria, pollutants, vapors from vehicle fluids, and corrosive agents (Mathur 2006, 2017a). Exposure to these must also be considered when selecting materials for seals and heat exchangers. Incorporating particulate and/or carbon filters to enhance interior air quality (IAQ) is becoming common. Air-handling systems in virtually all vehicles can exceed the ventilation recommendations for buildings and public transportation in ASHRAE *Standard* 62.1. However, the driver has complete control of the HVAC system in the vehicle, and can reduce cabin airflow to virtually zero when desired (e.g., before warm-up on cold days).

Power Consumption and Availability

Many aspects of vehicle performance have a significant effect on vehicular HVAC systems. Modern vehicles have a huge variety of electric-powered systems. The need to power these systems while maintaining fuel efficiency leads manufacturers to demand a high level of efficiency in electrical power usage. On some vehicles, electrical power use is monitored and reduced during times of minimal availability. The mass of the HVAC system is also closely controlled to maintain fuel efficiency and for ride or handling characteristics. The power source for the compressor is the vehicle's engine. At engagement, the need to accelerate the rotational mass as well as pump the refrigerant can double the engine torque. This sudden surge must not be perceptible to the driver, and is controlled through careful calibration of the engine controls. Automotive compressors must provide the required cooling while compressor speed varies with the vehicle condition rather than the load requirements. Vehicle engine speeds can vary from 8.3 to 100 rev/s. For electric vehicles, power consumption from electric compressors and heaters (PTC heaters) is extremely important, because it directly affects driving distance (Jeffers et al. 2016).

Physical Parameters, Access, and Durability

Durability of vehicle systems is extremely important. Hours of operation are short compared to commercial systems (260 000 km at 65 km/h = 4000 h), but the shock, vibration, corrosion, and other extreme conditions the vehicle receives or produces must not cause a malfunction or failure. Automotive systems have some unique physical parameters, such as engine motion, proximity to components causing adverse environments, and durability requirements, that are different from stationary systems. Relative to the rest of the vehicle, the engine moves both fore and aft because of inertia, and in rotation because of torque; this action is referred to as **engine rock**. Fore and aft movement may be as much as 13 mm; rotational movements at the compressor may be more than 19 mm from acceleration and 13 mm from deceleration when the length to center of rotation is considered. Additionally, the need for components to survive bumper impacts of up to 8 km/h leads to additional clearance and strength requirements. Vehicle components may also be exposed to many different types of chemicals, such as road salt, oil, hydraulic fluid (brakes and power steering), and engine coolant.

Automobiles also increasingly incorporate electrical and electronic components and functionality. This requires manufacturers to both limit the emissions of electrical signals from components and ensure that all components work when subjected to these same types of emissions. Manufacturers' requirements for electromagnetic compatibility are increasingly stringent regarding the frequencies of radio and communication devices.

Wiring, refrigerant lines, hoses, vacuum lines, and so forth must be protected from exhaust manifold heat and sharp edges of sheet metal. Normal service items such as oil filler caps, power steering filler caps, and transmission dipsticks must be accessible. Air-conditioning components should not have to be removed to access other components.

Noise and Vibration

The temperature control system should not produce objectionable sounds. During maximum heating or cooling operation, a slightly higher noise level is acceptable. Thereafter, it should be possible to maintain comfort at a lower blower speed with an acceptable noise level. Compressor-induced vibrations, gas pulsations, blower motor vibration, and noise must be kept to a minimum. Suction and discharge mufflers are often used to reduce noise. Belt-induced noises, engine torsional vibration, and compressor mounting all require particular attention. Manufacturers have different requirements and test methods. Although it is almost impossible to predict vehicle sound level from component testing, a decrease in the sound and vibration energy at the source of noise always decreases the noise level in vehicle (assuming there is not a shift in frequency), so most automobile manufacturers require continuous improvement in overall component sound level.

Vehicle Front-End Design

Front-end design affects performance of the climate control and engine cooling systems, especially at low speeds and at idle. The design should ensure that air flowing into the front end through the bumper and/or grille does not bypass either the condenser or radiator from the sides, top, or bottom. Air takes the path of least resistance, and if not forced over the heat exchangers, it usually bypasses them. In a good design, the condenser and radiator are the same size, and there should not be space between (Mathur 2005b). This eliminates the use of seals between the condenser and radiator. Typically, the front-end module has components in the following sequence: condenser, radiator, and fans (CRF); these systems are known as condenser-radiator-fan modules (CRFM). A good front-end design provides optimum performance for both air-conditioning and engine-cooling systems. Airflow over the front end couples these two systems; thus, performance of one system (e.g., air conditioning) influences the other system (engine cooling). This is most evident at idle.

In a typical design, sheet metal covers the entire area on the sides of the condenser. This prevents air from bypassing from either side of the condenser and radiator. To prevent recirculation of hot engine compartment air at idle, the front bottom part of the front end is usually covered by sheet metal or plastic sheet. To limit recirculation on the top, a seal is usually added atop the cross frame when the hood is closed. This prevents recirculation of the hot engine compartment air to approximately the top and bottom thirds of the condenser. Without this, condenser head pressure may increase greatly, further degrading system performance.

Enhanced R-134a systems require substantial changes to hardware and controls to achieve performance and energy requirement targets, although some of the strategies described here can be used to approach the targets.

2. AIR-HANDLING SUBSYSTEM

The in-cabin air-handling unit, commonly called an **air-conditioning module (ACM)**, provides air to the passenger cabin. It incorporates the following basic components: heater core, evaporator core, blower motor, air-distribution control, ram air control, body vents, and air temperature controls. In addition to the ACM, an air inlet plenum, distribution ducting, outlets, and body relief vents or drafters make up the complete air-handling subsystem. The evaporator core is a part of both the refrigeration and air-handling subsystems and links the two. The heater core is similarly the link with the heating subsystem.

The basic function of the air-handling system is as follows. The air intake valve allows air from either the exterior (taken directly from the air intake plenum or OA) or the cabin to be recirculated to the fan. The fan then pumps air through the evaporator and into the temperature control door, which forces the air to either flow through or bypass the heater core to obtain the desired temperature. The air then moves to the distribution area of the module, where it is directed to one or more of the heater, ventilation, or defrost outlets. Air in the cabin then either is recirculated or exits the vehicle through body vents or drafter(s).

There are many variations on the basic ACM system. Common ones include regulating the air discharge temperature using coolant flow control and separating the ACM into two or more subcomponents to better fit the system in the vehicle.

Air Delivery Modes

There are three basic modes in most vehicles: heater, defroster, and air conditioning (or vent for vehicles without air conditioning). Typical mixed modes include bilevel, blend, and ambient.

Heater Mode. Heater mode is designed to provide comfort heating to vehicle occupants. Typical maximum heater airflow is 60 to 95 L/s for a midsized automobile. Heater air is generally distributed into the lower forward (foot) compartment, under the front seat, and up into the rear compartment. Air distribution near the floor also makes the vehicle more comfortable by providing slightly cooler air at breathing level. Because the supply air temperature is relatively high, direct impingement on the occupant is not desirable. Heater air exhausts through body leakage points.

Heater mode warms air in the vehicle above the dew points of the surrounding air and of the vehicle's glass. To prevent condensation from occupant respiration or from rain or snow tracked in, most vehicles sold in North America draw only OA when in heater mode and do not allow recirculation. However, some vehicle designs do allow recirculation, avoiding the higher cost of including the electric or vacuum actuation system necessary to prevent it.

Most vehicles also provide a small bleed of air (typically 15 to 25% of total airflow) in heater (foot) mode to the windshield to isolate it from the car's interior. Properly designed, this prevents loss of visibility by window fogging under most conditions.

Defrost Mode. Defrost mode is provided to clear the windshield from frost and fog, both internally and externally. Typical maximum airflow for defrost systems is 70 to 95 L/s for a midsized automobile. Defrost mode requirements are given in the DOT's Federal Motor Vehicle Safety *Standard* (FMVSS) 103, which defines areas on the windshield for driver vision and a time frame in which they must be able to be cleared under extreme vehicle operating conditions. Most vehicles are also equipped with side window demisters that direct a small amount of heated air and/or air with lowered dew point to the front side windows. Rear windows are typically defrosted by heating wires embedded in the glass.

To prevent windshield fogging, most vehicles built in North America prevent air from being recirculated in defrost mode. In addition, many vehicles automatically operate the air-conditioning system in defrost if the ambient temperature is above a threshold (usually around 4°C). This provides an extra assist and safety factor by lowering the dew point of air exiting the ACM to below ambient temperature.

Air-Conditioning (or Panel) Mode. The air-conditioning mode is provided for occupant comfort cooling and to ventilate the vehicle. Typical airflow for panel mode is 95 to 140 L/s in a midsized car. Because of the lower temperature differentials in this mode, airflow is provided in such a way that direct impingement on the occupants can be achieved if desired. A minimum air velocity of 10 m/s at the outlet is desired, to provide adequate comfort to occupants in the front and rear of the cabin (Atkinson 2000). As discussed in the Design Factors section, the higher heat fluxes and higher initial temperature at vehicle start-up frequently require that the system be able to **spot cool**, providing the cooling airflow directly on the occupants, before lowering the overall cabin temperature. For these reasons, directability of the supply outlet on the occupants is very important. The air-conditioning system is designed to have sufficient capacity to bring the interior temperature down rapidly; panel outlets must also be positionable, to move the airflow off the occupants after a few minutes of operation.

To maximize energy efficiency and cooling rate, the A/C system is typically operated in recirculation mode. However, in this mode, carbon dioxide exhaled by occupants remains within the cabin and can negatively affect cabin air quality (Atkinson et al. 2017; Mathur 2016b, 2017a, 2018b). Carbon dioxide increases. The carbon dioxide inhaled by occupants enters their bloodstreams, which may be detrimental to occupants' health. A timed strategy (about 10 min) is therefore recommended for recirculation. After this time, the mode automatically changes to OA to reduce CO_2 levels inside the cabin. A carbon dioxide sensor can also be used in the cabin to monitor levels. If it exceeds a predetermined level, the blower unit's intake door goes to OA mode (Mathur 2007a, 2007b, 2008).

Bilevel Mode. The most common mixed mode, bilevel mode, is designed for moderate-temperature operation with high solar loading. The system provides air to both the lower outlets and the panel outlets. Typically, air from the panel outlets is 3 to 14 K cooler than the air from the lower outlets. This is to provide cooling to areas of the interior that have direct solar loading and to provide warm air to those that do not.

Blend Mode. The next most common mixed mode is blend mode, designed to provide a step between heater and defroster for times when extra heat is needed to keep the windshield clear but full defrost is not desired. A typical situation where blend mode is used is in city traffic during snowfall. The extra airflow to the windshield helps maintain a clear field of vision and still maintains adequate flow to lower outlets to keep occupants warm.

Outdoor Mode. This mode is also designed for mild ambients. It is intended to provide a relatively high total airflow through the cabin but without the high local air velocities of the other modes. Typically, vehicles with outdoor mode are also equipped with additional panel outlets not directed toward the occupants. The most common configuration provides air toward the ceiling from outlets in the middle of the dashboard.

Controls

The HVAC control head (i.e., controls for the ACM and refrigeration system) is located within easy reach of the driver and occupants. These controls must be easy to use and not distract the driver from the road. There are many variations, from the cable-controlled manual system to fully automatic systems that control the cockpit environment. The two main classifications are manual and automatic.

Manual control is typically the base system that provides control for mode, temperature valve position, air source, and air flow rate (blower speed). In addition to air-handling controls, the control head usually also has a button to engage the compressor (i.e., to turn on the A/C system). Additional functions, such as rear defrost and seat heating controls, are frequently added to the control head. Although manual control provides a temperature mix door control, this is not a temperature control; it only controls the opening of the temperature valve and fixes the amount of air that bypasses the heater core. Therefore, if there is significant variation in ambient temperature or vehicle coolant temperature, the manual system must be adjusted. Manual systems typically have four or five blower speeds.

Automatic control uses a control unit and vehicle sensors to establish a comfortable thermodynamic environment for vehicle occupants. Sensors measure air inlet temperature, vehicle cabin temperature, and ACM discharge air temperature. The automatic control then varies the mix door position, air flow rate, ACM mode, and air-conditioning compressor engagement. Some advanced systems measure cabin humidity for comfort control. Automatic systems usually have from 8 to 20 blower speeds.

Air quality control is also available in many vehicles (Mathur 2007a, 2007b). Most of these systems assume that a vehicle quickly passes through areas where the contamination source is prevalent. A sensor measures a **surrogate gas** (a gas that is not necessarily toxic but accompanies toxic gases that are more difficult to measure). When the surrogate gas is detected, the vehicle's air inlet door is positioned for recirculation to separate the occupants from the contamination source.

Air-Handling Subsystem Components

Air Inlet Plenum. The air inlet plenum (also called a **cowl**) is usually an integral part of the vehicle structure. There are two primary design considerations and several secondary design considerations for the air inlet plenum:

Primary

- Air that flows into the plenum should not be influenced by uncontrolled emissions from the vehicle systems (i.e., the plenum should be a source of clean air).
- The plenum should be located so that the aerodynamic effects of air movement over the vehicle increase pressure in the plenum, so when the vehicle operates with external air selected, air flows through the air-handling unit into the vehicle. This allows fresh air to flow through the vehicle and helps reduce the amount of external air that infiltrates into the vehicle from uncontrolled sources.

Secondary

- The pressure drop of the plenum should also be considered. Higher airflow pressure requires more power for the ACM blower and fan to provide adequate airflow.
- Airflow at the entrance to the ACM's blower should be uniform. In many vehicle applications, a significant loss in efficiency is caused by unbalanced airflow into the fan.
- The air inlet plenum also serves several other functions, such as water separation, protection from snow ingestion, and gross filtration (usually through a screen).
- The air inlet plenum should also be located such that when the vehicle is covered by snow, the plenum still can furnish sufficient air to clear the windshield and provide fresh air to the occupants.

The air inlet plenum is usually located at base of the windshield. If properly sealed from underhood areas of the vehicle, this provides a relatively high-pressure and clean source of air. Major plenum design considerations include the following (Mathur 2005a).

Separation of Water Droplets from Airstream. It is important that openings in the plenum cover be sized carefully. Openings that are too small result in a higher pressure, which reduces airflow and increases noise. Reduced airflow increases window fogging and significantly decreases occupants' perceived comfort. Surface tension can also cause rainwater to plug small openings and get sucked into the plenum when the blower is turned on in OA mode. On the other hand, very large openings can allow snow or sleet inside, where it can accumulate and block the path of airflow. Plenum cover opening sizes should be optimized to address both these issues.

Water droplets follow the air trajectory inside the plenum. Removing the droplets requires changing the airflow direction: because their momentum is greater, the droplets do not change direction but instead hit the sheet metal wall and then drain to the bottom of the plenum channel. Otherwise, filters may become saturated with water. Adding baffles inside the plenum channel can change airflow direction, but also increases air pressure drop, which affects both airflow rate and noise levels. Angling baffles in the flow direction helps alleviate this pressure drop increase.

Expanding the plenum's cross-sectional area is another way of removing water droplets from the airstream, but is not always possible because of space limitations. This is a good approach, though, around the wiper motor and linkages, which are housed inside the plenum channel and significantly reduce airflow area.

Snow Separation. As discussed previously, plenum cover opening size is crucial in keeping precipitation out of the plenum. Even with an optimum cover design, though, accumulated snow must be removed before the blower unit is turned on in OA mode. Otherwise, dry, powder like snow could enter the plenum and end up on the filter, saturating it and causing fogging issues.

Hard snow over the plenum cover is difficult to remove and significantly reduces airflow when the blower is turned on. As air flows over the openings, some of the ice is directly evaporated into the airstream by sublimation, increasing window fogging. To address this situation, some plenum cover openings in newer cars are under the hood, allowing some airflow into the cabin in this situation. Note, however, that this approach could be lethal in old cars that leak exhaust gases from faulty gaskets under the hood.

Distribution Ducting. Air from the air-handling unit is distributed to various areas of the vehicle through ducting. Typically, the main trunk duct exits the ACM near the middle of the dashboard. Ducting carries air from this central location to the extremes of the instrument panel, the floor, and even the rear seat (if so equipped). The design goal is to distribute air throughout the vehicle with as little pressure drop as possible, to provide sufficient airflow to the various outlets for occupant comfort. This goal is frequently compromised by the tight packaging constraints in modern vehicles. Ducts should be designed with no sharp edges inside the airflow stream, which could increase airflow rush noise.

Outlets. There are typically defrost, heater, side window, and panel air outlets in a vehicle. The defrost air outlet is located on top the instrument panel to distribute air to clear the windshield of frost and fog as quickly and efficiently as possible. Heater outlets are located on the bottom of the instrument panel to spread warm air over the floor of the vehicle. Panel outlets are designed to provide cool air to the occupants. The importance of panel outlets should not be underestimated. The ability to achieve direct air impingement on occupants with little diffusion is very important to comfort after a vehicle has been inoperative during extremely hot summer conditions. Likewise, it is important to be able to direct cool air away from occupants after the interior begins to cool down. The air pressure drop in the vent outlet changes as the direction of the vane or blade is changed, and can result in reduced airflow. This is necessary to direct the airflow over the desired area of the passenger. Being able to direct the jet air and reach the occupants under all conditions can result in satisfied consumers; the lack of this ability has led to dissatisfied consumers even in vehicles with exceptional airflow and capacity.

Body Relief Vents or Drafters. Body relief vents or drafters are designed to ensure airflow through the vehicle from front to rear. The drafters are located inside the trunk, under the carpet, on the sides near the wheel wells. Air flows from the cabin into the trunk through parcel shelf openings (holes that facilitate airflow from cabin to trunk), and then between the sheet metal and carpet to the drafters.

Typically, they are effectively low-pressure check valves, designed to allow airflow out of the vehicle when cabin pressure is above the local exterior pressure and to prevent air infiltration when the local exterior pressure is above that of the interior (i.e., when the vehicle is using recirculated air as the air source). Relief vents should be located where they will cause airflow inside the body to cover all occupant locations inside the vehicle.

A small number of openings in the vehicle body are required for wires, cables, and various attachment features; therefore, the body relief vent does not typically need to be large enough to exhaust the total airflow through the vehicle.

Heater Core. The heat transfer surface in an automotive heater is generally either copper/brass cellular, aluminum tube and fin, or aluminum-brazed tube and center. Each of these designs is in production in straight-through, U-flow, or W-flow configurations. The basics of each of the designs are outlined as follows:

- The **copper/brass cellular** design is not used frequently in new vehicles. It uses brass tube assemblies (0.15 to 0.4 mm wall thickness) as the water course, and convoluted copper fins (0.08 to 0.2 mm thick) held together with a lead/tin solder. The tanks and connecting pipes are usually brass (0.66 to 0.86 mm wall thickness) and are attached to the core by a lead/tin solder.
- The **aluminum tube-and-fin** design generally uses round copper or aluminum tubes, mechanically joined to aluminum fins. U tubes can take the place of a conventional return tank. The inlet/outlet tank and connecting pipes are generally plastic and attached to the core with a rubber gasket.
- The **aluminum-brazed tube-and-center** design uses flat aluminum tubes and convoluted fins or centers as the heat transfer surface. Tanks are either plastic and clinched onto the core or aluminum and brazed to the core. Connecting pipes are constructed of various materials and attached to the tanks various ways, including brazing, clinching with an O ring, fastening with a gasket, and so forth. Almost all original equipment manufacturers (OEMs) currently use brazed-aluminum heater cores (Jokar et al. 2004).

Air-side design characteristics include pressure drop and heat transfer. The pressure drop of the heater core is a function of the fin/louver geometry, fin density, and tube density. Capacity is adjusted by varying the face area of the core to increase or decrease the heat transfer surface area, adding coolant-side turbulators, or varying air-side surface geometry for turbulence.

Evaporator. Automotive evaporator materials and construction include (1) copper or aluminum tube and fin; (2) brazed-aluminum plate and fin, also known as a laminate evaporator; and (3) brazed serpentine tube and fin. This section addresses the air-side design of the evaporator. Air-side design parameters include air pressure drop, capacity, and condensate control. Evaporators are typically treated with hydrophilic coating that prevents build-up of water within the evaporator fins and plates (Mathur 2016a, 2017b).

A laminate evaporator consists of a number of stamped plates and louvered fins. The plates have clad material on both sides. The plates and fins are stacked and then either vacuum-brazed or controlled-atmospheric-brazed (CAB). The advantage of using CAB is that it is a continuous process, whereas vacuum brazing is a batch process. When brazed, the plate forms internal flow passages for refrigerant. The plates have diagonal ribs (or multiple dimples) to augment heat transfer and provide strength, and central partitioning ribs that facilitate reversal of refrigerant flow. These evaporators may have tanks on both ends or on one end only. For the same airflow area, a single-tank evaporator has better performance than a double-tank evaporator, because the available heat transfer area is greater (i.e., the ratio of total heat exchange area to total volume of the core is higher for evaporators with single tanks). Laminate evaporators typically have four to six refrigerant passes. Two-phase refrigerant enters the evaporator through the inlet pipe, and vapor exits the evaporator through the outlet pipe. Two-phase refrigerant enters the evaporator through the tank and moves downward in multiflow channels (or plates) in pass 1 and then flows upward in pass 2. The refrigerant reaches the tank section at the top and then flows downward in pass 3, flows upward in pass 4, and exits the evaporator as vapor (Mathur 2000a, 2001, 2002, 2003).

Typically, an ACM is designed to provide the airflow required for cooling for the vehicle. The combination of airflow, maximum allowable current draw for the blower motor, size constraints on the ACM, and ductwork act together to establish a required evaporator air-side pressure-drop characteristic. The air-side pressure drop of the core is typically a function of fin spacing, louver design, core depth, and face area. This characteristic varies with accumulation of condensate on the core, so adequate leeway must be allowed to achieve target airflow in humid conditions.

Conditions affecting evaporator capacity are different from those in residential and commercial installations in that the average operating time, from a hot-soaked condition, is less than 20 min. Inlet air temperature at the start of operation can be as high as 70°C, but decreases as the vehicle duct system is ventilated. Capacity requirements under multiple conditions must be considered when sizing an automotive evaporator, including steady-state operation at high or low speeds, and a point in a cooldown after an initial vehicle hot soak. Some of these requirements may also be set in recirculating conditions where the temperature and humidity of inlet air decrease as the car interior temperature decreases.

The evaporator load also has a slightly higher sensible heat portion than indicated by ambient temperature. Heat gain from the vehicle and temperature rise across the blower motor must be considered when sizing the evaporator.

During longer periods of operation, the system is expected to cool the entire vehicle interior rather than just produce a flow of cool air. During sustained operation, vehicle occupants want less air noise and velocity, so the air quantity must be reduced; however, sufficient capacity must be preserved to maintain satisfactory interior temperatures.

Condensate management is very important within a motor vehicle. In the process of cooling and dehumidifying the air, the evaporator extracts moisture from the air. It is imperative that liquid condensate be prevented from entering the vehicle interior, because this will damage the vehicle. This moisture should be carried out of the vehicle and not allowed to collect inside the ACM (Mathur 2000b). Many cars that have plugged condensate drain holes have a distinct odor, which is given off by common organisms (present almost everywhere) that grow in warm, moist environments.

Condensate management includes the following design objectives (Mathur 1999a):

- Ensure that moisture coming off the evaporator is in large enough droplets that it is not carried by the airstream (a combination of low velocity at the exit of the core and adequate ability of the core to allow surface tension to gather the water)
- Allow sufficient fin spacing for adequate condensate drainage
- Allow a large enough sump so that all water coming off the core can be collected for a short period of time when vehicle-maneuvering forces push water away from the drain
- Provide sufficient slope to the drain area so that water flows to the drain rather than collecting in the case
- Have a sufficient cross section in the drain so that water does not back up into the module, taking into account the fact that ACM interior pressure is usually 250 to 500 Pa above the exterior pressure

Vehicle attitude (slope of the road and inclines), acceleration, and deceleration should also be considered, because these factors can significantly affect the drain system. Drains can become plugged not only by contaminants but also by road splash.

Location of HVAC Unit. The HVAC unit consists of the blower intake unit, cooling unit, and a heater unit. The system also has several ducts that feed air to different circuits. These units are mounted inside the **cockpit module (CPM)**. U.S.-made vehicles use **modular design**, in which the blower, evaporator, and heater are individual units. **Integrated units** (Figure 2) that combine all three functions into one component have been developed, but their design is complex.

Blower Motor and Fans. Airflow in an automobile must provide sufficient cooling air to passengers in both the front and rear

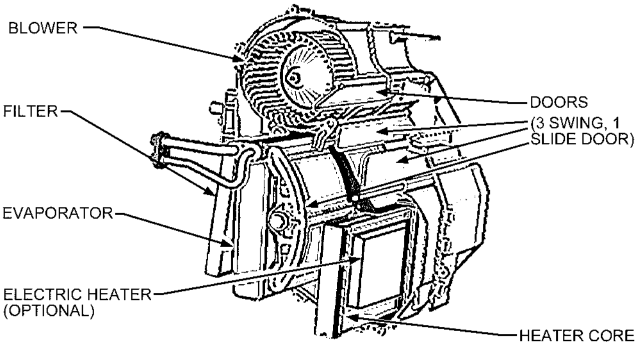

Fig. 2 Integrated HVAC Unit

seats. Designs for the blower motor and fan, which must fit in a relatively small space, are frequently a compromise between packaging, mass, airflow, and efficiency. Virtually all fans used in automotive ACMs are centrifugal, with fan diameters from 140 to 200 mm. Typical motor current draws vary from 14 to 25 A, depending on factors affecting optimization of the particular application. Both forward- and backward-inclined fan blades have been used.

Reducing the noise, vibration, and harshness (NVH) characteristics of the interior has significantly improved comfort levels. During integration of the blower motor and fan into the module, pay careful attention to any type of vibrational excitation the fan may impart to the ACM and other underdash components.

Electronic Blower Speed Control. Historically, the blower motor speed control was simply a selector switch that selected either from direct battery voltage at the blower motor or from one of two or more resistors in series with the blower motor to reduce voltage. In general, the lowest airflow selectable is usually driven by the need to provide adequate air pressure to cool the blower motor. Modern blower motor speed controls incorporate essentially infinite speed control using devices such as **pulse-width modulating (PWM)** controllers. The newer devices are usually found on upscale vehicles using automatic climate control systems, which reduce energy consumption and increase fuel efficiency. When incorporating devices such as PWMs into a vehicle system, pay careful attention to radio frequency interference because of the necessary proximity of all the electronics in a vehicle.

Valves. The typical ACM has valves for the air inlet source, temperature control (heater air bypass), and mode control. Some vehicles also have a ram air door, used to reduce ram effect at high speeds and provide consistent airflow. Door/valve designs are integral to the ACM design. Door types include flag style, rotary, guillotine, slider, and film valves. The optimal door type is almost always a function of the space in which a module must fit.

Actuators. Actuators on ACMs are usually cable, electric, and/or vacuum. **Cable-based actuation** is usually the least expensive and is most frequently found in entry-level vehicles. The valving system must be designed to retain a position with minimal restraining torque, have smooth operation with essentially constant torque level, and have minimal torque required to move the valve(s). There must be a suitable cable path from the HVAC controls to the module. Cable actuation does not allow electronic control of the air-conditioning system or an interlock to ensure outdoor air is selected in defrost mode.

The norm for U.S. automobiles 20 years ago, **vacuum actuation**, has been replaced by electronic actuators. Vacuum actuators provide only three position controls per actuator and require a cross-sectional area for the diaphragm proportional to the load on the door. The vacuum source is the vehicle's engine intake air manifold. Although this provides powerful control at engine idle, a great deal of variation exists in the working pressure differential, and must be taken into account in system design.

Electric actuators can control the ACM electronically and are available in variety of shapes. The possibility of linear positions allows for multiple modes, with one actuator on several doors, using a cam system. They also isolate the operator from torque variations, allowing the ACM to be optimized for other performance criteria.

Air Inlet. The air inlet interfaces the ACM with the vehicle body. If not accomplished upstream, it is necessary for the air inlet to separate out water from rain, car washes, etc. It also provides the selection of either outdoor air or air recirculated from the passenger compartment. On upscale performance vehicles, the ram air door is also located here. A primary design criterion for the air inlet is to provide proper flow patterns at the inlet of the blower motor. In many applications this is compromised to fit the ACM into the vehicle. The result is either turbulence or misdistribution of air into the fan, causing noise and lower efficiency.

Mode Control. Air is usually distributed at the ACM by one or more valves directing air to the desired vehicle outlets. This system may provide several discrete modes or a continuous variation from one mode to the next. ACM valving must be designed to work with the distribution ductwork and provide the desired air distribution to occupants.

Air Distribution. Air must be distributed in a way that minimizes pressure loss, thermal lag, and heat gain. Ductwork is usually designed around other underdash components, and frequently must follow a difficult path. Air for all outlets starts at one basic plenum pressure, and variations in pressure drop versus flow rate from side to side in the vehicle must be minimized to provide even airflow to both driver and passengers. Because of the instrument cluster in front of the driver and devices such as airbags, ductwork is almost never laterally symmetrical. Computational fluid dynamics is used to ensure proper air distribution design.

Air Filter. Air filters are increasingly common, typically located in either the air inlet plenum or the ACM. Filters may be particulate, charcoal, or both; they require regular service to prevent clogging and ensure proper system function. Removal of contaminants (e.g., pollen) may also be aided by condensate on evaporator surfaces. The concentration of the volatile organic compounds (VOCs) from the vehicle's interior (plastic parts, carpet, adhesive, etc.) along with tailpipe emissions (NO_x, CO, hydrocarbons) from automobiles, buses, and trucks can be reduced by using carbon filters. These filters should be replaced regularly, based on driving conditions, because a dirty filter can be the largest source for polluting cabin air.

3. HEATING SUBSYSTEM

The primary heat source is the vehicle's engine. Coolant from the engine cooling system circulates through the heater core. Modern efficiency and emissions improvements have led to many types of supplemental heating, including fuel-fired heaters, refrigerant heat pumps, electrical heaters, and heat storage systems.

The heater core must be designed to work within the design of the engine cooling system. Engine coolant pressure at the heater core inlet ranges up to 275 kPa (gage) in cars and 380 kPa (gage) in trucks.

Modern antifreeze coolant solutions have specific heats from 2.7 to 4.2 kJ/(kg·K) and boiling points from 120 to 135°C (depending on concentration) when a 103 kPa radiator pressure cap is used.

Controls

Engine coolant temperature is controlled by a thermostatically operated valve that remains closed until coolant temperature reaches 70 to 96°C. Coolant flow is a function of pressure differential and system restriction, but typically ranges from 0.04 L/s at idle to 0.6 L/s at higher engine speed. Coolant temperature below 70°C is not desirable, because it cannot meet occupants' comfort requirements. The mechanical pump should be able to deliver sufficient coolant flow, even at idle.

Components

The minimal components of the heating subsystem are the coolant flow circuit (water pump) and temperature control, both provided by the vehicle's engine; the heater core (part of the ACM); and coolant hoses.

4. REFRIGERATION SUBSYSTEM

Cooling is almost universally provided by a vapor cycle system. The thermodynamics of a vapor cycle system are described in Chapter 2 of the 2017 *ASHRAE Handbook—Fundamentals*. The automotive system is unique in several ways.

Refrigeration capacity must be adequate to bring the vehicle interior to a comfortable temperature and humidity quickly and then maintain it during all operating conditions and environments. A design may be established by mathematical modeling or empirical evaluation of known and predicted factors. A design trade-off in capacity is sought relative to criteria for vehicle mass, component size, and fuel economy. Automotive system components must meet internal and external corrosion, pressure cycle, burst, and vibration requirements.

Refrigerant-based system equipment is designed to meet the recommendations of SAE *Standard* J639, which includes several requirements for refrigerant systems. To be compliant, a system must have

- A high-pressure relief device
- Burst strength (of components subjected to high-side refrigerant pressure) at least 2.5 times the venting pressure of the relief device
- Electrical cutout of the clutch coil before pressure relief to prevent unnecessary refrigerant discharge
- Low-pressure-side components with burst strengths in excess of 2070 kPa

The relief device should be located as close as possible to the discharge gas side of the compressor, preferably in the compressor itself.

Controls

Refrigerant Flow Control. Cycling-clutch designs are the most common mechanisms for controlling refrigerant flow; schematics for the two most common versions are shown in Figures 3 and 4. The clutch is cycled by either a thermostat that senses evaporator temperature or a pressure switch that senses evaporator pressure. This thermostat or pressure switch serves two functions: it prevents evaporator icing, and maintains a minimum refrigerant density at the compressor's inlet, preventing overheating. Discharge air temperature is then increased, if necessary, by passing some (or all) of the evaporator outlet air through the heater core.

The clutch-cycling switch disengages at about 172 kPa (gage) and engages at about 310 kPa (gage). Thus, the evaporator defrosts on each off-cycle. The flooded evaporator has enough thermal inertia to prevent rapid clutch cycling. It is desirable to limit clutch cycling to a maximum of six cycles per minute because a large amount of heat is generated by the clutch at engagement. The pressure switch can be used with a thermostatic expansion valve in a dry evaporator if the pressure switch is damped to prevent rapid cycling of the clutch.

Cycling the clutch sometimes causes noticeable surges as the engine is loaded and unloaded by the compressor. This is more evident in cars with smaller engines. This system cools more quickly and at lower cost than a continuously running system.

For vehicles where clutch cycling is unwanted because of engine surge, or for high-end vehicles where no perceptible temperature swing is allowable, variable-displacement compressors are available, controlled either electronically or pneumatically.

In the **pneumatically controlled compressor**, a sensor (usually located in the compressor body) varies the compressor displacement so that a constant pressure is maintained at the compressor inlet. This provides a nearly uniform evaporator temperature under varied loading conditions. This type of system causes no perceptible engine surge with air-conditioning system operation.

The **electronically controlled variable-displacement compressor** opens up many possibilities for systems optimization. This type of compressor allows reduced reheat control, and evaporator temperature is maintained at such a level that comfort is achieved with less fuel consumption. A wide range of control schemes using electronically controlled variable-displacement compressors are being developed.

Other Controls. A cycling switch may be included to start an electric fan when insufficient ram air flows over the condenser. Also, output from a pressure switch or transducer may be used to put the ACM in recirculation mode, which reduces head pressure by reducing the load on the evaporator. Other possibilities include a charge loss/low-ambient switch, transducer evaporator pressure control, and thermistor control.

Components

Compressor. Piston compressors dominate the automotive market, although scroll and rotary vane types are also significant. For detailed information on compressor design, see Chapter 38 of the

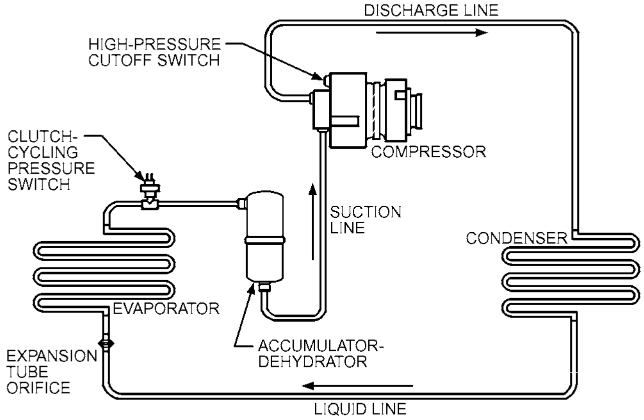

Fig. 3 Clutch-Cycling System with Orifice Tube Expansion Device

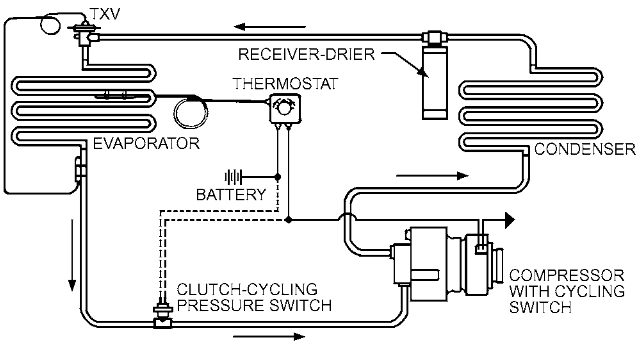

Fig. 4 Clutch-Cycling System with Thermostatic Expansion Valve (TXV)

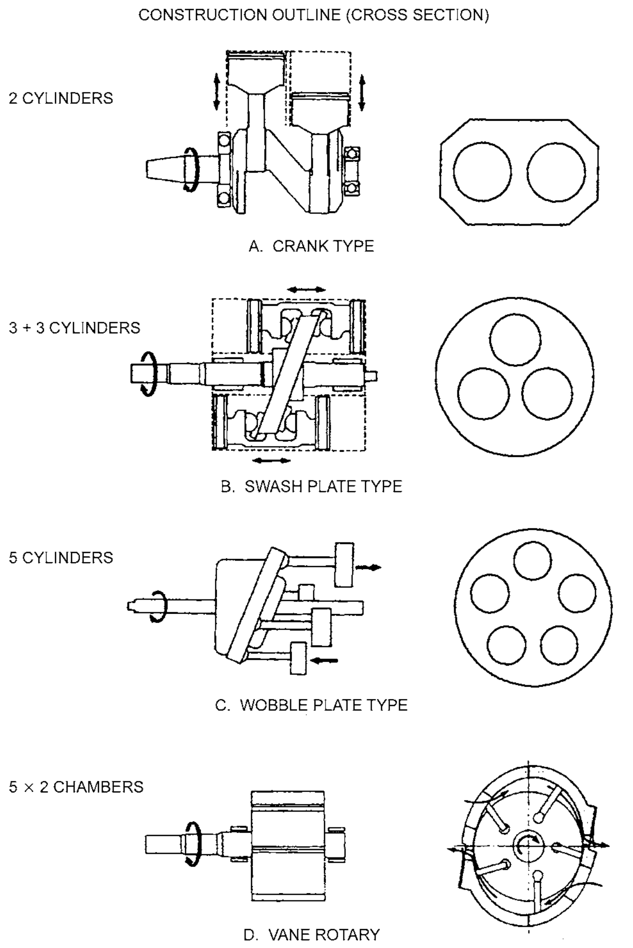

Fig. 5 Basic Compressor Designs for Automotive Application

2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Figure 5 illustrates basic automotive compressor types. The typical automotive compressor has the following characteristics:

- **Displacement.** Fixed-displacement compressors have displacements of 0.1 to 0.2 L/rev. Variable-displacement piston compressors typically have a minimum displacement of about 6% of their maximum displacement. A typical variable-capacity scroll compressor has a maximum displacement of 0.12 L/rev and a minimum displacement of 10% of the maximum.
- **Physical size.** Fuel economy, lower hood lines, and more engine accessories all decrease compressor installation space. These features, along with the fact that smaller engines have less accessory power available, promote the use of smaller compressors.
- **Speed range.** Most compressors are belt driven directly from the engine; they must withstand speeds of over 130 rev/s and remain smooth and quiet down to 8.3 rev/s. The drive ratio from the vehicle engine to the compressor typically varies from 1:1 to 2:1. In the absence of a variable drive ratio, the maximum compressor speed may need to be higher to achieve sufficient pumping capacity at idle.
- **Torque requirements.** Because torque pulsations cause or aggravate vibration problems, it is best to minimize them. Minimizing peak torque benefits the compressor drive and mount systems. Multicylinder reciprocating and rotary compressors aid in reducing vibration. An economical single-cylinder compressor reduces cost; however, any design must reduce peak torques and belt loads, which are normally at a maximum in a single-cylinder design.
- **Compressor drives.** A magnetic clutch, energized by power from the vehicle engine electrical system, drives the compressor. The clutch is always disengaged when air conditioning is not required. The clutch can also be used to control evaporator temperature (see the section on Controls).
- **Variable-displacement compressors.** Both axial and wobble-plate variable-displacement compressors are available for automobile air conditioning. The angle of the plate changes in response to the suction and discharge pressure to achieve a constant suction pressure just above freezing, regardless of load. A bellows valve or electronic sensor-controlled valve routes internal gas flow to control the plate's angle. A variable-displacement compressor reduces compressor power consumption, improving fuel efficiency. These compressors improve dehumidification and comfort, have low noise and vibration, and have high reliability and efficiencies.
- **Noise, vibration, and harshness (NVH).** With decreasing mass and increasing environmental quality in automobiles, compressor design is increasingly driven by NVH concerns. Vibrational input to the structure, suction and discharge line gas pulsations, and airborne noise must all be minimized. NVH minimization is now the main impetus behind most continuous improvement efforts in the automotive compressor industry.
- **Mounting.** Compressor mounts are an important part of a successful integration of a compressor into a vehicle system. Proper mounting of the compressor minimizes structural resonances and improves the NVH characteristics of any compressor.

Compressor Oil Return. It is important that there are no areas where the lubrication oil can accumulate (Mathur 2004a). At part-load conditions, refrigerant velocities should be high enough to ensure oil return to the compressor. The presence of oil in the system affects heat exchanger performance (Mackenzie et al. 2004). Some new compressors have a built-in oil separator.

Condenser. Automotive condensers are generally of the following designs: (1) tube-and-fin with mechanically bonded fins; (2) serpentine tube with brazed, multilouvered fins; or (3) header extruded tube brazed to multilouvered fins, also known as parallel-flow (PRF) condensers, which are primarily used in automotive applications (Figure 6). To prevent air bypass, condensers generally cover the entire radiator surface. Aluminum is popular for its low cost and mass.

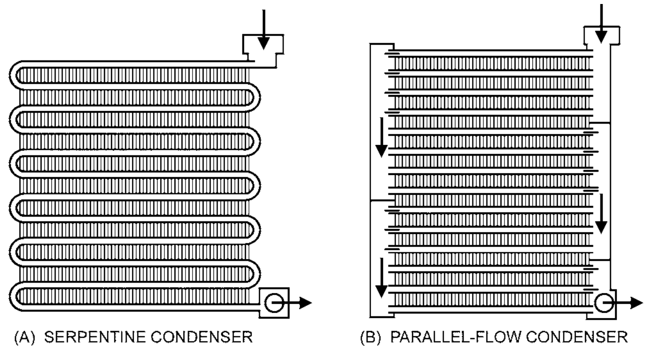

Fig. 6 Basic Automotive Condensers
(Mathur 1999b. Reprinted with permission from SAE *Paper* 1999-01-0236. Copyright © 1999 SAE International.)

Operation of Parallel-Flow Condenser. A PRF condenser consists of flat tubes that have multiple flow channels. Refrigerant is supplied directly to the tubes through the header. Louvered fins are currently used in automotive heat exchangers. A typical refrigerant tube has 2 mm thick wall with tube widths ranging from 18 to

22 mm, with 6 to 12 flow channels; smaller tubes are also available. Flat tubes have less projected frontal area to the airstream, which results in lower air-side pressure drop. Performance of a parallel-flow condenser is superior to that of a serpentine condenser (Mathur 1998), because the refrigerant is distributed in multiple tubes. For the same reason, refrigerant pressure drop in a PRF condenser is also much smaller.

Typically, in a PRF condenser, the first pass (see Figure 6B) has the largest number of refrigerant tubes, with fewer tubes in each successive pass. This is because the specific volume of superheated vapor coming out from the compressor is very large, and the density of refrigerant vapor is very small. This results in very high vapor velocities (m = ❒AV) in the tubes. At this condition, the refrigerant void fraction is unity, which results in a very high pressure drop. Therefore, this high volumetric flow must be subdivided into a large number of tubes to lower refrigerant velocities, and thus pressure drop. At some point along the condenser, refrigerant vapor temperature equals saturated temperature, and wall temperature falls below saturation temperature. At this time, condensation starts and the average density of the two-phase refrigerant mixture starts to increase. With the increase of the two-phase mixture density, the average refrigerant velocities start to decrease. This affects the condensation heat transfer coefficient and frictional pressure drop. When all vapors are condensed, the refrigerant flow becomes single-phase liquid. At this condition, the refrigerant flow velocity is lowest, which yields lower pressure drop. Thus, the last pass has the fewest tubes.

Condenser Design. Condensers must be properly sized. An undersized condenser results in high discharge pressures that reduce compressor capacity, increase compressor power requirements, and result in poorer discharge air temperatures. When the condenser is in series with the radiator, the air restriction must be compatible with the engine cooling fan and engine cooling requirements. Generally, the most critical condition occurs at engine idle under high-load conditions. An undersized condenser can raise head pressures sufficiently to stall small-displacement engines.

An oversized condenser may produce condensing temperatures significantly below the engine compartment temperature. This can result in evaporation of refrigerant in the liquid line where the liquid line passes through the engine compartment (the condenser is ahead of the engine and the evaporator is behind it). Engine compartment air has been heated not only by the condenser but also by the engine and radiator. Typically, this establishes a minimum condensing temperature between 5 and 17 K above ambient. Liquid flashing occurs more often at reduced load, when the liquid-line velocity decreases, allowing the liquid to be heated above saturation temperature before reaching the expansion valve. This is more apparent on cycling systems than on systems that have a continuous liquid flow. Liquid flashing is audibly detected as gas enters the expansion valve. This problem can be reduced by adding a subcooler or additional fan power to the condenser.

Internal pressure drop should be minimized to reduce compressor power requirements. Condenser-to-radiator clearances as low as 6 mm have been used, but 13 mm is preferable. Primary-to-secondary surface area ratios vary from 8:1 to 16:1. Condensers are normally painted black so they are not visible through the vehicle's grille.

Placing the condenser ahead of the engine-cooling radiator not only restricts air but also heats the air entering the radiator. Air conditioning increases requirements on the engine-cooling system, which requires an increase in radiator capacity, engine-cooling airflow, or both. Radiator capacity can be increased by adding fins, depth, or face area or by raising pump speed to increase coolant flow. Coolant velocity is not normally increased because it may cause excessive tube erosion or cavitation at the coolant pump inlet. With this configuration, engine-cooling airflow requirements increase; they are met by increasing fan size, number of blades, blade width, or blade pitch; by adding a fan shroud; or by a combination of these items. Increases in fan speed, diameter, and pitch raise the noise level and power consumption. For engine-driven fans (primarily used on trucks), temperature- and torque-sensitive drives (viscous drives or couplings) or flexible-blade fans reduce the increases in noise that come with the higher power. Virtually all automobiles rely on airflow produced by the car's forward motion to reduce the amount of air the engine-cooling fan must move to maintain adequate coolant temperatures. As vehicle speed increases, fan requirements drop, and electric fans are de-energized or engine-driven fans are decoupled by the action of the viscous drive.

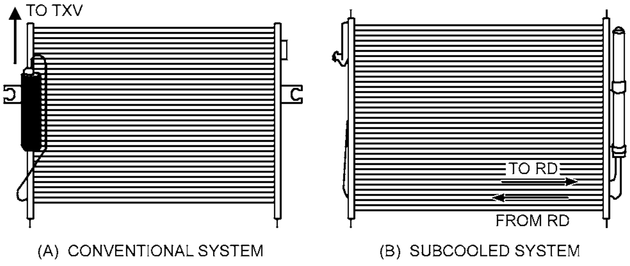

Fig. 7 Conventional and Subcooled PRF Condenser Designs

Some vehicles have a side-by-side condenser and radiator, each with its own motor-driven fan. This eliminates the effect of the condenser on the engine cooling air inlet temperature, but causes other issues with fan control and potential engine bay recirculation when one system is energized and the other is not.

Subcooled Condensers. There is a trend of using subcooled condensers to improve overall air-conditioning system performance. Thermodynamically, by increasing subcooling at the end of the condenser (on a *p-h* diagram), the overall system performance is increased (see Chapter 2 of the 2017 *ASHRAE Handbook—Fundamentals*) because the overall evaporator enthalpy difference (i.e., the difference in enthalpies between evaporator outlet to inlet) increases. Figure 7 shows a conventional PRF condenser in which refrigerant flows out from the condenser to the receiver-drier. In the subcooled PRF condenser, refrigerant from the second-last pass flows to the receiver-drier and then back to the condenser in the last path to subcool the refrigerant. In a subcooled PRF condenser, the size of the receiver-drier can be reduced because the condenser has more liquid refrigerant.

Hoses. Rubber hose assemblies are installed where flexible refrigerant transmission connections are needed because of relative motion between components (usually caused by engine rock) or where stiffer connections cause installation difficulties and noise transmission. Refrigerant permeation through the hose wall is a design concern. Permeation occurs at a reasonably slow and predictable rate that increases as pressure and temperature increase. Hose with a nylon core (**barrier hose**) is less flexible, has a smaller OD, is generally cleaner, and allows practically no permeation. However, because it is less flexible, it does not provide damping of gas pulsations as does other hose material. It is recommended for R-134a.

Reducing Noise and Vibration. Typically, refrigerant lines connected to the compressor (both suction and discharge sides) require hose that is a composite of rubber, nylon, and aluminum tube. This is necessary to eliminate or reduce transmission of clutch engagement noise to the cabin by metallic tubes. In some cases, mufflers are also used to reduce noise and vibrations from refrigerant flow.

Suction and discharge hoses and high-pressure liquid lines have connections for charging ports, sensor, and for service. Brackets and clips are also attached to the hoses and refrigerant lines to position and support the A/C lines.

Expansion Devices. Virtually all modern automobiles use either a thermostatic expansion valve (TXV) or an orifice tube (or both, for dual-evaporator systems) as the expansion device (see Chapter 11 of the 2018 *ASHRAE Handbook—Refrigeration* for more on these devices). Schematics of systems that use these devices are provided in the Controls section.

Automotive TXVs operate in the same manner as those for commercial HVAC systems. Both liquid- and gas-charged power elements are common. Internally and externally equalized valves are used as dictated by system design. Externally equalized valves are necessary where high evaporator pressure drops exist. A bulbless expansion valve, usually block-style, that senses evaporator outlet pressure without the need for an external equalizer is now widely used. TXV systems use a receiver-drier-filter assembly for refrigerant and desiccant storage.

Because of their low cost and high reliability, orifice tubes have become increasingly popular with automotive manufacturers. Developing an orifice tube system requires that components be matched to obtain proper performance. The orifice tube is designed to operate at 90 to 95% quality at the evaporator outlet, which requires a suction-line accumulator to protect the compressor from floodback and to maintain oil circulation. Because the orifice tube does not fully use the latent heat in the refrigerant systems, orifice-tube systems generally require higher refrigerant flow than TXV systems to achieve the same performance. However, an orifice tube ensures that the compressor receives a continuous flow of cool refrigerant from the accumulator, offering benefits in compressor durability over a TXV system. Orifice-tube systems use an accumulator-drier-filter for refrigerant and desiccant storage.

Receiver-Drier-Filter Assembly. A receiver-driver is installed in the A/C loop on the high-pressure side downstream of the condenser. Several types of desiccant are used, the most common of which is spherical molecular sieves; silica gel is occasionally used. The unit typically has desiccant either in a bag or cartridge, or sandwiched between two plates. The receiver-drier (1) serves as a reservoir for refrigerant from part- to full-load operating conditions, (2) removes moisture from the system, (3) filters out debris headed for the TXV, and (4) only allows liquid refrigerant to enter the TXV (liquid is removed from the top of the unit, and comes from the bottom via a tube connected to the top fitting).

The receiver-drier assembly accommodates charge fluctuations from changes in system load. It accommodates an overcharge of refrigerant to compensate for system leaks and hose permeation. The assembly houses the high-side filter and desiccant. Mechanical integrity (freedom from powdering) is important because of the vibration to which the assembly is exposed. For this reason, molded desiccants have not obtained wide acceptance. Moisture retention at elevated temperatures is also important. Consider the rate of release with temperature increase and the reaction while accumulating high concentration. Design temperatures should be at least 60°C.

Receivers are usually (though not always) mounted on or near the condenser. They should be located so that they are ventilated by ambient air. Pressure drop should be minimal. Typically, a receiver-drier has a pressure switch or a pressure transducer installed that controls A/C system operation at high pressure.

Suction-Line Accumulators. A suction-line accumulator is required with an orifice tube to ensure uniform return of refrigerant and oil to the compressor, to prevent slugging, and to cool the compressor. It also stores excess refrigerant. A typical suction-line accumulator is shown in Figure 8. A bleed hole at the bottom of the standpipe meters oil and liquid refrigerant back to the compressor. The filter and desiccant are contained in the accumulator because no receiver-drier is used with this system.

Evaporator. The evaporator connects the air side of the air-conditioning system to the refrigerant side. Design aspects for the air side are discussed in the Air-Handling Subsystem section. The primary design consideration for the refrigerant side of the evaporator is low pressure drop. Because the evaporator operates at saturation, higher-pressure-drop evaporators cause nonuniform discharge temperatures unless they are designed with careful attention to pass arrangement. The space available in an automotive system does not allow for distribution manifolds and capillary tube systems outside of the evaporator envelope; this must be done within the evaporator itself.

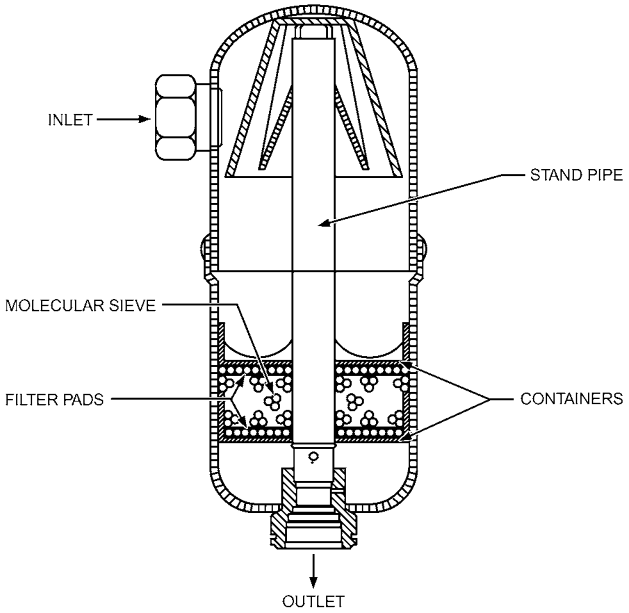

Fig. 8 Schematic of Typical Accumulator-Dehydrator

Automotive evaporators must also mask the variation in compressor capacity that occurs with accelerating and decelerating. To avoid undesirable temperature splits, sufficient liquid refrigerant should be retained at the last pass to ensure continued cooling during acceleration.

High refrigerant pressure loss in the evaporator requires externally equalized expansion valves. A bulbless expansion valve, called a block valve, provides external pressure equalization without the added expense of an external equalizer. The evaporator must provide stable refrigerant flow under all operating conditions and have sufficient capacity to ensure rapid cooldown of the vehicle after it has been standing in the sun.

Auxiliary Evaporators. Many sport-utility vehicles, vans, and limousines are equipped with auxiliary or secondary air-conditioning modules located to cool rear-seat passengers. These system extensions provide some unique challenges. Most of these systems operate only when there are passengers in the rear space. Consequently, sometimes there is refrigerant flow through the primary ACM and none through the secondary. Pay careful attention to refrigerant plumbing to avoid refrigerant and oil traps in the suction line. The auxiliary suction line must never allow liquid oil to run downhill from the front system when there is no flow to carry it back to the accumulator-dehydrator. Designing highly efficient oil separators into the line set results in frequent compressor failure.

Refrigerants and Lubricants. The 1997 Kyoto Protocol identified the almost universally used R-134a as a global warming gas, sparking a search for alternatives among vehicle manufacturers and their suppliers. To address the global warming concerns of R-134a, some OEMs around the world have started using hydrofluoroolefin (HFO-1234yf) as a replacement for HFC-134a. HFO-1234yf offers a good combination of energy efficiency, safety, and ease of customer conversion. It has a global warming potential (GWP) of less

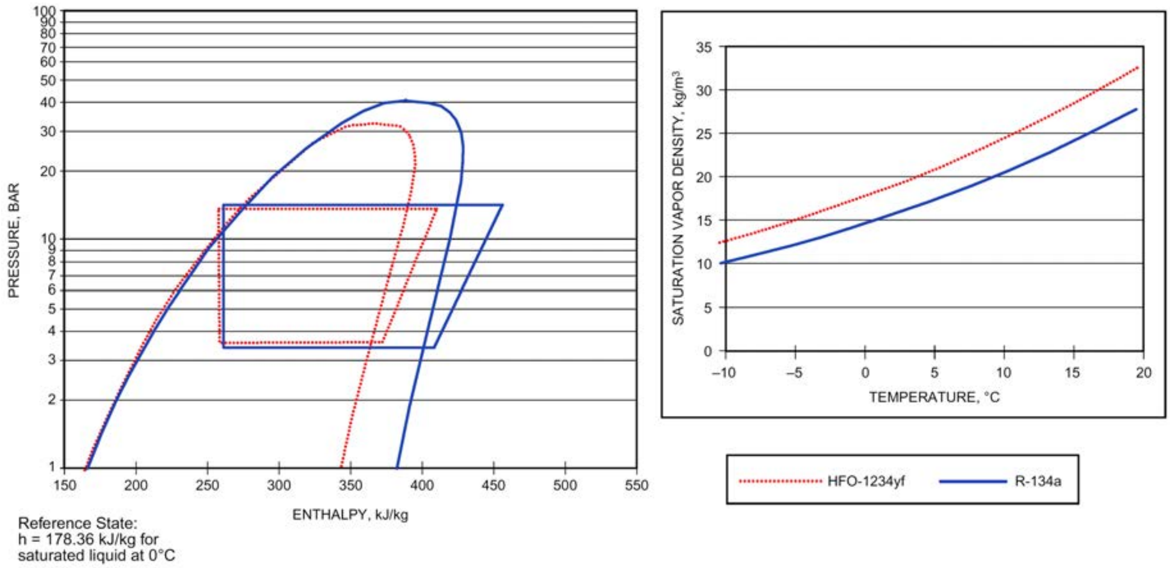

Fig. 9 Comparison of Thermodynamic Cycle Between Base Case (R-134a) and HFO-1234yf
(Spatz and Minor 2008)

than 1, which is 99.9% lower than HFC-134a, and is even less than CO_2 (GWP = 1). HFO-1234yf offers atmospheric lifetime and fuel efficiency benefits as well. This refrigerant has excellent environmental properties, low toxicity (similar to R-134a), and system performance similar to that of R-134a. It is being considered as a drop-in refrigerant for current mobile air-conditioning systems (MACS). Testing shows that both polyalkylene glycol (PAG) and polylol ester (POE) lubricants are compatible with HFO-1234yf in A/C systems with different types of compressors (Koban 2009; Spatz and Minor 2008, 2009). HFO-1234yf is being used by many OEMs globally, and as of December 2017, 45 million vehicles on the road used this refrigerant (Honeywell 2018).

Figure 9 compares R-134a and HFO-1234yf A/C cycles on the *p-h* diagram along with vapor density at suction temperatures (Spatz and Minor 2008). For HFO-1234yf, the latent heat of vaporization is lower and the vapor density at suction temperature is greater, compared to an R-134a system. Thus, for the same cooling capacity, the refrigerant mass flow rate for HFO-1234yf should be higher than in an R-134a system. Figure 10 compares the vapor pressures of the two fluids (Kontomaris and Leck 2009). Typical evaporating saturation pressures for HFO-1234yf are higher than for R-134a; HFO-1234yf pressure equals R-134a pressure at 37.8°C; and HFO-1234yf pressure is lower than R-134a above 37.8°C. Hence, in comparison to R-134a, a slightly higher evaporating pressure and slightly lower condensing pressure for HFO-1234yf reduces the pressure ratio, thereby improving system coefficient of performance (COP). Several OEMs and suppliers (Bang 2008; Mathur 2010a, 2010b, 2011a, 2011b, 2012, 2013, 2018a; Meyer 2008, 2009; Minor 2008) have conducted independent tests with HFO-1234yf. SAE also conducted tests with alternative refrigerants, including HFO-1234yf (Atkinson 2008), through cooperative research projects (Hill 2008).

European Regulation of Mobile Air Conditioning. The E.U. directive (Directive 2006/40/EC) scheduled phaseout of HFC-134a to start on January 1, 2011, for all new or significantly redesigned models introduced that year. As of that date, retrofitting vehicles with HFC-134a is not allowed. From January 1, 2017, no new vehicles sold in the E.U. can use HFC-134a or any fluorinated gas with a global warming potential higher than 150; all models must be redesigned by the 2017 deadline. Acceptable refrigerants (with a GWP < 150) include HFC-152a, CO_2, and HFO-1234yf. Refrigerant leakage rates for single- and dual-evaporator A/C systems have been defined as

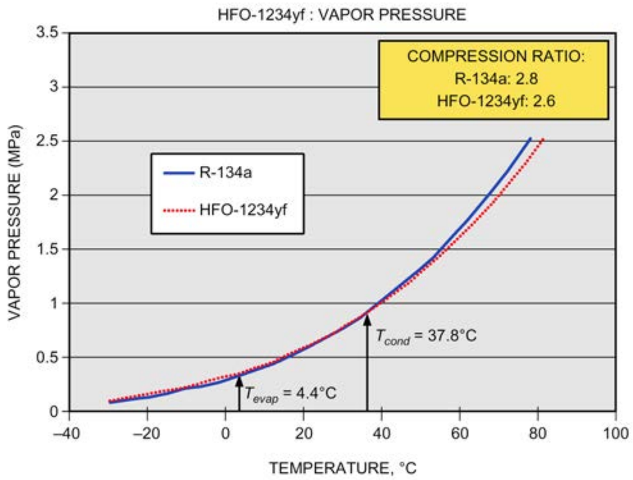

Fig. 10 Comparison of Vapor Pressure Between Base Case (R-134a) and HFO-1234yf
(Kontomaris and Leck 2009)

less than 40 and 60 g, respectively. Using non-refillable containers is no longer allowed. All fluorinated gases covered by the Kyoto protocol will be recovered.

Enhanced R-134a Systems. SAE initiated a program to improve the performance of existing R-134a systems. The goals are to (1) identify technologies to reduce mobile air-conditioning system R-134a refrigerant leakage by 50%, (2) improve R-134a mobile air-conditioning system COP by 30%, (3) reduce vehicle soak and driving heat loads by 30% over current vehicles to reduce cooling requirements, and (4) reduce refrigerant loss during service and at end of life by 50%.

Suction Line Heat Exchanger. A/C system performance can be improved by adding a suction line heat exchanger into the system. This directly influences the thermal comfort for the occupant along with fuel economy and exhaust emissions. A suction line heat exchanger in an A/C loop (1) increases system performance, (2) subcools liquid refrigerant to prevent flash gas formation at inlets to the expansion valve, and (3) fully evaporates any residual liquid that may remain in the suction line before reaching the compressor.

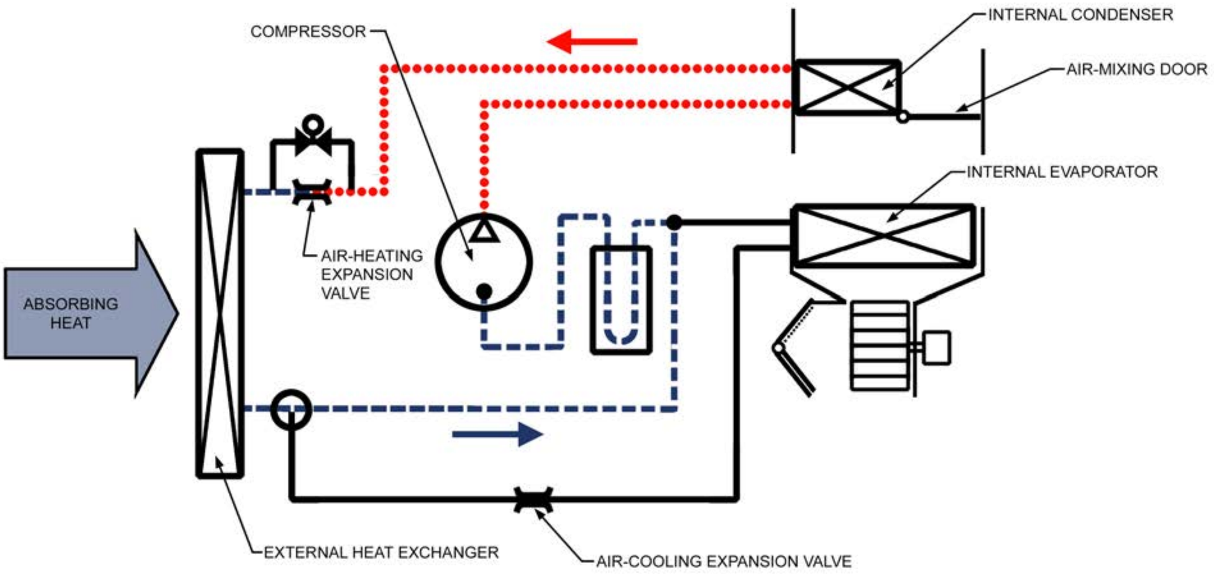

Fig. 11 Heat Pump System in Heating Mode
(Denso 2018)

Performance of mobile air conditioning systems can be enhanced from 6 to 12% (Kurata et al. 2007; Mathur 2009c, 2011a).

Electric Vehicles and Heat Pump Systems. Due to stricter environmental regulations and higher fuel economy standards from the government, car manufacturers are investigating different options for fuel economy. One of the options is electrification of the propulsion system, resulting in significant gains in fuel economy and a reduction of global warming gases. Currently, a majority of car makers either already offer electric vehicles (e.g., Nissan Leaf, GM Chevy Bolt, etc.) or have models in the process of design.

Customers expect the same level of comfort in EVs as they are accustomed to in conventional vehicles. However, heating and/or cooling has a big influence on vehicle energy efficiency. For conventional vehicles, heating and cooling affects fuel economy, but waste heat from the engine is available for heating the cabin. EVs do not have this waste heat, so it is necessary to use electric positive temperature coefficient (PTC) heaters. Using a heat pump system along with a PTC heater consumes a significant amount of battery power that could severely limit the driving range of the EV.

Typically, air-sourced heat pumps are used for the automotive industry (Feng and Hrnjak 2016). Heat pump systems are used in EVs to provide heating, cooling, and dehumidification. Electric compressor and electronic thermostatic expansion valves (TXVs) are used for the heat pump system to optimize for energy consumption. Typical automotive heat pump systems are shown in Figures 11 and 12 (Denso 2018).

Heating Mode (Figure 11). The compressor compresses low-temperature, low-pressure gas refrigerant into high-temperature, high-pressure gas refrigerant. The latter warms the vehicle cabin by releasing its heat to the cabin air as it passes through the internal condenser, while being cooled and condensed into a liquid state. The liquefied refrigerant expands across the air-heating expansion valve into a low-temperature, low-pressure gas/liquid two-phase refrigerant, extracts atmospheric thermal energy via the external heat exchanger, and flows back into the compressor.

Cooling Mode (Figure 12). The compressor compresses low-temperature, low-pressure gas refrigerant into high-temperature, high-pressure gas refrigerant. The high-temperature, high-pressure gas refrigerant passes through the internal condenser without heat exchange (the air-mixing door blocks the flow of air into the internal condenser) to the external heat exchanger where the refrigerant is cooled by the ambient air and condensed into a liquid state. The liquefied refrigerant expands across the air-cooling expansion valve into a low-temperature, low-pressure gas/liquid two-phase refrigerant, absorbs heat from the cabin air to cool the cabin as it passes through the evaporator, and then flows back into the compressor. Further details on the heat pump system and their operations are given in Chapter 49 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Advanced Technologies

HVAC suppliers are aggressively working on advancements for mobile HVAC to reduce energy consumption and improve thermal comfort for occupants. For instance, researchers are investigating using ventilated car seats to reduce air conditioning use and improve fuel efficiency without compromising thermal comfort (Lustbader 2005). Some other important technologies are as follows.

Micro Climatic Zone for Heating and Cooling. In a conventional vehicle, the entire cabin is conditioned to comfort conditions based on the set point decided by the driver. Maintaining a certain cabin temperature in winter or summer uses significant energy. Typically, for a midsized sedan, the total airflow through the HVAC unit is 150 L/s for cooling and 100 L/s for heating. In the United States, a vast majority of the vehicles are driven with only one occupant. In a conventional vehicle, the entire cabin has to be conditioned, even when only a single person is inside of the vehicle. Many companies (OEMS and suppliers) have been developing new concepts for heating and cooling by creating “micro-zones” for cooling and heating. The objective is to reduce energy consumption by providing thermal comfort to occupants on an individualized basis. In this case, the total airflow required per person to create microzones is about 7 L/s per person. Therefore, for a vehicle with four occupants, the total airflow will be 57 L/s, which is 38% of the total cabin airflow rate. This approach is extremely useful for EVs, because the HVAC energy consumption directly affects the vehicle’s driving range. **Ventilated seats** are also used by some OEMs to create microzones to provide quick thermal comfort to the occupants (Berry et al. 2017; Morishita et al. 2018).

Engine Start/Stop Feature for Energy Efficiency. In recent years, start/stop systems have been widely adopted for various vehi-

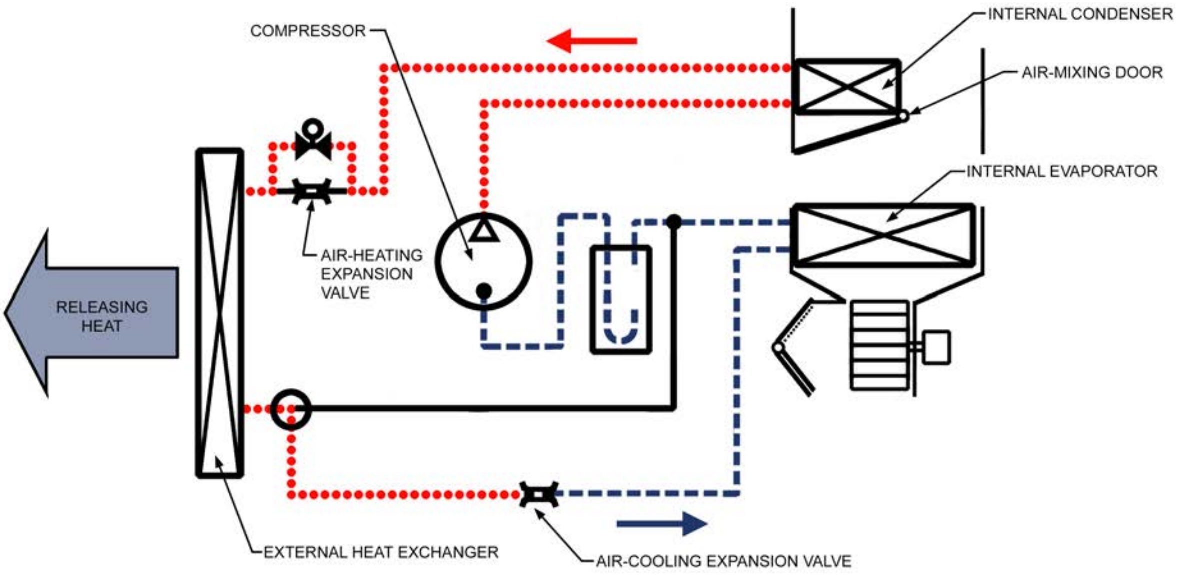

Fig. 12 Heat Pump System in Cooling Mode
(Denso 2018)

cles as a countermeasure to environmental problems caused by automobiles and to improve fuel economy. Stoppage at a red light can be 30 to 60 s; in some countries, the red light duration may be longer. According to a recent survey (Autobeat 2018), 70% of the vehicles produced in the United States will have this feature within the next 5 years. On such vehicles, air conditioner compressors driven by an engine stop when the vehicle stops at a traffic signal. As a result, comfort of occupants deteriorates because of a rise in air temperature from the A/C outlets (Uematsu et al. 2015). On the other hand, if the engine is started at a traffic signal to improve occupant comfort, the fuel economy deteriorates. To best support passenger comfort while the engine is stopped, the HVAC system should be able to continue providing thermal comfort. This can be accomplished using the following systems:

- *Secondary loop.* A secondary loop cooling system incorporates two different working fluids to provide cooling. In all systems, the primary loop is a traditional direct-expansion design that uses a phase-change refrigerant (e.g., R-134A) and a compressor to circulate the refrigerant (Ghodbane 2000; Ghodbane et al. 2007; Menken et al. 2016). Figures 3 and 4 are both schematics for traditional direct-expansion systems. A heat exchanger is used to transfer energy from the primary loop to the secondary loop, which is called a chiller (Figure 13). In most applications, the working fluid in the secondary loop is a single-phase fluid that is circulated by a pump to the cooling coil. This cooling coil is placed in the HVAC unit. Note that, in a secondary system, the heat exchanger in the HVAC is called a cooling coil (not an evaporator), given this is a single-phase fluid circuit. Typically, automotive coolant is used as the working fluid. The secondary fluid absorbs energy as the hot air passes through the cooling coil. Figure 13 is a schematic representation of this type of secondary loop. The cooled fluid is circulated in the HVAC unit through a coil that provides cold air to the cabin. The size of the chiller depends on vehicle stoppage times.
- *Evaporators with Phase-Change Materials (PCMs).* Currently, cool-storage evaporators are used on many vehicles to continue providing thermal comfort to the occupants during stops at traffic signals (LaClair et al. 2016; Sato et al. 2016). The cool-storage evaporator prevents temperature increase both of air through vents and of the cabin when the engine (and consequently the A/C compressor) stops. In cool-storage evaporators, some of the plates have phase-change material that stores the energy at cold temperatures. During a vehicle stoppage, the evaporator continues to provide thermal energy from the phase-change material. Figure 14 shows a cool storage evaporator (Morishita et al. 2018) that has five plates containing the phase-change material. These plates are stacked inside the evaporator so that the cold energy stored in these five plates, along with the aluminum heat exchanger, can be used to continue providing thermal comfort to occupants while the engine is off. Evaporators with thermal storage materials have been investigated for idle start/stop function (Automotive Engineering 2012). Many researchers have been conducting research on improvement of heating in electric vehicles using phase-change materials.

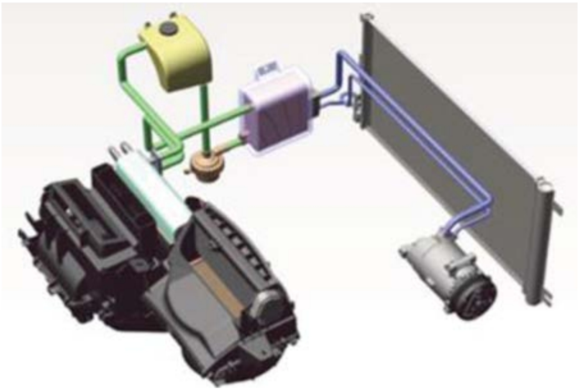

Fig. 13 Automotive HVAC Unit with a Secondary Loop
(Ghodbane 2007)

Brushless Motors. These motors are simpler than standard motors and are more reliable. Advantages include the following: (1) motor efficiency is higher, (2) commutation is accomplished electronically, (3) very high speeds and torque are possible without arcing, (4) thermal resistance is lower and the operating temperature range is thus wider, and (5) the absence of brushes reduces maintenance requirements and eliminates brush residue contamination of bearings or the environment. Because there is no brush arcing or com-

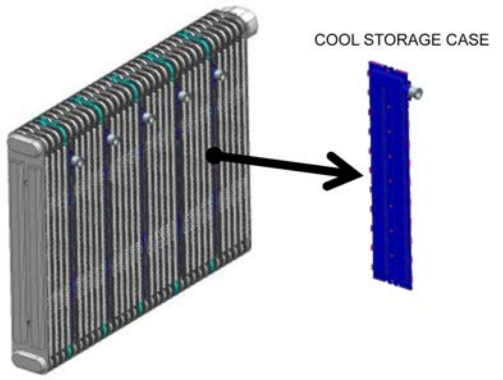

Fig. 14 Energy Storage Evaporator
(Morishita et al. 2018)

mutation, brushless motors are much quieter, both electrically and audibly.

Positive-Temperature-Coefficient (PTC) Heaters. PTC heaters are small, ceramic-based heaters that use less energy and less time to heat more quickly than conventional units. They self-regulate at a preset temperature by regulating resistance to vary their wattage. Thus, their greater thermal dissipation results in higher efficiency. These systems are maintenance-free and very reliable. PTC heaters could be used in the HVAC system to hasten cabin heating during cold start-ups by providing heat to occupants until the engine is warm (Hauck 2003).

Thermoelectric Devices. Thermoelectric devices (TEDs) are used to help create microzones to provide thermal cabin comfort. These devices work using the Peltier effect, wherein a voltage is applied between two wire joints with dissimilar materials. These devices are placed inside seats to provide quick thermal comfort to occupants (Arsie et al. 2014).

Water-Cooled Condensers. Water-cooled condensers are being investigated by OEMs and suppliers to reduce costs and space required for rejecting engine heat (Mathur et al. 2012). The advantage of this system is that a water-cooled condenser can be placed at any location, rather than just the front of the vehicle. However, the condenser head pressure increases due to high engine coolant temperatures, and that has a negative impact on vent outlet temperatures.

Magnetic Cooling. Magnetic refrigeration is a promising alternative cooling technology (Monfared et al. 2014; Yanik and Celik 2018). When a suitable magnetic material is exposed to a changing magnetic field, it undergoes a temperature change (**magneto-calorific effect**). When the material is magnetized (i.e., an increase in the magnetic field), its temperature increases. When the material is demagnetized (i.e., decrease in the magnetic field), its temperature decreases. The cooling intensity depends on the magnetic material used. Magnetic refrigeration essentially works by recapturing produced cooling energy via a heat transfer fluid, such as water. Magnetic cooling is quieter, safer, more compact, higher efficiency, and environmentally friendly (as no refrigerants are used for cooling). In MACS applications, approximately 200 W (at a Δt of 20 K; Torregrosa-Jaime et al. 2013) of cooling has been achieved with the currently available magnetic materials. A lot of research and development is being done in national laboratories, universities, and suppliers (within the United States and around the world) to develop new materials for magnets. The new material properties will result in improvement of cooling and heating power densities with relatively small magnets.

Smart Engine Cooling Systems with Electric Water Pumps (EWPs). These cooling systems use both an electric and mechanical water pump, or replace the mechanical water pump with a EWP (Wagner et al. 2003). Typically, an EWP system includes a 100 to 600 W electric pump, four-way water valve (Chanfreau and Farkh 2003), sensor, engine control management system, software, and a variable-speed radiator fan. At cold start-ups, allowing little or no flow to the radiator hastens engine warm-up, thus reducing emissions and improving fuel economy. Because the water (or coolant) temperature is precisely maintained, thermal stresses on the engine are less. Once the engine coolant is heated, this system can provide thermal comfort, even at idle or with the engine off, by pumping coolant through the heater core and running the blower.

42 V Systems. Energy requirements of modern vehicles have increased significantly as the needs of motors, actuators, and other electrical equipment have increased. Auto manufacturers are investigating using 42 V for high-load equipment (e.g., compressors, blower, condenser fans, PTC heaters, controls), and reserving the existing 12 V grid for lighting and other smaller-load accessories. This would improve air-conditioning system performance, because compressor speed would be independent of engine speed. These systems could be used for hybrid, electric, or fuel-cell vehicles.

Autonomous Vehicles. Autonomous vehicles (SAE *Standard* J3016) are self-driving, driverless, or robotic vehicles. A number of companies are working on such vehicles. Some of the proposed architecture, such as the front two seats turning 180° to face the rear occupants, is drastically different from traditional designs. These vehicles will have significant computing power (equivalent to that of about five to ten laptops) to process the data on a real-time basis. Expectations are that people will spend more time in autonomous vehicles, and that vehicle travel by nondrivers (e.g., older people who cannot drive anymore) will increase. One prediction is that a fleet of autonomous vehicles will be maintained by various companies and shared by the users, with reduced vehicle ownership. Advocates predict that by 2030 (Litman 2018), such vehicles will be sufficiently convenient and affordable to displace most human-operated vehicles, reduce driving stress, provide independent mobility to nondrivers, and be a panacea for congestion, accident, and pollution problems. The architecture of the HVAC system will be very different for autonomous vehicles. Additional heat generated by the computers will have to be removed by the HVAC system or using an independent cooling system. There is a strong need to develop extensive control strategies for heating, humidification, dehumidification, and cooling for these vehicles.

CHAPTER 12

MASS TRANSIT

Ventilation and Thermal Comfort 12.1
Thermal Load Analysis 12.2
Bus Air Conditioning 12.2
Rail Car Air Conditioning 12.5
Fixed-Guideway Vehicle Air Conditioning 12.7

THIS chapter describes air-conditioning and heating systems for buses, rail cars, and fixed-guideway vehicles that transport large numbers of people, often in crowded conditions. Air-conditioning systems for these vehicles generally use commercial components, but are packaged specifically for each application, often integral with the styling. Mass, envelope, power consumption, maintainability, and reliability are important factors. Power sources may be electrical (ac or dc), engine crankshaft, compressed air, or hydraulic. These sources are often limited, variable, and interruptible. Characteristics specific to each application are discussed in the following sections. Design aspects common to all mass-transit HVAC systems include passenger comfort (ventilation, thermal comfort, air quality, expectation) and thermal load analysis (passenger dynamic metabolic rate, solar loading, infiltration, multiple climates, vehicle velocity, and, in urban applications, rapid interior load change).

1. VENTILATION AND THERMAL COMFORT

The requirements of ASHRAE *Standards* 55 and 62.1 apply for transportation applications, with special considerations, because passengers in transit have different perceptions and expectations than typical building occupants. These considerations involve length of occupancy, occupancy turnover, infiltration, outdoor air quality, frequency and duration of door openings, personal preference, interior contamination sources such as smoking, and exterior contamination sources such as engine exhaust.

Historically, in nonsmoking air-conditioning and heating applications, outdoor air has been supplied to the vehicle interior by fans at 2.5 to 5 L/s per passenger at a predetermined nominal passenger loading. Nominal passenger load is based on the number of seats and may include a number of standees, up to the maximum number of standees possible if this type of loading is frequent. There are a few examples of no outdoor air being supplied by fans, but they are on short-duration trips such as people movers or urban buses with frequent door openings. Besides providing for survival, ventilation provides odor and contamination control. The amount needed for survival is less than the latter. Contamination control from interior sources is a factor in building design, but is less of a factor in vehicle design because of the ratio of people to furnishings and the lack of interior processes such as copy machines. Exterior contamination, such as from tunnel fumes, can be a problem, however. Door openings, if frequent enough, provide some additional intermittent ventilation, although this infiltration should be minimized for thermal comfort. Ventilation from doors may not be effective in controlling odors away from the doors. Fan-supplied outdoor air must be distributed equally in the vehicle for effective ventilation. Symptoms of inadequate ventilation are odors noticeable to passengers initially entering an occupied vehicle or when moving from section to section. Passengers on board who are exposed to slowly increasing odor levels may not be aware of them.

The preparation of this chapter is assigned to TC 9.3, Transportation Air Conditioning.

Based on ASHRAE research, ASHRAE *Standard* 161 established a ventilation rate for aircraft passengers at 3.5 L/s per passenger. This rate was based in part on the consideration that not all spaces in the enclosed area achieve 100% ventilation effectiveness. The minimum effective ventilation rate for several crowded but larger-volume spaces, as defined in ASHRAE *Standard* 62.1, is 2.5 L/s per person. It is recommended that ground mass transit applications use 3.5 L/s of outdoor air per passenger for most transit applications.

Emergency ventilation, such as windows or exits that can be opened or battery-powered ventilators, should be provided in case other systems fail. For example, a power interruption or a propulsion system failure may strand passengers in a situation where exit is not possible. Emergency situations include overtemperature, oxygen depletion, smoke, or toxic fumes. Operator-controlled dampers are now provided on some vehicles to close off fresh air when smoke or toxic fumes are encountered in tunnels. The duration that the dampers remain closed must be limited to avoid oxygen depletion, even though the air-conditioning system remains in operation. Fresh-air supply alone or battery-powered ventilators will not prevent overtemperatures when a full passenger load is present and/or a solar load exists in combination with high ambient temperature. Each emergency situation requires an independent solution.

The nature of the transit service may be roughly categorized by average journey time per passenger and interval between station stops, and this service type affects the necessary interior conditions in the vehicle. For example, a commuter rail or intercity bus passenger may have a journey time of an hour or more, with few stops; passengers may remove heavy outer clothing before being seated. In contrast, a subway or transit urban bus rider typically does not remove heavy clothing during a 10 min ride. Clothing and the environment from which passengers come, including how long they were exposed to those conditions and what they were doing (e.g., waiting for the train outdoors in winter), are important factors in transit comfort. At the opposite extreme, many subway stations are not climate controlled, and often reach dry-bulb temperatures over 38°C in the summer. Thus, when boarding a climate-controlled vehicle, these passengers immediately perceive a significant in-crease in comfort. However, a passenger adjusts to a new environment in about 10 to 20 min; after that, the traditional comfort indices begin to apply, and the same interior conditions that were perceived as comfortable may now be perceived as less than comfortable. Before stabilization, a passenger may prefer higher-velocity air or cooler or warmer temperatures, depending to some extent on clothing. At the same time, other passengers may already have stabilized and have completely different comfort control desires. Therefore, the transit system designer is presented with a number of unusual requirements in providing comfort for all.

Jones et al. (1994) evaluated the heat load imposed by people under transient weather and activity conditions as opposed to traditional steady-state metabolic rates. An application program, TRANMOD, was developed that allows a designer to predict the thermal loads imposed by passengers (Jones and He 1993). Variables are activity, clothing, wet- and dry-bulb temperatures, and precipitation.

European Committee for Standardization (CEN) *Standard* EN 13129-1 provides guidance in the area of railroad passenger comfort. Although this standard does not apply to countries outside the CEN, the information is valuable and may not be readily available elsewhere.

2. THERMAL LOAD ANALYSIS

Cooling Design Considerations

Thermal load analysis for transit applications differs from stationary, building-based systems because vehicle orientation and occupant density change regularly on street-level and subway vehicles and, to a lesser degree, on commuter and long-distance transportation. Summer operation is particularly affected because cooling load is affected more by solar and passenger heat gain than by outdoor air conditions. ASHRAE *Standard* 55 design parameters for occupant comfort may not always apply. Vehicle construction does not allow the low thermal conductivity levels of buildings, and fenestration material must have safety features not necessary in other applications. For these reasons, thermal loads must be calculated differently. Because main-line passenger rail cars and buses must operate in various parts of the country, the air conditioning must be designed to handle the national seasonal extreme design days. Commuter and local transit vehicles operate in a small geographical area, so only local design ambient conditions need be considered.

The following cooling load components should be considered:

- Ambient air conditions for locations in North America and worldwide are given in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*. For vehicles operating in an urban area, the heat island effect should be considered if the Handbook design values are derived from remote reporting stations. For subway car operation, tunnel temperatures should be considered. In humid regions, consider the wet-bulb temperature coincident with dry-bulb temperature relative to fresh-air loads.
- For vehicle interior comfort conditions, consult Figure 5 in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*. Total heat gain from passengers depends on passenger activity before boarding the vehicle, waiting time, journey time, and whether they are standing or seated during the journey. Representative values are given in Table 1 in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*.
- Ventilation air loads should be calculated using the method in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*, in the section on Infiltration and Moisture Migration Heat Gains. Air leakage and air entering during door dwell time should be taken into account.
- Interior heat includes that produced by the evaporator fan motor, indoor lighting, and electrical controls.
- The vehicle's conductivity, in W/K, should be provided by the vehicle designers. For outdoor skin temperature guidance, use the values in Table 1 in Chapter 29 of the 1997 *ASHRAE Handbook—Fundamentals*; however, consider that air over a vehicle in motion reduces these temperatures The car design dry bulb should be used as the interior temperature.
- The instantaneous solar gain through the glazing should be calculated using summer midafternoon data listed in Chapter 29 of the 1997 *ASHRAE Handbook—Fundamentals*, and the glass shading coefficient. The glass shading coefficient must be obtained from the window supplier. Adjustments for frequent change in vehicle direction or intermittent solar exposure may be justified. Additional information is shown in Chapter 15 of the 2017 *ASHRAE Handbook—Fundamentals*

The summer cooling analysis should be completed for different times of the day and different passenger densities to verify a reliable result. Cooling equipment capacity should consider fouling and eventual deterioration of heat transfer surfaces.

Heating Design Considerations

Winter outdoor design conditions can be taken from Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*. Interior temperatures can be taken from Figure 5 in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*. During winter, conductivity is the major heat loss. The heat required to temper ventilation air and to counteract infiltration through the body and during door openings must also be considered.

Other Considerations

Harsh environments and the incursion of dirt and dust inhibit the efficiency of HVAC units. Specifications should include precise maintenance instructions to avoid capacity loss and compromised passenger comfort.

3. BUS AIR CONDITIONING

In general, bus air-conditioning systems can be classified as interurban, urban, or small/shuttle bus systems. Bus air-conditioning design differs from other air-conditioning applications because of climatic conditions in which the bus operates, equipment size limitations, vehicle engine, electrical generator, and compressor rev/s. Providing a comfortable climate inside a bus passenger compartment is challenging because the occupancy rate per unit of surface and air recirculation volume is high, glazed area is very large, and outdoor conditions are highly variable. Factors such as high ambient temperatures, dust, rain, snow, road shocks, hail, and sleet should be considered in the design. Units should operate satisfactorily in ambient conditions from –30 to 50°C.

Ambient air quality must also be considered. Air intakes are usually subjected to thermal contamination from road surfaces, condenser air recirculation, or vehicle engine radiator air discharge. Vehicle motion also introduces pressure variables that affect condenser fan performance. In addition, engine speed governs compressor speed, which affects compressor capacity. R-134a is the current refrigerant of choice, but some units operate with refrigerants such as R-22 (pre-2010 production) and R-407C.

Bus air conditioners are initially performance-tested as units in a climate-controlled test cell. Performance tests encompass unit operation at different compressor speeds to make sure the compressor performance parameters [e.g., unit operation at maximum and minimum ambient conditions, thermostatic expansion valve (TXV) sizing, oil return, and vibration/shock] are within boundaries. In addition, individual components should be qualified before use. Larger test cells that can hold a bus are commonly used to verify installed unit performance. These tests are to measure the amount of time required to reduce the vehicle's interior temperature to a specified value, and they vary in performance and time requirements. Some commonly accepted tests include the Houston pulldown (extreme heat or performance when using higher-pressure refrigerant gas such as R-407C), modified pulldown (mild to hot climates with R-134a or equivalent), white book pulldown (mild to hot climates), and the profile test (mild to hot climates, 35 and 46.1°C ambient). All these tests are described in American Public Transportation Association (APTA) standard bus procurement and recommended practices for transit bus HVAC system instrumentation and performance testing.

Reliability and ease of maintenance are also important design considerations. All parts requiring service or regular maintenance should be readily accessible, and repairs should be achievable without removing any additional components and within a minimum time.

Heat Load

The main parameters that must be considered in bus air-conditioning system design include

- Occupancy data (number of passengers, distance traveled, distance traveled between stops, typical permanence time)
- Dimensions and optical properties of glass
- Outdoor weather conditions (temperature, relative humidity, solar radiation)
- Dimensions and thermal properties of materials in bus body
- Indoor design conditions (temperature, humidity, air velocity)
- Power and torque limitations of bus engine

The heating or cooling load in a passenger bus may be estimated by summing the heat flux from the following loads:

- Solid walls (side panels, roof, floor)
- Glass (side, front, and rear windows)
- Passengers
- Engine and ventilation (difference in enthalpy between outdoor and indoor air)
- Evaporator fan motor

Extreme loads for both summer and winter should be calculated. The cooling load is the most difficult load to handle; the heating load is normally handled by heat recovered from the engine, external heater, or electrical heat elements. An exception is that an idling engine provides marginal heat in very cold climates. Andre et al. (1994) and Jones and He (1993) describe computational models for calculating the heat load in vehicles, as well as for simulating the thermal behavior of the passenger compartment.

The following conditions can be assumed for calculating the summer heat load in an interurban vehicle similar to that shown in Figure 1:

- Capacity of 50 passengers
- Insulation thickness of 25 to 40 mm
- Double-pane tinted windows
- Outdoor air intake of 190 L/s
- Road speed of 100 km/h
- Indoor design temperatures of 16 to 27°C and 50% rh
- Ambient temperatures for location as listed in Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals*

Loads from 12 to 35 kW are calculated, depending on outdoor weather conditions and geographic location. The typical distribution of the different heat loads during a summer day at 40⊕ north latitude is shown in Figure 2.

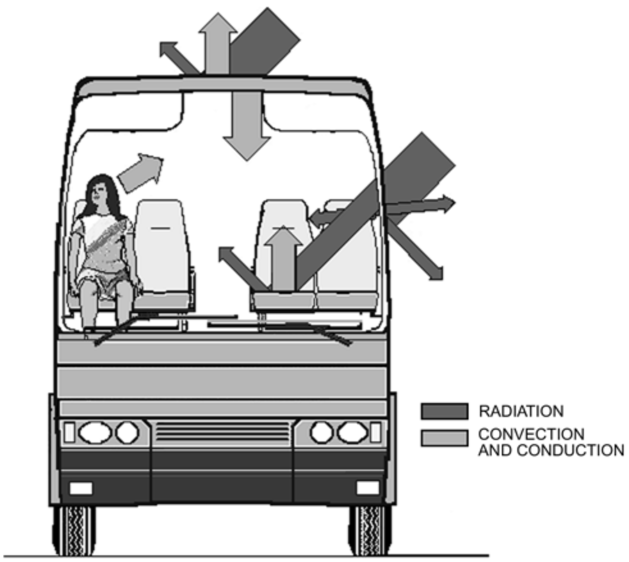

Fig. 1 Distribution of Heat Load (Summer)

Air Distribution

Air-conditioning units are configured to deliver air through ducts to outlets above the windows and to the middle aisle or to act as free-blow units. In the case of free-blow units, louvers guide the air distribution inside the bus.

Interurban Buses

These buses are designed to accommodate up to 56 passengers. The air-conditioning system is usually designed to handle extreme conditions. Interurban buses produced in North America are likely to have the evaporator and heater located under the passenger compartment floor. A four- or six-cylinder reciprocating compressor, in which some cylinders are equipped with unloaders, is popular. Some interurban buses have a separate engine-driven compressor, preferably scroll, to give more constant system performance. Figure 3 shows a typical air-conditioning arrangement for an interurban bus.

Urban Buses

Urban bus heating and cooling loads are greater than those of the interurban bus. A city bus may seat up to 50 passengers and carry a "crush load" of standing passengers. The fresh-air load is greater because of the number of door openings and the infiltration around

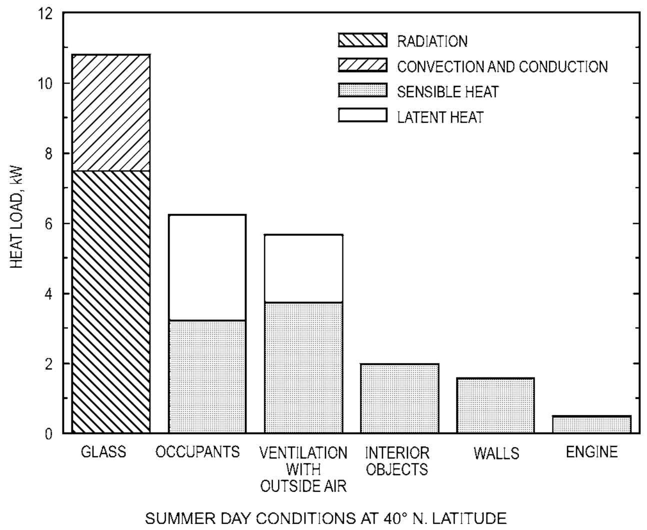

Fig. 2 Typical Main Heat Fluxes in Bus

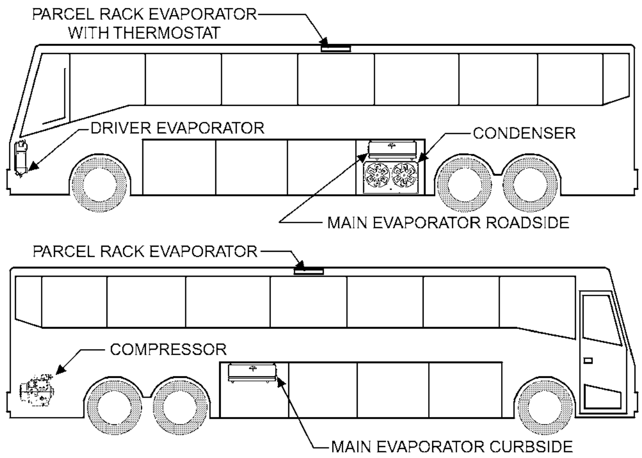

Fig. 3 Typical Arrangement of Air-Conditioning in Interurban Bus

doors. Cooling capacity required for a typical 50-seat urban bus is from 20 to 35 kW. The buses are usually equipped with a roof- or rear-mounted unit, as shown in Figure 4. One or two compressors are usually belt- or shaft-driven from the propulsion engine. Capacity control is very important, because the compressor may turn more quickly than necessary at high engine speeds. Therefore, capacity control must compensate for not only the thermal load but also the engine-induced load. Cylinder unloaders are the primary means of capacity control, although evaporator pressure regulators have been used with non-unloading compressors, as shown in Figure 4. This configuration was used on buses produced between 1975 and 1995.

The heater is located just downstream of the evaporator. Hot coolant from the engine-cooling system provides sufficient heat for most operations; however, additional sources may be required in colder climates for longer idling durations. Additional floor heaters may also be required to reduce the effects of stratification. Conditioned air is delivered through overhead combination light fixture/diffuser ducts (see Figure 5).

Low-profile, self-contained, rooftop-mounted units are used for urban and interurban buses. These units contain the entire air-conditioning system except for the compressor, which is shaft- or belt-driven from the bus engine (see Figure 6).

Because of increased air pollution and other environmental issues (e.g., noise, fuel consumption, unnecessary engine wear), using traditional engine-driven compressors for interurban, urban, or school bus or motor home air comfort systems is a great disadvantage, especially for parked vehicles. In response to these issues, most modern and efficient buses use **unitized electric packaged air-conditioning (UEPAC)** units, as shown in Figures 7 and 8. UEPACs have a self-contained, lightweight, integrated, modular design incorporating evaporators, condensers, valves, liquid receiver, filter-drier, electric heater elements, automatic climate controls, and scroll compressors. Electric power is supplied to the UEPAC system from onboard sources for hybrid electric and fuel-cell buses, or by a main-engine-driven generator on more traditional fuel or hybrid applications without an accessory power option. These systems enable use of shore (wayside) power while parked, eliminating idling where power is available.

Small or Shuttle Buses

For small or shuttle buses such as those typically operating around airports or for schools, the evaporator is usually mounted in the rear and the condenser on the side or the roof of the bus. The evaporator unit is typically a free-blow unit.

Refrigerant Piping

See Chapters 1 and 8 of the 2018 *ASHRAE Handbook—Refrigeration* for standard refrigerant piping practices. All components in the bus air-conditioning system are interconnected by copper tubing

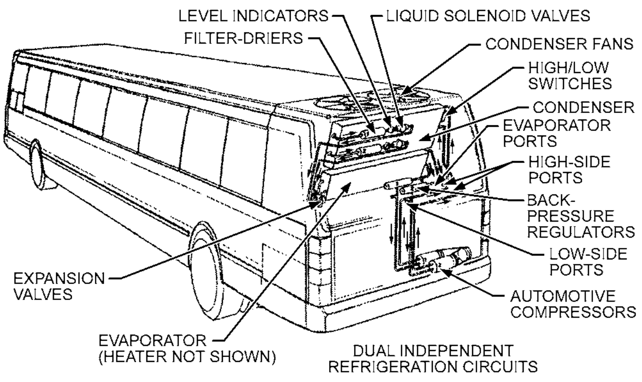

Fig. 4 Typical Mounting Location of Urban Bus Air-Conditioning Equipment

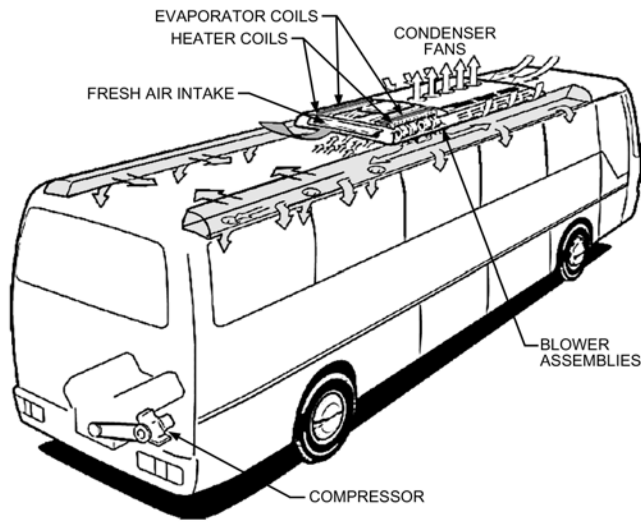

Fig. 6 Typical Mounting Location of Roof-Mounted Urban Bus Air-Conditioning Equipment with Single Compressor

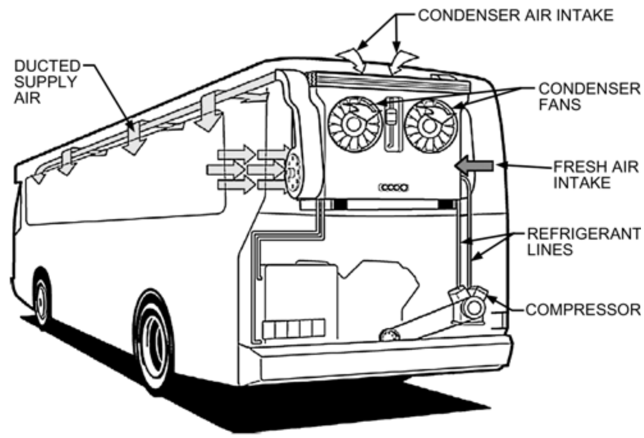

Fig. 5 Typical Mounting Location of Urban Bus Air-Conditioning Equipment with Single Compressor

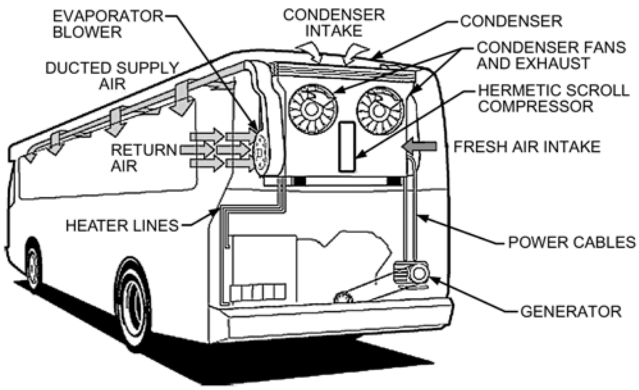

Fig. 7 Typical Mounting Location of Urban Bus Fully Electric Rear-Mounted Air-Conditioning Equipment with ac Generator

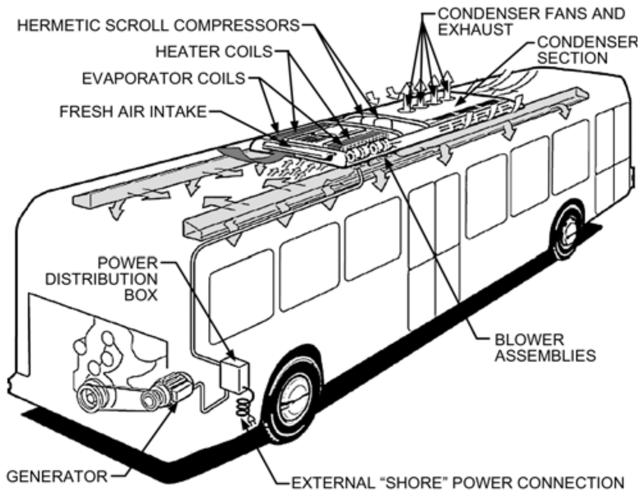

Fig. 8 Typical Mounting Location of Urban Bus Fully Electric Roof-Mounted Air Conditioning Equipment with ac Generator

or refrigerant hose. When using copper tubing, care should be taken to analyze the effect of vibration on the tubing. Vibrational effects can be minimized by using vibration absorbers or other shock-cushioning devices. When using refrigerant hose, properties such as moisture ingression, effusion, maximum operating temperature, and burst pressure need to be taken into account. The refrigerant hose chosen should have the minimum amount of wax extractables on interaction with oil and the refrigerant.

Shock and Vibration

Most transport air-conditioning manufacturers design components for shock loading and vibrational inputs. Vibration eliminators, flexible lines, and other shock-cushioning devices interconnect the various air-conditioning components. The vibration characteristics of each component are different; in addition, the evaporator and the condenser must undergo individual vibration and shake tests. The input levels for the shake test can be based on the worst road conditions that the bus will encounter. This input level will vary because of the mass of the unit and its mounting.

System Safety

Per the U.S. Department of Transportation, all buses with air-conditioning systems operating in North America should conform to Federal Motor Vehicle Safety *Standard* (FMVSS) 302 for flammability standards. In addition, all evaporator units inside the vehicle should be mounted away from the head impact zone, as specified by FMVSS 222.

Controls

Most buses have a simple driver control to select air conditioning, heating, or automatic operation (air conditioning, heating, and reheat). In both modes, a thermal sensing element controls these systems with on/off circuitry and actuators. Many systems use solid-state control modules to interpret the bus interior and outdoor ambient temperatures and to generate signals to operate full or partial cooling, reheat, or heating functions. These systems use thermistor temperature sensors, which are usually more stable and reliable than electromechanical controls. Control systems for urban buses can also include an outdoor-air ventilation cycle. The percentage of fresh-air intake during the ventilation cycle can vary based on individual requirements.

4. RAIL CAR AIR CONDITIONING

Passenger rail car air-conditioning systems are generally electromechanical, direct-expansion units. R-22, a hydrochlorofluorocarbon (HCFC), has been the refrigerant most commonly used since the phase-out for R-12. R-134a, a medium-pressure refrigerant, has been used as a retrofit refrigerant in North America on systems originally designed to operate with R-12, and is commonly used in Europe for new equipment, mainly variable-speed screw compressors that are competitive in mass to R-22 reciprocating compressors. Most equipment placed in service before the January 1, 2010, ban on manufacturing new R-22 equipment has used R-407C as the refrigerant. R-410A has been used in some equipment; however, it can only be used in relatively mild climates because the condensing temperatures found in transit applications may approach the refrigerant's critical point. In 2009, the U.S. Environmental Protection Agency (EPA) added R-438A to its significant new alternatives policy (SNAP) list of approved refrigerants for motor vehicle air conditioning use.

Electronic, automatic controls are common, with a trend toward microprocessor control with increasing capability for fault monitoring and logging. Electric heating elements in the air-conditioning unit or supply duct temper outdoor air brought in for ventilation and are also used to control humidity by reheating the conditioned supply air during cooling partial-load conditions.

Air-cycle technology has been tested for passenger rail car air conditioning in Germany (Giles et al. 1997); however, issues of greater mass, higher cost, and low efficiency need to be addressed before it is widely accepted.

Vehicle Types

Main-line intercity passenger rail service generally operates single and multilevel cars hauled by a locomotive. Locomotive-driven alternators or solid-state inverters distribute power via an intercar cable power bus to air-conditioning equipment in each car. A typical rail car has a control package and two air-conditioning systems. The units are usually either split, with the compressor/condenser units located in the car undercarriage area and the evaporator-blower portion mounted in the ceiling area, or self-contained packages mounted in interior equipment rooms. Underfloor and roof-mounted package units are less common in intercity cars.

Commuter cars used to provide passenger service from the suburbs into and around large cities are similar in size to main-line cars. Air-conditioning equipment generally consists of two evaporator-heater fan units mounted above the ceiling with a common or two separate underfloor-mounted compressor-condenser unit(s) and a control package, or self-contained packaged units mounted on the roof. These cars may be locomotive hauled, with air-conditioning arrangements similar to main-line intercity cars, but they are often self propelled by high-voltage direct-current (dc) or alternating-current (ac) power supplied from an overhead catenary or from a dc-supplied third-rail system. On such cars, the air conditioning may operate on ac or dc power. Self-propelled diesel-driven vehicles that use onboard-generated power for the air-conditioning systems still operate in a few areas.

Subway and **elevated rapid-transit cars** usually operate on a third-rail dc power supply. In the past, the air-conditioning system motors were commonly powered directly from the third-rail dc supply voltage. Most new equipment operates from three-phase ac power provided by a solid-state inverter. The inverter may be either an independent system or a component of the HVAC system. Split air-conditioning systems are common, with evaporators in the interior ceiling area and underfloor-mounted condensing sections, although unitary package units mounted on the roof or under the floor are increasingly common.

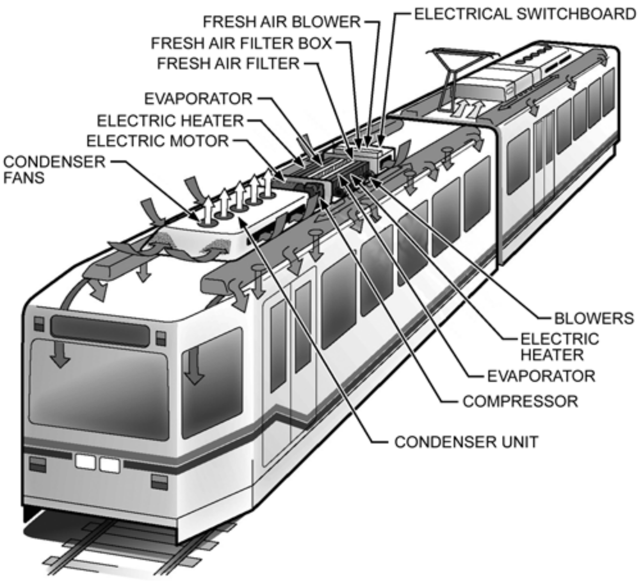

Fig. 9 Typical Light Rail Vehicle with Roof-Mounted HVAC System

Streetcars and **light-rail vehicles** usually run on ac or dc power transmitted via an overhead catenary wire, and have air-conditioning equipment similar to rapid-transit cars. Roof-mounted packages are used more often than undercar or split systems. This is largely because of the lack of undercar space. Figure 9 shows a typical configuration for these vehicles.

Equipment Design Considerations

Design considerations unique to transit HVAC equipment include the characteristics of the available power supply, mass limits, type of vehicle, and vehicle service parameters. Thus, ac-powered, semihermetic or hermetic compressors, which are lighter than open machines with dc motor drives, are a common choice. However, each car design must be examined in this respect because dc/ac inverters may increase not only the total mass, but also the total power draw, because of conversion losses.

Other concerns in equipment selection include the space required, location, accessibility, reliability, and maintainability. Interior and exterior equipment noise levels must be considered both during the early stages of design and later, when the equipment is coordinated with the car builder's ductwork and grilles.

Compressors. Reciprocating and vane compressors are commonly used, although scroll compressors are becoming increasingly common. The scroll compressor is inherently more tolerant of flooded starts and liquid slugging common in the rail application than any other type of positive-displacement compressor. The low clearance volume of the scroll compressor allows it to operate at high discharge pressure more effectively than reciprocating compressors. Lower mass and less vibration and noise are benefits, as well.

Power Supply Characteristics. Vehicles that draw their power from a stationary supply, such as a third rail or overhead catenary wire, are subject to frequent power interruptions as the train passes through gaps in the third rail or phase breaks in the overhead. These interruptions cause the HVAC equipment to shut down independently of the control system, and the design must take into account these losses of power and the subsequent need to restart the equipment. Vehicles that generate electrical power from an onboard source are less affected by power interruptions, although their capacity is limited. In either case, HVAC system control design must be coordinated with the vehicle's power supply and distribution system to avoid overloading vehicle systems during both steady-state and start-up (in-rush current) conditions. Additionally, it is desirable to prevent the vehicle's power supply from intentionally removing power from the HVAC equipment without an orderly shutdown sequence (including a pump-down cycle, if necessary).

Configuration and Space Constraints. Space underneath and inside a rail car is at a premium. Components are usually built to fit the configuration of the available space. Overall car height, roof profile, ceiling cavity, and wayside clearance restrictions often determine the shape and size of equipment.

Special Environmental Considerations. Dirt and corrosion constitute an important design factor, especially if the equipment is beneath the car floor, where it is subject to extremes of weather and severe dirt conditions. For this reason, corrosion-resistant materials and coatings must be selected. Aluminum has not proved durable in exterior exposed applications; the sandblasting effect tends to degrade any surface treatment on it. Because dirt pickup cannot be avoided, the equipment must be designed for quick and easy cleaning; access doors should be provided, and evaporator and condenser fin spacing is usually limited to 2.5 to 3.2 mm. Closer spacing causes more rapid dirt build-up and higher cleaning costs. Dirt and severe environmental conditions must also be considered in selecting motors and controls.

Maintenance Provisions. Railroad HVAC equipment is subjected to mechanical shock and vibration during operation, is frequently required to operate under conditions of elevated condensing temperature and pressure, and is subjected to frequent on/off cycling because of power supply interruptions and other conditions that are not typical for a stationary application. As a consequence, the rail HVAC system's components are more highly stressed than equivalent components in a stationary system, and thus require more frequent maintenance and servicing. Because a passenger rail car with sealed windows and a well-insulated structure becomes almost unusable if the air conditioning fails, high reliability is important. Equipment design needs to consider the ease of routine service and time needed to diagnose and repair the system. The control equipment thus often incorporates monitoring and diagnostic capabilities to allow quick diagnosis and correction of a failure. However, many trains are designed with several individual vehicles permanently coupled together, in which case the failure of a single HVAC unit causes multiple cars to become unavailable for service while the HVAC system is diagnosed and repaired. The time to diagnose and repair a system varies. Railroads, by their nature, are schedule driven, and varying, unknown repair time is incompatible with the need to provide scheduled service. Therefore, many users are moving away from fully on-car-serviceable air conditioners and toward modular, self-contained units with hermetically sealed refrigerant systems. These units are designed for rapid removal and replacement to allow the vehicle to return to service in a short, predictable time. The faulty HVAC equipment is diagnosed and repaired off-car in a dedicated air-conditioning service area.

Safety. Security of the air-conditioning equipment attachment to the vehicle must be considered, especially on equipment located beneath the car. Vibration isolators and supports should be designed to safely retain the equipment on the vehicle, even if the vibration isolators or fasteners fail completely. A piece of equipment that dangles or drops off could cause a train derailment. All belt drives and other rotating equipment must be safety guarded. High-voltage controls and equipment must be labeled by approved warning signs. Pressure vessels and coils must meet ASME test specifications for protection of passengers and maintenance personnel. Materials selection criteria include low flammability, low toxicity, and low smoke emission.

Special Design Considerations. The design, location, and installation of air-cooled condenser sections must allow for the possibility of hot condenser discharge air recirculation into the condenser inlet (in the case of split systems), or into the outdoor air intakes (in the case of roof-mounted unitary systems), as well as hot condenser discharge from trains on adjacent tracks that may occur at passenger loading platforms or in tunnels. To prevent a total system shutdown because of high discharge pressure, a capacity reduction control device is typically used to reduce the cooling capacity before system pressure reaches the high-pressure safety switch setting, thus temporarily reducing discharge pressure.

Even with coordination between the HVAC controls and the vehicle's power supply or distribution system, abrupt shutdown of the refrigeration system caused by power loss is common. The typical split-system arrangement places the compressor at or near the low point in the system. The combination of these factors results in undesired migration of refrigerant to the compressor during the *off* cycle. To reduce the likelihood of flooded compressor starts, using a suction line accumulator and crankcase heater is recommended.

Other Requirements

Most cars are equipped with both overhead and floor heat, typically provided by electric resistance elements. The control design commonly uses overhead heat to raise the temperature of the recirculated and ventilation air mixture to slightly above the car design temperature, while floor heat offsets heat loss through the car body. This arrangement is intended to limit stratification in the passenger compartment by promoting buoyant, convective air circulation. Times of maximum occupancy, outdoor ambient, and solar gain must be ascertained. The peak cooling load on urban transit cars usually coincides with the evening rush hour, and the peak load on intercity rail cars occurs in the midafternoon.

Heating capacity for the car depends on body construction, car size, and the design area-averaged relative wind-vehicle velocity. In some instances, minimum car warm-up time may be the governing factor. On long-distance trains, the toilets, galley, and lounges often have exhaust fans. Ventilation airflow must exceed forced exhaust air rates sufficiently to maintain positive car pressure. Ventilation air pressurizes the car and reduces infiltration.

Air Distribution and Ventilation

The most common air distribution system is a centerline supply duct running the length of the car between the ceiling and the roof. Air outlets are usually ceiling-mounted linear slot air diffusers. Louvered or egg crate recirculation grilles are positioned in the ceiling beneath the evaporator units. The main supply duct must be insulated from the ceiling cavity to prevent thermal gain/loss and condensation. Taking ventilation air from both sides of the roof line helps overcome the effect of wind. Adequate snow and rain louvers and, in some cases, internal baffles, must be installed on the outdoor air intakes. Separate outdoor air filters are usually combined with either a return or mixed-air filter. Disposable media or permanent, cleanable air filters are used and are usually serviced every month. Some long-haul cars, such as sleeper cars, require a network of delivered-air and return ducts. Duct design should consider noise and static pressure losses.

Piping Design

Standard refrigerant piping practice is followed. Pipe joints should be accessible for inspection and, on split systems, not concealed in car walls. Evacuation, leak testing, and dehydration must be completed successfully after installation and before charging. Piping should be supported adequately and installed without traps that could retard the flow of lubricant back to the compressor. Pipe sizing and arrangement should be in accordance with Chapter 1 of the 2018 *ASHRAE Handbook—Refrigeration*. Evacuation, dehydration, and charging should be performed as described in Chapter 8 of that volume. Piping on packaged units should also conform to these recommendations.

Control Requirements

Rail HVAC control systems typically automatically transition between cooling and heating operation, based on interior and exterior dry-bulb temperature. The cooling and heating set points are generally different. This difference provides a control dead band to prevent the system from cycling directly between cooling and heating, and accommodates passengers' seasonal clothing. System capacity is matched to part-load conditions with some combination of evaporator coil staging, evaporator fan speed control, compressor cylinder unloading, or variable-speed compressor control in cooling mode, and staging or duty cycling of heat in heating mode. The control system typically does not consider latent heat information in the control algorithm, although reheat is commonly used to increase the apparent interior sensible load as the interior dry-bulb temperature falls below the desired cooling set point, to maintain humidity removal. Unitary systems may use hot-gas bypass for this purpose rather than electric reheat. If the interior dry-bulb temperature falls below the desired cooling set point, even with capacity reduction and reheat, the refrigeration system will shut down and the HVAC system will provide ventilation only. If the interior temperature drops to the heating set point, the system transitions to heating mode. Before the development of analog electronic or microprocessor control systems, this dry-bulb based control algorithm was implemented by banks of thermostats. This arrangement resulted in multiple, load-dependent interior set points as the system established quasi-equilibrium conditions within the dead band of each individual thermostat. When analog electronic controls were introduced in the early 1980s, they emulated this thermostat-based control algorithm, which is still often followed today in North America. Recently, several European and Asian HVAC manufacturers have introduced proportional-integral-derivative (PID) control systems, common in those markets for several years, to the North American market. Higher energy costs and greater environmental concern in Europe and Asia have led some manufacturers to include energy conservation algorithms in controls intended for use in those markets.

The availability of robust, low-cost humidity sensors may lead to the use of latent heat information in control algorithms.

A pumpdown cycle and low-ambient lockout are recommended on split systems to protect the compressor from damage caused by liquid flooding the compressor and subsequent flooded starts. In addition, the compressor may be fitted with a crankcase heater that is energized during the compressor off cycle.

5. FIXED-GUIDEWAY VEHICLE AIR CONDITIONING

Fixed-guideway (FGW) systems, commonly called people movers, can be monorails or rubber-tired cars running on an elevated or grade-level guideway, as seen at airports and in urban areas. The guideway directs and steers the vehicle and provides electrical power to operate the car's traction motors (in some cases, the vehicle is propelled by a metal cable, driven by a motor mounted at the end of the guideway), lighting, electronics, air conditioner, and heater. People movers are usually unstaffed and computer-controlled from a central point. Operations control determines vehicle speed, headway, and the length of time doors stay open, based on telemetry from individual cars or trains. Therefore, reliable and effective environmental control is essential.

People movers are usually smaller than most other mass-transit vehicles, generally having spaces for 8 to 40 seated passengers and generous floor space for standing passengers. Under some conditions of passenger loading, a 12 m car can accommodate 100 passengers. The wide range of passenger loading and solar exposure make it essential that the car's air conditioner be especially responsive to the amount of cooling required at a given moment.

System Types

The HVAC for a people mover is usually one of three types:

- Conventional undercar condensing unit and compressor unit (which includes control box) connected with refrigerant piping to an evaporator/blower unit mounted above the car ceiling
- Packaged, roof-mounted unit having all components in one enclosure and mated to an air distribution system built into the car ceiling
- Packaged, undercar-mounted unit mated to supply and return air ducts built into the car body

Some vehicles are equipped with two systems, one at each end; each system provides one-half of the maximum cooling requirement. U.S. systems usually operate on the guideway's power supply of 460 to 600 V (ac), 60 Hz. Some newer systems with dc track power operate on 240 V (ac), 60 Hz from an inverter. Figures 10 and 11 show some arrangements used with fixed-guideway people mover vehicles, although similar arrangements could also apply to rail.

Refrigeration Components

Because commercial electrical power is available, standard semihermetic reciprocating compressors and commercially available fan motors and other components can be used. Compressors generally have one or two stages of unloaders, and/or hot-gas bypass is used to maintain cooling at low loads. Newer systems use scroll compressors with speed control, displacement control, or hot-gas bypass to control capacity. Condenser and evaporator coils are copper tube with copper or aluminum fins. Generally, flat fins are preferred for undercar condensers to make it simpler to clean the coils. Evaporator/blower sections must often be designed for the specific vehicle and fitted to its ceiling contours. Condensing units must also be arranged to fit in the limited space available and still ensure good airflow across the condenser coil. Because of the phaseout of R-22, R-407C is commonly used to meet environmental standards (zero ozone depletion potential). Some existing R-22 systems are being retrofitted with R-407C and R-422D.

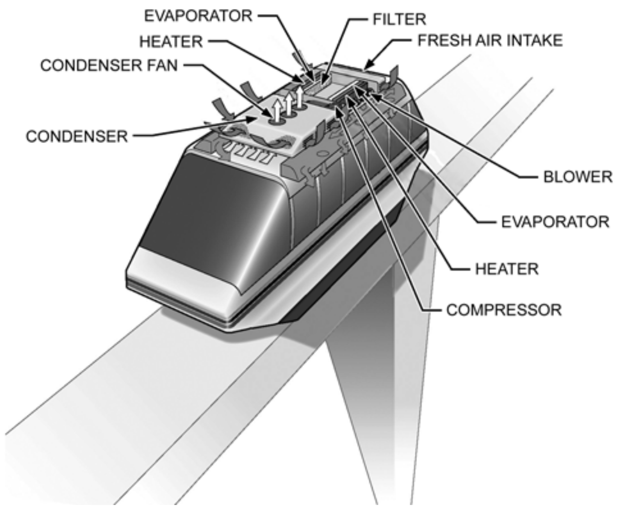

Fig. 10 Typical Small Fixed-Guideway Vehicle with Roof-Mounted HVAC System

Heating

Where heating must be provided, electric resistance heaters that operate on the guideway power supply are installed at the evaporator unit discharge. One or two stages of heat control are used, depending on the size of the heaters.

Controls

A solid-state control is usually used to maintain interior conditions, although newer systems use programmable logic controller (PLC) microprocessor-based controllers. The cooling set point is typically between 23 and 24°C. For heating, the set point is 15.6 to 20°C. Some controls provide humidity control by using electric heat. Between the cooling and heating set points, blowers continue to operate on a ventilation cycle. On rare occasions, two-speed blower motors are used, switching to low speed for the heating cycle. Some controls have internal diagnostic capability and can signal the operations center when a cooling or heating malfunction occurs.

Ventilation

With overhead air-handling equipment, outdoor air is introduced into the return airstream at the evaporator entrance. Outdoor air is usually taken from a grilled or louvered opening in the end or side of the car. Depending on the configuration of components, fresh air is filtered separately or directed so that the return air filter can handle both airstreams. For undercar systems, a similar procedure is used, except air is introduced into the system through an intake in the undercar enclosure. In some cases, a separate fan is used to induce outdoor air into the system.

The amount of mechanical outdoor air ventilation is usually expressed as litres per second per passenger on a full-load continuous basis. Passenger loading is not continuous at full load in this application, with the net result that more outdoor air is provided

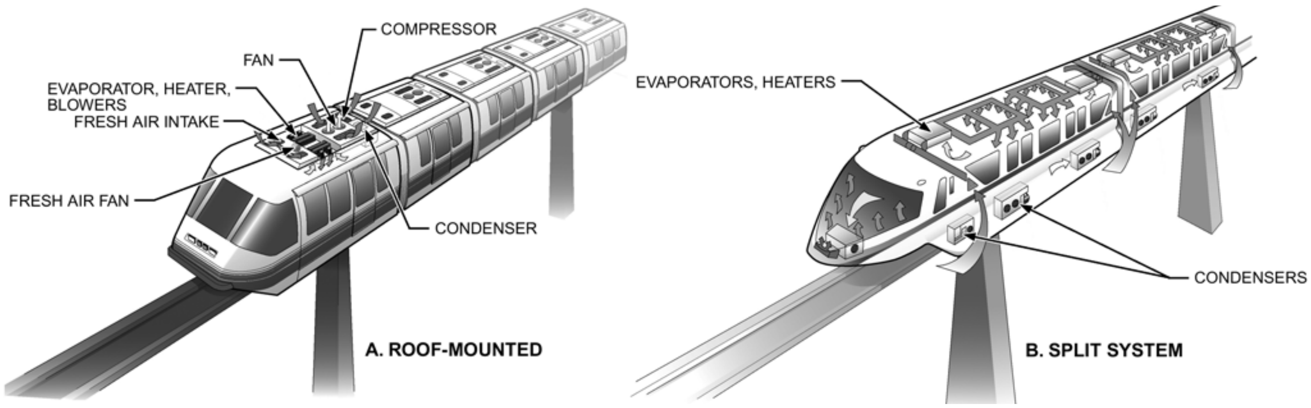

Fig. 11 Example Monorail HVAC System Configurations

than indicated. The passengers may load and unload in groups, which causes additional air exchange with the outdoors. Frequent door openings, sometimes on both sides at once, allows additional natural ventilation. The effective outdoor air ventilation per passenger is a summation of all these factors. The amount of outdoor air introduced through the HVAC system varies. Some new vehicles have no mechanical outdoor air supply, whereas others provide up to 4.25 L/s per passenger. Lower values of mechanical ventilation, typically 1.4 to 2.4 L/s or less per passenger, are associated with travel times of less than 2 min and large passenger turnover. Longer rides justify higher rates of mechanical ventilation.

Green initiatives have caused designers to take a closer look at all aspects of energy savings. Some systems are now designed with variable outdoor air rates, which are automatically lowered under low passenger load conditions or extreme temperature loads. This approach yields lower system cooling capacities and saves energy.

Air Distribution

With overhead equipment, air is distributed through linear ceiling diffusers that are often constructed as a part of the overhead lighting fixtures. Undercar equipment usually makes use of the void spaces in the sidewalls and below fixed seating. In all cases, the spaces used for air supply must be adequately insulated to prevent condensation on surfaces and, in the case of voids below seating, to avoid cold seating surfaces. The supply air discharge from undercar systems can be from overhead diffusers through sidewall duct or a windowsill diffuser. Recirculation air from overhead equipment flows through ceiling-mounted grilles. For undercar systems, return air grilles are usually found in the door wells or beneath seats.

Because of the vehicle’s typical small size and low ceilings, care must be taken to design the air supply so that it does not blow directly on passengers’ heads or shoulders. Because high flow rates are necessary to achieve capacities, diffuser design and placement are important. Some systems are designed so the air supply discharge hugs the vehicle’s ceiling and walls to avoid drafts on passengers. Total air quantity and discharge temperature must be carefully calculated to provide passenger comfort. Interior noise levels are typically 72 to 74 dBA for a stationary vehicle with doors shut.

CHAPTER 13

AIRCRAFT

Design Conditions 13.1
Typical Flight 13.11
Air Quality 13.13
Regulations 13.14

ENVIRONMENTAL control system (ECS) is a generic term used in the aircraft industry for the systems and equipment associated with ventilation, heating, cooling, humidity/contamination control, and pressurization in the occupied compartments, cargo compartments, and electronic equipment bays. The term ECS often encompasses other functions such as windshield defog, airfoil anti-ice, oxygen systems, and other pneumatic demands. The regulatory or design requirements of these related functions are not covered in this chapter.

1. DESIGN CONDITIONS

Design conditions for aircraft applications differ in several ways from other HVAC applications. Commercial transport aircraft often operate in a physical environment that is otherwise not survivable for humans. In flight, the ambient air may be extremely cold and dry, and can contain high levels of ozone. On the ground, the ambient air may be hot, humid, and contain many pollutants such as particulate matter, aerosols, and hydrocarbons. These conditions change quickly from ground operations to flight. A hot-day, high-humidity ground condition usually dictates the thermal capacity of the air-conditioning equipment, and flight conditions determine the supply air compressor's capacity. Maximum heating requirements can be determined by either cold-day ground or flight operations.

In addition to essential safety requirements, the ECS should provide a comfortable cabin environment for the passengers and crew. This presents a unique challenge because of the high-density seating of the passengers. Furthermore, aircraft systems must be low in mass, accessible for quick inspection and servicing, highly reliable, able to withstand aircraft vibratory and maneuver loads, and able to compensate for various possible system failures.

Ambient Temperature, Humidity, and Pressure

Figure 1 shows typical design ambient temperature profiles for hot, standard, and cold days. The ambient temperatures used for the design of a particular aircraft may be higher or lower than those shown in Figure 1, depending on the regions in which the aircraft is to be operated. The design ambient moisture content at various altitudes as recommended for commercial aircraft is shown in Figure 2. However, operation at moisture levels exceeding 30 g/kg of dry air is possible in some regions. The variation in ambient pressure with altitude is shown in Figure 3. Refer to the psychrometric chart for higher altitudes for cabin humidity calculations. Figure 4 shows a psychrometric chart for 2440 m altitude.

Heating/Air Conditioning Load Determination

The cooling and heating loads for a particular aircraft model are determined by a heat transfer study of the several elements that comprise the air-conditioning load. Heat transfer involves the following factors:

- Convection between the boundary layer and the outer aircraft skin

The preparation of this chapter is assigned to TC 9.3, Transportation Air Conditioning.

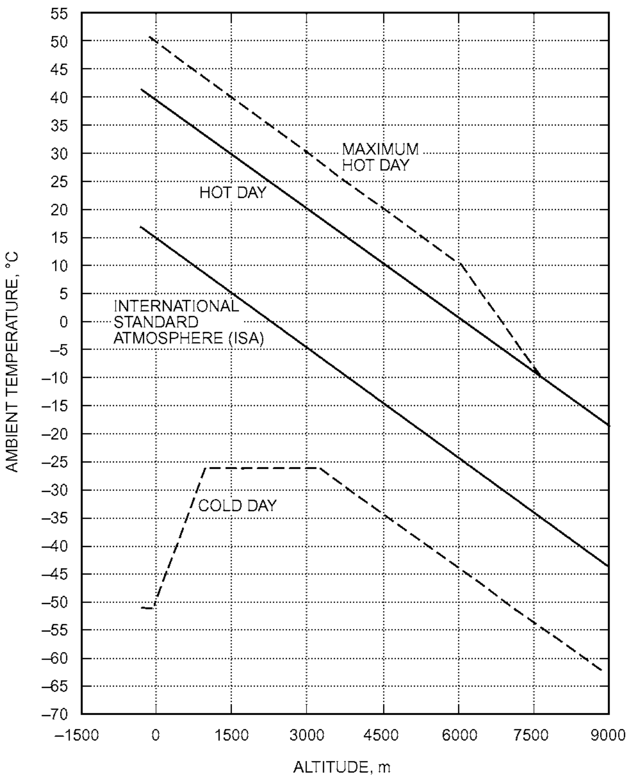

Fig. 1 Ambient Temperature Profiles

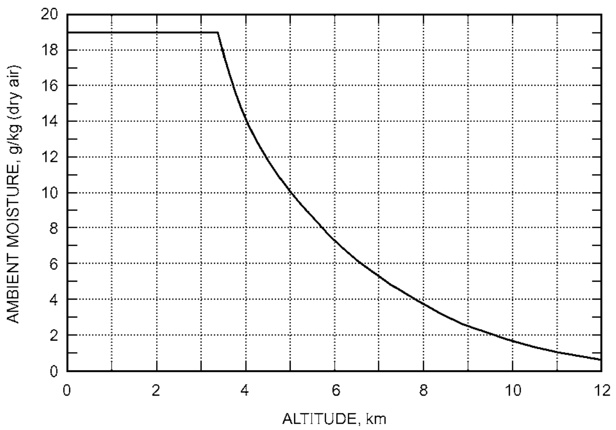

Fig. 2 Design Humidity Ratio

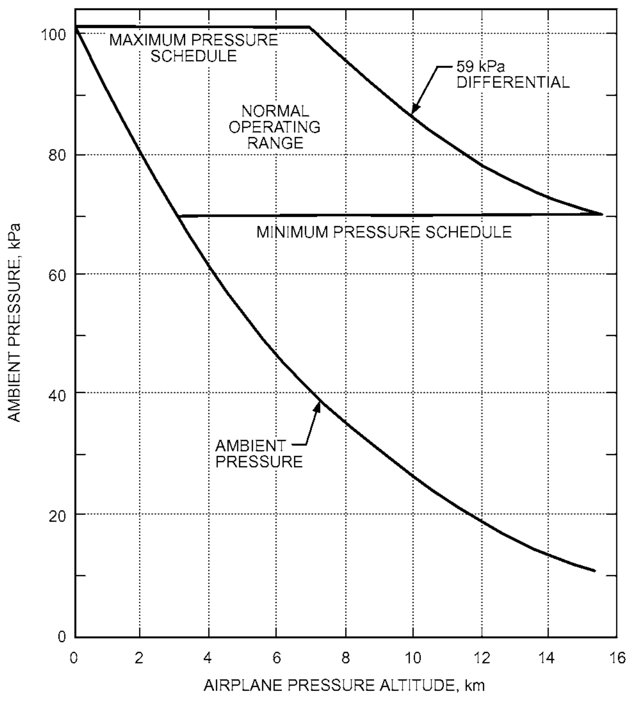

Fig. 3 Cabin Pressure Versus Altitude

- Radiation between the outer aircraft skin and the external environment
- Solar radiation through windows, on the fuselage, and reflected from the ground.
- Conduction through cabin walls and the aircraft structure
- Convection between the interior cabin surface and the cabin air
- Convection and radiation between the cabin and occupants
- Convection and radiation from internal sources of heat (e.g., electrical equipment)
- Latent heat from vapor cycle systems

Ambient Air Temperature in Flight

During flight, very cold ambient air adjacent to the outer surface of the aircraft increases in temperature through ram effects, and may be calculated from the following equations:

$$T_{AW} = T_\infty + r(T_T - T_\infty)$$

$$T_T = T_\infty\left(1 + \frac{k-1}{2}M^2\right)$$

or

$$T_{AW} = T_\infty\left(1 + r\frac{k-1}{2}M^2\right)$$

$$r = \mathrm{Pr}^{1/3}$$

where

Pr = Prandtl number for air (e.g., Pr = 0.73 at 240 K

T_∞ = ambient static temperature, K

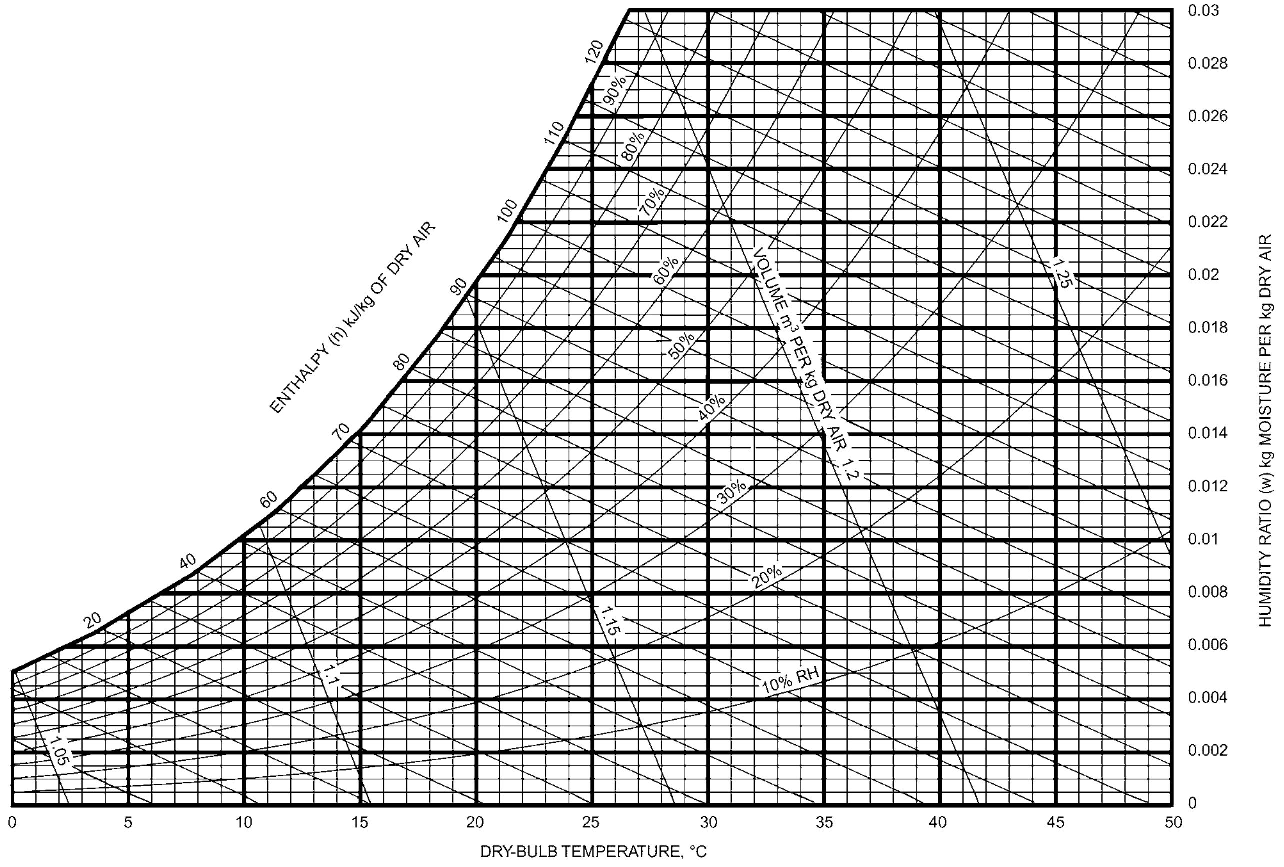

Fig. 4 Psychrometric Chart for Cabin Altitude of 2440 m

T_T = ambient total temperature, K
k = ratio of specific heat; for air, $k = 1.4$
M = airplane Mach number
r = recovery factor for turbulent boundary layer (i.e., fraction of total temperature recovered in boundary layer as air molecules rest on the surface)
T_{AW} = recovery temperature (or adiabatic wall temperature), K

Example 1. The International Civil Aviation Organization (ICAO) cold day at 9144 to 12 192 m altitude has a static temperature of –65°C (208 K) and a Prandtl number of 0.739. If an airplane is traveling at 0.8 Mach, what would the external temperature be at the airplane's skin?

Solution: Iteration is usually required. First guess for r » 0.9:

$$\text{Pr} = 0.728 \text{ at } 0.9(240 - 208) + 208 = 236.8 \text{ K}$$
$$r = \text{Pr} = (0.728)^{1/3} = 0.8996$$

$$T_T = T_\infty\left(1 + \frac{k-1}{2}M^2\right) = 208\left(1 + \frac{1.4-1}{2}[0.8]^2\right) = 235 \text{ K}$$

$$T_{AW} = T_\infty + r(T_T - T_\infty) = 208 + 0.8996(235 - 208)$$
$$= 232.3 \text{ K} \quad (-41°\text{C})$$

Air Speed and Mach Number

The airplane airspeed is related to the airplane Mach number by the local speed of sound:

$$u_\infty = M\sqrt{kRT_\infty}$$

where

k = ratio of specific heats; 1.4 for air
R = gas constant; 287 $m^2/(s^2 \cdot K)$
M = airplane Mach number
u_∞ = airplane airspeed, m/s

Ambient Pressure in Flight

The static pressure over most of the fuselage (the structure around the cabin) is essentially equal to the ambient pressure at the appropriate altitude.

$$P_s = P_{inf} + C_p\frac{1}{2}\rho_\infty u_\infty^2$$

where

P_s = pressure surrounding the fuselage, N/m^2
C_p = pressure coefficient, dimensionless; approximately zero for passenger section of fuselage
ρ_∞ = free-stream or ambient air density, kg/m^3

External Heat Transfer Coefficient in Flight

The fact that the fuselage is essentially at free-stream static pressure implies that a flat-plate analogy can be used to determine the external heat transfer coefficient at any point on the fuselage:

$$h = \rho_w c_p u_\infty 0.185(\log_{10}\text{Re}_x)^{-2.584}\text{Pr}^{-2/3}$$

$$(\text{note: } 10^7 < \text{Re}_x < 10^9)$$

$$\text{Re}_x = \frac{\rho_w u_\infty x}{\mu}$$

ρ_w, c_p, μ, Pr

$$\text{evaluated at } T^* = \frac{T_{AW} + T_\infty}{2} + 0.22(T_{AW} - T_\infty)$$

$$q = hA(T - T_{AW})$$

where

h = external heat transfer coefficient, $W/(m^2 \cdot K)$
Re_x = local Reynolds number, dimensionless
x = distance along the fuselage from nose to point of interest, m
c_p = constant-pressure specific heat; for air, J/(kg·K)
ρ_w = ambient air (weight) density at film temperature T^*, kg/m^3
μ = absolute viscosity of air at T^*; 3.673 × 10–9$(T^*)^{3/2}$ [408.2/(T^* + 120)] kg/(m·s)(mPa·s)
A = outside surface area, m^2
T = outer skin temperature, K
q = convective heat loss from outer skin, W
u_∞ = airplane airspeed, m/s

External Heat Transfer Coefficient on Ground

The dominant means of convective heat transfer depends on wind speed, fuselage temperature, and other factors. The (free convection) heat transfer coefficient for a large, horizontal cylinder in still air is entirely buoyancy-driven and is represented as follows:

$$\text{Gr} = \frac{g(\beta)(\Delta T)d^3}{\nu^2}$$

for $10^9 \le \text{GrPr} \le 10^{12}$:

$$h_{free} = \frac{0.13k(\text{GrPr})^{1/3}}{d}$$

where

g = gravitational acceleration, 9.8 m/s^2
k = thermal conductivity of air, W/(m·K)
ν = kinematic viscosity, m^2/s
d = fuselage diameter, m
h_{free} = free-convection heat transfer coefficient, $W/(m^2 \cdot K)$
β = expansion coefficient of air = $1/T_f$, where $T_f = (T_{skin} + T_\infty)/2$, K
ΔT = $T_{skin} - T_\infty$
T_{skin} = skin temperature, K
T_∞ = ambient temperature, K
Gr = Grashof number
Pr = Prandtl number

A relatively light breeze introduces a significant amount of heat loss from the same horizontal cylinder. The forced-convection heat transfer coefficient for a cylinder may be extrapolated from the following:

$$\text{Re} = \frac{Vd}{\nu}$$

for $4 \times 10^4 \le \text{Re} \le 4 \times 10^5$

$$h_{forced} = \frac{0.0266k(\text{Re})^{0.805}\text{Pr}^{1/3}}{d}$$

where V is wind speed in m/s, and ν is evaluated at $T_f = (T_{skin} + T_\infty)/2$.

Example 2. One approximation of the fuselage is a cylinder in cross-flow. The fuselage is 3.7 m in diameter and 37 m long, in a 4.3 m/s crosswind and a film temperature of 319 K. The surface temperature varies with the paint color and the degree of solar heating. For instance, a typical white paint could be 17 K higher than the ambient air temperature, so the heat transfer from the fuselage would be

Free convection:

$$\text{Gr} = \frac{g(\beta)(\Delta T)d^3}{\nu^2} = \frac{9.8(0.00313)(17)(3.7)^3}{(1.77 \times 10^{-5})^2} = 8.43 \times 10^{10}$$

for $10^9 \le \text{GrPr} \le 10^{12}$.

$$h_{free} = \frac{0.13k(\mathrm{Gr\,Pr})^{1/3}}{d} = \frac{0.13(0.028)[8.43 \times 10^{10}(0.704)]^{1/3}}{3.7}$$
$$= 3.84 \text{ W/(m}^2\cdot\text{K)}$$

Forced convection:

$$\mathrm{Re} = \frac{Vd}{\nu} = \frac{4.3(3.7)}{1.77 \times 10^{-5}} = 8.98 \times 10^5$$

for $4 \times 10^4 \le \mathrm{Re} \le 4 \times 10^5$. Note that, although this Reynolds number is beyond the recommended range, the extrapolation has about a 10% error (underprediction) when compared to other more complicated methods.

Comparison of heat transfer coefficients shows that, in this situation, heat transfer is dominated by forced convection, so the free-convection aspect can be ignored.

External Radiation

The section of airplane fuselage that surrounds the cabin radiates primarily to the sky. At sea level, the sky temperature is about 17 K cooler than the surrounding air temperature (depending on humidity and other factors). As the airplane climbs, there is a decreasing amount of air above to radiate to, so the difference between air temperature and sky temperature increases. For example, at a cruising altitude of 9000 to 11 000 m, the sky temperature is about 56 K cooler than the air temperature (free-stream static). The limiting condition, of course, is outer space, where the sky temperature is the cosmic background radiation (CBR). The sky temperature in this case is only about 3 K. The heat loss to the sky by radiation is

$$qR = A\sigma(\varepsilon)\,(T^4 - T_{sky}^4)$$

where

q_R = radiation heat loss from outer skin, W
A = outside surface area, m²
T = outer skin temperature, K
σ = Stephan-Boltzmann constant, 5.67×10^{-8} W/(m²·K⁴)
ε = emissivity of surface, paint, etc.
T_{sky} = sky temperature, K

Solar radiation on the ground is covered in detail elsewhere (e.g., Chapter 36); however, during cruising, the incident solar radiation should be adjusted for altitude. The column of air between the sun and the airplane varies with time of day (angle) and altitude. Standard sea-level solar flux, for a given latitude and time of day, can be adjusted for altitude using Beer's law:

$$I_{SL} = I_o e^{-na_{ms}}$$

$$I_y = I_o e^{-na_{ms}m}$$

$$C_y = I_y/I_{SL}$$

$$q_s = A\alpha(C_y)I$$

where

I = solar radiation to a surface at sea level after accounting for latitude and time of day, W/m²
I_o = solar constant, 1355 W/m²
I_y = normal solar flux at altitude, W/m²
I_{SL} = normal solar flux at sea level, W/m²
C_y = correction factor for altitude
n = turbidity factor: 2.0 for clear air, 4 to 5 for smog
m = relative thickness of air mass, P_y/P_{SL} = (altitude pressure)/(sea level barometric pressure)
a_{ms} = molecular scattering coefficient = 0.128-0.054 $\log_{10}(m)$
α = solar absorptivity of surface, window, paint, etc.
A = outside surface area, m²

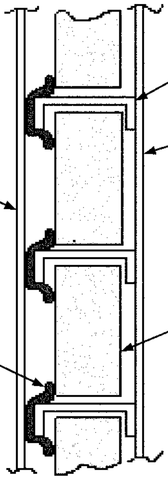

Fig. 5 Example of Aircraft Insulation Arrangement

Conduction

The conductive path from the air in the cabin to the surrounding environment is generally described as several heat transfer elements in series and in parallel with each other. The structure is typically quite conductive (e.g., aluminum), and must be insulated to avoid a direct heat path from inside to outside. The structure typically has an outer skin supported by circumferential and longitudinal ribs. The members require a structurally efficient attachment, which often is also thermally efficient, so that the entire structure is essentially at the same temperature. As a result, the effective "fin" area may be much larger than the simple outside surface area of the fuselage. Figure 5 shows an example of an aircraft insulation arrangement.

For occupant comfort, the cabin wall temperature should not be drastically different from the air temperature within the cabin, because the passengers frequently are in contact with this and other interior surfaces. The insulation accommodates this requirement as well as noise reduction, which on occasion is the dominant requirement.

Stack Pressure across Cabin Wall

The cold outer skin during flight generates buoyancy-driven flow between the cabin and the cavity formed by the cabin wall and the outer skin. Because this cavity is normally filled with insulation blankets, it may be relatively porous to airflow. The outer skin is frequently below the cabin dew point (and below freezing), so water condenses on the structure and ice may build up with time. The amount of flow in and out of the cavity depends on the leakage area of the cabin wall. Leakage commonly occurs through panel joints and gaps surrounding penetrations, as well as around doors, where additional structure and mechanisms may provide addition thermal conductivity and air passages to the outer skin. A certain amount of flow in and out of the cavity is unavoidable because of normal pressurization and depressurization of the cabin during descent and climb. The driving pressure, or stack pressure, is simply the density difference between the connected volumes:

$$\Delta P_{stack} = (\rho_{cavity1} - \rho_{cavity2})gh$$

$$= \frac{P_{cabin}\left(\dfrac{1}{T_{cavity1}} - \dfrac{1}{T_{cavity2}}\right)gy}{R}$$

where

y = cavity height, m
T = temperature, K

ρ = air density, kg/m^3
g = gravitational constant =9.8 m/s^2
R = gas constant, 287 m^2/(s^2·K)
ΔP = stack pressure, Pa
P_{cabin} = absolute cabin pressure, N/m^2

Metabolic Heat from Occupants

A thorough treatment of metabolic heat from humans is covered in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*. Because an airplane cabin is frequently at higher altitudes, the balance between sensible and latent heat changes slightly from that given in that chapter. To correct for altitude, the following approach is recommended. First, examining the heat transfer coefficient:

For low air velocity ($V < 0.2$ m/s), flow is dominated by natural convection:

$$h = \frac{k}{d}C(\text{Gr Pr})^m = \frac{k}{d}C\left(\frac{\rho^2 g\beta(\Delta T)d^3\text{Pr}}{\mu^2}\right)^m \rightarrow h \propto \rho^{2m}$$

For a cylindrical approximation of an adult at rest, Gr = 10^7, so $C = 0.59$ and $m = 1/4$, which leads to

$$h_{alt} = h_{SL}\left(\frac{\rho_{alt}}{\rho_{SL}}\right)^{2(1/4)} = h_{SL}\left(\frac{P_{alt}}{P_{SL}}\right)^{0.5}$$

For higher air velocity ($0.2 < V < 4$ m/s), flow is dominated by forced convection:

$$h = \frac{k}{d}C(\text{Re})^n\text{Pr}^{1/3} = \frac{k}{d}C\left(\frac{\rho V d}{\mu}\right)^n \text{Pr}^{1/3} \rightarrow h \propto \rho^n$$

For a cylindrical approximation of an adult at rest, Re > 4000, so $C = 0.193$ and $n = 0.618$, which leads to

$$h_{alt} = h_{SL}\left(\frac{\rho_{alt}}{\rho_{SL}}\right)^{0.618} = h_{SL}\left(\frac{P_{alt}}{P_{SL}}\right)^{0.618}$$

These two correction factors have been combined (see Equation [37] in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*) to produce a simpler relationship that applies to the full velocity range ($0 < V < 4$ m/s):

$$h_{alt} \approx h_{SL}\left(\frac{P_{alt}}{P_{SL}}\right)^{0.55}$$

Next, examining the evaporation or mass transfer from the occupants, the evaporative heat transfer coefficient varies inversely with the ambient pressure (see Equation [38] in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals*):

$$h_e = (LR)(h)$$

$$h_{e,alt} = LR_{alt}h_{SL}\left(\frac{P_{alt}}{P_{SL}}\right)^{0.55} \quad \text{and} \quad h_{SL} = \frac{h_{e,SL}}{LR_{SL}}$$

$$h_{e,alt} = LR_{alt}h_{SL}\left(\frac{h_{e,SL}}{LR_{SL}}\right)\left(\frac{P_{alt}}{P_{SL}}\right)^{0.55}$$

Substitute

$$LR_{alt} = \frac{R_{air}h_{fg}\left(\frac{D_v}{\alpha}\right)^{2/3}}{P_{alt}c_{p,air}R_w}$$

$$LR_{SL} = \frac{R_{air}h_{fg}\left(\frac{D_v}{\alpha}\right)^{2/3}}{P_{SL}c_{p,air}R_w}$$

$$h_{e,alt} \approx h_{e,SL}\left(\frac{P_{SL}}{P_{alt}}\right)^{0.45}$$

where

LR = Lewis relation, °C/Pa
h = heat transfer coefficient, W/(m^2·K)
h_{SL} = heat transfer coefficient at sea level, W/(m^2·K)
h_e = evaporative heat transfer coefficient, W/(m^2·Pa)
$h_{e,alt}$ = evaporative heat transfer coefficient at altitude, W/(m^2·Pa)
$h_{e,SL}$ = evaporative heat transfer coefficient at sea level, W/(m^2·Pa)
P_{alt} = cabin pressure at altitude, N/m^2
P_{SL} = pressure at sea level; 2116 N/m^2
R_{air} = gas constant for air; 286.5 m^2/(s^2·K)
h_{fg} = evaporation enthalpy at human skin temperature, 2.41 × 10^6 J/kg
D_v = mass diffusivity of water vapor in air; 2.55 × 10^{-5} m^2/s
α = diffusivity; 2.16 × 10^{-5} m^2/s
$c_{p,air}$ = specific heat of air; 1005 J/(kg·K)
R_w = gas constant for water vapor; approximately 461 m^2/(s^2·K)

About 70% of the metabolic heat is lost through convection/radiation (72 W sensible or 29 W convection, $h = 0.55$, plus 43 W radiation, $h_r = 0.83$) and 30% through evaporation (31 W latent) while seated at rest at sea level (see Table 1). At 2440 m cabin altitude, in still air, the sensible heat would drop to (2.67/3.12)29 = 25 W convection, the radiation would remain at 43 W, and the latent heat would rise to (732/642)31 = 35 W for a total of 103 W. This would indicate a slightly higher temperature for comfort, or a net effect of a slightly cooler sensation at altitude, compared to the 102.6 W total required.

Internal Heat Sources

When considering heat sources in the cabin, there are several parallels to commercial and residential HVAC. Many heat sources such as appliances (refrigerators, conventional ovens, microwave ovens), lighting, and entertainment (TV, stereo), may be in the cabin. In addition, the electronics and equipment associated with the

Table 1 Heat and Mass Transfer Coefficients for Human Body Versus Altitude

operation of a commercial aircraft put demands on the airplane's environmental control system.

Cooling Requirements. The sizing criteria for air conditioning are usually ground operation on a hot, humid day with the aircraft fully loaded and the doors closed. A second consideration is cooldown of an empty, heat-soaked aircraft before passenger loading; a cooldown time of less than 30 min is usually desired. A cabin temperature of between 24 and 27°C is typically specified for these hot-day ground design conditions. During cruise, the system should maintain a cabin temperature of 24°C with a full passenger load. The cooling load is entirely sensible in most cases when air-cycle machines are used. When a vapor-cycle recirculation system is used, latent heat is added.

Heating Requirements. Heating requirements are based on a partially loaded aircraft on a very cold day. Cabin temperature warm-up for a cold-soaked aircraft is desired to be within 30 min as well. A cabin temperature of 21°C is typically specified for cold-day ground-operating conditions. During cruise, the system should able to maintain a cabin temperature of 24°C with a 20% passenger load, a cargo compartment temperature above 4.4°C, and cargo floor temperatures above 0°C to prevent freezing of cargo.

Temperature Control

Whenever a section of the cabin or flight deck has capability for independent supply temperature control, it is termed a **zone**. Commercial aircraft (over 19 passengers) can have as few as two zones (cockpit and cabin) and as many as seven. These crew and passenger zones are individually temperature-controlled to a crew-selected temperature for each zone, ranging from 18 to 29°C. Some systems have limited temperature control in the passenger zones that can be adjusted by the flight attendants. The selected zone temperature is controlled to within 1 K of the sensed temperature, and temperature uniformity in the zone should be within 3 K. Separate temperature controls can be provided for cargo compartments.

Temperature control may also be the predominant driver of ventilation requirements. The interior of the fuselage has several electronic/electrical heat sources that are required for the aircraft's operation, as well as heat loads from ambient and from occupants and their activities. These increasing heat loads are accommodated by reducing supply temperatures:

$$T_{supply} = T_{cabin} - \frac{q_{sources}}{c_p \dot{m}}$$

where

$q_{sources}$ = all heat into cabin, W
$\dot{m}$ = air mass flow, kg/s
c_p = specific heat; 1006 J/(kg·K) for air
T = temperature, K

Supply temperatures in each of the zones have practical limits, such as the freezing temperature of water (humidity), when either the heat loads are too large or the mass flow is too low.

Air Velocity

The passenger cabin is most similar to buildings with very high occupant densities, such as theaters or lecture halls. In these situations, the air-conditioning system is typically in cooling mode (i.e., the supply diffuser temperature is cooler than the room temperature). The ducting and diffuser networks are best described as cold-air systems, in which the duct velocities are higher, duct temperatures lower, and the fraction of recirculated air smaller (about 50% of the mixture) than in buildings (which use up to 95%). The cold-air diffuser is also in much closer proximity to the occupants in an aircraft cabin. The design challenge is to deliver cool air to the passengers without uncomfortable drafts.

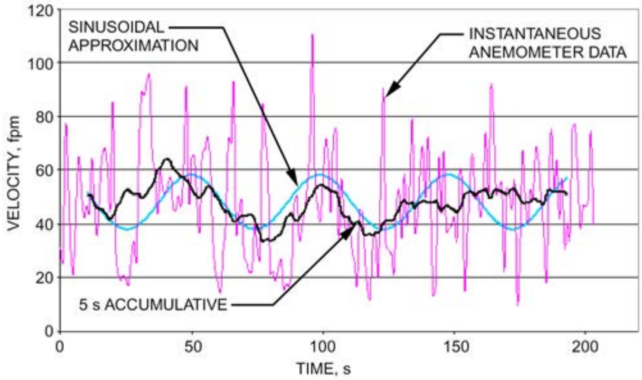

Fig. 6 Transient Air Velocity Measured in Seated Area of Aircraft Cabin

The velocity characteristics of an airplane cabin are uniquely affected by transitional flow behavior. The supply diffuser Reynolds number is typically between 3000 and 5000. Turbulence induced by the diffuser affects the perceived draftiness. Figure 6 shows the unsteady velocity variations measured in an aircraft cabin.

At any instant in time, the velocity field in the cabin will change, but an overall pattern develops for the time-averaged velocity. An example of this comes from computational fluid dynamics (CFD) modeling of a passenger cabin. Ventilation air enters the cabin near the center and blows outward in two directions. Air leaves near the floor on both sides, as shown in Figure 7.

Several comfort indices are used to evaluate air velocity, such as predicted percent dissatisfied (PPD) or predicted mean vote (PMV). Draft-sensitive areas of the body such as the ankles or neck receive special attention during air distribution system design. The velocity requirements are described in detail in Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* and ASHRAE *Standard* 55.

Ventilation

Air drawn from the compressor section of the jet engine is called **bleed air** (also known as outside air, fresh air, outdoor air, or ambient air). When air is provided by sources other than the engine, it is not bleed air in the strict sense, because it is no longer bled from the engines. The current FAA requirement is to provide 4 g/s of bleed/outdoor air per person. Because this requirement is expressed as a mass flow, the bleed air ventilation rate as a volumetric flow varies with cabin pressure and temperature. Cabin altitude is a convenient way of expressing cabin pressure by referencing the cabin pressure to a standard atmosphere. The required 4 g/s is equivalent to about 3.3 L/s at sea level and 24°C. Based on ASHRAE research, ASHRAE *Standard* 161 established a ventilation rate for aircraft passengers at 3.5 L/s per passenger. This rate was based in part on the consideration that not all spaces in the enclosed area achieve 100% ventilation effectiveness. At other cabin pressures or altitudes, flow volumes can be found with the following equation:

$$Q_{FR} = \frac{\dot{m}}{\rho} = \frac{\dot{m}}{\left(\frac{P_c}{RT_c}\right)} = \frac{\dot{m}RT_c}{P_c}$$

where

$\dot{m}$ = 0.00416 kg/s
R = 0.2865 $m^2/(s^2 \cdot K)$
T_c = cabin temperature; 21°C = 294 K
P_c = cabin pressure from Table 2, kPa

In many aircraft, the bleed/outdoor air flow is augmented by filtered or recirculated air. There are currently no regulatory require-

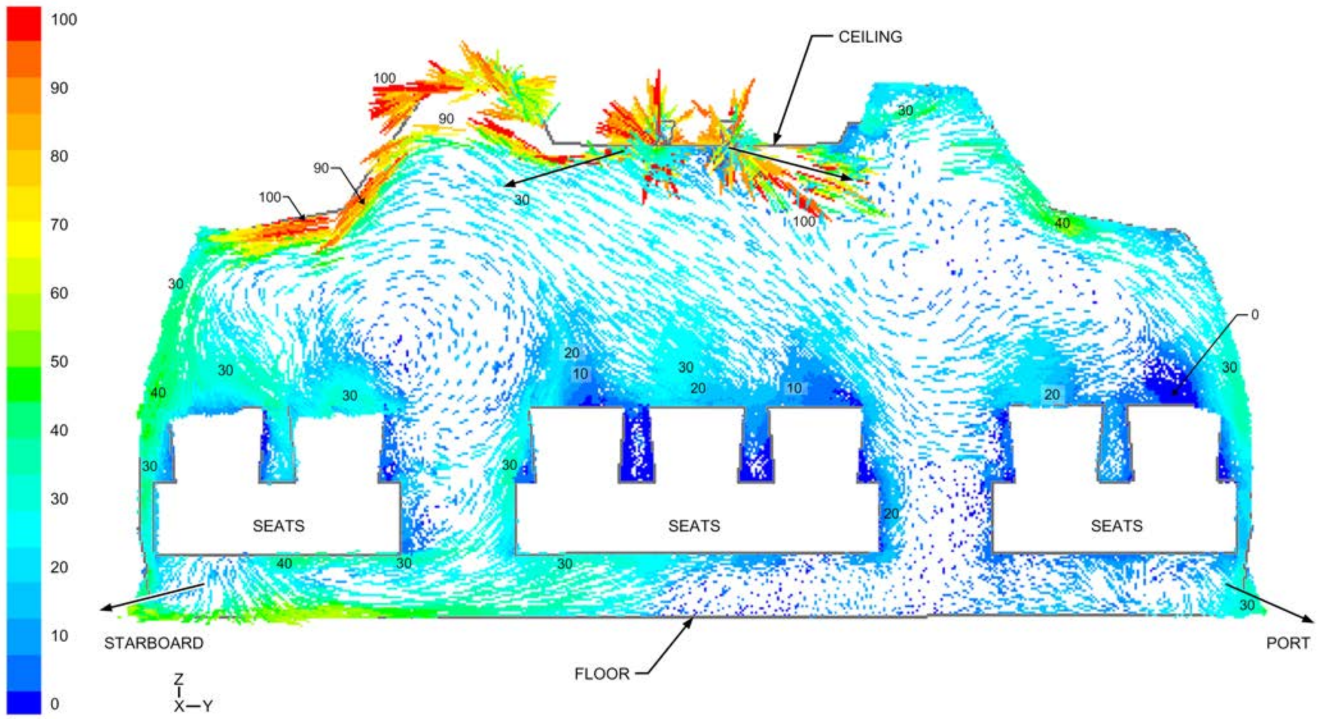

Fig. 7 Cabin Air Velocities from CFD, fpm
(Lin et al. 2005)

ments on the amount of recirculated air that enters the cabin, but it is customary to provide about 4.7 L/s per person of recirculated air in addition to the bleed air required by regulation, for a total of about 9.4 L/s per person at 2440 m cabin altitude.

Ventilation Effectiveness. ASHRAE *Standards* 62.1-2018 and 161-2018 address ventilation effectiveness (VE), a measure of mixing within the volume relative to a perfectly mixed system (*Standard* 62.1 uses the term **zone air distribution effectiveness E_z** instead of VE). It is described with the following equations:

$$VE = \frac{c_{mixed} - c_{in}}{c_{local} - c_{in}}$$

where c = contaminant concentration, or

$$VE = \frac{Q_{local}}{Q_{cabin}}$$

where

c_{local} = local contaminant concentration by volume
c_{in} = inlet contaminant concentration
c_{mixed} = concentration if perfectly mixed
Q_{cabin} = contaminant flow to cabin or zone, L/s
Q_{local} = flow delivered to breathing zone, L/s

Contaminant concentrations in a perfectly mixed system are the same in the cabin volume as at the exit (floor grilles), and the concentration in the exit is based only on the ventilation rate and generation rate (including source and sink). Therefore, ventilation effectiveness indicates the degree of contaminant stratification with the volume. VE > 1 means that concentrations in the breathing zone are lower than in a perfectly mixed system; VE < 1 means they are higher.

There is a distinction between VE for bleed air and VE for total ventilation. For bleed air, the inlet concentration c_{in} is the concentration of gases in the supply air to the entire system (i.e., bleed air concentration). The local concentration will be larger than the inlet concentration only if the contaminant is generated within the cabin. For total ventilation, VE uses the c_{in} at the nozzle (i.e., supply mixture concentration) and includes contaminants from the recirculation system. The practical use of this VE applies to particulate levels in the cabin, because the recirculated air is equivalent to bleed air in this regard.

Contaminant concentrations in the cabin can be converted to flows delivered to the breathing zone Q_{local} using the following relationship:

$$Q_{local} = \frac{q_{gen}}{c_{local} - c_{in}}$$

Table 2 FAA-Specified Bleed Air Flow per Person

Cabin Pressure, kPa	Altitude, m	Required Flow per Person at 24°C, L/s
101.325	0	3.49
99.505	150	3.54
97.719	305	3.63
95.954	460	3.68
94.210	610	3.78
92.500	760	3.82
90.811	915	3.92
89.149	1070	3.96
87.508	1220	4.06
85.895	1370	4.11
84.309	1525	4.20
82.744	1680	4.29
81.200	1830	4.34
79.683	1980	4.44
78.187	2135	4.53
76.711	2290	4.63
75.263	2440	4.72

Substitute

$$q_{gen} = Q_{supplied}(c_{mixed} - c_{in})$$

$$Q_{local} = Q_{supplied}\frac{c_{mixed} - c_{in}}{c_{local} - c_{in}}$$

where

q_{gen} = CO_2 generation rate, 0.005 L/s at standard conditions
c_{local} = local CO_2 concentration by volume
c_{in} = inlet CO_2 concentration
$Q_{supplied}$ = flow to cabin or zone, L/s
Q_{local} = flow delivered to breathing zone, L/s

Some consideration can be given to distribution effectiveness (DE), where flows to higher-occupant-density sections of the cabin (e.g., coach) are used to set minimum flows to the cabin, and lower-density sections (e.g., first class) may subsequently be over-ventilated:

$$\text{DE} = \frac{Q_{zone}/n_{zone}}{Q_{cabin}/n_{cabin}}$$

where

Q_{zone}/n_{zone} = flow per person in zone
Q_{cabin}/n_{cabin} = average flow per person for entire cabin

Distribution effectiveness accounts for a system that provides a uniform flow per length of cabin yet has varying seating densities along the length. For bleed air distribution, this effectiveness is tempered somewhat by occupant diversity *D* (see ASHRAE *Standard* 62.1), because underventilated zones feed into the same recirculation flow. For total flow (bleed + recirculated) and for systems without recirculation, however, occupant diversity does not apply.

System ventilation efficiency (SVE) is a measure of how well mixed the recirculated air is with the bleed air before it enters the cabin. The SVE can be determined from the concentration variations in the ducts leaving the mix manifold (see Figure 11), for instance. The SVE is similar to VE in formulation:

$$\text{SVE} = \frac{c_{all\ zones} - c_{amb}}{c_{zone} - c_{amb}}$$

where

$c_{all\ zones}$ = average concentration of all supply ducts
c_{zone} = concentration in individual supply duct
c_{amb} = ambient reference concentration = C_{fr} (bleed air concentration)

Dilution Ventilation and TLV

Contaminants that are present in the supply air and are also generated within the cabin require increasing dilution flows to avoid reaching Threshold Limit Values (TLVs®) (ACGIH). For example, suppose carbon monoxide is present in the atmosphere at 210 ppb and that each person generates 0.168 mL CO per minute, or 2.8×10^{-6} L/s (Owens and Rossano 1969). The amount of bleed air required to stay below the EPA guideline of 9000 ppb will depend on the ambient CO levels, the human generation rate, and the CO contribution of the ventilation system:

$$Q_{req} = \frac{q_{gen}}{C_{TLV} - \Delta C_{system} - C_{fr}} = \frac{q_{gen}}{C_{TLV} - C_{supply}}$$

where

C_{TLV} = allowable concentration
ΔC_{system} = concentration rise from system
C_{supply} = concentration in supply (air entering cabin)
C_{fr} = concentration in bleed air
q_{gen} = CO generated per person

Example 3. If the ventilation system does not contribute carbon monoxide to the supply air, then the required ventilation rate to stay below the threshold is

C_{TLV} = 9000 ppb = 0.000009

$q_{gen} = 2.8 \times 10^{-6}$ L/s

$\Delta C_{system} = 0$

C_{fr} = 210 ppb = 2.1×10^{-7}

$$Q_{req} = \frac{q_{gen}}{C_{TLV} - \Delta C_{system} - C_{fr}} = \frac{2.8 \times 10^{-6}}{0.000009 - 0 - 2.1 \times 10^{-7}}$$
$$= 0.32 \text{ L/(s·person)}$$

If, however, the ventilation system produces a 1000 ppb rise in carbon monoxide, then the required ventilation is

C_{TLV} = 9000 ppb = 0.000009

$q_{gen} = 2.8 \times 10^{-6}$ L/s

ΔC_{system} = 1000 ppb = 0.000001

C_{fr} = 210 ppb = 2.1×10^{-7}

$$Q_{req} = \frac{q_{gen}}{C_{TLV} - \Delta C_{system} - C_{fr}} = \frac{2.8 \times 10^{-6}}{0.000009 - 0.000001 - 2.1 \times 10^{-7}}$$
$$= 0.36 \text{ L/(s·person)}$$

It is important to note that, under certain circumstances, q_{gen} and ΔC_{system} may change sign as contaminant sources become contaminant sinks. This simplified approach shown here is more conservative, and could overpredict contaminant levels in real situations.

Air Exchange

High occupant density ventilation systems have higher air exchange rates than most buildings (i.e., offices). The typical airplane may have an air exchange rate of 10 to 20 air changes per hour (ach), whereas an office might have 1 ach. The air is not replaced in a mixed system at every air exchange. Actually, the ratio Q/V (air exchange rate) is more like the inverse of decay time constant τ. An airplane cabin can be approximated as a partially mixed volume (a volume with ventilation effectiveness) as long as the contaminant sources are uniformly distributed throughout the volume. For a well-mixed volume, contaminant in equals contaminant out plus contaminant accumulated in the volume, or

$$Qc_{in} = Qc_{out} + V\frac{dc}{dt}$$

Accounting for ventilation effectiveness, the concentration leaving the volume c_{out} is related to the concentration within the volume c and the concentration entering the volume c_{in} by the ventilation effectiveness VE:

$$\text{VE} = \frac{c_{mixed} - c_{amb}}{c_{local} - c_{amb}} = \frac{c_{out} - c_{amb}}{c_{local} - c_{amb}} \rightarrow c_{out} = c_{in} + \text{VE}(c - c_{in})$$

Substituting,

$$Qc_{in} = Q[c_m + \text{VE}(c - c_{in})] + V\frac{dc}{dt}$$

which leads to

$$c = c_{in} - (c_{in} - c_o)e^{-\frac{Q(\text{VE})}{V}t}$$

Although air exchange rates are occasionally used as requirements on the ventilation system, in the case of cabin ventilation, there is no basis for setting one. Air exchange rate can be a surrogate (only for similarly sized volumes) for temperature uniformity, air quality, or smoke clearance. The flow-per-person specification is preferred, because it can be related to the predominant pollutant source more directly. Air exchange rates therefore indirectly provide valid ventilation comparisons between airplanes of similar volume and seating density. However, comparisons with buildings are misleading: occupant densities could be 30 times higher in aircraft, and bioeffluent doses (defined here as the time integral of the concentration of occupant-generated contaminants) for the same ventilation rate per person are greater in aircraft passenger cabins, depending upon occupancy times (see the section on Air Quality).

Filtration

Most airplane manufacturers have provisions for recirculated air filtration. Common practice is to install high-efficiency particulate air (HEPA) filters. The current industry standard for new build production aircraft is EU class H13 according to EN *Standard* 1822-1 and ISO *Standard* 29463-1 class 35H (i.e., 99.95% minimum removal efficiency by sodium flame test) (Eurovent 4/4, BS3928). This is equivalent to 99.97% minimum removal efficiency of approximately 0.3 µm when tested according to Institute of Environmental Sciences and Technology *Recommended Practice* RP-CC001.5 (IEST 1997).

Filters are required to have sufficient particulate capacity to remain effective between normal maintenance intervals. The life of the filter is related to the recirculation system pressure drop, system operating pressure, and the recirculation fan curve. As the filter becomes loaded, pressure drop increases. When added to the system losses, the effect is a reduction in flow, as shown in Figure 8.

It is important to change the filters at least as often as recommended by the manufacturer to maintain flow capacity.

Carbon/HEPA filters are available on the recirculation system for some aircraft models. Performance is not fully characterized. Filters must be tested and certified for each aircraft design. Currently available designs are intended to replace standard HEPA filters. The system designer must verify with the filter manufacturer the service life of the filter for the intended application. Most systems have no filtration of the engine bleed air supply as standard equipment, although some technologies (e.g., combined VOC/ozone converters and bleed air centrifugal cleaners) are sometimes offered as optional equipment.

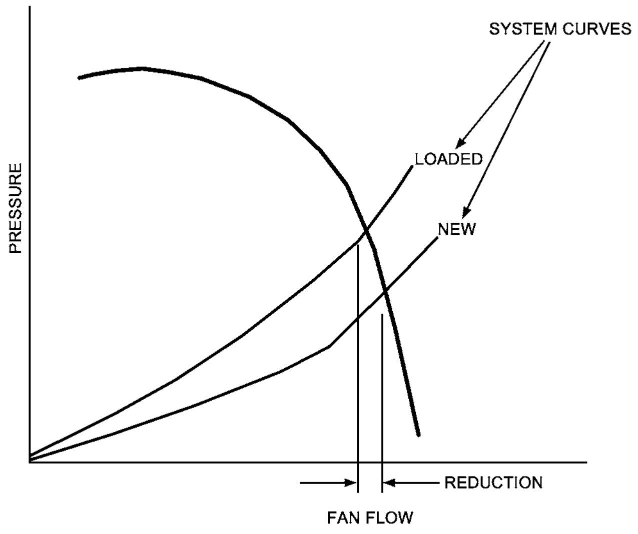

Fig. 8 Flow Reduction Caused by Filter Loading

Pressurization/Oxygen

Cabin pressurization achieves the required partial pressures of oxygen for the crew and passengers during high-altitude flight. At altitudes above 2440 m, the occupied cabin must be pressurized to an equivalent altitude of 2440 m or less to allow normal physiological functions without supplemental oxygen. The maximum pressure difference between the cabin and outside environment is limited by aircraft structural design limits. The differential pressure control provides a cabin pressure based on the flight altitude of the aircraft. A typical cabin altitude schedule is shown in Figure 3. Additional provisions that are separate from normal cabin pressure controls must be provided for positive- and negative-pressure relief to protect the aircraft structure.

A DOT-sponsored study (DOT 1989) concluded that current pressurization criteria and regulations are generally adequate to protect the traveling public. The study also noted that the normal maximum rates of change of cabin pressure (approximately 2.5 m/s in increasing altitude and 1.5 m/s in decreasing altitude) do not pose a problem for the typical passenger.

However, pressurization of the cabin to equivalent altitudes of up to 2440 m, as well as changes in the normal rates of pressure during climb and descent, may create discomfort for some people, such as those suffering from upper respiratory or sinus infections, obstructive pulmonary diseases, anemia, or certain cardiovascular conditions. In those cases, supplemental oxygen may be recommended. Children and infants sometimes experience discomfort or pain because of pressure changes during climb and descent. Injury to the middle ear has occurred to susceptible people, but is rare.

During a sudden cabin depressurization in flight, passengers and crew are provided with overhead masks supplying supplemental oxygen. Passengers with respiratory diseases can bring portable oxygen containers on board.

Humans at rest breathe at a rate of approximately 0.15 L/s while consuming oxygen at a rate of 0.007 L/s at 2440 m. The percent oxygen makeup of the supply air remains at approximately 21% at cruise altitude. A person receiving 4.7 L/s of outside air and 4.7 L/s of recirculation air would therefore receive approximately 2 L/s of oxygen. The level drops to 1.98 L/s as it leaves the cabin. Consequently, the content of oxygen in cabin air is little affected by breathing (i.e., it drops 0.33%). Although the percentage of oxygen in cabin air remains virtually unchanged (20.93%) at all normal flight altitudes, the partial pressure of oxygen decreases with increasing altitude, which decreases the amount of oxygen held by the blood's hemoglobin. The increase in cabin altitude may cause low-grade hypoxia (reduced tissue oxygen levels) in some people. However, the National Academy of Sciences (NAS 1986, 2002) concluded that pressurization of the cabin to an equivalent altitude of 1524 to 2440 m is physiologically safe for healthy individuals: no supplemental oxygen is needed to maintain sufficient arterial oxygen saturation.

System Description

The outdoor air supplied to the airplane cabin is usually provided by the compressor stages of the engine, and cooled by air-conditioning packs located under the wing center section. An air-conditioning pack uses the compressed ambient air as the refrigerant in air-cycle cooling.

Air is supplied and exhausted from the cabin on a continuous basis. As shown in Figure 9, air enters the passenger cabin from supply nozzles that run the length of the cabin. Exhaust air leaves the cabin through return air grilles located in the sidewalls near the floor, running the length of the cabin on both sides. Exhaust air is continuously extracted from below the cabin floor by recirculation fans that return part of the air to the distribution system. The remaining exhaust air passes to an outflow valve, which directs the air overboard. The cabin ventilation system is designed to deliver air uniformly along the length of the cabin.

Pneumatic System

The pneumatic system, or **engine bleed air system**, extracts a small amount of the gas turbine engine compressor air to ventilate and pressurize the aircraft compartments. A schematic of a typical system is shown in Figure 10. During climb and cruise, bleed air is usually taken from the mid-stage engine bleed port for minimum-horsepower extraction (bleed penalty). During idle descent it is taken from the high-stage engine bleed port, where maximum available pressure is required to maintain cabin pressure and ventilation. The auxiliary power unit (APU) is also capable of providing the pneumatic system with compressed air on the ground and in flight. Bleed air is pressure-controlled to meet the requirements of the system using it, and it is usually cooled to limit bleed manifold temperatures to meet fuel safety requirements. In fan jets, engine fan air is extracted for use as a heat sink for bleed air using an air-to-air heat exchanger called a precooler; for turboprop engines, ram air is used, which usually requires an ejector or fan for static operation. Other components include bleed-shutoff and modulating valves, a fan-air-modulating valve, sensors, controllers, and ozone converters. The pneumatic system is also used intermittently for airfoil and engine cowl anti-icing, engine start, and several other pneumatic functions.

Each engine has an identical bleed air system for redundancy and to equalize the compressor air bled from the engines. The equipment is sized to provide the necessary temperature and airflow for airfoil and cowl anti-icing, or cabin pressurization and air conditioning with one system or engine inoperative. The bleed air used for airfoil anti-icing is controlled by valves feeding piccolo tubes extending along the wing leading edge. Similar arrangements may be used for anti-icing the engine cowl and tail section.

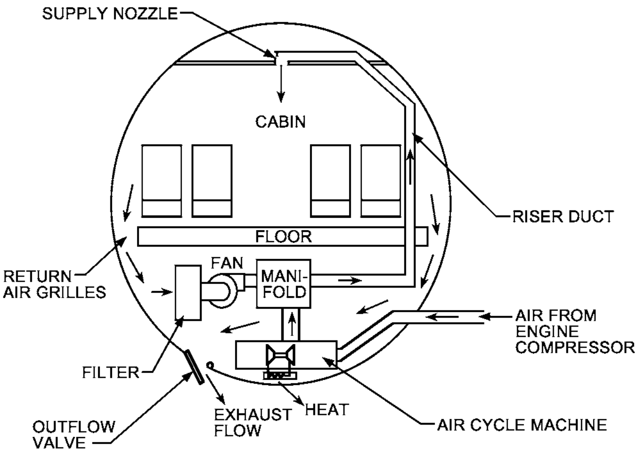

Fig. 9 Cabin Airflow Path

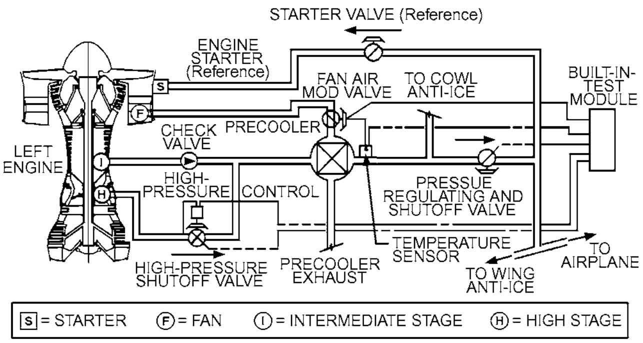

Fig. 10 Engine/APU Bleed System

Air Conditioning

Air-cycle refrigeration is the predominant means of air conditioning for commercial and military aircraft. The reverse-Brayton cycle or Brayton refrigeration cycle is used, as opposed to the Brayton power cycle that is used in gas turbine engines. The difference between the two cycles is that, in the power cycle, fuel in a combustion chamber adds heat, and in the refrigeration cycle, a ram-air heat exchanger removes heat. The familiar Rankine vapor cycle, which is used in building and automotive air conditioning and in domestic and commercial refrigeration, is used for military aircraft as well as galley cooling on larger commercial transports.

In an air cycle, compression of the ambient air by the gas turbine engine compressor provides the power input. The heat of compression is removed in a heat exchanger using ambient air as the heat sink. This cooled air is refrigerated by expansion across a turbine powered by the compressed bleed air. The turbine energy resulting from the isentropic expansion is absorbed by a second rotor, which is either a ram air fan, bleed air compressor, or both. This assembly is called an **air cycle machine (ACM)**.

The most common types of air-conditioning cycles for commercial transport aircraft are shown in Figure 11. All equipment in common use on commercial and military aircraft is open loop, although many commercial aircraft systems include various means of recirculating cabin air to minimize engine bleed air use without sacrificing cabin comfort. The basic differences between the systems are the type of air cycle machine used and its means of water separation. Hybrid ACM/vapor cycle systems are discussed in Chapter 27 of the 2018 *ASHRAE Handbook—Refrigeration*.

The most common of these air cycle machines in use are the bootstrap ACM consisting of a turbine and compressor; the three-wheel ACM consisting of a turbine, compressor, and fan; and the four-wheel ACM consisting of two turbines, a compressor, and a fan. The bootstrap ACM is most commonly used for military applications, although many older commercial aircraft models use the bootstrap cycle. The three-wheel ACM (simple bootstrap cycle) is used on most of the newer commercial aircraft, including commuter aircraft and business aircraft. The four-wheel ACM (condensing cycle) was first applied in 777 aircraft.

The compartment supply temperature may be controlled by mixing ram-cooled bleed air with the refrigerated air to satisfy the range of heating and cooling. Other more sophisticated means of temperature control are often used; these include ram air modulation, various bypass schemes in the air-conditioning pack, and downstream controls that add heat for individual zone temperature control.

The bleed airflow is controlled by a valve at the inlet of the air-conditioning pack. The flow control valve regulates flow to the cabin for ventilation and repressurization during descent. Most aircraft use two or three air cycle packs operating in parallel to compensate for failures during flight and to allow the aircraft to be dispatched with certain failures. However, many business and commuter aircraft use a single pack. High-altitude aircraft that have a single pack also have emergency pressurization equipment that uses ram-cooled bleed air.

If the engine ingests water, or if the air cycle drops significantly below the dew point, some water separation devices are installed to avoid water spray in the cabin. Low- or high-pressure water separation may be used. A **low-pressure water separator**, located downstream from the cooling turbine, has a cloth lining that coalesces fine water particles entrained in the turbine discharge air into droplets. The droplets are collected, drained, and sprayed into the ram airstream using a bleed-air-powered ejector; this process

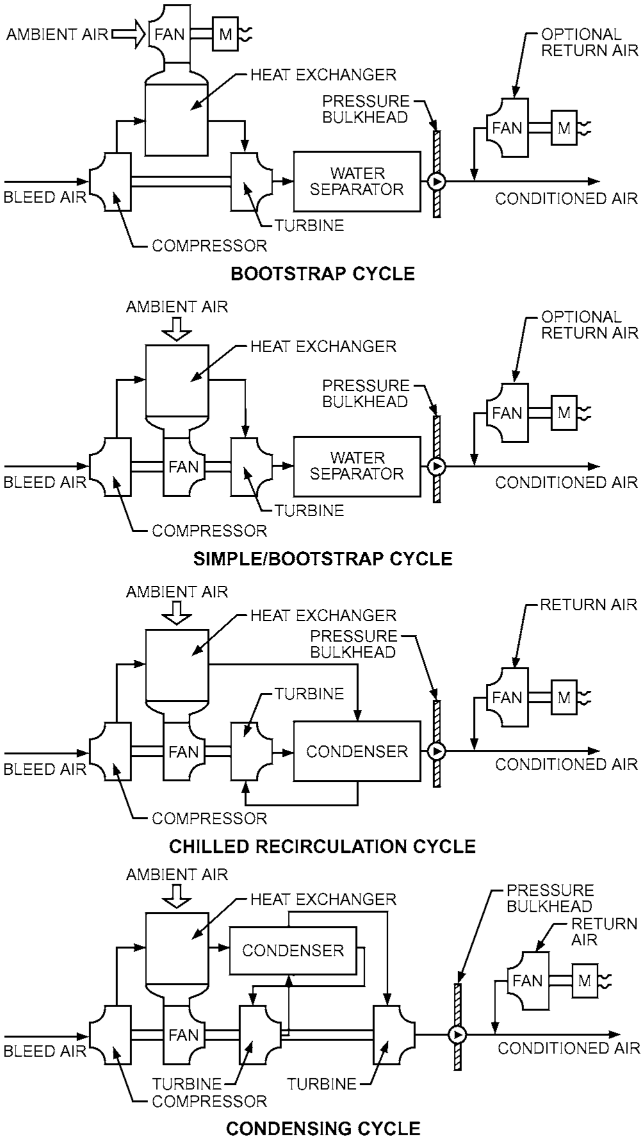

Fig. 11 Some Aircraft Refrigeration Cycles

increases pack cooling capacity by depressing the ram air heat sink temperature.

The **high-pressure water separator** condenses and removes moisture at high pressure upstream of the cooling turbine. A heat exchanger uses turbine discharge air to cool the high-pressure air sufficiently to condense most of the moisture present in the bleed air supply. The moisture is collected and sprayed into the ram airstream.

In the condensing cycle one turbine removes the high-pressure water and the second turbine does the final expansion to subfreezing temperature air that is to be mixed with filtered, recirculated cabin air. Separating these functions recovers the heat of condensation, which results in a higher cycle efficiency. It also eliminates condenser freezing problems because the condensing heat exchanger is operated above freezing conditions.

The air-conditioning packs are located in unpressurized areas of the aircraft to minimize structural requirements of the ram air circuit that provides the necessary heat sink for the air-conditioning cycle. This location also provides protection against cabin depressurization in the event of a bleed or ram air duct rupture. The most common areas for the air-conditioning packs are the underwing/wheel

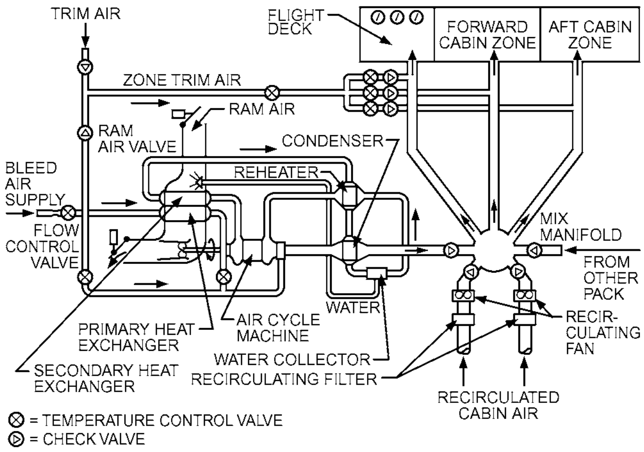

Fig. 12 Aircraft Air-Conditioning Schematic

well area and the tail cone area aft of the rear pressure bulkhead. Other areas include the areas adjacent to the nose wheel and overwing fairing. The temperature control components and recirculating fans are located throughout the distribution system in the pressurized compartments. The electronic pack and zone temperature controllers are located in the electrical/electronic (E/E) bay. The air-conditioning control panel is located in the flight deck. A schematic of a typical air-conditioning system is shown in Figure 12.

Cabin Pressure Control

Cabin pressure is controlled by modulating airflow discharged from the pressurized cabin through one or more cabin outflow valves. The cabin pressure control includes the outflow valves, controller, selector panel, and redundant positive-pressure relief valves. Provisions for negative-pressure relief are incorporated in the relief valves and/or included in the aircraft structure (door). The system controls the cabin ascent and descent rates to acceptable comfort levels, and maintains cabin pressure altitude in accordance with cabin-to-ambient differential pressure schedules. Modern controls usually set landing field altitude, if not available from the flight management system (FMS), and monitor aircraft flight through the FMS and the air data computer (ADC) to minimize cabin pressure altitude and rate of change.

The cabin-pressure-modulating and safety valves (positive-pressure relief valves) are located either on the aircraft skin, in the case of large commercial aircraft, or on the fuselage pressure bulkhead, in the case of commuter, business, and military aircraft. Locating outflow valves on the aircraft skin precludes handling of large airflows in the unpressurized tailcone or nose areas and provides some thrust recovery; however, these double-gate valves are more complex than the butterfly or poppet-type valves used for bulkhead installations. Safety valves are poppet-type valves for either installation. Most commercial aircraft have electronic controllers located in the E/E bay. The cabin pressure selector panel is located in the flight deck.

2. TYPICAL FLIGHT

A typical flight scenario from London's Heathrow Airport to Los Angeles International Airport would be as follows:

While the aircraft is at the gate and the engines have not been started yet, the ECS can be powered by compressed air supplied by the auxiliary power unit (APU), or bleed air from a ground cart. The APU or ground-cart bleed air is ducted directly to the bleed air manifold upstream of the air-conditioning packs. Once started, the engines become the compressed air source and the ground carts are disconnected.

Taxiing from the gate at Heathrow, the outside air temperature is 15°C with an atmospheric pressure of 101.3 kPa. The aircraft engines are at low thrust, pushing the aircraft slowly along the taxiway.

Engine Bleed Air Control

As air from outside enters the compressor stages of the engine, it is compressed to 220 kPa (gage) and a temperature of 166°C. Some of this air is then extracted from the engine core through one of two openings (bleed ports) in the side of the engine. Which bleed port extracts the air depends on the positioning of valves that control the ports. One bleed port is at a higher engine compressor stage (e.g., fifteenth stage), commonly called high stage. The second is at a lower compressor stage (e.g., eighth stage), commonly called low stage or intermediate stage. The exact stage varies depending on engine type. At low engine power, the high stage is the only source of air at sufficient pressure to meet the needs of the bleed system. Bleed stage selection is totally automatic, except for a shutoff selection available to the pilots on the overhead panel in the flight deck.

As the aircraft turns onto the runway, the pilots advance the engine thrust to takeoff power. The engine's high stage compresses the air to 650°C and 2965 kPa. This energy level exceeds the requirements for the air-conditioning packs and other pneumatic services; approximately 50% of the total energy available at the high-stage port cannot be used, so the bleed system automatically switches to the low-stage port to conserve energy.

Because the engine must cope with widely varying conditions from ground level to flight at an altitude of up to 13 140 m, during all seasons and throughout the world, air at the high or low stage of the engine compressor seldom exactly matches the pneumatic systems' needs. Excess energy must be discarded as waste heat. The bleed system constantly monitors engine conditions and selects the least wasteful port. Even so, bleed port temperatures often exceed fuel auto-ignition temperatures. The precooler automatically discharges excess energy to the atmosphere to ensure that the temperature of the pneumatic manifold is well below that which could ignite fuel in the event of a fuel leak.

The aircraft climbs to a cruise altitude of 11 900 m, where the outside air temperature is –57°C at an atmospheric pressure of 20 kPa, and the partial pressure of oxygen is 4 kPa. Until the start of descent to Los Angeles, the low-stage compressor is able to compress the low-pressure cold outdoor air to more than 210 kPa and above 200°C. This conditioning of the air is all accomplished through the heat of compression: fuel is added only after the air has passed through the compressor stages of the engine core.

Figure 13 shows the temperature of the air leaving the bleed system (labeled "to airplane" in Figure 10) from the time of departure to the time of arrival at Los Angeles.

The air then passes through an ozone converter on its way to the air-conditioning packs located under the wing at the center of the aircraft.

Ozone Protection

While flying at 11 900 m, several ozone plumes are encountered. Some have ozone concentrations as high as 0.8 ppm, or 0.62 ppm sea-level equivalent (SLE). This assumes a worst-case flight during the month of April, when ozone concentrations are highest. If this concentration of ozone were introduced into the cabin, passengers and crew could experience chest pain, coughing, shortness of breath, fatigue, headache, nasal congestion, and eye irritation.

Atmospheric ozone dissociation occurs when ozone goes through the compressor stages of the engine, the ozone catalytic converter (which is on aircraft with a route structure that can encounter high ozone concentrations), and the air-conditioning packs. The ozone further dissociates when contacting ducts, interior surfaces, and the

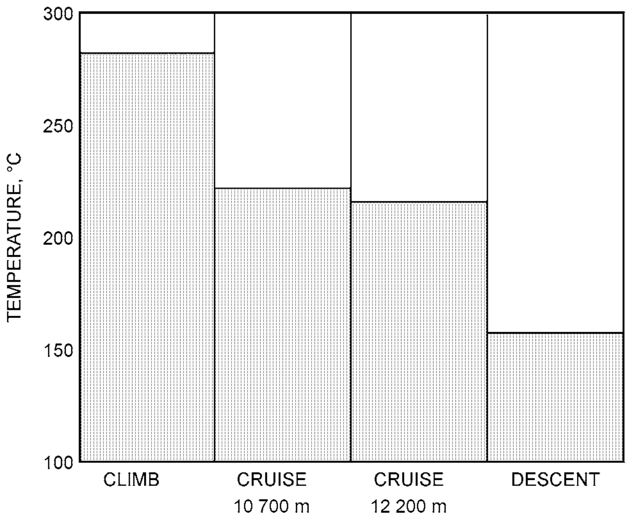

Fig. 13 Bleed Air Temperatures

recirculation system. The ozone converter dissociates ozone to oxygen molecules by using a noble catalyst such as palladium. A new converter dissociates approximately 95% of the ozone entering the converter to oxygen. It has a useful life of about 12 000 flight hours.

As the air leaves the ozone converter, it is still at 204°C and a pressure of 207 kPa. Assuming a worst case when the converter is approaching the end of its useful life, with an ozone conversion efficiency of 60%, the ozone concentration leaving the converter is about 0.25 ppm SLE. This air goes through the air-conditioning packs and enters the cabin. The ozone concentration in the cabin is about 0.09 ppm. As mentioned in the section on Regulations, the FAA sets a 3 h time-weighted average ozone concentration limit in the cabin of 0.1 ppm and a peak ozone concentration limit of 0.25 ppm.

Air Conditioning and Temperature Control

Air next enters the air-conditioning packs, which provide essentially dry, sterile, and dust-free conditioned air to the airplane cabin at the proper temperature, flow rate, and pressure to satisfy pressurization and temperature control requirements. For most aircraft, this is approximately 2.4 L/s per passenger. To ensure redundancy, typically two (or more) air-conditioning packs provide a total of about 4.8 L/s of conditioned air per passenger. An equal quantity of filtered, recirculated air is mixed with air from the air-conditioning packs for a total of approximately 9.5 L/s per passenger. Automatic control for the air-conditioning packs constantly monitors airplane flight parameters, the flight crew's selection for temperature zones, cabin zone temperature, and mixed distribution air temperature. The control automatically adjusts the various valves for a comfortable environment under normal conditions. The pilot's controls are located on the overhead panel in the flight deck, along with the bleed system controls. Normally, pilots are required only to periodically monitor the compartment temperatures from the overhead panel. Temperatures can be adjusted based on flight attendant reports of passengers being too hot or too cold. Various selections are available to the pilots to accommodate abnormal operational situations.

Air Recirculation

The air has now been cooled and leaves the air-conditioning packs. It leaves the packs at 16°C and 81 kPa. The relative humidity is less than 1% and ozone concentration is less than 0.25 ppm. The carbon dioxide concentration remains unchanged from that of the outside air at about 350 ppm. As this air enters a mixing chamber, it is combined with recirculated air.

The recirculated air is filtered before entering the mix manifold. Over 99.9% of the bacteria and viruses that reach the recirculation filters are removed from recirculated air by HEPA filters, which are used on most modern aircraft.

Air Distribution

The filtered and bleed air mixture leaves the mixing chamber on its way through the air distribution system. At this time, its humidity has increased relative to bleed air by about 5 to 10% rh. The temperature of the mixture is determined by the cooling requirements of the dominant zone. Control for the remaining zones is achieved by adding hot air to the zone supply. The hot-air source is the same bleed supply as the packs, so very small amounts of air are required to adjust the temperature.

Carbon dioxide levels in the distribution system are about halfway between the levels in bleed air and in the cabin. At a 1830 m cabin altitude, the level is about 1000 ppm in the distribution system.

The mixture leaves the air distribution system and enters the cabin through high-velocity diffusers. The diffusers run the length of the cabin. In order to minimize fore-to-aft flow and mixing between zones, flow is provided at a uniform amount per unit length of cabin. Even though the air change rates are high compared to buildings, they are low when looking at the plug flow velocity. If ventilation air were provided uniformly across the cabin, as in plug flow, the velocity would be less than 0.025 m/s. Momentum from the diffusers increases velocity up to comfortable levels of 0.08 to 0.33 m/s.

Once the air mixes with the air in the cabin, the humidity rises by another 5 to 10% rh to stabilize at 10 to 20% rh, and the carbon dioxide level rests at about 1700 ppm (at 1830 m cabin altitude).

Cabin Pressure Control

The cabin pressure control system continuously monitors ground and flight modes, altitude, climb, cruise or descent modes, and the airplane's holding patterns at various altitudes. It uses this information to position the cabin pressure outflow valve to maintain cabin pressure as close to sea level as practical, without exceeding a cabin-to-outside pressure differential of 59.3 kPa. At a 11 900 m cruise altitude, the cabin pressure is equivalent to 2100 m or a pressure of 80 kPa. In addition, the outflow valve repositions itself to allow more or less air to escape as the airplane changes altitude. The resulting cabin altitude is consistent with airplane altitude within the constraints of keeping pressure changes comfortable for passengers. The cabin pressure control system panel is located in the pilot's overhead panel near the other air-conditioning controls. Normally, the cabin pressure control system is totally automatic, requiring no attention from the pilots.

Finally, as descent to LAX begins, the cabin pressure controller follows a prescribed schedule for repressurization. The cabin altitude eventually reaches sea level, the doors can then be opened at the gate, and passengers depart.

3. AIR QUALITY

Factors Affecting Perceived Air Quality

Several factors can influence comfort and *perceived* cabin air quality. These cabin environmental parameters, in combination with maintenance-, operations-, individual-, and job-related factors, collectively influence the cabin crew and passenger perceptions of the cabin environment. **Cabin environmental quality (CEQ)** must be differentiated from **cabin air quality (CAQ)**, because many symptoms, such as eye irritation, for example, may be caused by humidity (CEQ) as well as contaminants (CAQ).

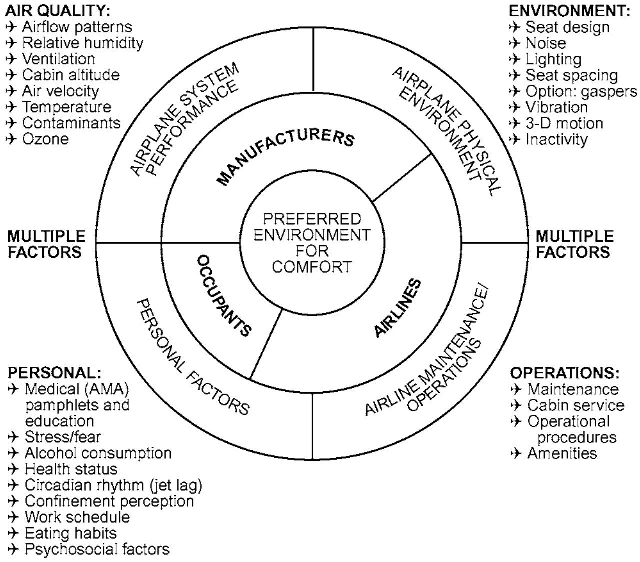

Fig. 14 Multiple Comfort Factors
(Adapted, with permission, from STP 1393—Air Quality and Comfort in Airliner Cabins, copyright ASTM International, 100 Barr Harbor Drive, West Conshohocken, PA 19428)

Strictly, air quality is a measure of pollutant levels. Aircraft cabin air quality is function of many variables including: the quantity of ventilation flow, ambient air quality, the design of the cabin volume, the design of the ventilation and pressurization systems, the way the systems are operated and maintained, the presence of sources of contaminants, and the strength of such sources.

Figure 14 depicts the three groups that can influence cabin environmental quality: manufacturers, airlines, and the occupants themselves. Airplane manufacturers influence the physical environment by the design of the environmental control system integrated with the rest of the systems on the airplane. Airlines affect the environmental conditions in the cabin by seating configuration, amenities offered, and procedures for maintaining and operating the aircraft. Finally, cabin environmental comfort is influenced by the individual and job-related activities of the cabin crew and passengers.

Factors that can individually or collectively affect aircraft cabin air quality are discussed in the following sections.

Airflow

The airflow per unit length of the airplane is typically the same for all sections. However, economy class has a lower airflow per passenger because of its greater seating density compared to first class and business class.

The flight deck is provided with a higher airflow per person than the cabin in order to (1) maintain a positive pressure in the cockpit to prevent smoke ingress from adjacent areas (abnormal condition), (2) provide cooling for electrical equipment, and (3) account for increased solar loads and night heat loss through the airplane skin and windows.

The bleed or outdoor air quantity supplied on some aircraft models can be reduced by shutting off one air-conditioning pack. The flight crew has control of these packs to provide flexibility in case of a system failure or for special use of the aircraft. However, packs should be in full operation whenever passengers are on board.

Air Changes

Confusion abounds over the use of air exchange rate (also called "air change rate") when making comparisons between dissimilar systems. Further, there is no air quality equivalence in the comparison of systems unless the occupied volumes are equal. This is because high air exchange rates can be achieved in two ways. As airflow increases, the air change rate increases; however, as volume decreases, the air change rate also increases but without a proportionate increase in air quality. Air exchange rate is the ratio of ventilation flow to volume:

$$ACR = \frac{Q}{V}$$

where

ACR = air change rate, h^{-1}
Q = flow, m^3/h
V = volume, m^3

A close inspection of the definition reveals the subtle relationship between air quality $c = q/Q$ (steady state) and air exchange rate:

$$c = \text{Air quality} = q/(\text{ACR})V$$

where

c = contaminant levels
q = contaminant generation rate

It is incorrect to assume that a smaller, single-aisle aircraft has better air quality than a larger, double-aisle aircraft simply because the air exchange rate is higher. Similarly, comparisons of buildings are in error. Remember, air quality is related to flow, which is the product of air change and volume.

The air exchange rate (bleed air to volume ratio) for an airplane cabin is typically between 11 and 15 ach [air changes per hour (ACH)]. Dilution rates for these air changes are between 25 and 18 min for replacement of 99% of the air. The particulate equivalent of an air exchange rate (total ventilation to volume ratio, where total ventilation = bleed + HEPA filtered recirculation) is between 20 and 30 equivalent air changes per hour.

Ozone

Ozone is present in the atmosphere as a consequence of the photochemical conversion of oxygen by solar ultraviolet radiation. Ozone levels vary with season, altitude, latitude, and weather systems. A marked and progressive increase in ozone concentration occurs in the flight altitude of commercial aircraft. The mean ambient ozone concentration increases with increasing latitude, is maximal during the spring (fall season for southern latitudes), and often varies when weather causes high ozone plumes to descend.

Residual cabin ozone concentration is a function of the ambient concentration; design, operation, and maintenance of the air distribution system; and whether catalytic ozone converters are installed.

Cabin ozone limits are set by FAR *Standards* 121.578 and 25.832. Catalytic ozone converters are generally required on airplanes flying mission profiles where the cabin ozone levels are predicted to exceed these limits (refer to the FAA Code of Federal Regulations for other compliance methods).

Microbial Aerosols

Biologically derived particles that become airborne include viruses, bacteria, actinomycetes, fungal spores and hyphae, arthropod fragments and droppings, and animal and human dander. One study has documented the occurrence of an outbreak of infectious disease related to airplane use. In 1977, because of an engine malfunction, an airliner with 54 persons onboard was delayed on the ground for 3 h, during which the airplane ventilation system was reportedly turned off. Within 3 days of the incident, 72% of the passengers became ill with influenza. One passenger (the index case) was ill while the airplane was delayed. With the ventilation system shut off, no bleed air was introduced into the cabin to dilute microbial aerosols and CO_2 or to control cabin temperatures.

The airplane ventilation system should never be shut off when passengers are on board, although the air packs (but not recirculation fans) may be shut off for a short time during takeoff only.

To remove particulates and biological particles from the recirculated air, use filter assemblies that contain a HEPA filter with a minimum efficiency of 99.97% on a dioctyl phthalate (DOP) test, as measured by MIL-STD-282. A HEPA filter is rated using 0.3 µm size particles. A filter's efficiency increases over time as particulates become trapped by the filter. However, system performance degrades because of increased pressure drop. Overlapping capture mechanisms in a filter also increase efficiency for particles smaller and larger than the most penetrating particle size (MPPS). For an airplane filter, the MPPS is about 0.1 to 0.2 µm.

Viruses typically range from about 0.01 to 0.2 µm, and are effectively removed by the air filtration mechanism of diffusional interception. Bacteria are typically about 0.5 to 1.5 µm, and are effectively removed by inertial impaction.

Activity Levels

Respiratory rates (also called minute ventilation) and, hence, air contaminant doses vary with activity level. Elevated activity levels increase respiration rate, and thereby may increase the dose of some airborne contaminants. Breathing rates range from approximately 0.14 L/s for a seated passenger to 0.28 L/s for a working flight attendant.

Volatile Organic Compounds

Volatile organic compounds (VOCs) can be emitted by material used in furnishings, pesticides, disinfectants, cleaning fluids, and food and beverages.

Carbon Dioxide

Carbon dioxide is the product of normal human metabolism, which is CO_2's predominant source in aircraft cabins. Concentration in the cabin varies with bleed-air flow rate, number of people present, and their individual rates of CO_2 production, which vary with activity and, to a smaller degree, with diet and health. CO_2 has been widely used as an indicator of indoor air quality, typically serving the function of a surrogate. According to the DOT (1989), measured cabin CO_2 values of 92 randomly selected smoking and nonsmoking flights averaged 1500 ppm.

The environmental exposure limit adopted by the Association of German Engineers (VDI 2004) and the American Conference of Governmental Industrial Hygienists (ACGIH) is 5000 ppm as the time-weighted average (TWA) limit for CO_2; this value corresponds to a bleed air ventilation rate of about 1.1 L/s per person at sea level, if the only source of CO_2 is the occupants at rest. Other sources of CO_2 within the cabin or cargo (e.g., dry ice) would of course require more ventilation. 14CFR/CS/JAR 25.831 also limits CO_2 to 5000 ppm (0.5%).

4. REGULATIONS

The Federal Aviation Administration (FAA) regulates the design of transport category aircraft for operation in the United States under section 14 of the Code of Federal Regulation (CFR) Part 25 (commonly referred to as the Federal Aviation Regulations [FARs]). ECS equipment and systems must meet these requirements, which are primarily related to safety of the occupants. Certification and operation of these aircraft in the United States is regulated by the FAA in FAR Part 121. Similar regulations are applied to European nations by the European Aviation Safety Agency (EASA), which represents the combined requirements of the airworthiness authorities of the participating nations; the current equivalent design regulation is Certification Specification (CS) 25, although many airplanes were designed and certified to the former Joint Aviation Regulations (JARs) Part 25. Operating rules based on FAA or EASA regulations are applied individually by the nation of registry. Regulatory agencies may impose special conditions on the design, and compliance is mandatory.

Several 14 CFR and CS/JAR Part 25 paragraphs apply directly to transport category aircraft ECS. Those most germane to the ECS design requirements of this chapter are as follows:

- 14CFR/CS/JAR 25.831 Ventilation
- 14CFR/CS 25.832 Cabin ozone concentration
- 14CFR/CS/JAR 25.841 Pressurized cabins
- 14CFR/CS/JAR 25.1301 Function and installation
- 14CFR/CS/JAR 25.1309 Equipment, systems, and installations
- 14CFR/CS/JAR 25.1438 Pressurization and pneumatic systems
- 14CFR/CS/JAR 25.1461 Equipment containing high energy rotors

These regulatory requirements are summarized in the following sections; however, the applicable FAR, CS and JAR paragraphs, amendments and advisory material should be consulted for the latest revisions and full extent of the rules.

14 CFR/CS/JAR Paragraph 25.831: Ventilation

- Each passenger and crew compartment must be ventilated.
- Each crew member must have enough bleed air to perform their duties without undue fatigue or discomfort (minimum of 4.8 L/s).
- Crew and passenger compartment air must be free from hazardous concentration of gases and vapors:
  - CO limit is 1 part in 20 000 parts of air
  - CO_2 limit is 0.5% by volume, sea level equivalent. Many airplanes were designed/certified to a carbon dioxide limit of 3% by volume (the former requirement)
  - CO and CO_2 limits must be met after reasonably probable failures
- Smoke evacuation from the cockpit must be readily accomplished without depressurization.
- Occupants of the flight deck, crew rest area, and other isolated areas must be able to control the temperature and quantity of ventilating air to their compartments independently.

14 CFR 25.831, Amendment 25-87 (specifies new requirements)

- Under normal operating conditions, the ventilation system must be designed to provide each occupant with airflow containing at least 0.25 kg of bleed air per minute (or about 4.8 L/s at 2440 m).
- The maximum exposure at any given temperature is specified as a function of the temperature exposure.

FAA Advisory Circular (AC) 25-20/ Acceptable Means of Compliance/Advisory Circular-Joint 25.831

- The ventilation system should be designed to provide enough fresh air to prevent accumulation of odors and pollutants such as carbon dioxide.
- In the event of loss of one source or probable failure conditions, the supply of bleed air should not be less than 0.25 kg/min per person for any period exceeding 5 min. This is derived from the ventilation rate procedure of ASHRAE *Standard* 62-1981. However, temporary reductions below this flow rate may be accepted if the compartment environment can be maintained at a level that is not hazardous to the occupant.

14 CFR/CS 25.832: Cabin Ozone Concentration

Specifies the cabin ozone concentration during flight must be shown not to exceed the following:

- 0.25 ppm by volume, sea level equivalent, at any time above flight level 320 (9750 m)
- 0.10 ppm by volume, sea level equivalent, time-weighted average during any 3 h interval above flight level 270 (8230 m)

At present, JAR 25 has no requirement for cabin ozone concentration.

14 CFR/CS/JAR 25.841: Pressurized Cabins

- Maximum cabin pressure altitude is limited to 2440 m at the maximum aircraft operating altitude under normal operating conditions.
- For operation above 7620 m, a cabin pressure altitude of not more than 4570 m must be maintained in the event of any reasonably probable failure or malfunction in the pressurization system.
- The makeup of the cabin pressure control components, instruments, and warning indication is specified to ensure the necessary redundancy and flight crew information.

14 CFR Amendment 25-87

This revision imposes additional rules for high-altitude operation.

14 CFR/CS/JAR 25.1301: Function and Installation

Each item of installed equipment must be of a kind and design appropriate to its intended function, be properly labeled, be installed according to limitations specified for that equipment, and function properly.

14 CFR/CS/JAR 25.1309: Equipment, Systems, and Installations

- Systems and associated components must be designed such that any failure that would prevent continued safe flight and landing is extremely improbable, and any other failure that reduces the ability of the aircraft or crew to cope with adverse operating conditions is improbable.
- Warning information must be provided to alert the crew to unsafe system operating conditions so they can take corrective action.
- Analysis in compliance with these requirements must consider possible failure modes, probability of multiple failures, undetected failures, current operating condition, crew warning, and fault detection.

FAR *Advisory Circular* AC 25.1309-1A, CS AMJ 25.1309, and JAR ACJs 1 to 25.1309 define the required failure probabilities for the various failure classifications: probable, improbable, and extremely improbable for the FAR requirements; and frequent, reasonably probable, remote, and extremely remote for the CS/JAR requirements.

14 CFR/CS 25.1438: Pressurization and Pneumatic Systems

This standard specifies the proof and burst pressure factors for pressurization and pneumatic systems as follows:

- Pressurization system elements
  - Proof pressure: 1.5 times max normal pressure
  - Burst pressure: 2.0 times maximum normal pressure
- Pneumatic system elements
  - Proof pressure: 1.5 times maximum normal pressure
  - Burst pressure: 3.0 times maximum normal pressure

CS/JAR 25.1438 and AMJ/ACJ 25.1438 specify the proof and burst pressure factors for pressurization and pneumatic systems as follows:

- Proof pressure
  - 1.5 times worst normal operation
  - 1.33 times worst reasonable probable failure
  - 1.0 times worst remote failure

- Burst pressure
  - 3.0 times worst normal operation
  - 2.66 times worst reasonably probable failure
  - 2.0 times worst remote failure
  - 1.0 times worst extremely remote failure

14 CFR/CS/JAR 25.1461: Equipment Containing High-Energy Rotors

Equipment must comply with at least one of the following three requirements:

- High-energy rotors contained in equipment must be able to withstand damage caused by malfunctions, vibration, and abnormal temperatures.
  - Auxiliary rotor cases must be able to contain damage caused by high-energy rotor blades.
  - Equipment control devices must reasonably ensure that operating limitations affecting the integrity of high-energy rotors will not be exceeded in service.
- Testing must show that equipment containing high-energy rotors can contain any failure that occurs at the highest speed attainable with normal speed control devices inoperative.
- Equipment containing high-energy rotors must be located where rotor failure will neither endanger the occupants nor adversely affect continued safe flight.

Categories and Definitions

Commercial users categorize their ECS equipment in accordance with the Air Transport Association of America (ATAA) *Specification* 100. The following ATAA chapters define ECS functions and components:

- **Chapter 21**, Air Conditioning, discusses heating, cooling, moisture/contaminant control, temperature control, distribution, and cabin pressure control. Common system names are the air-conditioning system (ACS) and the cabin pressure control system (CPCS).
- **Chapter 30**, Ice and Rain Protection, covers airfoil ice protection; engine cowl ice protection; and windshield ice, frost, or rain protection.
- **Chapter 35**, Oxygen, includes components that store, regulate, and deliver oxygen to the passengers and crew.
- **Chapter 36**, Pneumatic, covers ducts and components that deliver compressed (bleed) air from a power source (main engine or auxiliary power unit) to connecting points for the using systems (which are detailed in Chapters 21, 30, and 80). The pneumatic system is also commonly called the engine bleed air system (EBAS).

CHAPTER 14

SHIPS

Merchant Ships 14.1
Naval Surface Ships 14.3

THIS chapter covers air conditioning for oceangoing surface vessels, including naval ships, commercial vessels, fishing boats, luxury liners, pleasure craft, and inland and coastal boats, as well as oil rigs. Although the general principles of air conditioning for land installations also apply to marine applications, factors such as weight, size, fire protection, smoke control, and corrosion resistance take on greater importance, and new factors (e.g., tolerance for pitch and roll, shipboard vibration, watertightness) come into play.

The importance of shipboard air conditioning depends on a ship's mission. On passenger vessels that focus completely on passenger comfort, such as cruise ships and casino vessels, air conditioning is vital and a significant energy consumer. Aboard commercial vessels (tankers, bulkers, container ships, etc.), air conditioning provides an environment in which personnel can live and work without heat stress. Shipboard air conditioning also improves reliability of electronic and other critical equipment, as well as weapons systems aboard naval ships. Air conditioning on oil rigs serves the same purpose as with commercial vessels (i.e., providing a suitable environment for workers), and for larger rigs with significant accommodation areas, the amount of cooling can be substantial, similar to passenger vessels. Oil rig applications also introduce the additional consideration of operating within areas classified as hazardous.

This chapter discusses merchant ships, which includes passenger and commercial vessels, and naval surface ships. In general, the details of merchant ship air conditioning also apply to warships. However, all ships are governed by their specific ship specifications, and warships are often also governed by military specifications, which ensure air-conditioning system and equipment performance in the extreme environment of warship duty.

1. MERCHANT SHIPS

Load Calculations

The cooling load estimate considers the following factors (discussed in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*):

- Solar radiation
- Heat transmission through hull, decks, and bulkheads
- Heat (latent and sensible) dissipation from occupants
- Heat gain from lights
- Heat (latent and sensible) gain from ventilation air
- Heat gain from motors or other electrical equipment
- Heat gain from piping, machinery, and equipment

The heating load estimate should include the following:

- Heat losses through decks and bulkheads
- Ventilation air
- Infiltration (when specified)

In addition, the construction and transient nature of ships present some complications, as addressed in the following:

SNAME. The Society of Naval Architects and Marine Engineers (SNAME 2015) *Technical and Research Bulletin* 4-16 can be used as a guide for shipboard load calculations.

The preparation of this chapter is assigned to TC 9.3, Transportation Air Conditioning.

ISO. The International Organization for Standardization's (ISO) *Standard* 7547 discusses design conditions and calculations for marine HVAC systems.

Outdoor Ambient Temperature and Humidity. The service and type of vessel determine the proper outdoor design temperature, which should be based on temperatures prevalent in a ship's area of operation. Use Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* to select ambient conditions, with special attention paid to high-wet-bulb data; a ship's load is often driven by the latent load associated with the outdoor air. It is also common for different locations to be used for cooling and heating criteria. In general, for cooling, outdoor design conditions are 35°C db and 25.5°C wb; for semitropical runs, 35°C db and 26.5°C wb; and for tropical runs, 35°C db and 28°C wb. For heating, –18°C is usually the design temperature, unless the vessel will always operate in warmer climates. Design temperatures for seawater are 32°C in summer and –2°C in winter.

Solar Gain. Ships require special consideration for solar gain because (1) they do not constantly face in one direction and (2) the reflective properties of water increase solar load on outer boundaries not directly exposed to sunlight. For compartments with only one exterior boundary, the temperature difference (outdoor dry-bulb temperature – indoor dry-bulb temperature) across horizontal surfaces should be increased by 28 K and vertical surfaces by 17 K. For compartments with more than one exterior boundary, the temperature difference should be increased by 19 K for horizontal surfaces and 11 K for vertical surfaces. For glass surfaces, the solar cooling load (SCL) is taken to be 500 W/m^2 for spaces with one exterior boundary and 380 W/m^2 for spaces with more than one exterior boundary. A more modern approach is to use appropriate building energy simulation software (a full list of which is maintained by the U.S. Department of Energy) to model the ship's accommodation spaces. These programs generally allow building exposure to be changed globally, making it easy to examine the change in ship loads as the route direction changes.

Infiltration. Infiltration through weather doors is generally disregarded. However, specifications for merchant ships occasionally require an assumed infiltration load for heating steering gear rooms and the pilothouse.

Transmission Between Spaces. For heating loads, heat transmission through boundaries of machinery spaces in either direction is not of consequence. Allowances are not made for heat gain from warmer adjacent spaces. For cooling loads, the cooling effect of adjacent spaces is not considered unless temperatures are maintained with refrigeration or air-conditioning equipment.

Ventilation Requirements. Ventilation is a very important consideration, because it is frequently the main contributor to overall energy usage of the system. Rules and guidance are provided by conflicting standards, including ISO *Standard* 7547, SNAME *Technical and Research Bulletin* 4-16, and ASHRAE *Standard* 62.1-2016. Ultimately, that stated in the ship's specification and what is acceptable to the authority having jurisdiction (AHJ) govern ventilation requirements. However, given the opportunity to reduce energy (fuel) consumption and the need to ensure passenger health and safety, it behooves the system designer to apply modern tools, such as building energy simulation and demand-controlled ventilation to optimize the quantity of fresh air introduced under all conditions. There is a unique opportunity for fresh-air optimization aboard ships because the number of passengers is fixed and each person can only be in one location at a time. Significant overventilation that can occur by catering to the maximum fresh-air requirement in each space simultaneously.

Heat Transmission Coefficients. The overall heat transmission coefficients *U* for the composite structures common to shipboard construction do not lend themselves to theoretical derivation; they are usually obtained from full-scale panel tests. SNAME *Bulletin* 4-7 gives a method to determine these coefficients when tested data are unavailable. ISO *Standard* 7547 also gives some guidance in this area, as well as default values if better information is not available.

Indoor Air Temperature and Humidity. Thermal environmental conditions for human occupancy are given in ASHRAE *Standard* 55-2017.

People. Ships normally carry a fixed number of people. The engineer must select the location where the ship's fixed complement of people creates the greatest heat load, and then not apply the people load elsewhere. Note that occupants are only counted once when determining the chiller or condensing-unit load; however, air coils in each zone must be capable of removing the heat load associated with the maximum number of people in the zone.

Ventilation in the zone can also be reduced when occupants are not present. For the ventilation load, occupants are counted once, in the location where they create the greatest ventilation requirement. The practical way to apply this concept is by measuring CO_2 levels in a space and adjusting outdoor air accordingly. Although using this principle can reduce required chiller or condensing-unit capacity on all ships, it is most significant for passenger ships.

Equipment

In general, equipment used for ships is much more rugged than that used on land. Sections 6 through 10 of ASHRAE *Standard* 26 list HVAC equipment requirements for marine applications. When selecting marine duty air-conditioning equipment, consider the following:

- It should function properly under dynamic roll and pitch and static trim and heel conditions. This is especially important for compressor oil sumps, oil separators, refrigerant drainage from a condenser and receiver, accumulators, and condensate drainage from drain pans.
- Construction materials should withstand the corrosive effects of salt air and seawater. Materials such as stainless steel, nickel-copper, copper-nickel, bronze alloys, and hot-dipped galvanized steel are used extensively.
- It should be designed for uninterrupted operation during the voyage and continuous year-round operation. Because ships en route cannot be easily serviced, some standby capacity, spare parts for all essential items, and extra oil and refrigerant charge should be carried.
- It should have no objectionable noise or vibration, and must meet noise criteria required by the ship's specification.
- It should occupy minimum space, commensurate with its cost and reliability. Mass should also be minimized.
- A ship may pass through one or more complete cycles of seasons on a single voyage and may experience a change from winter to summer operation in a matter of hours. Systems should be flexible enough to compensate for climatic changes with minimal attention from the ship's crew.

The following general items should be considered when selecting specific air conditioning components:

Fans. Fans must be selected for stable performance over their full range of operation and should have adequate isolation to prevent transmitting vibration to the deck. Because fan rooms are often adjacent to or near living quarters, effective sound treatment is essential.

Cooling Coils. If more than 30% outdoor air is brought across a cooling coil, consider using copper tube, copper fin, epoxy-coated coils, or other special treatment. To account for the ship's movement, drain pans should have two drain connections, and should ideally be dual sloping, with extra depth. Because of size constraints, care must be taken to prevent moisture carryover. Face velocity limits (in m/s) for different coil materials and different fin spacing are as follows:

Fin Spacing, mm	Aluminum Fins	Copper or Coated Fins
3.2	2.8	2.6
2.3	2.8	2.1
1.8	2.8	1.9

Off-coil temperatures are another concern. Ships typically have low ceiling heights and cannot tolerate low air-introduction temperatures. Typically 12.8°C db and 12.2°C wb are used as limiting off-coil temperatures.

Electric Heaters. U.S. Coast Guard (USCG) approved sheathed-element heaters are typically required. The only exception is when the electric heaters, approved by a regulatory body such as UL, are incorporated in a packaged unit.

Air Diffusers. Care must be taken with selection of air diffusers because of the low ceilings typical of shipboard applications.

Air-Conditioning Compressors. Compressors of all types are used for marine applications. Care must be taken when using a centrifugal compressor because low-load, high-condensing temperature is a common off-load condition.

When high discharge temperatures are a concern, seawater-cooled heads are not normally an option; other methods such as fan cooling or liquid injection must be considered for maintaining acceptable discharge temperatures.

Typical Systems

All types of systems may be considered for each marine application. The systems are the same as in land applications; the difference is the relative weighting of their advantages and disadvantages for marine use. This section does not review all the systems used aboard ships, but rather some of the more common ones.

Direct refrigerant cooling systems are often used for small, single-zone applications. Aboard ships, places like control rooms and pilot houses lend themselves to a direct refrigerant system. For larger spaces, air distribution is of more concern; direct refrigerant cooling is thus less likely to be the optimum solution.

Two-pipe and **four-pipe fan coil systems** are often used for large systems. The water piping used in these systems takes up only a fraction of the space used by an all-air ducted system. Fan noise in the space being cooled is the disadvantage. In addition, limited humidity control and fresh-air requirements often need to be addressed separately.

Many types of **all-air systems** are used aboard ships. Space, cost, noise, and complexity are among the leading parameters when comparing different all-air systems. Using high-velocity air distribution for an all-air system offers many advantages; unitary (factory-assembled) central air-handling equipment and prefabricated piping, clamps, and fittings facilitate installation for both new construction and conversions. Substantial space-saving is possible compared to conventional low-velocity sheet metal ducts. Maintenance is also reduced. Noise is the one major drawback of a high-velocity system, which often leads to selection of a low-velocity system.

Terminal reheat air conditioning (described in Chapter 4 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*) is commonly used because of its simplicity and good zone control characteristics. However, as systems become larger, this system's energy inefficiency becomes a significant drawback. For large passenger ships, where energy efficiency is absolutely essential, the designer should consider more modern approaches. One method is delivering tempered ventilation air from a central-station air handler to the passenger staterooms, each of which is outfitted with a dedicated cabin fan-coil unit, including a chilled-water-cooling and hot-water-heating coil. The individual cabin is then either heated or cooled from a neutral temperature, using central loops, depending on specific needs. The efficiency of this approach is further improved by having reclaimed heat sources (e.g., from the central chillers or the main engine cooling system) to maintain the hot-water loop temperature.

Dual-duct systems (also described in Chapter 4 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*) have the following advantages:

- All conditioning equipment is centrally located, simplifying maintenance and operation
- Can heat and cool adjacent spaces simultaneously without cycle changeover and with minimum automatic controls
- Because only air is distributed from fan rooms, no water or steam piping, electrical equipment, or wiring are in conditioned spaces

The major drawback is the inability to finely control temperature and humidity. This disadvantage is enough to preclude the use of these systems in many passenger vessel applications.

Aboard ships, **constant-volume systems** are most common. Their advantages include simplicity (for maintenance, operation, and repair) and low cost. However, for large passenger vessels, the energy efficiency and the tight control of zone temperature make **variable-volume/temperature systems** very attractive.

Air Distribution Methods

Good air distribution in staterooms and public spaces is difficult to achieve because of low ceiling heights and compact space arrangements. Design should consider room dimensions, ceiling height, volume of air handled, air temperature difference between supply and room air, location of berths, and allowable noise. For major installations, mock-up tests are often used to establish exacting performance criteria.

Air usually returns from individual small spaces either by a sight-tight louver mounted in the door or by an undercut in the door leading to the passageway. An undercut door can only be used with air quantities of 35 L/s or less. Louvers are usually sized for face velocity of 2 m/s based on free area.

Ductwork on merchant ships is generally constructed of steel. Ducts, other than those requiring heavier construction because of susceptibility to damage or corrosion, are usually made with riveted seams sealed with hot solder or fire-resistant duct sealer, welded seams, or hooked seams and laps. They are made of hot-dipped, galvanized, copper-bearing sheet steel, suitably stiffened externally. The minimum thickness of material is determined by the diameter of round ducts or by the largest dimension of rectangular ducts, as listed in Table 1.

Table 1 Minimum Thickness of Steel Ducts

All vertical exposed ducts	16 USSG	1.52 mm
Horizontal or concealed vertical ducts		
less than 150 mm	24 USSG	0.62 mm
160 to 300 mm	22 USSG	0.76 mm
310 to 460 mm	20 USSG	0.91 mm
470 to 760 mm	18 USSG	1.21 mm
over 760 mm	16 USSG	1.52 mm

The increased use of high-velocity, high-pressure systems has resulted in greater use of prefabricated round pipe and fittings, including spiral-formed sheet metal ducts. It is important that field-fabricated ducts and fittings be airtight. Using factory-fabricated fittings, clamps, and joints effectively minimizes air leakage for these high-pressure ducts.

In addition to the space advantage, small ductwork saves mass, another important consideration for this application.

Control

The conditioning load, even on a single voyage, varies over a wide range within short periods. Not only must the refrigeration plant meet these load variations, but the controls must readily adjust the system to sudden climatic changes. Accordingly, it is general practice to equip the plant with automatic controls. Increasingly, fully communicating network controls are being applied to optimize operation of the entire system under transient conditions. Moreover, such controls now can collect large amounts of operational data and offer proactive diagnostics based on these data, helping the ship operator maximize efficiency and reliability throughout the life cycle.

Regulatory Agencies

Merchant vessels that operate under the U.S. flag come under the jurisdiction of the U.S. Coast Guard. Accordingly, the installation and components must conform to the Marine Engineering Rules and Marine Standards of the Coast Guard covered under the *Guide to Structural Fire Protection* (USCG 2010).

Certified pressure vessels and electric components approved by independent agencies (e.g., ASME, UL) must be used. Wherever possible, equipment used should comply with ABS rules and regulations. This is especially important when vessels are equipped for carrying cargo refrigeration, because air-conditioning compressors may serve as standby units in the event of a cargo compressor failure. This compliance eliminates the need for a separate, spare cargo compressor. The International Convention for the Safety of Life at Sea (SOLAS) (IMO 2014) governs the use of fire-dampers and duct wall thickness when passageways or fire boundaries are crossed.

2. NAVAL SURFACE SHIPS

Design Criteria

Outdoor Ambient Temperature. Design conditions for naval vessels have been established as a compromise, considering the large cooling plants required for internal heat loads generated by machinery, weapons, electronics, and personnel. Temperatures of 32°C db and 27°C wb are used for worldwide applications, with 29.5°C seawater temperatures. Heating-season temperatures are –12°C for outdoor air and –2°C for seawater.

Indoor Temperature. Naval ships are generally designed for space temperatures of 26.5°C db with a maximum of 55% rh for most areas requiring air conditioning. USN (1969) gives design conditions established for specific areas, and USMA (1965) lists temperatures for ventilated spaces.

Ventilation Requirements. As for merchant ships, there is conflicting guidance regarding ventilation requirements; see ISO *Standard* 7547, SNAME *Technical and Research Bulletin* 4-16, and ASHRAE *Standard* 62.1-2016.Ventilation must meet the requirements of the ship's specification and the U.S. government, but as with merchant ships, the system designer should apply modern tools, such as building energy simulation and demand controlled ventilation, to optimize the quantity of fresh air introduced under all conditions, ensuring safe operation and technical justification.

Air-Conditioned Spaces. Naval ship design requires that air-conditioning systems serving living and berthing areas on surface ships replenish air in accordance with damage control classifications, as specified in USN (1969):

- Class Z systems: 2.4 L/s per person
- Class W systems for troop berthing areas: 2.4 L/s per person

- All other Class W systems: 4.7 L/s per person. The flow rate is increased only to meet either a 35 L/s minimum branch requirement or to balance exhaust requirements. Outdoor air should be kept at a minimum to limit the size of the air-conditioning plant.

Load Determination

The cooling load estimate consists of coefficients from USN's *Design Data Sheet* DDS511-2, *General Specifications for Building Naval Ships*, or *Document* 0938-018-0010 (USN 1969) and has allowances for the following:

- Solar radiation
- Heat transmission through hull, decks, and bulkheads
- Heat (latent and sensible) gain of occupants
- Heat gain from lights
- Heat (latent and sensible) gain from ventilation air
- Heat gain from motors or other electrical equipment
- Heat gain from piping, machinery, and equipment

Loads should be derived from requirements indicated in USN (1969). The heating load estimate should include the following:

- Heat losses through hull, decks, and bulkheads
- Ventilation air
- Infiltration (when specified)

Some electronic spaces listed in USN (1969) require adding 15% to the calculated cooling load for future growth and using one-third of the cooling-season equipment heat dissipation (less the 15% added for growth) as heat gain in the heating season.

Heat Transmission Coefficients. The overall heat transmission coefficient *U* between the conditioned space and the adjacent boundary should be estimated from USN's *Design Data Sheet* DDS511-2. Where new materials or constructions are used, new coefficients may be used from SNAME (2015) or calculated using methods found in DDS511-2 and SNAME.

Heat Gain from People. USN (1969) gives heat gain values for people in various activities and room conditions.

Heat Gain from Sources in the Space. USN (1969) gives heat gain from lights and motors driving ventilation equipment. Heat gain and use factors for other motors and electrical and electronic equipment may be obtained from the manufacturer or from Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*.

Equipment Selection

The equipment described for merchant ships also applies to U.S. naval vessels, except as follows:

Fans. A family of standard fans is used by the navy, including vaneaxial, tubeaxial, and centrifugal fans. Selection curves used for system design are found on USN's NAVSEA *Standard Drawings* 810-921984, 810-925368, and 803-5001058. Manufacturers are required to furnish fans that are dimensionally identical to the standard plan and within 5% of the delivery. No belt-driven fans are included.

Cooling Coils. The U.S. Navy uses eight standard sizes of direct-expansion and chilled-water cooling coils. All coils have eight rows in the direction of airflow, with a face area range of 0.06 to 0.93 m^2.

Coils are selected for a face velocity of 2.5 m/s maximum; however, sizes 54 DW to 58 DW may have face velocity up to 3.2 m/s if the bottom of the duct on the discharge is sloped up at 15° for a distance equal to the height of the coil. Construction and materials are specified in MIL-PRF-2939G.

Chilled-water coils are most common and are selected based on 7.2°C inlet water with approximately a 3.7 K rise in water temperature through the coil. This is equivalent to 65 mL/s per kilowatt of cooling.

Heating Coils. The standard naval steam and electric duct heaters have specifications as follows:

Steam Duct Heaters

- Maximum face velocity is 9.1 m/s.
- Preheater leaving air temperature is 5.5 to 10°C.
- Steam heaters are served from a 350 kPa (gage) steam system.

Electric Duct Heaters

- Maximum face velocity is 7.1 m/s.
- Temperature rise through the heater is per MIL-PRF-22594C, but is in no case more than 27 K.
- Power supply for the smallest heaters is 120 V, three-phase, 60 Hz. All remaining power supplies are 440 V, three-phase, 60 Hz.
- Pressure drop through the heater must not exceed 85 Pa at 5 m/s. Use manufacturers' tested data in system design.

Filters. Characteristics of the seven standard filter sizes used by the U.S. Navy are as follows:

- Filters are available in steel or aluminum.
- Filter face velocity is between 1.9 and 4.6 m/s.
- A filter-cleaning station on board ship includes facilities to wash, oil, and drain filters.

Air Diffusers. Although the U.S. Navy also uses standard diffusers for air conditioning, they are generally a commercial type similar to those used for merchant ships.

Air-Conditioning Compressors. In the past, the U.S. Navy primarily used reciprocating compressors up to approximately 530 kW; for larger capacities, open, direct-drive centrifugal compressors are used. On new designs, the U.S. Navy primarily uses rotary compressors (e.g., screw and centrifugal), frequently semihermetic. R-134a is the U.S. Navy's primary refrigerant. Seawater is used for condenser cooling at 90 mL/s per kilowatt for reciprocal compressors and 72 mL/s per kilowatt for centrifugal compressors, but in all cases, the maximum seawater velocity of 1.8 m/s must be deferred to in order to prevent tube erosion.

Typical Air Systems

On naval ships, zone reheat is used for most applications. Some ships with sufficient electric power use low-velocity terminal reheat systems with electric heaters in the space. Some newer ships use a fan-coil unit with fan, chilled-water cooling coil, and electric heating coil in spaces with low to medium sensible heat per unit area of space requirements. The unit is supplemented by conventional systems serving spaces with high sensible or latent loads.

Air Distribution Methods

Methods used on naval ships are similar to those discussed in the section on Merchant Ships. The minimum thickness of materials for ducts is listed in Table 2.

Control

The navy's principal air-conditioning control uses a two-position dual thermostat that controls a cooling coil and an electric or steam reheater. This thermostat can be set for summer operation and does not require resetting for winter operation.

Steam preheaters use a regulating valve with (1) a weather bulb controlling approximately 25% of the valve's capacity to prevent freeze-up, and (2) a line bulb in the duct downstream of the heater to control the temperature between 5.5 and 10°C.

Other controls are used to suit special needs. Pneumatic/electric controls can be used when close tolerances in temperature and humidity control are required, as in operating rooms. Thyristor controls are sometimes used on electric reheaters in ventilation systems.

Modern ship designs use fully communicating networked controls that optimize system operation and provide useful data and feedback to the operator. The Navy is increasingly implementing energy-saving measures aboard all of its ships.

Table 2 Minimum Thickness of Materials for Ducts

Sheet for Fabricated Ductwork				
	Non-Watertight		Watertight	
Diameter or Longer Side	Galvanized Steel	Aluminum	Galvanized Steel	Aluminum
Up to 150	0.46	0.64	1.90	2.69
160 to 300	0.76	1.02	2.54	3.56
310 to 460	0.91	1.27	3.00	4.06
470 to 760	1.22	1.52	3.00	4.06
Above 760	1.52	2.24	3.00	4.06
Welded or Seamless Aluminum Tubing				
Tubing Size	Non-Watertight		Watertight	
50 to 150	0.89		2.69	
160 to 300	1.27		3.56	
Spirally Wound Duct (Non-Watertight)				
Diameter	Steel		Aluminum	
Up to 200	0.46		0.64	
Over 200	0.76		0.81	

Note: All dimensions in millimetres.

Operation and Maintenance ... 15.9
Heat Recovery and Energy Conservation ... 15.10
Control Systems ... 15.10
Life and Property Safety ... 15.10
Commissioning ... 15.11

THIS chapter addresses air-conditioning systems for industrial facilities such as manufacturing plants, laboratories, processing plants, and power plants. HVAC systems provide the process environment (including temperature, humidity, air motion, air quality, noise, and cleanliness) to facilitate industrial processes and provide for the health, safety, and comfort of personnel.

Many industrial buildings require large amounts of energy, in both manufacturing and maintaining building environmental conditions. This chapter provides system and building design guidance for energy conservation by using insulation, ventilation, and waste heat recovery.

1. GENERAL REQUIREMENTS

Typical temperatures, relative humidities, and specific filtration requirements for storage, manufacture, and processing of various commodities are listed in Table 1. Requirements for a specific application may differ from those in the table.

Industrial processes or regulatory requirements may change over time; thus, systems should be able to provide for future requirements (to the extent practical).

Outdoor design requirements and indoor temperature, humidity, cleanliness, noise, and allowable variations should be established by agreement with the owner. A compromise between requirements for product or process conditions and those for comfort may optimize quality and production costs.

An environment that allows a worker to safely perform assigned duties without fatigue caused by temperature and humidity may enhance performance.

Special Warning: Some industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), the American Conference of Governmental Industrial Hygienists (ACGIH), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses personnel safety.

The cascade-ventilation-system design for toxic agents or similar hazardous materials is a potential fit for such facilities. This can include a once-through, "push-pull" system, drawing air from the highly toxic areas to lower ones, with air change rates varying from 10 to 60 ach; pressures from –808.6 Pa to –62.2 Pa; and temperatures of 10 to 38°C. Applicable federal, state, and industry codes, and standards must be applied in the design of these facilities.

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

Terminology

The **supply system** includes **air-handling units (AHUs)** with steam and hot water heating and chilled water cooling coils, ductwork, dampers, and accessories.

Transfer air (TA) assemblies consist of ductwork, dampers, blast valves, fast-actuating dampers, and accessories.

The **exhaust air filtration system** includes **exhaust air filter units (EAFUs)** with two HEPA filters and six charcoal filters to capture highly toxic agent vapors, ductwork, dampers, accessories, and stacks.

The HVAC units are powered by off-site and essential power, and the **instrumentation and facility control system (FCS)** are fed from **uninterruptible power supply (UPS)**. FCS is a **safety instrumented system (SIS)**.

2. PROCESS AND PRODUCT REQUIREMENTS

An industrial product or process may require control of the indoor environment if it affects one or more of the following factors.

Rate of Chemical Reaction

Some processes require temperature and humidity control to regulate chemical reactions. In rayon manufacturing, for example, pulp sheets are conditioned, cut to size, and mercerized. The temperature directly controls the rate of reaction, and the relative humidity maintains the solution at a constant strength and rate of evaporation.

In drying varnish, oxidizing depends on temperature. Desirable temperatures vary with the type of varnish. High relative humidity retards surface oxidation and allows internal gases to escape as chemical oxidizers cure the varnish from within. Thus, a bubble-free surface is maintained with a homogeneous film throughout.

Rate of Crystallization

The cooling rate determines the size of crystals formed from a saturated solution. Both temperature and relative humidity affect the cooling rate and change the solution density by evaporation.

In coating pans for pills, a heavy sugar solution is added to the tumbling mass. As water evaporates, sugar crystals cover each pill. Moving the correct quantity of air over the pills at the correct temperature and relative humidity forms a smooth, opaque coating. If cooling and drying are too slow, the coating will be rough, translucent, and have an unsatisfactory appearance. If the cooling and drying are too fast, the coating will chip through to the interior.

Rate of Biochemical Reaction

Fermentation requires both temperature and humidity control to regulate the rate of biochemical reactions. Many fermentation vessels are jacketed to maintain consistent internal temperatures. Fermentors are held at different temperatures, depending on the process involved. In brewing, typical fermentor temperatures range from 7 to 11°C.

Table 1 Design Requirements for Industrial Air Conditioning[1]

Process	Dry Bulb, °C	rh, %
ABRASIVE		
Manufacture	26	50
CERAMICS		
Refractory	43 to 66	50 to 90
Molding room	27	60 to 70
Clay storage	16 to 27	35 to 65
Decalcomania production	24 to 27	48
Decorating room	24 to 27	48

Use high-efficiency (MERV 13 or better) in decorating room. To minimize the danger of silicosis in other areas, a dust-collecting system or medium-efficiency particulate air filtration may be required.

Process	Dry Bulb, °C	rh, %
DISTILLING		
General manufacturing	16 to 24	45 to 60
Aging	18 to 22	50 to 60

Low humidity and dust control are important where grains are ground. Use high-efficiency filtration for all areas to prevent mold spore and bacteria growth. Use ultrahigh-efficiency filtration where bulk flash pasteurization is performed.

Process	Dry Bulb, °C	rh, %
ELECTRICAL PRODUCTS		
Electronics and x-ray		
Coil and transformer winding	22	15
Semiconductor industry	21	45
Electrical instruments		
Manufacture and laboratory	21	50 to 55
Thermostat assembly and calibration	24	50 to 55
Humidistat assembly and calibration	24	50 to 55
Small mechanisms		
Close tolerance assembly	22*	40 to 45
Meter assembly and test	24	60 to 63
Switchgear		
Fuse and cutout assembly	23	50
Capacitor winding	23	50
Paper storage	23	50
Conductor wrapping with yarn	24	65 to 70
Lightning arrester assembly	20	20 to 40
Thermal circuit breakers assembly and test	24	30 to 60
High-voltage transformer repair	26	5
Water wheel generators		
Thrust runner lapping	21	30 to 50
Rectifiers		
Processing selenium and copper oxide plates	23	30 to 40

*Temperature to be held constant.

Dust control is essential in these processes. Minimum control requires medium-efficiency filters (MERV 11 or better). Degree of filtration depends on the type of function in the area. Smaller tolerances and miniature components suggest high-efficiency particulate air (HEPA) filters.

Process	Dry Bulb, °C	rh, %
FLOOR COVERING		
Linoleum		
Mechanical oxidizing of linseed oil*	32 to 38	
Printing	27	
Stoving process	70 to 120	

*Precise temperature control required.

Medium-efficiency particulate air filtration is recommended for the stoving process.

Process	Dry Bulb, °C	rh, %
FOUNDRIES*		
Core making	16 to 21	
Mold making		
Bench work	16 to 21	
Floor work	13 to 18	
Pouring	4	
Shakeout	4 to 10	
Cleaning room	13 to 18	

*Winter dressing room temperatures. Spot coolers are sometimes used in larger installations.

In mold making, provide exhaust hoods at transfer points with wet-collector dust removal system. Use 280 to 380 L/s per hood, with a target capture velocity of approximately 2.5 m/s.

In shakeout room, provide exhaust hoods with wet-collector dust removal system. Exhaust 190 to 240 L/s in grate area. Room ventilators are generally not effective.

In cleaning room, provide exhaust hoods for grinders and cleaning equipment with dry cyclones or bag-type collectors. In core making, oven and adjacent cooling areas require fume exhaust hoods. Pouring rooms require two-speed powered roof ventilators. Design for minimum of 10 L/s of floor area at low speed. Shielding is required to control radiation from hot surfaces. Proper introduction of air minimizes preheat requirements.

Process	Dry Bulb, °C	rh, %
FUR		
Drying	43	
Shock treatment	−8 to −7	
Storage	4 to 10	55 to 80

Shock treatment or eradication of any insect infestations requires lowering the temperature to −8 to −7°C for 3 to 4 days, then raising it to 16 to 21°C for 2 days, then lowering it again for 2 days and raising it to the storage temperature.

Furs remain pliable, oxidation is reduced, and color and luster are preserved when stored at 4 to 10°C.

Humidity control is required to prevent mold growth (which is prevalent with humidities above 80%) and hair splitting (which is common with humidities lower than 55%).

Process	Dry Bulb, °C	rh, %
GUM		
Manufacturing	25	33
Rolling	20	63
Stripping	22	53
Breaking	23	47
Wrapping	23	58
LEATHER		
Drying	20 to 52	75
Storage, winter room temperature	10 to 16	40 to 60

After leather is moistened in preparation for rolling and stretching, it is placed in an atmosphere of room temperature and 95% relative humidity.

Leather is usually stored in warehouses without temperature and humidity control. However, it is necessary to keep humidity sufficiently low to prevent mildew. Medium-efficiency particulate air filtration is recommended for fine finish.

Process	Dry Bulb, °C	rh, %
LENSES (OPTICAL)		
Fusing	24	45
Grinding	27	80

Table 1 Design Requirements for Industrial Air Conditioning[1] (*Continued*)

Process	Dry Bulb, °C	rh, %
MATCHES		
Manufacture	22 to 23	50
Drying	21 to 24	60
Storage	16 to 17	50

Water evaporates with the setting of the glue. The amount of water evaporated is 8 to 9 kg per million matches. The actual match production rate must be known to determine the actual moisture load in the space.

Process	Dry Bulb, °C	rh, %
PAINT APPLICATION		
Lacquers: Baking	150 to 180	
Oil paints: Paint spraying	16 to 32	80

The required air filtration efficiency depends on the painting process. On fine finishes, such as car bodies, high-efficiency particulate air filters are required for the outdoor air supply. Other products may require only low- or medium-efficiency filters.

Makeup air must be preheated. Spray booths must have 0.5 m/s face velocity if spraying is performed by humans; lower air quantities can be used if robots perform spraying. Ovens must have air exhausted to maintain fumes below explosive concentration. Equipment must be explosion-proof. Exhaust must be cleaned by filtration and solvents reclaimed or scrubbed.

Process	Dry Bulb, °C	rh, %
PHOTO STUDIO		
Dressing room	22 to 23	40 to 50
Studio (camera room)	22 to 23	40 to 50
Film darkroom	21 to 22	45 to 55
Print darkroom	21 to 22	45 to 55
Drying room	32 to 38	35 to 45
Finishing room	22 to 24	40 to 55
Storage room (black and white film and paper)	22 to 24	40 to 60
Storage room (color film and paper)	40 to 50	40 to 50
Motion picture studio	22	40 to 55

The above data pertain to average conditions. In some color processes, elevated temperatures as high as 40°C are used, and a higher room temperature is required.

Conversely, ideal storage conditions for color materials necessitate refrigerated or deep-freeze temperatures to ensure quality and color balance when long storage times are anticipated.

Heat liberated during printing, enlarging, and drying processes is removed through an independent exhaust system, which also serves the lamp houses and dryer hoods. All areas except finished film storage require a minimum of medium-efficiency particulate air filters.

Process	Dry Bulb, °C	rh, %
PLASTICS		
Manufacturing areas		
Thermosetting molding compounds	27	25 to 30
Cellophane wrapping	24 to 27	45 to 65

In manufacturing areas where plastic is exposed in the liquid state or molded, high-efficiency particulate air filters may be required. Dust collection and fume control are essential.

Process	Dry Bulb, °C	rh, %
PLYWOOD		
Hot pressing (resin)	32	60
Cold pressing	32	15 to 25
RUBBER-DIPPED GOODS		
Manufacture	32	
Cementing	27	25 to 30*
Dipping surgical articles	24 to 27	25 to 30*
Storage prior to manufacture	16 to 24	40 to 50*
Testing laboratory	23	50*

*Dew point of air must be below evaporation temperature of solvent.

Solvents used in manufacturing processes are often explosive and toxic, requiring positive ventilation. Volume manufacturers usually install a solvent recovery system for area exhaust systems.

Process	Dry Bulb, °C	rh, %
TEA		
Packaging	18	65

Ideal moisture content is 5 to 6% for quality and mass. Low-limit moisture content for quality is 4%.

Process	Dry Bulb, °C	rh, %
TOBACCO		
Cigar and cigarette making	21 to 24	55 to 65*
Softening	32	85 to 88
Stemming and stripping	24 to 29	70 to 75
Packing and shipping	23 to 24	65
Filler tobacco casing and conditioning	24	75
Filter tobacco storage and preparation	25	70
Wrapper tobacco storage and conditioning	24	75

*Relative humidity fairly constant with range as set by cigarette machine.

Before stripping, tobacco undergoes a softening operation.

Process	Dry Bulb, °C	rh, %
TOXIC AGENTS/HAZARDOUS MATERIALS		
Process areas	20 to 39	<65

[1]Filtration as discussed in the table should correspond to the following minimums as defined in ASHRAE *Standard* 52.2:

Low efficiency	MERV 7 to MERV 8
Medium efficiency	MERV 10 to MERV 12
High efficiency	MERV 13 to MERV 14
Ultrahigh efficiency	MERV 15
HEPA	MERV 17 to MERV 20

The process engineer and owner should determine the process and HVAC filtration specifications for the specific application.

Because of vessel jacketing, tight control of room temperature may not be required. Usually, space temperatures should be held as close as practical to the process temperature inside the fermentation vessel.

Designing such spaces should take into account gases and other by-products generated by fermentation. Typically, carbon dioxide is the most prevalent by-product of fermentation in brewing and presents the greatest potential hazard if a fermentor overpressurizes the seal. Provide adequate ventilation in case carbon dioxide escapes the process.

In biopharmaceutical processes, hazardous organisms can escape a fermentor; design of spaces using those fermentors should allow containment. Heat gains from steam-sparged vessels should also be accounted for in such spaces.

Product Accuracy and Uniformity

Air temperature and cleanliness affect quality in manufacturing precision instruments, lenses, and tools. When manufacturing tolerances are within 5 µm, close temperature control (typically ±2.8 K) prevents expansion and contraction of the material; constant temperature over time is more important than the temperature level.

Table 2 Regain of Hygroscopic Materials*

Classification	Material	Description	Relative Humidity 10	20	30	40	50	60	70	80	90
Natural textile fibers	Cotton	Sea island—roving	2.5	3.7	4.6	5.5	6.6	7.9	9.5	11.5	14.1

*Moisture content expressed in percent of dry mass of the substance at various relative humidities, temperature 24°C.

Usually, conditions are selected for personnel comfort and to prevent a film of moisture on the surface. A high-efficiency particulate air (HEPA) or ultralow-penetration air (ULPA) filter may be required.

Product Formability

Manufacturing pharmaceutical tablets requires close control of humidity for optimum tablet formation. Tableting typically requires less than 40% rh at 20°C.

Moisture Regain

Air temperature and relative humidity markedly influence production rate and product mass, strength, appearance, and quality in manufacturing or processing hygroscopic materials such as textiles, paper, wood, leather, and tobacco. Moisture in vegetable and animal materials (and some minerals) reaches equilibrium with moisture in the surrounding air by **regain** (the percentage of absorbed moisture in a material compared to that material's bone-dry mass). For example, if a material sample with a mass of 2.5 kg has a mass of only 2.25 kg after thorough drying under standard conditions of 105 to 110°C, the mass of absorbed moisture is 0.25 kg, 10% of the sample's bone-dry mass. Therefore, the regain is 10%.

Table 2 lists typical regain values for materials at 24°C in equilibrium at various relative humidities. Temperature change affects the rate of absorption or drying, which generally varies with the thickness, density, and nature of the material. Sudden temperature changes cause slight changes in regain even with fixed relative humidity, but the major change occurs as a function of relative humidity.

Hygroscopic materials deliver sensible heat to the air in an amount equal to the latent heat of the absorbed moisture. The amount of heat liberated should be added to the cooling load if it is significant, but it is usually quite small. Manufacturing economy requires regain to be maintained at a level suitable for rapid and satisfactory manipulation. Uniform relative humidity allows high-speed machinery to operate efficiently.

Some materials may be exposed to the required humidity during manufacturing or processing, and others may be treated separately after conditioning and drying. Conditioning removes or adds hygroscopic moisture. Drying removes both hygroscopic moisture and free moisture in excess of that in equilibrium. Drying and conditioning can be combined to remove moisture and accurately regulate the final moisture content in products such as tobacco and textiles. Conditioning or drying is frequently a continuous process in which the material is conveyed through a tunnel and subjected to controlled atmospheric conditions. For more detail, see Chapter 24 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Corrosion, Rust, and Abrasion

In manufacturing metal products, temperature and relative humidity must be kept sufficiently low to prevent hands from sweating, thus protecting the finished article from fingerprints, tarnish, and/or etching. Salt and acid in perspiration can cause corrosion and rust in as little as a few hours. Manufacture of polished surfaces and of steel-belted radial tires usually requires medium-efficiency to HEPA filtering to prevent surface abrasion.

Air Cleanliness

Each application must be evaluated to determine the filtration needed to counter the adverse effects on the product or process of dust particles, airborne bacteria, smoke, spores, pollen, and radioactive particles. These effects include chemically altering production material, spoiling perishable goods, and clogging small openings in precision machinery. See Chapter 29 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for details.

Static Electricity

Static electricity is often detrimental in processing light materials such as textile fibers and paper, and extremely dangerous where potentially explosive atmospheres or materials are present. Static electric charges are generally minimized when relative humidity is above 35%. Room relative humidity may need to be maintained at 65% or higher because machinery heat raises the machine ambient temperature well above the room temperature, creating localized areas of low relative humidity. Such areas could be sources of static electricity. The parts assembly area of an ammunition plant should have design conditions of 24°C and 40 to 60% rh. In addition, air-moving equipment (fans) should be spark resistant.

According to NFPA *Standard* 77, humidification increases a material's surface conductivity, but the static electric charge dissipates only if there is a conductive path to ground.

However, humidification is not a cure-all for static electricity problems. Some insulators do not adsorb or absorb moisture from the air, and high humidity does not noticeably decrease their surface resistivity. Examples include uncontaminated surfaces of some polymeric materials (e.g., plastic piping and containers, films), and the surface of petroleum liquids. These surfaces can accumulate static electric charge even when the atmosphere has a humidity of 100%.

3. PERSONNEL REQUIREMENTS

Space conditions required by health and safety standards to avoid excess exposure to high temperatures and airborne contaminants are often established by the American Conference of Governmental Industrial Hygienists (ACGIH). In the United States, the National Institute of Occupational Safety and Health (NIOSH) does research and recommends guidelines for workplace environments. The Occupational Safety and Health Administration (OSHA) sets standards based on these guidelines, with enforcement usually assigned to a corresponding state agency.

Standards for safe levels of contaminants in the work environment or in air exhausted from facilities do not cover everything that may be encountered. Minimum safety standards and design criteria are available from U.S. Department of Health agencies such as the National Institute of Health, National Cancer Institute, and Public Health Service. The U.S. Department of Energy and Nuclear Regulatory Commission establish standards for radioactive substances.

Thermal Control Levels

Industrial plants are usually designed for an internal temperature of 16 to 32°C and a maximum of 60% rh. Tighter controls are often dictated by the specific operations and processes located in the building. ACGIH (2016) established guidelines to evaluate high temperature and humidity levels in terms of heat stress (Dukes-Dobos and Henschel 1971). See Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* for a more detailed analysis of work rate, air velocity, rest, and the effects of radiant heat.

Temperature control becomes tighter and more specific if personnel comfort, rather than avoidance of heat stress, becomes the criterion. Nearly sedentary workers prefer a winter temperature of 22°C and a summer temperature of 26°C at a maximum of 60% rh. Workers at a high rate of activity prefer 18°C; they are less sensitive to temperature changes and can be cooled by increasing the air velocity. ASHRAE *Standard* 55 provides more detailed information.

Contamination Control Levels

Toxic and/or hazardous materials are present in many industrial plants and laboratories. Gases and vapors are found near acid baths and tanks holding process chemicals. Plating operations, spraying, mixing, abrasive cleaning, and other processes generate dust, fumes, and mists. Many animal and laboratory procedures (e.g., grinding, blending, sonication, weighing) generate aerosols. Air-conditioning and ventilation systems must minimize exposure to these materials. When airborne, these materials greatly expand their range and potential for affecting more people. Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals*, OSHA requirements, and ACGIH (2016) give guidance on the health effects of various materials.

Concentrations of gaseous flammable substances must also be kept below explosive limits. Acceptable concentrations of these substances are a maximum of 25% of the lower explosive limit. Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals* provides data on flammable limits and their means of control.

Instruments are available to measure concentrations of common gases and vapors, but specific monitoring requirements and methods must be developed for uncommon ones.

4. DESIGN CONSIDERATIONS

Required environmental conditions for equipment, process, and personnel comfort must be known before selecting HVAC equipment. The engineer and owner jointly establish design criteria, including the space-by-space environment in facilities, process heat loads and exhaust requirements, heat and cooling energy recovery, load factors and equipment diversity, lighting, cleanliness, etc. Consider separating dirty processes from areas that require progressively cleaner air.

Insulation should be evaluated for initial cost and operating and energy cost savings. When high levels of moisture are required in the building, the air-conditioning and structural envelope must prevent unwanted condensation and ensure a high-quality product. Condensation can be prevented by eliminating thermal short circuits, installing proper insulation, and using vapor barriers. See Chapters 25 and 27 of the 2017 *ASHRAE Handbook—Fundamentals* for further details.

Personnel engaged in some industrial processes may be subject to a wide range of activity levels for which a broad range of temperatures and humidities are desirable. Chapter 9 of the 2017 *ASHRAE Handbook—Fundamentals* addresses recommended indoor conditions for a variety of activity levels.

If layout and construction drawings are not available, a complete survey of existing premises and a checklist for proposed facilities are necessary (Table 3).

New industrial buildings are typically single story with a flat roof and ample height to distribute air and utilities without interfering with process operations. Fluorescent fixtures are commonly mounted at heights up to 4 m, high-output fluorescent fixtures up to 6 m, and high-pressure sodium or metal halide fixtures above 6 m; LED fixtures are used at all heights. Lighting design considers light quality, diffusion, room size, mounting height, and economics. Illumination levels should conform to recommendations of the Illuminating Engineering Society of North America.

Air-conditioning systems can be located on the roof of the building or (ideally) in an interior equipment room. Air intakes should not be located too close to loading docks or other sources of contamination. (See the section on Air Filtration Systems.) HVAC system installation must be coordinated with other systems and equipment that compete for building space, such as piping systems, electrical bus, fire sprinklers, lighting, cranes, structural elements, etc.

Operations in the building must also be considered: some require close control of temperature, humidity, and/or contaminants. A schedule of operations is helpful in determining heating and cooling loads.

Table 3 Facilities Checklist

Construction
1. Single or multistory
2. Type and location of doors, windows, crack lengths
3. Structural design live loads
4. Floor construction
5. Exposed wall materials
6. Roof materials and color
7. Insulation type and thicknesses
8. Location of existing inlet and exhaust equipment
9. Building orientation

Use of Building
1. Product needs
2. Surface cleanliness; acceptable airborne contamination level
3. Process equipment: type, location, and exhaust requirements
4. Personnel needs, temperature levels, required activity levels, and special workplace requirements
5. Floor area occupied by machines and materials
6. Clearance above floor required for material-handling equipment, piping, lights, or air distribution systems
7. Unusual occurrences and their frequency, such as large cold or hot masses of material moved indoors
8. Frequency and length of time doors open for loading or unloading
9. Lighting: location, type, and capacity
10. Acoustical levels
11. Machinery loads, such as electric motors (size, diversity), large latent loads, or radiant loads from furnaces and ovens
12. Potential for temperature stratification

Design Conditions
1. Design temperatures: indoor and outdoor dry and wet bulb
2. Altitude
3. Wind velocity
4. Makeup air required
5. Indoor temperature and allowable variance
6. Indoor relative humidity and allowable variance
7. Indoor air quality definition and allowable variance
8. Outdoor temperature occurrence frequencies
9. Operational periods: number per day and duration
10. Waste heat availability and energy conservation incentives
11. Pressurization required
12. Mass loads from the energy release of productive materials

Code and Insurance Requirements
1. State and local code requirements for ventilation rates, etc.
2. Occupational health and safety requirements
3. Insuring agency requirements

Utilities Available and Required
1. Gas, oil, compressed air (pressure), electricity (characteristics), steam (pressure), water (pressure), wastewater, interior and site drainage
2. Rate structures for each utility
3. Potable and fire water

Material Handling (MH) Airlock Interface

Material handling airlock interfaces can be used in facilities that process toxic agents or similarly hazardous materials. Each MH conveyor airlock has one in gate and one out gate. These gates are equipped with position switches that send signals to the FCS to indicate the gate positions (open/closed). When both gates are closed, continuous air purging is required; when either of the gates is open, sufficient capture velocity is required to prevent backflow. Both gates should not be open simultaneously.

Each MH airlock is provided with one set of inlet and outlet transfer air assemblies. The inlet assembly consists of one big and one small on/off isolation damper. The outlet assembly has a pressure control damper. The FCS opens both inlet isolation dampers and modulates the outlet pressure control damper to satisfy the design airlock pressure. When one gate is open, the FCS adjusts the positions of the isolation and pressure control dampers to allow an airflow rate that satisfies both ventilation and design capture velocity requirements.

Process Exhaust Interface with Exhaust System. Offgas treatment (OT) process exhausts are discharged from the process blowers into the HVAC exhaust air inlet headers. The FCS enables OT blower operation only when HVAC exhaust air inlet headers are maintained at the set negative pressure. Space pressure controllers of the adjacent rooms modulate the respective dampers in the supply air ducts to balance airflow and keep the downstream room at set negative pressure.

System Shutdown. The ventilation/filtration system of toxic areas is in continuous operation. If negative pressure cannot be maintained because of a loss of essential power off site, the system is automatically shut down via the FCS, and all normally open TA isolation dampers in the toxic areas of the cascading airflow paths are closed to prevent toxic vapor migration. The fast-actuating isolation valves remain open to keep the blast resistant rooms vented to the EAFUs.

5. LOAD CALCULATIONS

Table 1 and specific product chapters of this Handbook discuss product requirements. Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals* provides appropriate heating and cooling load calculation techniques.

Solar and Transmission

The roof load is usually the largest solar load on the envelope. Solar loads on walls are often insignificant, particularly because modern factory buildings tend to be windowless. Insulating the building walls and roof almost always benefits HVAC cost and performance. Because roof surfaces can become dirty, use a dark roof color in load calculations.

Internal Heat Generation

Internal heat generated by equipment and processes, as well as products, lighting, people, and utilities, may satisfy heating load requirements. Understanding equipment operating schedules allows an appropriate diversity factor to be applied to the actual power consumption. Using connected loads may greatly oversize the system. Processes tend to operate continuously, but may be shut down on weekends or at night. Heating to some minimal level without equipment and/or process load should be considered. Consult ASHRAE research project RP-1104 (White and Pahwa 2003) for further information.

The latent load in most industrial facilities is minimal, with people and outdoor air being the primary contributors, but some processes and products do generate a latent load, which can dominate the HVAC system design. Mist collectors serving operations that use heated washers or water-based coolants operating above the targeted space temperature can contribute excessive latent loading in wet machining operations. Quantifying the latent impact for each source can help determine which exhaust streams should be discharged outdoors and not recirculated back to the space. Moisture condensation on cold surfaces must be managed when the latent load becomes very large.

Stratification Effect

The cooling load may be dramatically reduced in a work space that takes advantage of temperature stratification. A stagnant blanket of warm air directly under the roof has little effect on occupants or equipment as long as it remains undisturbed. Heat sources near the stagnant air have little effect on the cooling load. When the ceiling or roof is high, 20 to 60% of the heat energy rises out of the cooling zone, depending on building construction and the temperature of heat sources. Switching to a return air location near the roof could be cost effective, because it takes advantage of higher temperatures at the roof.

Supply and return air ducts should be installed as low as practical to avoid mixing the warm boundary layers in cooling mode. The location of supply air diffusers generally establishes the stratified air boundary. Spaces with a low occupant-to-floor-area ratio adapt well to using low quantities of supply air with spot cooling for personnel.

Makeup Air

Makeup air provides ventilation and building pressurization. It must be filtered and conditioned to blend with return air and then distributed to the conditioned space. The quantity of makeup air must exceed that of the exhaust air to positively pressurize the building. Makeup air quantity may be varied to accommodate an exhaust system with intermittently operating elements. Heat and cooling recovery from the exhaust airstream can substantially reduce the outdoor air load.

Processes requiring an extensive amount of exhaust air should ideally be placed in an area of the plant provided with minimal heating and no refrigerated air conditioning. Ventilation air may be required to reduce the quantity of health-threatening fumes, airborne bacteria, fugitive aerosols, or radioactive particles. Minimum ventilation rates must meet the requirements of ASHRAE *Standard* 62.1. Consult the owner's industrial hygiene or engineering representative to determine if ventilation rates in excess of this standard may be warranted.

Economizers can take advantage of ambient conditions and possibly satisfy HVAC loads without added heating or cooling for much of the year.

Fan Heat

Heat is generated by fans that move and pressurize the air. This heat is not felt by the occupants but does add to the cooling load. The discharge air temperature of a draw-through cooling arrangement requires cooler air to the fan to accommodate the temperature increase of air passing through the fan. The increase is more significant in systems with higher discharge air pressures.

6. PRESSURIZATION

Room-to-room pressurization is an essential method for contamination control. Without pressurization, surrounding contamination (e.g., particulates, gases, hot or cold air, moisture) can enter the room by infiltration through doors, windows, cracks, pass-throughs and penetrations for pipes or ducts, etc. The cleanest room should have the highest room pressure, with decreasing pressure corresponding to decreasing cleanliness. A differential pressure around 12.5 or 25 Pa is often used.

Pressurization calculations can be performed by using the procedures and charts in Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*, or those in Chapter 5 of Spitler (2009). Using the charts in Spitler, calculate the building exfiltration at designated room pressurization level. Also, in accordance with ASHRAE *Standard* 62.1, determine the required outdoor air rate using the actual number of occupants, and identify the total exhaust air volume from the building. The sum of exfiltration air volume plus exhaust rate (or required outdoor air, whichever is greater) is the total ventilation rate under the designated building pressurization.

To ensure the designated pressurization level, perform a leak test for exterior and interior walls, partitions, doors, and windows between two adjacent areas with different pressurization levels, roof, exterior doors and windows, connections between wall and roof, and any building elements between two areas with different pressurization levels. All major leaks must be eliminated before HVAC systems start-up.

If pressurization is a critical attribute for maintaining room cleanliness in areas such as plant process control rooms, computer rooms, etc., then the crack area may need to be estimated and the pressurization air quantity calculated using an equation such as Equation (11) or (12) in Chapter 54, where the crack is treated as an orifice and the required airflow is defined as a function of pressure differential. Adequate design margins should be incorporated in the pressurization system design to allow for building envelope seal degradation over the structure's life. If the pressurization is required for safety or code compliance, make provisions in the design for periodic surveillance and testing.

Explosion Management

Particularly in facilities that process toxic agents and other hazardous materials, the possibility of explosion should be addressed. Blast valve assemblies are installed at points of air transfer and exhaust air penetrations through the blast-resistant building envelope. An explosion-generated pressure wave of 103.5 kPa or greater immediately closes the affected blast valves (spring balanced pressure disks). The inlet and outlet blast valves close within 10 ms. The fast-actuating dampers are provided in series with the blast valve assemblies. On receiving alarms from explosion switches located within the affected blast-resistant rooms, the FCS automatically closes the corresponding fast-actuating isolation dampers, and fast-actuating isolation dampers powered by the nitrogen system close within 500 ms.

The blast valves are fully automatic in operation. After an explosion, when the room pressure decreases to the facility-specific set pressure, the FCS opens the exhaust-side fast-acting dampers first, and then opens those in the transfer air assemblies when the room pressure decreases to a lower (facility specific) set pressure, to restore the cascading ventilation path.

Any room involved in an explosion immediately raises all related upstream room pressures due to the cascading airflow blockage. Based on the room pressure control, the FCS automatically throttles the respective pressure dampers installed in the supply air ducts to minimize the pressure upset in the upstream rooms. The airflow blockage may create a ripple effect that causes the system header pressure controller to slow the fan speeds of the EAFU and supply AHU. In some rooms, there is a bypass exhaust pathway open to bypass exhaust to allow venting from rooms to the exhaust header.

7. SYSTEM AND EQUIPMENT SELECTION

Industrial air-conditioning equipment includes heating and cooling sources, air-handling and air-conditioning apparatus, filters, and an air distribution system. Components should be selected and the system designed for long life with low maintenance and operating costs conducive to low life-cycle cost.

Systems may consist of the following:

- Heating-only in cool climates, where ventilation air provides comfort for workers
- Air washer systems, where high humidities are desired and where the climate requires cooling
- Heating and evaporative cooling, where the climate is dry
- Heating and mechanical cooling, where temperature and humidity control are required and other means of cooling are insufficient

All systems include air filtration appropriate to the contaminant control required.

Careful evaluation should determine zones that require temperature control, especially in large, high-bay areas where the occupied zone is a small portion of space volume. ASHRAE *Standard* 55 defines the occupied zones as from the floor to 1.8 m high, more than 1 m from exterior walls or fixed conditioning equipment, and 0.3 m from interior walls.

8. HEATING SYSTEMS

Floor Heating

Floor heating is often desirable in industrial buildings, particularly in large, high-bay buildings, garages, and assembly areas where workers must be near the floor, or where large or fluctuating outdoor air loads make maintaining ambient temperature difficult.

Floors may be tempered to 18 to 21°C by embedded hydronic systems, electrical resistance cables, or warm air ducts as an auxiliary to the main heating system. Heating elements may be buried deep in the floor (150 to 450 mm) to allow slab warm-up at off-peak times, thus using the floor mass as heat storage to save energy during periods of high use.

Floor heating may be the primary or sole heating means, but floor temperatures above 29°C are uncomfortable, so such use should be limited to small, well-insulated spaces.

Unit and Ducted Heaters

Gas, oil, electric, hot-water, or steam-fired unit heaters with centrifugal or propeller fans are used for spot heating areas and may be arranged in multiples for heating an entire building. Temperatures can be varied by individual thermostatic control. Unit heaters should be located so that the discharge (throw) reaches the floor adjacent to and parallel with the outer wall, and spaced to produce a ring of warm air moving peripherally around the building. In industrial buildings with heat-producing processes, heat tends to stratify in high-bay areas. In large buildings, additional heaters should be placed in the interior so that their discharge reaches the floor to reduce stratification. Downward-discharge unit heaters in high bays and large areas may have a revolving discharge. Gas- and oil-fired unit heaters should not be used where corrosive vapors are present. Furthermore, care must be taken to avoid selecting a unit configuration wherein return air from the space is drawn through the combustion zone of any direct-fired gas burners, because unintended byproducts of combustion may result.

Ducted heaters include large direct- or indirect-fired heaters, door heaters, and heating and ventilating units. They usually have centrifugal fans.

Unit heaters and makeup air heaters commonly temper outdoor air that enters buildings through open doors. Mixing quickly brings the space temperature back to the desired setting after the door is closed. The makeup air heater should be applied as a door heater in buildings where the doors are large and open for extended periods, such as doors for large trucks or railroad cars. Such large doors often use ductwork drops across the top and along both sides of the door, with slotted diffusers to induce an air-curtain effect.

Unit heaters are also needed in buildings that have considerable leakage or a sizeable negative pressure. These units help pressurize the door area, mix the incoming cold air, temper it, and quickly bring the area back to the desired temperature after the door is closed.

Door heating units that resemble a vestibule operate with airflow down across the opening and recirculated from the bottom, which helps reduce cold drafts across the floor. These units are effective on high-usage doors under 3 m tall. Additional information on heating is given in Chapter 27 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Infrared Heaters

High-intensity gas, oil, or electric infrared heaters transfer heat directly to the occupants, equipment, and floor in the space without appreciably warming the air, though some air heating occurs by convection from objects heated by the infrared heaters. These heaters are classified as either near- or far-infrared heaters, depending on how close the wavelengths they emit are to visible light. Near-infrared heaters emit a substantial amount of visible light.

Both vented and unvented gas-fired infrared heaters are available as either individual radiant panels or as a continuous radiant pipe. Pipe-type heaters include burners 4.5 to 9 m apart and an exhaust vent fan at the end of the pipe. Unvented heaters require exhaust ventilation to remove flue products from the building and to prevent moisture from collecting on the walls and ceiling.

Infrared heaters are common in the following applications:

- High-bay buildings, where heaters are usually mounted 3 to 9 m above the floor, along outer walls, and tilted to direct maximum radiation to the floor. If the building is poorly insulated, the controlling thermostat should be shielded to avoid influence from the radiant effect of the walls and the cold walls.
- Semi-open and outdoor areas, where people can be comfortably heated directly and objects can be heated to avoid condensation.
- Loading docks, where snow and ice can be controlled by strategic placement of near-infrared heaters.

Additional information on both electric and gas infrared heating is given in Chapter 16 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

9. COOLING SYSTEMS

Common cooling systems include refrigeration equipment, evaporative coolers, and high-velocity ventilation air.

For manufacturing operations, particularly in heavy industry where mechanical cooling cannot be economically justified, evaporative cooling systems often provide good working conditions, as discussed in Chapter 41 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. If the operation requires heavy physical work, spot cooling by ventilation, evaporative coolers, or refrigerated air can be used. To minimize summer discomfort, high outdoor ventilation rates may be adequate in some hot-process areas. A mechanical air supply with good distribution is needed in all these operations.

Refrigerated Cooling Systems

The most commonly used refrigerated cooling systems are roof-mounted, direct-expansion packaged units. Larger systems may use chilled water distributed to air-handling units.

Central system condenser water rejects heat through a cooling tower. Refrigerated heat recovery is particularly advantageous in buildings with simultaneous need to heat exterior spaces and cool interior spaces.

Mechanical cooling equipment should be selected in multiple units. This lets the equipment match its response to fluctuations in the load and allows maintenance during off-peak operation periods. Packaged refrigeration equipment commonly uses positive-displacement (reciprocating, scroll, or screw) compressors with air-cooled condensers. When equipment is on the roof, the condensing temperature may be affected by warm ambient air, often 5 to 10 K higher than design outdoor air temperature. ASHRAE *Standard* 15 provides rules for the type and quantity of refrigerant in direct air-to-refrigerant exchangers.

Desiccant-based systems should be considered for processes that require dew points below 10°C (e.g., pharmaceutical processing).

Evaporative Cooling Systems

Evaporative cooling systems may be direct or indirect evaporative coolers or air washers. Evaporative coolers have water sprayed directly on wet surfaces through which air passes. Any excess water drains off. Air washers recirculate water, and the air flows through a heavily misted area. Water atomized in the airstream evaporates, cooling the air. For either type, using refrigerated water simultaneously cools and dehumidifies the air. For spaces that require an air washer and high relative humidities (e.g., tobacco and textile processing areas), heat provided to the sump should provide sufficient energy for humidification beyond that recovered in the return airstream.

Temperature and humidity of the exit airstream may be controlled by varying the temperature of the chilled water and reheat coil and by varying the quantity of air passing through the reheat coil with a dew-point thermostat.

It may be necessary to filter air entering the evaporative cooler to ensure that dust or lint does not accumulate and clog the nozzles or evaporating pads. Chemical treatment of the water may be necessary to prevent mineral build-up or biological growth on the pads or in the pans.

10. AIR FILTRATION SYSTEMS

Air filtration systems remove contaminants from the building supply or exhaust airstreams. Supply air filtration at the equipment intake removes particulate contamination that may foul heat exchange surfaces, contaminant products, or present a health hazard to people, animals, or plants. Gaseous contaminants must sometimes be removed to prevent exposing personnel to odors or health-threatening fumes. Return air with a significant potential for carrying contaminants should be recirculated only if it can be filtered enough to minimize personnel exposure. Return air should be exhausted if monitoring and contaminant control cannot be ensured.

The supply filtration system usually includes collection media or a filter, a media-retaining device or filter frame, and a filter housing or plenum. For more on filtration systems, see Chapter 29 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Exhaust Air Filtration Systems

Exhaust air systems are either (1) general systems that remove air from large spaces or (2) local systems that capture aerosols, heat, or gases at specific locations in a room and transport them so they can be collected, inactivated, and safely discharged to the atmosphere. Air in a general system usually requires minimal or no treatment before being discharged to the atmosphere. Air from local exhaust systems can sometimes be safely discharged to the atmosphere, but may require contaminant removal before being discharged. Exhausted air must meet appropriate air quality standards when defined as a release point based on plant air permitting requirements. Chapters 31 and 32 of this volume and Chapter 30 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* have more information on industrial ventilation and exhaust systems.

In exhaust air emission control, fabric-bag filters, glass-fiber filters, venturi scrubbers, and electrostatic precipitators all collect particles. Packed-bed or sieve towers can absorb toxic gases. Activated carbon columns or beds, often with oxidizing agents, are frequently used to absorb toxic or odorous organics and radioactive gases.

Outdoor air intakes should be carefully located to avoid recirculating contaminated exhaust air. Wind direction, building shape, and location of effluent source strongly influence concentration patterns.

Air patterns from wind flowing over buildings are discussed in Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals*. The leading edge of the roof interrupts smooth airflow, reducing air pressure at the roof and on the lee side. Exhaust air must be discharged through either a vertical stack terminating above the building turbulent-air boundary or a shorter stack with a high enough discharge velocity to project the effluent through the air boundary into the undisturbed air passing over the building. The high discharge prevents fume damage to both the roof and roof-mounted equipment, and keeps fumes away from building air intakes. A high vertical stack is the safest, simplest solution to fume dispersal.

Contamination Control

In addition to maintaining thermal conditions, air-conditioning systems should control contaminant levels to provide a safe and healthy environment, good housekeeping, and quality control for the processes. Contaminants may include gases, fumes, mists, or airborne particulate matter. They may be produced by a process in the building or contained in the outdoor air.

Contamination can be controlled by preventing the release of aerosols or gases into the room and by diluting room air contaminants. If the process cannot be enclosed, it is best to capture aerosols and gases near their source with a local exhaust system that includes a hood or enclosure, ducts, fan, motor, and exhaust stack.

Dilution controls contamination in many applications but may not provide uniform safety for personnel. High local concentrations of contaminants can exist despite a high overall dilution rate.

11. EXHAUST SYSTEMS

An exhaust system draws a contaminant away from its source and removes it from the space. An exhaust hood surrounding the point of generation contains the contaminant as much as is practical. The contaminant is transported through ductwork from the space, cleaned as required, and exhausted to the atmosphere. The hood inlet air quantity is established by the velocities required to convey the airborne contaminant. Chapter 33 has more information on local exhaust systems.

Design values for average and minimum face velocities are a function of the characteristics of the most hazardous material the hood is expected to handle. Minimum values may be prescribed in codes for exhaust systems. Contaminants with greater mass may require higher face velocities for control. Design face velocities should be set carefully: too high a velocity can be as hazardous as one too low. Refer to ACGIH (2016) and ASHRAE *Standard* 110 for more information.

Exhaust ductwork should be sized to provide velocities high enough to keep contaminants in suspension. Velocities should exceed the settling velocities for the expected particle size distribution.

Selection of materials and construction of exhaust ductwork and fans depend on the nature of the contaminant, ambient temperature, lengths and arrangement of ducts, method of hood fan operation, and flame and smoke spread ratings. Exhausts containing acids, alkalis, solvents, or oils should address corrosion, dissolution, and melting.

Condensation in ferrous metal ducts may contribute to corrosion. Consider the dew point of process gases with respect to the surrounding ambient temperature. Condensation can be managed by reducing the dew point of the exhaust stream, by vapor barriers, or by using thermal insulation.

12. OPERATION AND MAINTENANCE

Equipment room layout should provide space for cleaning, servicing, and replacing components quickly to minimize system outages. Maintenance of refrigeration and heat rejection equipment is essential for proper performance without energy waste. Maintenance includes changing system filters periodically. Industrial applications are dirty, so proper selection of filters, careful installation to avoid air bypassing the filter, and prudent filter changing to prevent overloading and blowout are required. Dirt lodging on the tips of forward-curved fan blades appreciably reduces air-handling capacity. Fan and motor bearings require lubrication, and fan belts need periodic inspection. Direct- and indirect-fired heaters should be inspected annually. Steam and hot-water heaters have fewer maintenance requirements than comparable equipment with gas or oil burners.

For system compatibility, water treatment is essential. Air washers and cooling towers should not be operated unless the water is properly treated.

13. HEAT RECOVERY AND ENERGY CONSERVATION

The process industry often presents opportunities to recover heat from the exhaust airstream for use in preconditioning makeup air. Extreme care must be taken to ensure compatibility of heat exchanger components and materials with contaminants often found in exhaust streams. For example, brewery spaces are held between 1.7 and 10°C. Exhaust air passes over a heat recovery wheel to precondition outdoor makeup air, which in turn controls the level of carbon dioxide contamination. Coated aluminum heat recovery wheels can be subject to premature failure because of caustic cleaning materials conveyed in the exhaust system.

Additional consideration should be given to the assessment of risk associated with the heat recovery strategy. Frequently, downtime in large industrial facilities can exceed millions of dollars per hour. Costs associated with failure of a heat recovery device can easily overcome savings in energy costs if the result is a facility shutdown.

14. CONTROL SYSTEMS

Control systems for industrial processes and air-conditioning systems differ from commercial direct digital control (DDC) systems in important ways. Modern industrial control systems fall into three categories:

- **Programmable logic controller (PLC) systems.** These systems are chosen for industrial environments because of their inherent robustness and speed. They are rated to operate in environments of 50°C, as opposed to 40°C for DDC systems. Also, because the controller does not look up point information from a central database, the program scan speed is much greater: a total program scan time of less than 0.1 s is not unusual. Local display screens are available for field panel mounting; however, one of the following two systems is required to provide overall plantwide data gathering and reporting.
- **Distributed control systems (DCS).** Like commercial DDC systems, DCS systems are defined as shared logic controllers as opposed to programmable logic controllers. A shared logic controller shares the resources a common database of point names to provide point attribute data such as units (% rh, kPa, etc.), point range (0 to 100% rh, 0 to 690 kPa, etc.), logical point name, and software address. This information is shared across all controllers in a given network of controllers and then reported to the user through the graphical user interface (GUI). DCS systems can provide an embedded GUI like DDC systems do, or can work seamlessly with a third-party SCADA system.
- **Supervisory control and data acquisition (SCADA) systems.** SCADA systems are typically overlays that acquire and store data from subordinate DCS, PLC, or other systems. They provide the GUI and display operating system parameters. By contrast, commercial DDC or building management systems (BMS) have the graphic engine and data acquisition and storage system embedded into the base operating system. Industrial requirements typically preclude DDC systems to act as a SCADA system because of their limited data communication networks and inability to reliably handle large numbers (>10,000) of input and output points in a given system.

Industrial controllers can be installed, configured, and/or maintained by third-party providers (known as **system integrators**) or by the manufacturer themselves. They have open communication protocols and exchange information over various network protocols such as Modbus (North America) or Profibus (EU). These protocols allow communication between different brands of controllers and the overall network, with BACnet® capability for occasional integration with commercial DDC system where deemed necessary. Industrial systems also allow Ethernet-based protocol (TCP/IP) for data exchange in high-speed networks as well as remote Internet-based monitoring and control.

Industrial control systems are documented differently than commercial-based DDC systems. The American National Standards Institute (ANSI), in cooperation with International Society of Measurement and Control (ISA), established a standard that defines how engineering documents are prepared (e.g., process and instrumentation diagrams [P&IDs], instrument naming or tagging convention). Commercial systems generally are documented using standards defined by the system manufacturer, who installs and maintains the systems, and their technicians can operate across several facilities or in different cities.

Industrial instrumentation is also quite different from commercial DDC systems. Instruments are typically in housings listed for hazardous environments that also provide excellent protection from the moisture, dust, and dirt frequently found in an industrial environment. Signal types are usually 4 to 20 mA over the range of 0 to 100% of the transmitter span. Hazardous locations use instruments listed specifically for the hazard division and group. Intrinsic safety barriers provide a level of protection by limiting the amount of power consumed by these devices to 1 W or less.

15. LIFE AND PROPERTY SAFETY

Human life and property safety must be thoroughly considered in all types of industrial project design, construction, installation, startup, testing, operation, and maintenance. The life and property safety concern should include (but not be limited to) hazards generated in the property and related prevention, effective fire and hazardous gas detection and alarm systems, active fire protection systems, room-to-room pressurization and smoke control, homeland security and emergency response plans, etc. Refer to related NFPA and ACGIH publications for detailed regulations.

Toxic Agent/Hazardous Materials Processing Facility

Fire. When the fire alarm control panel (FACP) receives alarm signals from local smoke/heat detectors, it sends signals to shut off the smoke/fire dampers (BDs) in the affected fire zone. The FACP also sends an alarm signal to the FCS. The position switch from each BD sends a feedback signal to FCS confirming that the BD has been fully closed; otherwise, a fault alarm is activated at the FCS. Due to airflow blockage, the cascading system upstream room pressure increases, and downstream room pressure decreases further. To minimize room pressure upsets, the FCS automatically throttles the upstream supply air pressure control dampers and downstream exhaust air pressure control dampers.

During the pressure surge transition, the cascading system pressures may rise at the supply air plenum and become more negative at the exhaust air inlet headers. FCS pressure feedback control automatically reduces the fan speed of the AHUs and EAFUs accordingly. If pressure surges are significant and occur faster than the FCS pressure control response, pressure and vacuum relief dampers in the supply and exhaust headers automatically open to protect ductwork from damage.

After the fire has been cleared, the smoke/fire dampers are manually reset to the open position from the FACP. Bypass exhausts are provided within fire zones and located strategically to mitigate pressure excursion resulting from a fire in critical process rooms. When the bypass mode is initiated, FCS closes the inlet transfer air isolation dampers to suppress fire spread, which prevents heat and smoke damage to the EAFUs; activates the bypass exhaust; and places pressure controllers into automatic pressure control mode to minimize pressure surge and airflow impact to surrounding rooms.

Loss of Power. During loss of off-site power, essential power is provided to EAFUs and AHUs by the dedicated generator and the standby generators to maintain the toxic areas at slight negative pressure relative to ambient to prevent toxic vapor escaping. The adjustable-speed drives (ASDs) of the fans of EAFUs and AHUs are programmed to allow fast ramp-up when power is restored. If a dedicated generator starts and standby generators fail, the FCS continuously monitors and controls the cascading ventilation system to maintain slight negative pressure with reduced flows. When all the generators fail to start, and the total exhaust airflow rate drops to 15% of the system design capacity, the FCS starts closing all TA isolation dampers to prevent toxic vapor migration from highly toxic areas to areas of lower concentrations.

16. COMMISSIONING

Several types of HVAC commissioning processes are used for industrial HVAC projects: (1) overall HVAC project commissioning, (2) construction HVAC project commissioning, and (3) existing-building HVAC commissioning (**retrocommissioning**). The process described here applies to both new construction and major renovations.

For new construction, commissioning should start at the project's inception during the predesign phase, and continue through design, construction, acceptance, training, operation, maintenance, and postacceptance.

The owner should retain an HVAC commissioning authority (CA) at the very beginning of the predesign phase. The CA develops the scope of the commissioning and reviews the design intent during predesign to ensure the project accommodates the commissioning process. The CA also coordinates with the owner, design engineer, and HVAC contractor during preparation of project design and construction documents; this includes the overall project execution schedule, preparation and issue of commissioning and construction specifications, and review of contractor submittals. This paves the way for commissioning, and the CA continues to carry out and complete the implementation of the planning commissioning process.

Participants include the start-up personnel listed during start up, the test and balance company, the process operators, the owner's project authorities, and the commissioning personnel.

Commissioning documents include the following:

- Certificates and warranties of system completion, along with a complete set of as-built drawings submitted by mechanical, electrical, plumbing, control, and fire protection contractors.
- If available, all major equipment installation, operation, and maintenance (IOM) manuals from equipment manufacturers.
- Records of significant problems and solutions that occurred during start-up and testing.
- Certified system test and balance reports, including verified major equipment models and capacities, and tested performance values conforming to system criteria.
- A complete room-to-room pressurization map submitted by the test and balance company.
- A control system IOM submitted by the control contractor.
- When applicable, a certificate of as-built cleanroom cleanliness. The report should be based on testing when the cleanroom facility is complete and all services are connected and functional, but without equipment and operating personnel in the cleanroom.
- If the contract scope requires, a certificate of cleanroom cleanliness with process running and with operating personnel in the facility.
- A commissioning report signed by all attendees.

Commissioning requirements for industrial air-conditioning systems (particularly central heating and cooling equipment such as chillers, boilers, air compressors, etc., or nonprocess air-handling systems) often can follow the procedures outlined in ASHRAE *Guidelines* 0 and 1.1, which use statistical evaluations to define the scope of commissioning activities. Most industrial applications, however, use full commissioning of each point instead of statistical evaluation, because of the process requirements for reliability and the basic functional requirements.

In facilities regulated by government agencies, **qualification** (or **validation**) of the air-conditioning systems may be required. In these cases, use the appropriate government and industry-specific guidelines instead of ASHRAE *Guidelines* 0 and 1.1. Qualification follows a more rigorous set of standards for acceptance than commercial commissioning:

- **Risk assessment** determines the level of qualification that a given system should undergo. It considers the severity the risk presents (e.g., loss of life or of the system) and the likelihood of occurrence (e.g., once during system life, once a year). The highest risks are those that have the greatest severity as well as the most likely occurrence. In those cases, the qualification requirements are the highest.
- **Life-cycle assessment** is most often used in industrial control systems. Required documentation typically consists of specifications for user requirements, functionality, and design, and the system is qualified under an installation qualification to verify the design specification. An operational qualification verifies the requirements of the functional specification, and the performance qualification verifies the requirements of the user requirement specification.
- **Testing plans and strategies** should reflect the results of the risk assessment and life-cycle assessment. The plans and strategies should also address the resources required to conduct the qualification, the documentation to be developed, and the appropriate owner team to accept the results. Most importantly, it defines the procedure to be followed when a discrepancy is found.

Testing documentation is developed to qualify the system so it can pass an audit by the regulatory agency or a third party retained by the owner.

For more information on commissioning, see Chapter 44 and ASHRAE *Standard* 202-2013.

CHAPTER 16

ENCLOSED VEHICULAR FACILITIES

Tunnels 16.1
Parking Garages 16.18
Automotive Repair Facilities 16.23
Bus Garages 16.24
Bus Terminals 16.26
Tollbooths 16.29
Diesel Locomotive Facilities 16.30
Equipment 16.35
National and International Safety Standards and Guidelines 16.40

ENCLOSED vehicular facilities include buildings and infrastructure through which vehicles travel, are stored, or are repaired.Vehicles can include those driven by internal combustion engines or electric motors. This chapter discusses ventilation requirements for these facilities, accounting for climate and temperature control, contaminant level control, and emergency smoke management. Design approaches for various natural and mechanical ventilation systems are covered in this chapter.

Tunnel issues are addressed first, followed by the unique aspects of rail and road tunnels, rail stations, bus garages, bus terminals, and enclosed spaces for equipment maintenance in later sections. Finally, information on applicable ventilation equipment is presented.

1. TUNNELS

Transport tunnels are unique; **vehicles travel at normal speeds, possibly carrying cargo** (which may be unknown in road tunnels), and may include the traveling public (as passengers and/or motorists) during both normal and emergency operations. A tunnel is a linear-configured facility, as opposed to most buildings, which are typically more rectangular. This concept is important when confronting the need to fight a fire within a tunnel. A tunnel cannot be compartmentalized as readily as a building, which means the fire can only be fought from within the actual fire zone. Limited access and compartmentation create difficulties with containing and suppressing a fire. This combination of circumstances requires unique design approaches to both normal and emergency operation.

Tunnel Ventilation Concepts

Tunnel ventilation must accommodate normal, congested, and emergency conditions. In some cases, temporary ventilation may also be necessary.

Normal Mode. Normal ventilation is required during normal operations to control temperature, provide comfort, or control level of pollutants in the facility during normal operations and under normal operating conditions, primarily to ensure the health and comfort of patrons and employees.

Congested Mode. Congested ventilation is required during service periods where traffic is slow moving, leading to a reduction or elimination of piston effect. The goals are the same as for normal mode.

Emergency Mode. Emergency ventilation is required during an emergency to facilitate safe evacuation and to support firefighting and rescue operations. This is often due to a fire, but it can be any nonnormal incident that requires unusual control of the environment in the facility. This includes control of smoke and high temperature from a fire, control of exceedingly high levels of contaminants, and/or control of other abnormal environmental conditions.

Temporary Mode. Temporary ventilation is needed during original construction or while maintenance-related work is carried out in a tunnel, usually during nonoperational hours. The temporary ventilation is typically removed after construction or after the maintenance work is completed. Ventilation requirements for such temporary systems are specified by either state or local mining laws, industrial codes, or the U.S. Occupational Safety and Health Administration (OSHA) and are not addressed specifically in this chapter.

Tunnel Ventilation Systems

There are two categories of ventilation systems used in most tunnels: natural and mechanical.

Natural Ventilation. Naturally ventilated facilities rely primarily on atmospheric conditions to maintain airflow and provide a satisfactory environment in the facility. The chief factor affecting the facility environment is the pressure differential created by differences in elevation, ambient air temperature, or wind effects at the boundaries of the facility. Unfortunately, most of these factors are highly variable with time, and thus the resultant natural ventilation is often neither reliable nor consistent. If vehicles are moving through a tunnel-type facility, the piston effect created by the moving vehicles may provide additional natural airflow.

Mechanical Ventilation. A tunnel that is long, has a heavy traffic flow, or experiences frequent adverse atmospheric conditions requires fan-based mechanical ventilation. Among the alternatives available are longitudinal and transverse ventilation.

Longitudinal Ventilation. This type of ventilation introduces or removes air from the tunnel at a limited number of points, primarily creating longitudinal airflow along its length. Longitudinal ventilation can be accomplished either by injection, using central fans, using jet fans mounted in the facility, or a combination of injection and extraction at intermediate points.

Transverse Ventilation. Transverse ventilation uses both a supply duct system and an exhaust duct system to uniformly distribute supply air and collect vitiated air throughout the length of the facility. The supply and exhaust ducts are served by a series of fixed fans, usually housed in a ventilation building or structure. A variant of this type of ventilation is **semitransverse ventilation**, which uses either a supply or exhaust duct, not both. The balance of airflow is made up via the tunnel portals.

Design Approach

General Design Criteria. The air quality and corresponding ventilation system airflow requirements in enclosed vehicular spaces are determined primarily by the type and quantity of contaminants that are generated or introduced into the tunnel and the amount of ventilation needed to limit the high air temperatures or concentrations of these contaminants to acceptable levels for the specific time exposures.

Normal and Congested Modes. The maximum allowable concentrations and levels of exposure for most contaminants are determined by national governing agencies such as the U.S. Environmental Protection Agency (EPA), OSHA, and the American Conference of Governmental Industrial Hygienists (ACGIH).

The contaminant generators can be as varied as gasoline or diesel automobiles, diesel or compressed natural gas (CNG) buses and trucks, and diesel locomotives. Even heat generated by air conditioning on

The preparation of this chapter is assigned to TC 5.9, Enclosed Vehicular Facilities.

electric trains stopped at stations and the pressure transients generated by rapid-transit moving trains can be considered contaminants, the effects of which need to be mitigated.

Emergency Mode. Design provisions may be necessary to manage smoke and other products of combustion released during fires to allow safe evacuation, to support firefighting and rescue operations, and to protect the tunnel structure and station infrastructure during fires (Bendelius 2008).

In designing for fires, the design fire scenario and associated fire heat release rate need to be quantified. Depending on the level of analysis, the generation of smoke and other products of combustion may also need to be quantified. As a minimum, design for life safety during fires must conform to the specific standards or guidelines of the National Fire Protection Association (NFPA), where applicable. NFPA *Standard* 130's ventilation requirements are for systems to maintain a "tenable environment along the pathway of egress from the fire." *Standard* 130 (2017) defines a tenable environment as "an environment that permits self-rescue of occupants for a specific period of time"; NFPA *Standard* 502 (2017) includes a similar definition.

Other NFPA codes and standards; ICC (2009a, 2009b, 2009c) building, mechanical, and fire codes; and other statutory requirements may apply. Separation and pressurization requirements between adjacent facilities should also be considered.

Temporary. A temporary mode may be necessary during construction or other special condition.

Technical Approach. The technical approach differs with facility type; however, there are many similarities in the initial stages of the design process.

Determining the length, gradient, and cross section for tunnels is an important first step. Establishing the facility's dynamic clearance envelope is of extreme importance, especially for a tunnel, because all appurtenances, equipment, ductwork, jet fans, etc., must be located outside the envelope, and this may eventually determine the type of ventilation system used.

Vehicle speeds, vehicle cross-sectional areas, vehicle design fire scenarios, and fuel-carrying capacity are important considerations for road tunnels, as are train speeds, train headway, and rail car combustibility and design fire scenarios for rapid transit and railroad tunnels.

Types of cargo to be allowed through the facility, and their respective design fire scenarios, should be investigated to determine the ventilation rates and the best system for the application. Similarly, for railroad tunnels, it should be determined whether passenger, freight, or both types of trains will be using the facility and if the passenger trains will be powered by diesel/electric power or by electric traction power.

The emergency ventilation approach must be fully coordinated with the overall fire protection strategy, the evacuation plan, and the emergency response plan, providing a comprehensive overall life safety program for the tunnel or station. Egress systems must provide for safe evacuation under a wide range of emergency conditions. The emergency response plan must help facilitate evacuation and allow for appropriate response to emergencies.

Rail and bus stations are large unique structures designed to allow efficient movement of large populations and to serve occupants that often arrive in large groups. Stations can be below ground, above ground, or at grade. Although each type of station poses specific challenges, underground facilities tend be the most challenging. Stations can be further complicated by connections to non-transit structures (Tubbs and Meacham 2007).

Rail and road tunnels pose a different set of evacuation challenges. These facilities are long, narrow, and underground, often with limited opportunities for stairwells to grade. The linear nature limits initial evacuation, which can pose challenges to the ventilation design. Further, the trackway in rail tunnels can be a dangerous environment for untrained occupants.

The ventilation and other protection systems must support the evacuation plan. NFPA *Standards* 502 and 130 provide specific criteria for components of the life safety and evacuation systems, but are not universally adopted by authorities. Where road and rail infrastructure interface with buildings, the *International Building Code®* and *International Fire Code®* may apply. Several documents are available to provide additional guidance on life safety concepts, evacuation strategies, and calculation methodologies (Bendelius 2008; Colino and Rosenstein 2006; Fruin 1987; Gwynne and Rosenbaum 2008; Proulx 2008; Tubbs and Meacham 2007).

Critical Velocity. Manual calculations and resources for the emission and combustion data are given for each enclosed vehicular facility type in the respective sections. A first step in determining the order of magnitude for the ventilation rate required to control the movement of the heat and smoke layer generated by a fire in a tunnel is to apply the critical velocity criterion. This approach is described here, and can be used for all types of tunnel applications.

The simultaneous solution of Equations (1) and (2), by iteration, determines the critical velocity (Kennedy et al. 1996), which is the minimum steady-state average bulk velocity of ventilation air moving toward the fire needed to prevent backlayering:

$$V_C = K_1 K_G \left(\frac{gHq}{\rho c_p A T_F} \right)^{1/3} \tag{1}$$

$$T_F = \left(\frac{q}{\rho c_p A V_C} \right) + T \tag{2}$$

where

V_C = critical velocity, m/s
T_F = average temperature of fire site gases, K
K_1 = 0.606
K_G = grade factor (see Figure 1)
g = acceleration caused by gravity, m/s^2
H = height of duct or tunnel at fire site, m
q = heat that fire adds directly to air at fire site, kW
ρ = average density of approach (upstream) air, kg/m^3
c_p = specific heat of air, kJ/(kg·K)
A = area perpendicular to flow, m^2
T = temperature of approach air, K

It is usual to study several alternative ventilation schemes, each using different variants and/or combinations of ventilation systems (longitudinal, transverse, etc.). Some types of systems, such as fully transverse, are almost exclusively used on road tunnels only.

When selecting ventilation equipment and the number of fans and types of drives, consideration should be given to efficiency, reliability, and noise. Most of these equipment attributes are reflected in a life-cycle cost analysis of the alternatives.

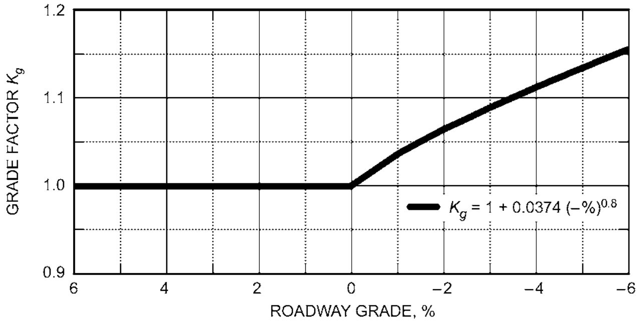

Fig. 1 Roadway Grade Factor

If the effectiveness of the system to provide for fire life-safety conditions is not evident from the manual analysis or one-dimensional computer models such as subway environment simulation (SES), the designer should investigate using a computational fluid dynamics (CFD) program to accurately determine the smoke and temperature distribution in both the steady-state and transient conditions.

Computer Modeling and Simulation. The applicable NFPA standards for road tunnels (NFPA *Standard* 502) and for railroad rapid transit tunnels (NFPA *Standard* 130) require engineering analysis for tunnels greater than a certain length, to prove that the smoke and heat layer is controlled. Often the best way to show that the requirements are met is by using a CFD program with post-processing capabilities that feed the results into another program capable of producing a still picture and/or animated graphical representation of the results. All the commonly used computer programs and their specific capabilities are discussed in the following paragraphs.

SES. The predominant worldwide tool for analyzing the aerothermodynamic environment of rapid transit rail tunnels is the Subway Environment Simulation (SES) computer program (DOT 1997a). SES is a one-dimensional network model that is used to evaluate longitudinal airflow in tunnels. The model predicts airflow rates, velocities and temperatures in the subway environment caused by train movement or fans, as well as the station cooling loads required to maintain the public areas of the station to predetermined design conditions throughout the year. This program contains a fire model that can simulate longitudinal airflow required to overcome backlayering and control smoke movement in a tunnel. Output from the SES can be applied as boundary or initial conditions for three-dimensional CFD modelling of the tunnel and station environments. The SES program is in the public domain, available from the Volpe National Transportation Systems Center in Cambridge, MA.

TUNVEN. This program solves coupled one-dimensional, steady-state tunnel aerodynamic and advection equations. It can predict quasi-steady-state longitudinal air velocities and concentrations of CO, NO_x, and total hydrocarbons along a road tunnel for a wide range of tunnel designs, traffic loads, and external ambient conditions.

The program can also be used to model all common road tunnel ventilation systems (i.e., natural, longitudinal, semitransverse, and transverse). The user must update emissions data for the calendar year of interest. The program is available from the National Technical Information Service (NTIS 1980).

Computational Fluid Dynamics (CFD). CFD software can model operating conditions in tunnels and stations and predict the resulting environment. In areas of geometrical complexity, CFD is the appropriate tool to predict three-dimensional patterns of airflow, temperature, and other flow variables, including concentration of species, which may vary with time and space. Computational fluid dynamics software is the design tool of choice to obtain an optimum design, because experimental methods are costly, complex, and yield limited information.

SOLVENT. SOLVENT is a specific CFD model developed as part of the Memorial Tunnel Fire Ventilation Test Program for simulating road tunnel fluid flow, heat transfer, and smoke transport. SOLVENT can be applied to all ventilation systems used in road tunnels, including those based on natural airflow. The program results have been validated against data from Massachusetts Highway Department and Federal Highway Authority (MHD/FHWA 1995).

Fire Dynamics Simulator (FDS). FDS is a Computational Fluid Dynamics (CFD) model of buoyancy-driven fluid flow from a fire. A separate code called Smokeview is used to visualize data output from FDS. These applications can also be configured to model pollutant levels outside the portals and around the exhaust stacks of tunnels. Both of these public domain programs are under active development and can be obtained from National Institute of Standards and Technology (NIST).

Other CFD programs (too numerous to include here), both commercially available and in the public domain, have been used to model fire scenarios in road and rapid transit tunnels and stations. The strengths and weaknesses of each program should be investigated beforehand, and validation of results against experimental data or an equivalent program is encouraged.

Tunnel Fires

Fires occurring in tunnels are more difficult to deal with than those occurring in one of the other enclosed vehicular facilities, in a normal building, or in the open. In a tunnel, firefighting is extremely complex, because access to the tunnel is difficult in the event of a fire. The fire cannot be fought from outside the tunnel, as can be done with a building; it must be fought from within the tunnel, often in the same space where the fire is burning.

Fires occur in tunnels far less frequently than in buildings; however, because of the unique nature of a tunnel fire, they are more difficult to suppress and extinguish and usually get more attention. There is a long list of tunnel fires; the most complete history of fires in tunnels exists for road tunnels, a partial listing of which is included in Table 1. Similar information is available for rail fires (Meacham et al. 2010).

Design Fires. Design fires form the base input for emergency ventilation design analyses and are defined in terms of heat release rate, species output, and soot yields as functions of time. A design fire scenario is an input parameter that defines the ignition source, fire growth on the first item, possible spread of fire to adjacent combustibles, interaction between the fire and the enclosure and environment, and eventual fire decay and extinction.

Limited data are available regarding the magnitude and severity of vehicle design fires. In the absence of more specific data, the information available provides first-order guidance in selecting an appropriate design fire for the evaluation of an enclosed vehicular facility such as a tunnel (road or rail) or station (bus or rail).

PIARC (1999) and NFPA *Standard* 502 provide summaries of vehicle fire tests. Additional information can be found in Atkinson et al. (2001), Ingason (2006), Joyeux (1997), and Mangs and Keski-Rahkonen (1994a, 1994b).

Fire Detection. Fire detection systems are necessary to alert tunnel operators of potential unsafe conditions. There are a range of methods available to detect fire and smoke within road/rail tunnels and rail stations, including linear (line-type) heat detection, CCTV video image smoke detection, flame detection, smoke and heat detectors, and spot-type detection. Fire detection systems should be selected to support the fire safety goals and objectives and the overall fire safety program, which can include notifying occupants to allow for safe evacuation, modifying tunnel ventilation or operations, and notifying emergency responders.

NFPA *Standards* 130 and 502 provide general requirements for fire detections systems in transportation tunnels. These documents reference codes, such as NFPA *Standard* 72, that provide design requirements for fire detection and occupant notification. Publications developed by the Road Tunnel Operation Technical Committee of PIARC (2007b, 2008) include specific guidance on the application of these systems. There have been several research projects that can also provide additional information to assist with developing detection system concepts and designs (Liu et al. 2006, 2009; Kashef et al. 2009; Zalosh and Chantranuwat 2003). Bendelius (2008) provides information on advantages and disadvantages and selection of fire detection methods in tunnels.

Road Tunnels

A road tunnel is an enclosed vehicular facility with an operating roadway for motor vehicles passing through it. Road tunnels may be underwater (subaqueous), mountain, or urban, or may be created by air-right structures over a roadway or overbuilds of a roadway.

Table 1 List of Road Tunnel Fires

Year	Tunnel	Country	Length, m	Fire Duration	Damage: People	Damage: Vehicles	Damage: Structure
1949	Holland	United States	2 550	4 h	66 injured	10 trucks 13 cars	Serious
1974	Mont Blanc	France/Italy	11 600	15 min	1 injured	—	—

All road tunnels require ventilation to remove contaminants produced during normal engine operation. Normal ventilation may be provided by natural means, by traffic-induced piston effects, or by mechanical equipment. The method selected should be the most economical in both construction and operating costs.

Ventilation must also provide control of smoke and heated gases from a fire in the tunnel. Smoke flow control is needed to provide an environment suitable for both evacuation and rescue in the evacuation path. Emergency ventilation can be provided by natural means, by taking advantage of the buoyancy of smoke and hot gases, or by mechanical means.

Ventilation Modes. A range of mechanical ventilation is typically considered for road tunnels: normal, congested, emergency, and temporary, as discussed in the section on Tunnel Ventilation Concepts.

Ventilation Systems. Ventilation must dilute contaminants during normal and congested tunnel operations and control smoke during emergency operations. Factors affecting ventilation system selection include tunnel length, cross section, and grade; surrounding environment; traffic volume, direction (i.e., unidirectional or bidirectional), and mix; and construction cost.

Natural and traffic-induced ventilation systems are adequate for relatively short tunnels, and for those with low traffic volume or density. Long, heavily traveled tunnels should have mechanical ventilation systems. The tunnel length at which this change takes effect is somewhere between 350 and 650 m.

Natural Ventilation. Airflow through a naturally ventilated tunnel can be portal-to-portal (Figure 2A) or portal-to-shaft (Figure 2B). Portal-to-portal flow functions best with unidirectional traffic, which produces a consistent, positive airflow. In this case, air speed in the roadway area is relatively uniform, and the contaminant concentration increases to a maximum at the exit portal. Under adverse atmospheric conditions, air speed may decrease and contaminant concentration may increase, as shown by the dashed line in Figure 2A.

Introducing bidirectional traffic into such a tunnel further reduces longitudinal airflow and increases the average contaminant concentration. The maximum contaminant level in a tunnel with bidirectional traffic will not likely occur at the portal, and will not necessarily occur at the midpoint of the tunnel.

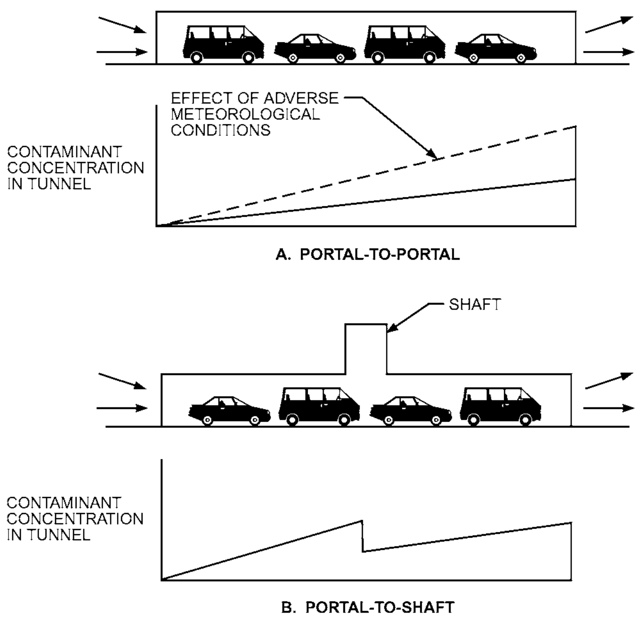

Fig. 2 Natural Ventilation

A naturally ventilated tunnel with an intermediate shaft (Figure 2B) is better suited for bidirectional traffic; however, airflow through the shaft is also affected by adverse atmospheric conditions. The stack effect benefit of the shaft depends on air/rock temperatures, wind, and shaft height. Adding more than one shaft to a tunnel may be more of a disadvantage than an advantage, because a pocket of contaminated air can be trapped between the shafts.

Naturally ventilated tunnels under 1000 m long do not require emergency ventilation to extract smoke and hot gases generated during a fire if it can be shown by an engineering analysis that the level of safety provided by a mechanical ventilation system can be equaled or exceeded by enhancing the means of egress, natural ventilation, or the use of smoke storage as approved by the authority having jurisdiction (per NFPA *Standard* 502). Because of the uncertainties of natural ventilation, especially the effects of adverse meteorological and operating conditions, reliance on natural ventilation to maintain carbon monoxide (CO) levels for tunnels over 240 m long should be thoroughly evaluated. This is particularly important for tunnels with anticipated heavy or congested traffic. If natural ventilation is deemed inadequate, a mechanical system should be considered for normal operations.

Smoke from a fire in a tunnel with only natural ventilation is driven primarily by the buoyant effects of hot gases and tends to flow upgrade. The steeper the grade, the faster the smoke moves, thus restricting the ability of motorists trapped between the incident and a portal at higher elevation to evacuate the tunnel safely. As shown in Table 2, the Massachusetts Highway Department and Federal Highway Administration (MHD/FHWA) (1995) demonstrated how smoke moves in a naturally ventilated tunnel.

Mechanical Ventilation. A tunnel that is long, has a heavy traffic flow, or experiences frequent adverse atmospheric conditions, requires fan-based mechanical ventilation. Options include longitudinal ventilation, semitransverse ventilation, and full transverse ventilation.

Longitudinal ventilation introduces or removes air from the tunnel at a limited number of points, creating longitudinal airflow along the roadway. Longitudinal ventilation can be accomplished either by push-pull vent shafts, injection, jet fan operation, or a combination of injection and extraction at intermediate points in the tunnel. Injectors and jet fans are classified as impulse systems, because they impart a momentum to the tunnel flow, as the primary high-velocity jet diffuses out. At start-up, this thrust causes the air in the tunnel to accelerate until equilibrium is established between this force and the opposing drag forces due to viscous friction and the additional pressure losses at the tunnel portals, traffic, wind, and fire, etc.

Injection longitudinal ventilation, frequently used in rail tunnels, uses externally located fans to inject air into the tunnel through a high-velocity Saccardo nozzle, as shown in Figure 3A. This air injection, usually in the direction of traffic flow, induces additional longitudinal airflow. The Saccardo nozzle functions on the principle that a high-velocity air jet injected at a small angle to the tunnel axis can induce a high-volume longitudinal airflow in the tunnel. The

Table 2 Smoke Movement During Natural Ventilation Tests

Test No.	Fire Heat Release Rate, MW: Nominal	Fire Heat Release Rate, MW: Peak	Smoke Layer Begins Descent, min	Smoke Fills Tunnel Roadway, min	Peak Smoke Velocity, m/s
501	20	29	3+	5	6.1
502	50	57	1+	3	8.1

Note: Tunnel grade is 3.2%.

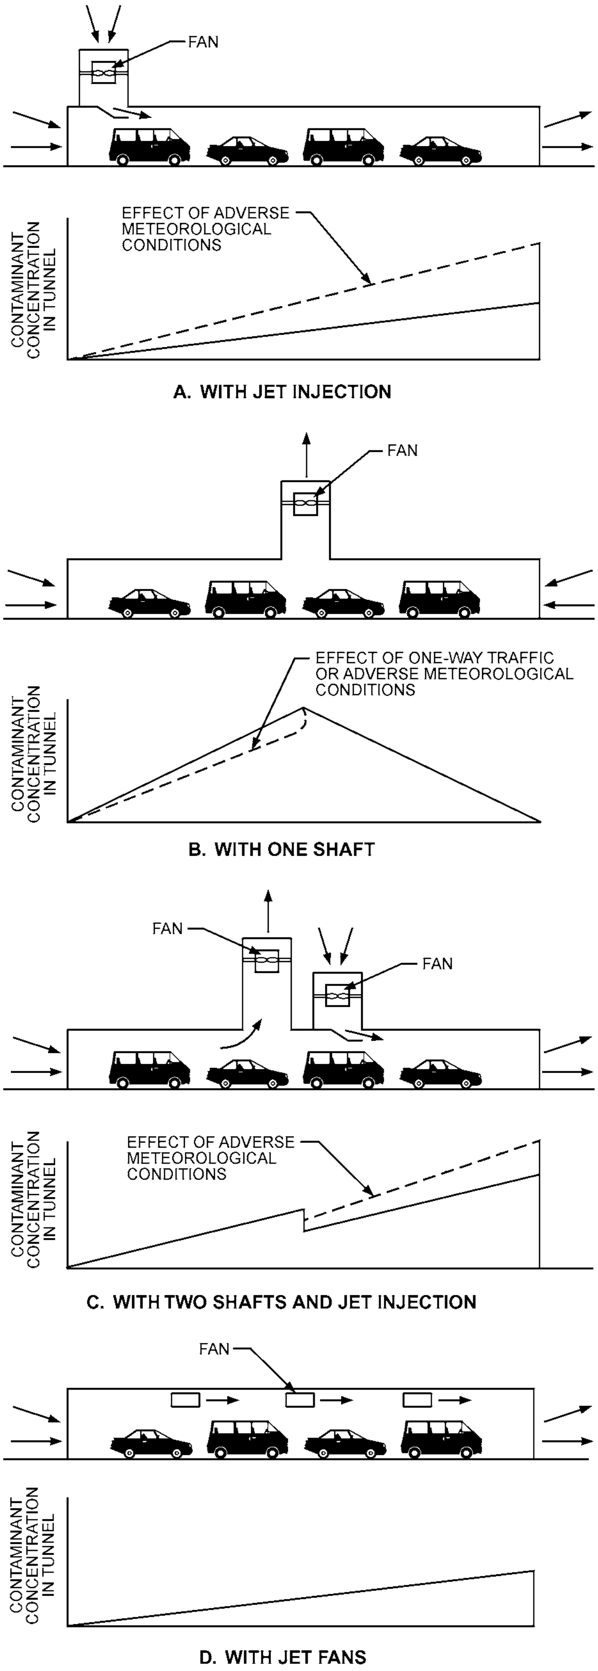

Fig. 3 Longitudinal Ventilation

amount of induced flow depends primarily on the nozzle area, discharge velocity and angle of the nozzle, as well as downstream air resistances. This type of ventilation is most effective with unidirectional traffic flow.

With injection longitudinal ventilation, air speed remains uniform throughout the tunnel, and the contaminant concentration increases from zero at the entrance to a maximum at the exit. Adverse atmospheric conditions can reduce system effectiveness. The contaminant level at the exit increases as airflow decreases or tunnel length increases.

Injection longitudinal ventilation, with supply at a limited number of tunnel locations, is economical because it requires the fewest fans, places the least operating burden on fans, and requires no distribution air ducts. As the length of the tunnel increases, however, disadvantages become apparent, such as excessive air velocities in the roadway and smoke being drawn the entire length of the roadway during an emergency.

The main aerodynamic differences between the jet fan and Saccardo injectors are that the injectors impart thrust at one location in the tunnel, whereas in jet fan systems this thrust is distributed along the tunnel. Injectors use outdoor air as primary flow, whereas the primary airflow in jet fans enters the fan inlet from the tunnel.

Saccardo injectors may operate in a flow induction mode (low tunnel air resistance) or flow rejection (high tunnel air resistance); both are acceptable. This means there may be flow reversal at the nozzle position with flow exiting the near portal, whereas jet fans always induce flow from one portal to the other. Flow under jet fans in a highly resistive tunnel may recirculate, but this is a strictly local feature.

A brief comparison of the technical and economic features of the two longitudinal impulse ventilation systems reveals the following:

- Jet fans have little or no civil engineering costs for installation, but have significant electrical cabling costs. Saccardo injectors require expensive civil engineering work to install the fans at the tunnel portal, with no cabling distribution costs.
- Routine maintenance or emergency repair work on jet fans usually requires disruption of normal tunnel service and availability; this is not the case for Saccardo injectors, which can be accessed externally.
- Saccardo injectors eliminate electrical cabling in the tunnel, providing a clear safety and cost advantage over jet fans.
- Jet fans take up headroom in the tunnel ceiling, which limits the effective dynamic clearance envelope of the traffic, whereas Saccardo injectors are located outside the tunnel, making them ideal in tightly configured tunnels.
- Saccardo injectors deliver their thrust at a single point, making them quite vulnerable to local tunnel fixtures. For example, a badly placed traffic sign, LED display, lighting equipment, or any significant blockage near the outlet of an ejector can cause a dramatic drop in ejector performance, whereas jet fans are less affected, because their thrust is distributed.
- Jet fans are also derated when operating at elevated temperatures during a fire (lower density), whereas injectors are both safely outside the fire's reach as well as immune to thrust reduction by virtue of using fresh air for primary intake. This makes Saccardo injectors ideal for emergency smoke clearance. The high air velocities in the path of egress should be assessed.

These relative merits are crucial at the initial concept phase, when deciding on the type of ventilation system for any particular tunnel.

A longitudinal ventilation system with one fan shaft (Figure 3B) is similar to the naturally ventilated system with a shaft, except that it provides a positive stack effect. Bidirectional traffic in a tunnel ventilated this way causes peak contaminant concentration at the shaft. For unidirectional tunnels, contaminant levels become unbalanced.

Another form of longitudinal system has two shafts near the center of the tunnel: one for exhaust and one for supply (Figure 3C). In this arrangement, part of the air flowing in the roadway is replaced by the interaction at the shafts, which reduces the concentration of contaminants in the second half of the tunnel. This concept is only effective for tunnels with unidirectional traffic flow. Adverse wind conditions can reduce tunnel airflow by short-circuiting the flow of air from the supply fan shaft/injection port to the exhaust fan/shaft, which causes contaminant concentrations to increase in the second half of the tunnel.

Construction costs of two-shaft tunnels can be reduced if a single shaft with a dividing wall is constructed. However, this significantly increases the potential for short-circuited airflows from supply shaft to exhaust shaft; under these circumstances, the separation between exhaust shaft and intake shaft should be maximized.

Jet fan longitudinal ventilation has been installed in a number of tunnels worldwide. With this scheme, specially designed axial fans (jet fans) are mounted at the tunnel ceiling (Figure 3D). This system eliminates the space needed to house ventilation fans in a separate structure or ventilation building, but may require greater tunnel height or width to accommodate the jet fans so that they are outside of the tunnel's dynamic clearance envelope. This envelope, formed by the vertical and horizontal planes surrounding the roadway in a tunnel, defines the maximum limits of the predicted vertical and lateral movement of vehicles traveling on the roadway at design speed. As tunnel length increases, however, disadvantages become apparent, such as excessive air speed in the roadway and smoke being drawn the entire length of the roadway during an emergency.

Longitudinal ventilation is the most effective method of smoke control in a road tunnel with unidirectional traffic. A ventilation system must generate sufficient longitudinal air velocity to prevent **backlayering** of smoke (movement of smoke and hot gases against ventilation airflow in the tunnel roadway). The air velocity necessary to prevent backlayering over stalled or blocked motor vehicles is the minimum velocity needed for smoke control in a longitudinal ventilation system and is known as the **critical velocity**.

Semitransverse ventilation can be configured for supply or exhaust. This type of ventilation involves the uniform distribution (supply) or collection (exhaust) of air throughout the length of a road tunnel. Semitransverse ventilation is normally used in tunnels up to about 2000 m; beyond that length, tunnel air velocity near the portals becomes excessive.

Supply semitransverse ventilation in a tunnel with bidirectional traffic produces a uniform level of contaminants throughout, because air and vehicle exhaust gases enter the roadway area at the same uniform rate. With unidirectional traffic, additional airflow is generated by vehicle movement, thus reducing the contaminant level in the first half of the tunnel (Figure 4A).

Because tunnel airflow is fan-generated, this type of ventilation is not adversely affected by atmospheric conditions. Air flows the length of the tunnel in a duct with supply outlets spaced at predetermined distances. Fresh air is best introduced at vehicle exhaust pipe level to dilute exhaust gases immediately. The pressure differential between the duct and the roadway must be enough to counteract the effects of piston action and adverse atmospheric winds.

If a fire occurs in the tunnel, the supply air initially dilutes the smoke. Supply semitransverse ventilation should be operated in reverse mode for the emergency, so that fresh air enters through the portals and creates a tenable environment for both emergency egress and firefighter ingress. Therefore, a supply semitransverse ventilation system should preferably have a ceiling supply (in spite of the disadvantage during normal operations) and reversible fans, so that smoke can be drawn up to the ceiling during a tunnel fire.

Exhaust semitransverse ventilation (Figure 4B) in a tunnel with unidirectional traffic flow produces a maximum contaminant concentration at the exit portal. In a tunnel with bidirectional traffic

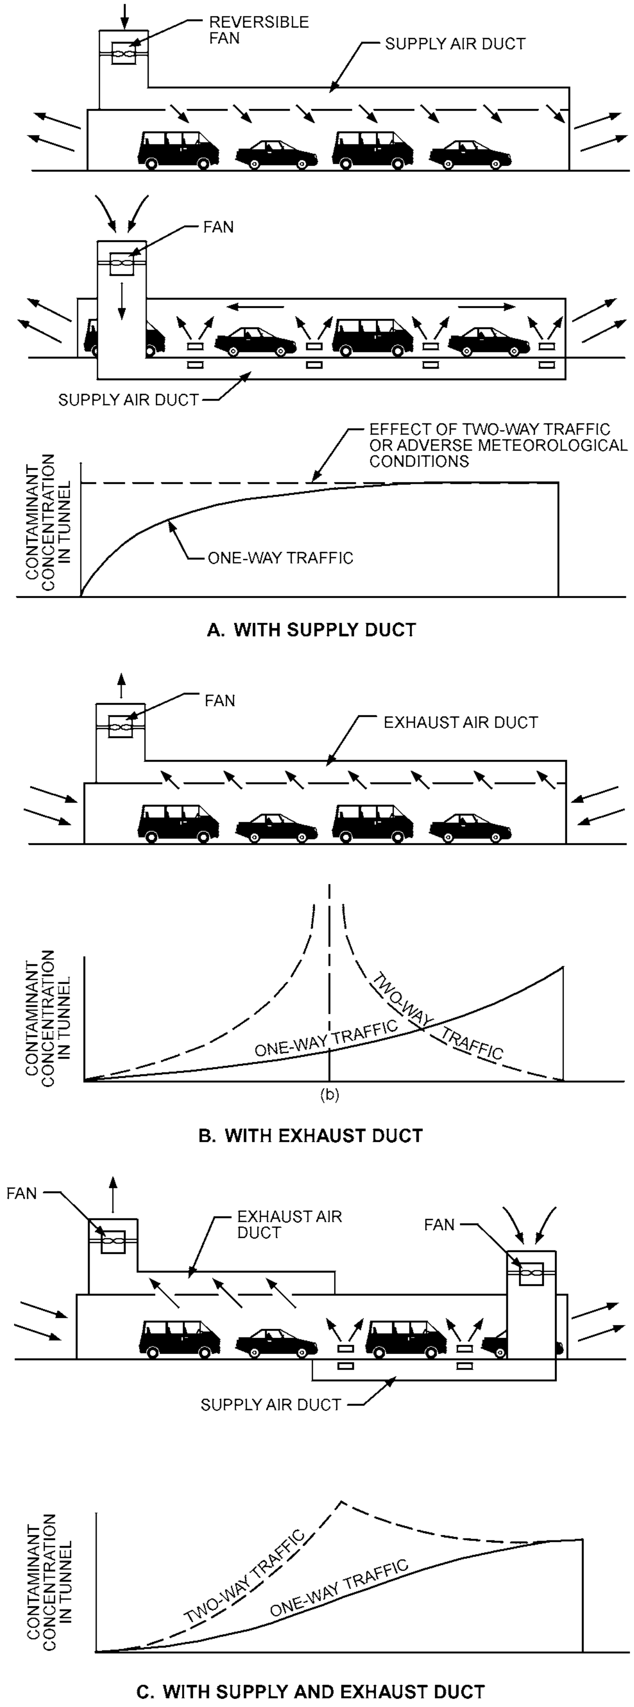

Fig. 4 Semitransverse Ventilation

flow, the maximum concentration of contaminants is located near the center of the tunnel. A combination supply and exhaust semitransverse system (Figure 4C) should be applied only in a unidirectional tunnel where air entering with the traffic stream is exhausted in the first half of the tunnel, and air supplied in the second half of the tunnel is exhausted through the exit portal.

In a fire emergency, both exhaust semitransverse ventilation and (reversed) semitransverse supply create a longitudinal air velocity in the tunnel roadway, and extract smoke and hot gases at uniform intervals.

Full transverse ventilation is used in extremely long tunnels and in tunnels with heavy traffic volume. It uses both a supply and an exhaust duct system to uniformly distribute supply air and collect vitiated air throughout the tunnel length (Figure 5). Because a tunnel with full transverse ventilation is typically long and served by more than one mechanical ventilation system, it is usually configured into ventilation zones, each served by a dedicated set of supply and exhaust fans. Each zone can be operated independently of adjacent zones, so the tunnel operator can change the direction of airflow in the tunnel by varying the level of operation of the supply and exhaust fans. This feature is important during fire emergencies.

With this ventilation system arrangement in balanced operation, air pressure along the roadway is uniform and there is no longitudinal airflow except that generated by the traffic piston effect, which tends to reduce contaminant levels. The pressure differential between the ducts and the roadway must be sufficient to ensure proper air distribution under all ventilation conditions.

During a fire, exhaust fans in the full transverse system should operate at the highest available capacity, and supply fans should operate at a somewhat lower capacity. This allows the stratified smoke layer (at the tunnel ceiling) to remain at that higher elevation and be extracted by the exhaust system without mixing, and allows fresh air to enter through the portals, which creates a tenable environment for both emergency egress and firefighter ingress.

In longer tunnels, individual ventilation zones should be able to control smoke flow so that the zone with traffic trapped behind a fire is provided with maximum supply and no exhaust, and the zone on the other side of the fire (where unimpeded traffic has continued onward) is provided with maximum exhaust and minimum or no supply.

Full-scale tests conducted by Fieldner et al. (1921) showed that supply air inlets should be at vehicle exhaust pipe level, and exhaust outlets should be in the tunnel ceiling for rapid dilution of exhaust gases under nonemergency operation. Depending on the number of traffic lanes and tunnel width, airflow can be concentrated on one side, or divided over two sides.

Other Ventilation Systems. There are many variations and combinations of the road tunnel ventilation systems described here. Most hybrid systems are configured to solve a particular problem faced in the development and planning of a specific tunnel, such as excessive air contaminants exiting at the portal(s). Figure 6 shows a hybrid system developed for a tunnel with a near-zero level of acceptable contaminant discharge at one portal. This system is essentially a semitransverse supply system, with a semitransverse exhaust system added in section 3. The exhaust system minimizes pollutant discharge at the exit portal, which is located near extremely sensitive environmental receptors.

Ventilation System Enhancements. **Single-point extraction** is an enhancement to a transverse system that adds large openings to the extraction (or exhaust) duct. These openings include devices that can be operated during a fire emergency to extract a large volume of smoke as close to the fire source as possible. Tests proved this concept effective in reducing air temperature and smoke volume in the tunnel. The size of the duct openings tested ranged from 9.3 to 28 m^2 (MHD/FHWA 1995).

Oversized exhaust ports are simply expanded exhaust ports installed in the exhaust duct of a transverse or semitransverse ventilation system. Two methods are used to create this configuration. One is to install a damper with a fusible link; another uses a material that, when heated to a specific temperature, melts and opens the airway. Meltable materials showed only limited success in testing (MHD/FHWA 1995).

Normal Ventilation Air Quantities.

Contaminant Emission Rates. Because of the asphyxiate nature of the gas, CO is the exhaust gas constituent of greatest concern from spark-ignition engines. From compression-ignition (diesel) engines, the critical contaminants are nitrogen oxides (NO_x) such as nitric oxide (NO) and nitrogen dioxide (NO_2). Tests and operating experience indicate that, when CO level is properly diluted, other dangerous and objectionable exhaust by-products are also diluted to acceptable levels, although this trend needs review with respect to newer vehicle fleets. An exception is the large amount of unburned hydrocarbons from vehicles with diesel engines; when diesel-engine vehicles exceed 15% of the traffic mix, visibility in the tunnel can become a serious concern. In addition, suspended particles from tires and general road dust are gradually forming a larger percentage of particulate matter in the tunnel environment, and must be considered in addition to engine emissions. The section on Bus Terminals includes further information on diesel engine contaminants and their dilution.

Vehicle emissions of CO, NO_x, and hydrocarbons for any given calendar year can be predicted for cars and trucks operating in the United States by using the MOBILE models, developed and maintained by the U.S. Environmental Protection Agency (EPA 2002). In contaminant emission rate analyses, the following practices and assumptions may be implemented:

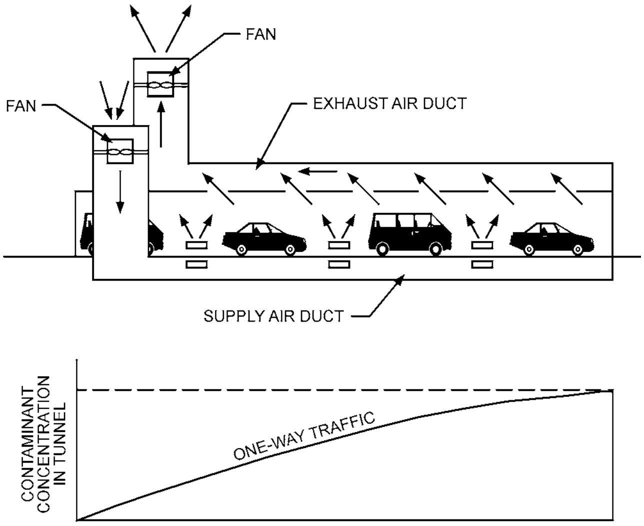

Fig. 5 Full Transverse Ventilation

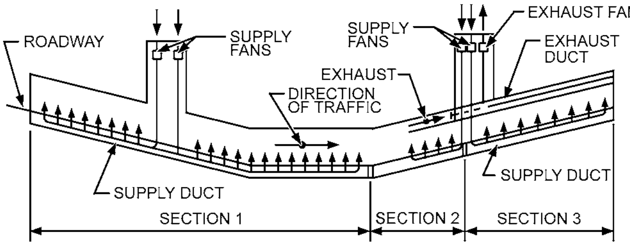

Fig. 6 Combined Ventilation System

- CO emission rates are higher during acceleration and deceleration than at constant speed; this effect may be accounted for by adding a 10% safety factor to the computations.
- The effect of positive or negative grades up to 2% is usually neglected. Engineers should use judgment, or available data, in applying correction factors for positive grades greater than 2%.
- Traffic is assumed to move as a unit, with a constant space interval between vehicles, regardless of roadway grade.
- Average passenger vehicle dimensions may be assumed where specific vehicle data are unavailable.

Table 3 presents typical physical data for automobiles for use in normal ventilation air quantity analyses.

Allowable Carbon Monoxide. EPA's (1975) supplement to its *Guidelines for Review of Environmental Impact Statements* concerns the concentration of CO in tunnels. This supplement evolved into a design approach based on keeping CO concentration at or below 143 mg/m^3 (125 ppm), for a maximum 1 h exposure time, for tunnels located at or below an altitude of 1000 m. In 1989, the EPA revised its recommendations for maximum CO levels in tunnels located at or below an altitude of 1500 m to the following:

- A maximum of 137 mg/m^3 (120 ppm) for 15 min exposure
- A maximum of 74 mg/m^3 (65 ppm) for 30 min exposure
- A maximum of 52 mg/m^3 (45 ppm) for 45 min exposure
- A maximum of 40 mg/m^3 (35 ppm) for 60 min exposure

These guidelines do not apply to tunnels in operation before the adoption date.

At higher elevations, vehicle CO emissions are greatly increased, and human tolerance to CO exposure is reduced. For tunnels above 1500 m, the engineer should consult with medical authorities to establish a proper design value for CO concentrations. Unless otherwise specified, the material in this chapter refers to tunnels at or below an altitude of 1500 m.

Outdoor air standards and regulations such as those from the Occupational Safety and Health Administration (OSHA) and the American Conference of Governmental Industrial Hygienists (ACGIH) are discussed in the section on Bus Terminals.

Emergency Ventilation Air Quantities. A road tunnel ventilation system must be able to protect the traveling public during the most adverse and dangerous conditions (e.g., fires), as well as during normal conditions. Establishing the requisite air volume requirements is difficult because of many uncontrollable variables, such as the possible number of vehicle combinations and traffic situations that could occur during the lifetime of the facility.

For many years, the rule of thumb has been 0.155 m^3/s per lane-metre. The Memorial Tunnel Fire Ventilation Test Program (MHD/FHWA 1995) showed that this value is, in fact, a reasonable first pass at an emergency ventilation rate for a road tunnel.

Longitudinal flow, single-point extraction, and dilution are three primary methods for controlling smoke flow in a tunnel. Both longitudinal flow and single-point extraction depend on the ability of the emergency ventilation system to generate the critical velocity necessary to prevent backlayering.

Critical Velocity. The concept of critical velocity is addressed in the section on Design Approach, under Tunnels.

Design Fire Size. The design fire size selected significantly affects the magnitude of the critical velocity needed to prevent backlayering. Table 4 provides typical fire size data for a selection of road tunnel vehicles.

Temperature. A fire in a tunnel significantly increases air temperature in the tunnel roadway and exhaust duct. Thus, both the tunnel structure and ventilation equipment are exposed to the high smoke/gas temperature. The air temperatures shown in Table 5 provide guidance in selecting design exposure temperatures for ventilation equipment.

Testing. The Memorial Tunnel Fire Ventilation Test Program was a full-scale test program conducted to evaluate the effectiveness of various tunnel ventilation systems and ventilation airflow rates to control smoke from a fire (MHD/FHWA 1995). The results are useful in developing both emergency tunnel ventilation systems and emergency operational procedures.

Pressure Evaluation. Air pressure losses in tunnel ducts must be evaluated to compute the fan pressure and drive requirements. Fan selection should be based on total pressure across the fans, not on static pressure alone.

Fan total pressure (FTP) is defined by ASHRAE *Standard* 51/AMCA *Standard* 210 as the algebraic difference between the total pressures at fan discharge (TP_2) and fan inlet (TP_1), as shown in Figure 7. The fan velocity pressure (FVP) is defined as the pressure (VP_2) corresponding to the bulk air velocity and air density at the fan discharge:

$$FVP = VP_2 \quad (3)$$

Fan static pressure (FSP) is equal to the difference between fan total pressure and the fan velocity pressure:

Table 3 Average Dimensional Data for Automobiles Sold in the United States

Size/Class	Wheelbase, m	Length, m	Frontal Area, m^2
Subcompact	2.4	4.3	1.6
Compact	2.7	4.8	1.8
Midsize	3.0	5.5	2.0
Large	3.0	5.6	2.1
Average	2.80	5.06	1.89

Table 4 Typical Fire Size Data for Road Vehicles

Cause of Fire	Peak Fire Heat Release Rate, MW
Passenger car	5 to 10
Multiple passenger cars (2 to 4 Vehicles)	10 to 20
Bus	20 to 30
Heavy goods truck	70 to 200
Tanker[3]	200 to 300

Source: NFPA *Standard* 502 (2008).
Notes:
1. The designer should consider rate of fire development peak heat release rates may be reached within 10 min), number of vehicles that could be involved in fire, and potential for fire to spread from one vehicle to another.
2. Temperatures directly above fire can be expected to be as high as 1000 to 1400°C.
3. Flammable and combustible liquids for tanker fire design should include adequate drainage to limit area of pool fire and its duration. Heat release rate may be greater than listed if more than one vehicle is involved.

Table 5 Maximum Air Temperatures at Ventilation Fans During Memorial Tunnel Fire Ventilation Test Program

Nominal FHRR, MW	Temperature at Central Fans,[a] °C	Temperature at Jet Fans,[b] °C
20	107	232
50	124	371
100	163	677

Source: MHD/FHWA (1995)
FHRR = Fire heat release rate

[b]Jet fans located 52 m downstream of fire site.

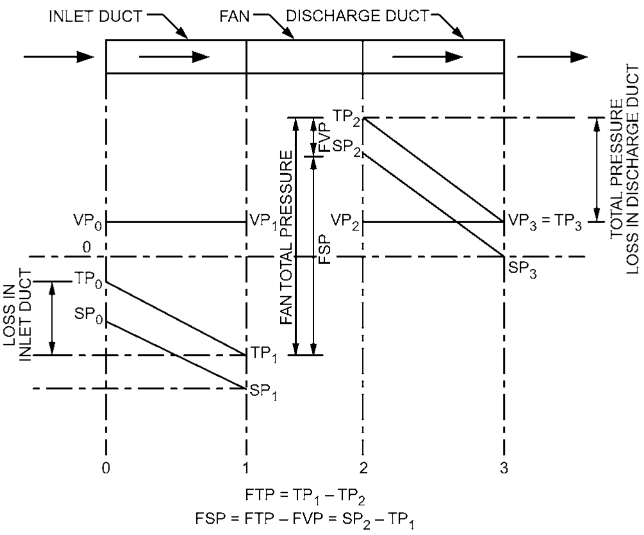

Fig. 7 Fan Total Pressure

$$\text{FSP} = \text{FTP} - \text{FVP} \tag{4}$$

TP_2 must equal total pressure losses $\Delta\text{TP}_{2\text{-}3}$ in the discharge duct and exit pressure TP_3. Static pressure at the exit SP_3 is equal to zero.

$$\text{TP}_2 = \Delta\text{TP}_{2\text{-}3} + \text{TP}_3 = \Delta\text{TP}_{2\text{-}3} + \text{VP}_3 \tag{5}$$

Likewise, total pressure at fan inlet TP_1 must equal the total pressure losses in the inlet duct and the inlet pressure:

$$\text{TP}_1 = \text{TP}_0 + \Delta\text{TP}_{0\text{-}1} \tag{6}$$

Straight Ducts. Straight ducts in tunnel ventilation systems either (1) transport air or (2) uniformly distribute (supply) or collect (exhaust) air. Several methods have been developed to predict pressure losses in a duct of constant cross-sectional area that uniformly distributes or collects air. The most widely used method was developed for the Holland Tunnel in New York (Singstad 1929). The following relationships, based on Singstad's work, give pressure losses at any point in a duct.

Total pressure for a **supply duct**

$$P_T = P_1 + \left(\frac{\rho_a}{g_c}\right)\left\{\frac{V_o^2}{2}\left[\frac{\alpha L Z^3}{3H} - (1-K)\frac{Z^2}{2}\right] + \frac{\beta L Z}{2H^3}\right\} \tag{7}$$

Static pressure loss for an **exhaust duct**

$$P_S = P_1 + \left(\frac{\rho_a}{g_c}\right)\left\{\frac{V_o^2}{2}\left[\frac{\alpha L Z^3}{(3+c)H} + \frac{3Z^2}{(2+c)}\right] + \frac{\beta L Z}{2H^3(1+c)}\right\} \tag{8}$$

where

P_T = total pressure loss at any point in duct, Pa
P_S = static pressure loss at any point in duct, Pa
P_1 = pressure at last outlet, Pa
ρ_a = density of air, kg/m^3
V_o = velocity of air entering duct, m/s
L = total length of duct, m
X = distance from duct entrance to any location, m
Z = $(L - X)/L$
H = hydraulic radius, m
K = constant accounting for turbulence = 0.615
α = constant related to coefficient of friction for concrete = 0.0035
β = constant related to coefficient of friction for concrete = 0.00012 m^4/s^2
c = constant relating to turbulence of exhaust port = 0.20 for exhaust rates less than 0.31 m^3/s per metre = 0.25 for exhaust rates greater than 0.31 m^3/s per metre
g_c = gravitational constant = 1.0 (m·kg)/(N·s^2)

The geometry of the exhaust air slot connection to the main duct is a concern in deriving the exhaust duct equation. The derivation is based on a 45° angle between the slot discharge and the main airstream axes. Variations in this angle can greatly affect the energy losses at the convergence from each exhaust slot, with total pressure losses for a 90° connection increasing by 50 to 100% over those associated with 45° angles (Haerter 1963).

For **distribution ducts** with sections that differ along their length, these equations may also be solved sequentially for each constant-area section, with transition losses considered at each change in section area. For a **transport duct** with constant cross-sectional area and constant air velocity, pressure losses are due to friction alone and can be computed using the standard expressions for losses in ducts and fittings (see Chapter 21 of the 2017 *ASHRAE Handbook—Fundamentals*).

Carbon Monoxide Analyzers and Recorders. Air quality in a tunnel should be monitored continuously at several key points. CO is the contaminant usually selected as the prime indicator of tunnel air quality, although in some of the more recent European road tunnels, NO_x and visibility levels are now the main indicators driving ventilation requirements, perhaps because of the prominence of diesel cars. CO-analyzing instruments base their measurements on one of the following three processes:

- **Catalytic oxidation (metal oxide)** analysis offers reliability and stability at a moderate initial cost. Maintenance requirements are low, plus these instruments can be calibrated and serviced by maintenance personnel after only brief instruction.
- **Infrared** analysis is sensitive and responsive, but has a high initial cost. This instrument is precise but complex, and requires a highly trained technician for maintenance and servicing.
- **Electrochemical** analysis is precise; the units are compact, lightweight, and moderately priced, but they have a limited life (usually not exceeding two years) and thus require periodic replacement.

As shown in Figures 1 to 4, the location of the peak emission concentration level in a road tunnel is a function of both traffic operation (unidirectional versus bidirectional) and type of ventilation provided (natural, longitudinal, semitransverse, or full transverse). Generally, time-averaged CO concentrations for the full length of the tunnel are needed to determine appropriate ventilation rates and/or required regulatory reporting. Time-averaged concentrations are particularly important in road tunnels where the ventilation system control is integrated with the CO monitoring system.

CO sampling locations in a road tunnel should be selected carefully to ensure meaningful results. For example, samples taken too close to an entry or exit portal do not accurately represent the overall level that can be expected throughout the tunnel. Multiple sampling locations are recommended to ensure that a reasonable average is reported. Multiple analyzers are also recommended to provide a reasonable level of redundancy in case of analyzer failure or loss of calibration. In longer road tunnels, which may have multiple, independently operated ventilation zones, the selected sampling locations should provide a representative CO concentration level for each ventilation zone. Strip chart recorders and microprocessors are commonly used to keep a permanent record of road tunnel CO levels.

CO analyzers and their probes should not be located directly in a roadway tunnel or in its exhaust plenum. Instead, an air pump should draw samples from the tunnel/exhaust duct through a sample line to the CO analyzer. This configuration eliminates the possibility of in-tunnel air velocities adversely affecting the instrument's accuracy. The length of piping between sampling point and CO analyzer should be as short as possible to maintain a reasonable air sample transport time.

Haze or smoke detectors have been used on a limited scale, but most of these instruments are optical devices and require frequent or constant cleaning with a compressed air jet. If traffic is predominantly diesel-powered, smoke haze and NO_x gases require individual monitoring in addition to that provided for CO.

Local regulations should be reviewed to determine whether ventilation exhaust monitoring is required for a particular road tunnel. If so, for tunnels using full transverse ventilation systems, CO and NO_2 pollutant sampling points should be placed carefully within the exhaust stacks/plenums. For longitudinally ventilated tunnels, sampling points should be located at least 30 m in from the exit portal.

Controls.

Centralized Control. To expedite emergency response and to reduce the number of operating personnel for a given tunnel, all ventilating equipment should be controlled at a central location. New tunnels are typically provided with computer-based control systems, which function from operational control centers. In some older tunnel facilities, fan operation is manually controlled by an operator at a central control board. The control structure for newer road tunnel ventilation systems is typically supervisory control and data acquisition (SCADA), with programmable logic controllers (PLCs) providing direct control hardware over the associated electrical equipment. The operational control center varies from one stand-alone PC (with SCADA software providing dedicated ventilation control), to redundant client/server configurations providing an integrated control system and real-time database and alarm systems for tunnel operations (Buraczynski 1997). Communication links are required between the supervisory SCADA and PLCs.

The SCADA system operator controls the ventilation equipment through a graphical user interface, developed as part of the ventilation system design. Preprogrammed responses allow the operator to select the appropriate ventilation plan or incident response mode.

The SCADA system allows the operator to view equipment status, trend data values, log data, and use an alarm system. Whereas older tunnel facilities used chart recorders for each sampling point to demonstrate that the tunnel was sufficiently ventilated and compliant with environmental air quality standards, new tunnels use SCADA to log CO levels directly onto a nonvolatile medium, such as a CD-ROM.

Emergency response functions for road tunnel ventilation require that control system design meets life safety system standards. A high-availability system is required to respond on demand to fire incidents. High availability is obtained by using high-quality industrial components, and by adding built-in redundancy. The design must protect the system against common event failures; therefore, redundant communication links are segregated and physically routed in separate raceways. High-integrity software for both the PLCs and the SCADA system is another major consideration.

Once a supervisory command is received, the PLC control handles equipment sequencing (e.g., fan and damper start-up sequence), least-hours-run algorithms, staggered starting of fans, and all interlocks. The PLC also receives instrumentation data from the fan and fan motor, and can directly shut down the fan if needed (e.g., because of high vibration). Conditions such as high vibration and high temperature are tolerated during emergency operation.

CO-Based Control. When input to the PLC, recorded tunnel air quality data allow fan control algorithms to be run automatically. The PLC controls fans during periods of rising and falling CO levels. Fan operations are usually based on the highest level recorded from several analyzers. Spurious high levels can occur at sampling points; the PLC control algorithm prevents the ventilation system from responding to short-lived high or low levels. PLC control also simplifies hardwired systems in older tunnel facilities, and increases flexibility through program changes.

Timed Control. This automatic fan control system is best suited for installations that experience heavy rush-hour traffic. With timed control, the fan operation schedule is programmed to increase the ventilation level, in preset increments, before the anticipated traffic increase; it can also be programmed for weekend and public holiday conditions. The timed control system is relatively simple and is easily revised to suit changing traffic patterns. Because it anticipates an increased airflow requirement, the associated ventilation system can be made to respond slowly and thus avoid expensive demand charges from the local utility company. One variation of timed control is to schedule the minimum anticipated number of fans to run, and to start additional fans if high CO levels are experienced. As with the CO-based control system, a manual override is needed to cope with unanticipated conditions.

Traffic-Actuated Control. Several automatic fan control systems have been based on the recorded flow of traffic. Most require installation of computers and other electronic equipment needing specific maintenance expertise.

Local Fan Control. Local control panels are typically provided for back-up emergency ventilation control and for maintenance/servicing requirements. The local panels are often hardwired to the fan starters to make them independent from the normal SCADA/PLC control system. Protocols for handing over fan control from the SCADA/ PLC system to the local panel must also be established, so that fans do not receive conflicting operational signals during an emergency.

Rapid Transit Tunnels and Stations

Modern high-performance, air-conditioned subway vehicles consume most of the energy required to operate rapid transit and are the greatest source of heat in the underground areas of a transit system. An environmental control system (ECS) is intended to maintain reasonable comfort during normal train operations and help keep passengers safe during a fire emergency. Minimizing traction power consumption and vehicle combustible contents reduces ventilation requirements. The large amount of heat produced by rolling stock, if not properly controlled, can cause passenger discomfort, shorten equipment life, and increase maintenance requirements. Tropical climates present additional concerns for underground rail transit systems and make environment control more critical.

Temperature, humidity, air velocity, air pressure change, and rate of air pressure change help determine ECS performance. These conditions are affected by time of day (i.e., morning peak, evening peak, or off-peak), circumstance (i.e., normal, congested, or emergency operations), and location in the system (i.e., tunnel, station platform, entrance, or stairway). The *Subway Environmental Design Handbook* (SEDH) (DOT 1976) provides comprehensive and authoritative design aids on ECS performance; information in the SEDH is based on design experience, validated by field and model testing.

Normal operations involve trains moving through the subway system and stopping at stations according to schedule, and passengers traveling smoothly through stations to and from transit vehicles. The piston action of moving trains is the chief means of providing ventilation and maintaining an acceptable environment (i.e., air velocity and temperature) in the tunnels. Because normal operations are predominant, considerable effort should be made to optimize ECS performance during this mode.

One concern is limiting the air velocity caused by approaching trains on passengers waiting on the platform. Piston-induced platform air velocities can be reduced by providing a pressure relief shaft (also known as a blast shaft) at each end of affected platforms.

During normal train operations, platform passenger comfort is a function of the temperature and humidity of ambient and station air, platform air velocity, and duration of exposure to the station environment. For example, a person entering a 29°C station from 32°C outdoor conditions will momentarily feel more comfortable, particularly after a fast-paced walk ending with total rest, even if standing. However, in a short time, usually about 6 min, the person's metabolism adjusts to the new environment and produces a similar level of comfort as before. If a train were to arrive during this period, a relatively high station air temperature would be acceptable. Traditionally, the relative warmth index (RWI) has quantified this transient effect, allowing the designer to select an appropriate design air temperature for the station based on the transient, rather than steady-state, sensation of comfort. More recently, new transient thermal comfort models have been developed, leading to more advanced comfort indices being proposed (Gilbey 2006; Guan et al. 2009). Design temperatures based on the transient approach are typically higher (often 3 to 5 K) than those selected by the steady-state approach, and hence result in reduced cooling load and air-conditioning system requirements.

Congested operations result from delays or operational problems that prevent the normal dispatch of trains, such as missed headways or low-speed train operations. Trains may wait in stations, or stop at predetermined locations in tunnels during congested operations. Delays usually range from 30 s to 20 min, although longer delays may occasionally be experienced. Passenger evacuations or endangerment are not expected to occur. Congested ventilation analyses should focus on the potential need for forced (mechanical) ventilation, which may be required to control tunnel air temperatures in support of continued operation of train air-conditioning units. The aim of forced ventilation is to maintain onboard passenger comfort during congestion by operating the vehicle air conditioning system to prevent passengers from evacuating the train.

Emergency operations occur as a result of a fire in a subway tunnel or station. Fire emergencies include trash fires, track electrical fires, train electrical fires, and acts of arson. Some fires may involve entire train cars. Station fires are mostly trashcan fires. Statistically, most fire incidents reported in mass transit systems (up to 99%) are small and low in smoke generation; these fires typically cause only minor injuries and operational disturbances. The most serious emergency condition is a fire on a stopped train in a tunnel; this event disrupts traffic and requires passenger evacuation. For this case, adequate tunnel ventilation is required to control smoke flow and enable safe passenger evacuation and safe ingress of emergency response personnel. Though rare, tunnel fires must be considered because of their potential life-safety ramifications.

Design Concepts. Elements of underground rail transit ventilation design may be divided into four interrelated categories: natural, mechanical, and emergency ventilation; and station air conditioning.

Natural Ventilation. Natural ventilation (e.g., ambient air infiltration and exfiltration) in subway systems primarily results from trains moving in tightly fitting tunnels, where air generally moves in the direction of train travel. The positive air pressure generated in front of a moving train expels warm air from the subway through tunnel portals, pressure relief shafts, station entrances, and other openings; the negative pressure in the wake induces airflow into the subway through these same openings.

Considerable short-circuiting of airflow occurs in subways when two trains, traveling in opposite directions, pass each other; especially in stations or tunnels with porous walls (those with intermittent openings to allow air passage between trackways). Short-circuiting can also occur in stations and tunnels with nonporous walls where alternative airflow paths (e.g., open bypasses, cross-passageways, adits, crossovers) exist between the trackways. This short-circuited airflow reduces the net ventilation rate and increases air velocities on platforms and in entrances. During peak operating periods and high ambient temperatures, short-circuited airflow can cause undesirable heat build-up in the station.

To counter the negative effects of short-circuiting airflow, ventilation shafts are customarily located near interfaces between tunnels and stations. Shafts in station approach tunnels are often called blast shafts, because part of the tunnel air pushed by an approaching train is expelled through them before it affects the station environment. Shafts in station departure tunnels are known as relief shafts, because they relieve the negative air pressure created by departing trains. Relief shafts also induce outdoor airflow through the shaft, rather than through station entrances.

Additional shafts may be provided for natural ventilation between stations (or between portals, for underwater crossings), as dictated by tunnel length. The high cost of such ventilation structures necessitates a design that optimizes effectiveness and efficiency. Internal resistance from offsets and bends in the ventilation shaft should be kept to a minimum; shaft cross-sectional area should approximately equal the cross-sectional area of a single-track tunnel (DOT 1976).

Mechanical Ventilation. Mechanical ventilation in subways (1) supplements the natural ventilation effects of moving trains, (2) expels warm air from the system, (3) introduces fresh outdoor air, (4) supplies makeup air for exhaust, (5) restores the cooling potential of the tunnel heat sink by extracting heat stored during off hours or system shutdown, (6) reduces airflow between the tunnel and station, (7) provides outdoor air for passengers in stations or tunnels during an emergency or other unscheduled interruptions of traffic, and (8) purges smoke from the system during a fire, protecting the passengers' evacuation.

The most cost-effective design for a mechanical ventilation system serves multiple purposes. For example, a vent shaft designed for natural ventilation may also be used for emergency ventilation if a fan is installed in parallel, as part of a bypass (Figure 8). Current safety standards require emergency fans to be reversible (NFPA *Standard* 130).

Several ventilation shafts and fan plants may be required to work together to achieve many, if not all, of the eight design objectives. Depending on the shaft location, design, and local train operating characteristics, a shaft with an open bypass damper and a closed fan damper may serve as a blast or relief shaft. With the fan damper open and the bypass damper closed, air can be mechanically supplied to or exhausted from the tunnel, depending on fan rotation direction. Except for emergency ventilation, fan rotation direction is usually predetermined for various operating modes.

If a station is not air conditioned, warm air in the subway should be exchanged, at the maximum rate possible, with cooler outdoor

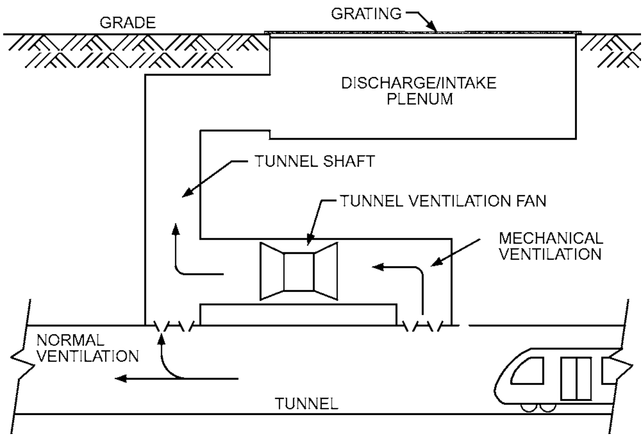

Fig. 8 Tunnel Ventilation Shaft

air. If a station is air conditioned below the ambient temperature, inflow of warmer outdoor air should be limited and controlled.

Figure 9 shows a typical tunnel ventilation system between two subway stations. Here, flow of warm tunnel air into the station is minimized by either normal or mechanical ventilation effects. In Figure 9A, air pushed ahead of the train on Track 2 diverts partially to the bypass ventilation shaft and partially into the wake of a train on Track 1, as a result of pressure differences. Figure 9B shows an alternative operation with the same ventilation system where mid-tunnel fans operate in exhaust mode; when outdoor air conditions are favorable, makeup air is introduced through the bypass ventilation shafts. This alternative can also either provide or supplement station ventilation. To achieve this, the bypass shafts are closed, and makeup air for the mid-tunnel exhaust fans enters through station entrances.

For forced air flow blown under car brake resistor grids, a more direct mechanical ventilation system (Figure 10) can be designed to remove station heat at its primary source, the underside of the train. Field tests have shown that trackway ventilation systems not only reduce upwelling of warm air into the platform areas, but also remove significant portions of heat generated by other undercar sources, such as dynamic-braking resistor grids and, in some cases, air-conditioning condenser units (DOT 1976), as long as consistent and steady air movement can be maintained from the heat source towards the exhaust grille. Ideally, makeup air for trackway exhaust should be introduced at track level, as in Figure 10A, to provide positive control over the direction of airflow; however, obstructions in the vehicle undercarriage area must be avoided when planning underplatform exhaust port and makeup air supply locations.

A more direct mechanical ventilation system (Figure 10) can be designed to remove station heat at its primary source, the underside of the train. Field tests have shown that trackway ventilation systems not only reduce upwelling of warm air into the platform areas, but also remove significant portions of heat generated by other undercar sources, such as dynamic-braking resistor grids and, in some cases, air-conditioning condenser units (DOT 1976). Ideally, makeup air for trackway exhaust should be introduced at track level, as in Figure 10A, to provide positive control over the direction of airflow; however, obstructions in the vehicle undercarriage area must be avoided when planning underplatform exhaust port and makeup air supply locations.

A trackway ventilation system without a dedicated makeup air supply (Figure 10B), also known as an underplatform exhaust (UPE) system, is the least effective alternative for heat removal. General design experience shows that where UPE grilles cannot be placed in close proximity to the source of undercar heat because of space constraints, or when a steady airflow cannot be established over the heat source towards the UPE grilles, heated undercar air can escape up through the gap between the car and platform edge, and the UPE effectiveness is reduced (Tabarra and Guan 2009). With a UPE system, a quantity of air equal to that withdrawn by the underplatform exhaust enters the station control volume, either from the outdoors or from the tunnels. When the ambient, or tunnel, air temperature is higher than the station design air temperature, a UPE system reduces station heat load by removing undercar heat, but it also increases station heat load by drawing in warmer air, which may affect platform passenger comfort. Because of these drawbacks, the effectiveness of a UPE system should be carefully considered and if possible modeled early, before the station design advances too far.

Figure 10C shows a cost-effective compromise: makeup air is introduced from the ceiling above the platform. Although heat removal effectiveness of this system may be less than that of the system with track-level makeup air, the inflow of warm tunnel air that may occur in a system without makeup air supply is negated.

Newer vehicles have air-conditioning grids above, generating heat near the ceiling during dwell time in the station. To exhaust this heat, an overtrack exhaust (OTE) system should be provided. OTE may be appropriate to remove fire smoke and heat. If analysis indicates that acceptable environmental conditions are achieved with OTE under normal and emergency conditions, the designer may consider evaluating the efficiency of the UPE system. The relative geometries of heat sources must be verified early in the design cycle, to enable the designer to make an informed decision.

Emergency Ventilation. During a subway tunnel fire, mechanical ventilation is an important part of the response and smoke control

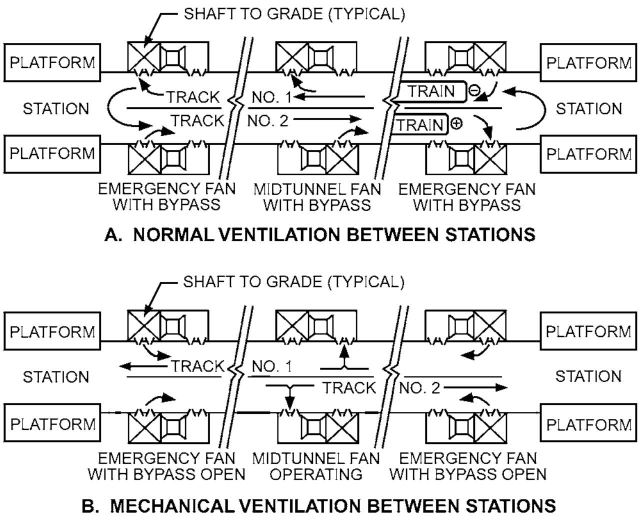

Fig. 9 Tunnel Ventilation Concept

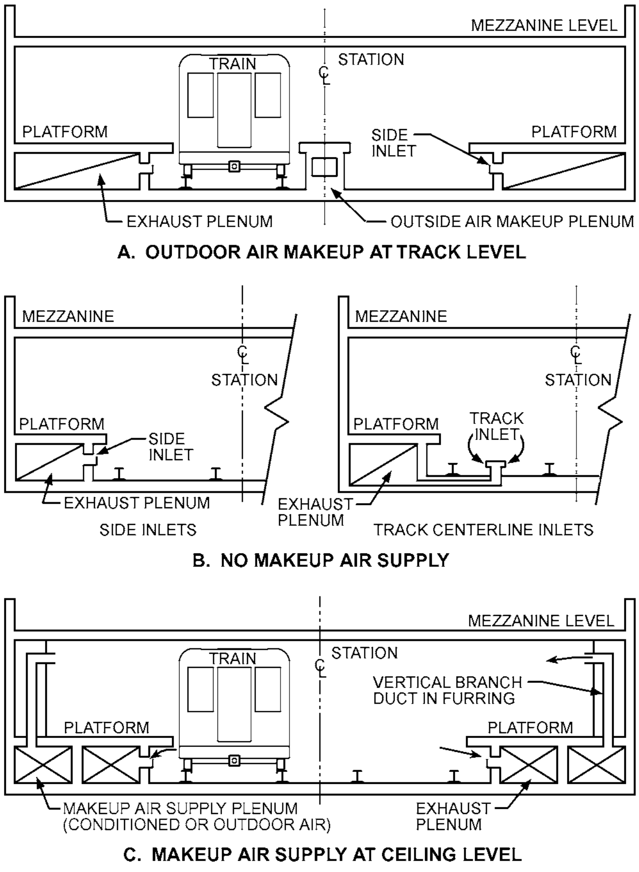

Fig. 10 Trackway Ventilation Concept (Cross-Sections)

strategy. Within subway systems or other enclosed trainways, an emergency ventilation system is necessary to control the direction of smoke migration and allow safe evacuation of passengers and access by firefighters (see NFPA *Standard* 130). Depending on vehicle configuration, ventilation fan sizes, and tunnel geometry, emergency ventilation has the potential to affect fire size and smoke generation.

The most common method of ventilating a tunnel during a fire is push-pull fan operation: fans on one side of the fire operate in supply mode, while fans on the opposite side operate in exhaust mode. Emergency ventilation analyses should focus on determining the airflow required to preserve tenable conditions in a single evacuation path from the train. The criterion used to design emergency ventilation for underground transit systems is critical velocity, similar to that presented in the section on Road Tunnels. The presence of nonincident trains should be considered in planning the emergency ventilation system response to specific fire incidents.

Emergency ventilation system design must allow for the unpredictable location of both the disabled train and the fire source. Therefore, emergency ventilation fans should have full reverse-flow capability, so that fans on either side of a disabled train can operate together to control airflow direction and counteract undesired smoke migration.

When a disabled train is stopped between two stations and fire or smoke is discovered, outdoor air is supplied by the emergency ventilation fans at the nearest station, and smoke-laden air is exhausted past the opposite end of the train by emergency ventilation fans at the next station, unless the location of the fire dictates otherwise. Passengers can then be evacuated along the tunnel walkways via the shortest possible route (Figure 11).

Emergency ventilation analysis should consider the possibility of nonincident trains stopped behind the disabled train. In this case, emergency fans should be operated so that nonincident trains are kept in the fresh airstream; if possible, they may be used to evacuate incident-train passengers. For long subway tunnels, in particular, analysis should also consider evacuating passengers to a nonincident trackway (through cross passageways), where a dedicated rescue train can move them to safety. Emergency ventilation analyses should identify passenger evacuation/firefighter ingress routes for evaluated scenarios, and fan modes to preserve tenable conditions in those routes.

When a train fire is discovered, the train should be moved if possible to the next station, to make passenger evacuation and fire suppression easier. Emergency management plans must include provisions to (1) quickly assess any fire or smoke event, (2) communicate the situation to an operations control center, (3) establish the location of the incident train, (4) establish the general location of the fire, (5) determine the best passenger evacuation route, and (6) quickly activate emergency ventilation fans to establish smoke flow control.

Midtunnel and station trackway (OTE) ventilation fans may be used to enhance emergency ventilation; therefore, these fans must also operate under high temperatures and have reverse-flow capability.

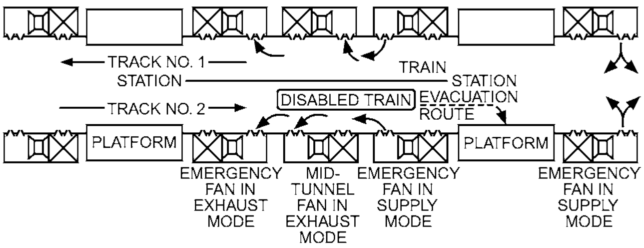

Fig. 11 Emergency Ventilation Concept

The possibility of a fire on the station platform or in another public area should also be considered. These fires are generally created by rubbish or wastepaper and are thus much smaller than train fires. However, small station fires can generate considerable smoke and create panic among passengers. Therefore, stations should be equipped with efficient fire suppression and smoke extraction systems. Stations with platform-edge doors should have fire suppression and smoke extraction systems designed specifically for that configuration.

The fire heat release rate is an important parameter in subway emergency ventilation system design. The fire heat release rate for each vehicle type depends on initiation fire, combustibility of interior materials, size of the compartment, and ventilation (door and window openings), and thus must be established individually (see the Design Fires section for more information). Typical fire size data for single transit vehicles are as follows:

- Older transit vehicle ≈ 14.7 MW
- New, hardened vehicle ≈ 10.3 MW
- Light rail vehicle ≈ 8.8 MW

Smoke obscuration is a key factor in defining a tenable environment for passenger evacuation, and visibility is often the governing criterion for station design. The smoke release rate should be calculated following acceptable procedures (e.g., Society of Fire Protection Engineers [SFPE] 2008).

Station Air Conditioning. Faster station approach speeds and closer headways, both made possible by computerized train control, have increased heat gains in subway stations. The net internal sensible heat gain for a typical two-track subway station, with 40 trains per hour per track traveling at a top speed of 80 km/h, may reach 1.5 MW, even after some tunnel heat is removed by the heat sink, station underplatform exhaust system, or tunnel ventilation system. To remove this heat from a station with a ventilation system using outdoor air and a maximum air temperature increase of 1.7 K, for example, would require roughly 660 m^3/s of outdoor air. This would be costly, and air velocities on the platforms would be objectionable to passengers.

The same amount of sensible heat gain, plus the latent heat and outdoor air loads (based on a station design air temperature 4 K lower than ambient), could be handled by about 2.2 MW of refrigeration. Even if station air conditioning is more expensive at the outset, long-term benefits include (1) reduced design airflow rates, (2) reduced ventilation shaft/duct sizing, (3) improved passenger comfort, (4) increased service life of other station equipment (e.g., escalators, elevators, fare collection), (5) reduced maintenance requirements for station equipment and structures, and (6) increased acceptance of the subway as a viable means of public transportation. Air conditioning should also be considered for other station ancillary areas, such as concourse levels and transfer levels. However, unless these walk-through areas are designed to attract patronage to concessions, the cost of air conditioning is usually not warranted.

The physical configuration of the station platform level usually determines the cooling distribution pattern. Platform areas with high ceilings, local warm spots created by trains, high-density passenger accumulation, or high-level lighting may need spot cooling. Conversely, where the train length equals platform length and the ceiling height above the platform is limited to 3 to 3.5 m, isolating heat sources and using spot cooling are usually not feasible.

In air-conditioned stations, when the enthalpy of outdoor air is higher than the station air, station air recirculation may be more economical. Thus, the station cooling system should have the flexibility of reducing the volume of outdoor air in favor of station air, based on suitably located temperature and humidity sensors. Provision for dedicated return air ducts from platforms or concourse areas with accessible filters should be considered early in station cooling design.

Air conditioning is more attractive and efficient for stations with platform-edge doors, which limit air exchange between platform and tunnels. In tropical climates, separate ventilation systems are typically used to minimize station air exfiltration and tunnel air infiltration through platform-edge doors.

Space use in a station structure for air-distribution systems is of prime concern because of the high cost of underground construction. Overhead distribution ductwork could add to the depth of excavation during subway construction. The space beneath a subway station platform is normally an excellent area for low-cost distribution of supply, return, and/or exhaust air.

Design Method. Subways typically have two discrete sets of environmental criteria: one for normal and congested train operations and one for emergency fire/smoke operations. Criteria for normal operations include limits on tunnel air temperature (through tunnel ventilation or tunnel cooling) and humidity for various times of the year, minimum ventilation rates to dilute contaminants generated in the subway, and limits on the air velocity and rate of air pressure change to which passengers may be exposed. Some of these criteria are subjective and may vary based on demographics. Criteria for emergency operations include a minimum purge time to remove smoke from a subway, critical air velocity for smoke flow control during a tunnel fire, and minimum and maximum fan-induced tunnel air velocities.

Given a set of criteria, outdoor design conditions, and appropriate tools for estimating interior heat loads, heat sink effect, ventilation requirements, tunnel air velocity, and rate of air pressure changes, design engineers can select components for the environmental control system (ECS). ECS design should consider controls for tunnel air temperature, velocity, and quality, and the air pressure change rate. Systems selected generally combine natural and mechanical ventilation, overtrack and underplatform exhaust, and station air conditioning.

Train propulsion/braking systems and configuration of the tunnels and stations greatly affect the subway environment. Therefore, the ECS must often be considered during the early stages of subway system design. Factors affecting a subway environmental control system are discussed in this section. The *Subway Environmental Design Handbook* (SEDH) (DOT 1976) and NFPA *Standard* 130 have additional information.

Analytical Data. ECS design should be based on all the parameters affecting its operation, including ambient air conditions, train operating characteristics, applicable ventilation methods, new or existing ventilation structures, and calculated heat loads. ECS efficiency should be addressed early during transit system design. The tunnel ventilation system should be integrated with the design of other tunnel systems (including power, signaling, communications, and fire/life safety systems) and with the station ventilation system design. The ECS design must satisfy the project design criteria and comply with applicable local and national (or international) codes, standards, and regulations.

The ventilation engineer should be familiar with these requirements and apply suitable design techniques, such as computer modeling and simulations (using verified/validated engineering software).

Comfort Criteria. Because passenger exposure to the subway environment is transient, comfort criteria are not as strict as those for continuous occupancy. As a general principle, the station environment should provide a smooth transition between outdoor air conditions and thermal conditions in the transit vehicles. Except where platform edge doors are installed, train movement usually generates desirable air movement in stations, but air velocity should not exceed 5 m/s in public areas during normal train operations.

Air Quality. Air quality in a subway system is influenced by many factors, some of which are not under the direct control of the HVAC engineer. Some particulates, gaseous contaminants, and odorants in the ambient air can be prevented from entering the subway system by judicious selection of ventilation shaft locations. Particulate matter, including iron and graphite dust generated by normal train operations, is best controlled by regularly cleaning stations and tunnels. However, the only viable way to control gaseous contaminants, such as ozone (produced by electrical equipment) and CO_2 (from human respiration), in a subway system is through adequate ventilation with outdoor air.

Subway system air quality should be analyzed either by engineering calculations or by computer modeling and simulations. The analysis should consider both the tunnel airflow induced by the piston effect of moving trains and the outdoor airflow required to dilute gaseous contaminants to acceptable levels. The results should comply with the *Subway Environmental Design Handbook* (DOT 1976) recommendation for at least 4 ach, as well as the recommendation of ASHRAE *Standard* 62.1 to have a minimum of 3.5 L/s outdoor air per person. Maximum station occupancy should be used in the analysis.

Pressure Transients. Trains passing through aerodynamic discontinuities in a subway cause changes in tunnel static pressure, which can irritate passengers' ears and sinuses. Based on nuisance factor criteria, if the total change in the air pressure is greater than 697 Pa, the rate of static pressure change should be kept below 423 Pa/s. Pressure transients also add to the dynamic load on various equipment (e.g., fans, dampers) and appurtenances (e.g., acoustical panels). The formula and methodology of pressure transient calculations are complex; this information is presented in the SEDH (DOT 1976).

Air Velocity. During fires, emergency ventilation must be provided in the tunnels to control smoke flow and reduce air temperatures to permit both passenger evacuations and firefighting operations. The minimum air velocity in the affected tunnel should be sufficient to prevent smoke from backlayering (flowing in the upper cross section of the tunnel in the direction opposite the forced ventilation airflow). The method for ascertaining this critical air velocity is provided in the section on Design Approach, under Tunnels. The maximum tunnel air velocity experienced by evacuating passengers should not exceed 11 m/s.

Interior Heat Loads. Heat in a subway is generated mostly by the following sources:

- Train deceleration/braking: Between 40 and 50% of heat generated in a subway arises from train deceleration/braking. Many vehicles use non-regenerative braking systems, in which the kinetic energy of the train is dissipated to the tunnel as heat, through dynamic and/or frictional brakes, rolling resistance, and aerodynamic drag. Regenerative systems dissipate less braking heat.
- Train acceleration: Heat is also generated as a train accelerates. Many vehicles use cam-controlled variable-resistance elements to regulate voltage across dc traction motors during acceleration. Electrical power is dissipated by these resistors (and the third rail) as heat into the subway. The heat released during train acceleration also comes from traction motor losses, rolling resistance, and aerodynamic drag. Heat from acceleration generally amounts to 10 to 20% of the total heat released in a subway system.

In subway systems with closely spaced stations, more heat is generated because of the frequent acceleration and deceleration.

- Vehicle air conditioning: Most new transit vehicles are fully climate controlled. Air-conditioning equipment removes passenger and lighting heat from the cars and transfers it, along with condenser fan and compressor heat, into the subway. Vehicle air-conditioning system capacities generally range from 35 kW per vehicle for shorter rail cars (about 15 m long), up to about 70 kW for longer rail cars (about 21 m long). Heat from vehicle air

Table 6 Typical Heat Source Emission Values

Source of Heat	Heat Rejection, kW
Train A/C system (per vehicle)	42
Escalator (7.5 kW, 75% load factor)	5.6[a]
Fare collection machine	0.8[a]
Station lighting	0.032 per square metre[a]
People (walking, standing)	0.073 sensible[b]
	0.073 latent[b]

[a]See *Subway Environmental Design Handbook*, Part 3 (DOT 1976).
[b]See 2017 *ASHRAE Handbook—Fundamentals*, Chapter 9.

conditioning and other accessories is generally 25 to 30% of total heat generated in a subway.

- Other sources: Tunnel heat also comes from people, lighting, induced outdoor air, miscellaneous equipment (e.g., fare collecting machines, escalators), and third-rail/catenary systems. These sources can generate 10 to 30% of the total heat released in a subway.

In a typical subway heat balance analysis, a control volume is defined around each station and heat sources are identified and quantified. The control volume usually includes the station and its various approach/departure tunnels. Typical values for heat emission/rejection data are given in Table 6.

Heat Sink. The amount of heat flow from tunnel air to subway walls varies seasonally, as well as during morning and evening rush-hour operations. Short periods of abnormally high or low outdoor temperature may cause a temporary departure from the normal heat sink effect in unconditioned areas of the subway, changing the average tunnel air temperature. However, any change from the normal condition is diminished by the thermal inertia of the subway structure. During abnormally hot periods, heat flow from the tunnel air to subway walls increases. Similarly, during abnormally cold periods, heat flow from the subway walls to tunnel air increases.

For subway systems where daily station air temperatures are held constant by dedicated heating and cooling systems, heat flux from station walls is negligible. Depending on the amount of station air flowing into adjoining tunnels, heat flux from tunnel sections may also be reduced. Other factors affecting the heat sink component are soil type (dense rock or light, dry soil), extent of migrating groundwater or the local water table, and surface configuration of tunnel walls (ribbed or flat).

Measures to Limit Heat Loads. Various measures have been proposed to limit interior heat loads in subway systems, including regenerative braking, thyristor motor controls, track profile optimization, underplatform exhaust systems, and cooling dumping.

Electrical regenerative braking converts kinetic energy into electrical energy for use by other trains. Flywheel energy storage, an alternative form of regenerative braking, stores part of the braking energy in high-speed flywheels for use during vehicle acceleration. These methods can reduce the heat generated in train braking by approximately 25%.

Cam-controlled propulsion applies a set of resistance elements to regulate traction motor current during acceleration. Electrical energy dissipated by these resistors appears as waste heat in a subway. **Thyristor motor controls** replace the acceleration resistors with solid-state controls, which reduce acceleration-related heat losses by about 10% on high-speed subways, and by about 25% on low-speed subways.

Track profile optimization refers to a tunnel design that is lower between the stations. Less power is used for acceleration, because some of the potential energy of a standing train is converted to kinetic energy as the train accelerates toward the tunnel low point. Conversely, some of the kinetic energy of a train at maximum speed is converted to potential energy during braking, as the train approaches the next station. Track profile optimization reduces the maximum vehicle heat loss from acceleration and braking by about 10%.

An **overtrack exhaust (OTE)** and/or **underplatform exhaust (UPE)** system, described in the section on Mechanical Ventilation, uses extract grilles at regular intervals to remove heat generated by vehicle equipment located either at car roof level or under the car (e.g., resistors, compressors, air-conditioning condensers) from the station environment. For forced-blown resistor grids and cases where the airflow pattern is well controlled over the source of the undercar heat, SEDH (DOT 1976) provides a table (based on field test results in a given station platform geometry) of various UPE airflow rates versus UPE system efficiency. Care should be taken when extending these data to other platform geometries. For preliminary calculations, it may be assumed that (1) the train heat release (from braking and air conditioning) in the station box is about two-thirds of the control-volume heat load, and (2) the UPE is about 50% effective (provided the geometry and airflow pattern conditions are fulfilled). Sanchez (2003) studied the impact of OTE/UPE for air-conditioned stations.

In tropical areas, where there are only small daily differences in the ambient air temperature, tunnel walls do not cool off during the night; consequently the heat sink effect is negligible. In such cases, **cooling dumping** (releasing cooler air from the vehicle or its air-conditioning system) can be considered to limit heat accumulation in subway tunnels. However, the effect of cooling dumping on vehicle air-conditioning systems must be considered.

Railroad Tunnels

Railroad tunnels for diesel locomotives require ventilation to remove residual diesel exhaust, so that each succeeding train is exposed to a relatively clean air environment. Ventilation is also required to prevent locomotives from overheating while in the tunnel. For short tunnels, ventilation generated by the piston effect of a train, followed by natural ventilation, is usually sufficient to purge the tunnel of diesel exhaust in a reasonable time period. Mechanical ventilation for locomotive cooling is usually not required in short tunnels, because the time that a train is in the tunnel is typically less than the time it would take for a locomotive to overheat. However, under certain conditions, such as for excessively slow trains or during hot weather, locomotive overheating can still become a problem. For long tunnels, mechanical ventilation is required to purge the tunnel of diesel exhaust, and may also be required for locomotive cooling, depending on the speed of the train and the number and arrangement of locomotives used.

The diesel locomotive is essentially a fuel-driven, electrically powered vehicle. The diesel engine drives a generator, which in turn supplies electrical power to the traction motors. The power of these engines ranges from about 750 to 4500 kW. Because the overall efficiency of the locomotive is generally under 30%, most of the energy generated by the combustion process must be dissipated as heat to the surrounding environment. Most of this heat is released above the locomotive through the engine exhaust stack and the radiator discharge (Figure 12).

In a tunnel, this heat is confined to the region surrounding the train. Most commercial trains are powered by more than one locomotive, so the last unit is subjected to heat and exhaust smoke released by preceding units. If sufficient ventilation is not provided, the air temperature entering the radiator of the last locomotive will exceed its allowable limit. Depending on the engine protection system, this locomotive will then either shut down or drop to a lower throttle position. In either event, the train will slow down. But, as discussed in the next section, a train relies on its speed to generate sufficient ventilation for cooling. As a result of the train slowing down, a domino effect takes place, which may cause the train to stall in the tunnel.

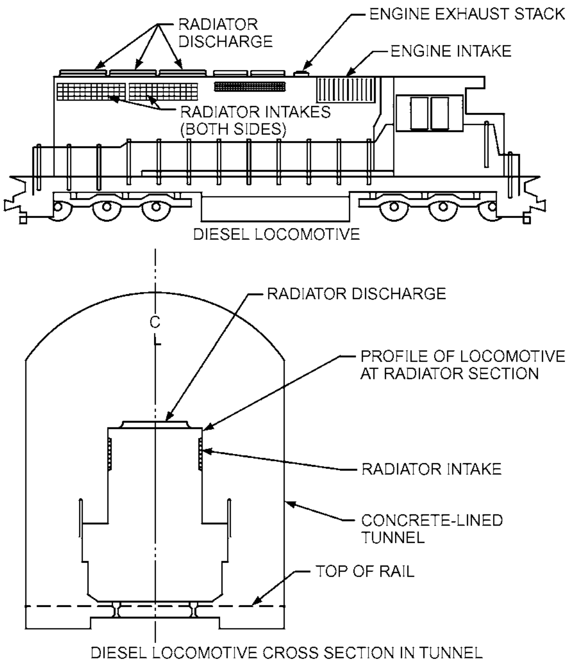

Fig. 12 Typical Diesel Locomotive Arrangement

Design Concepts. Most long railroad tunnels (over 8 km) in the western hemisphere that serve diesel operation use a ventilation concept using both a tunnel door and a system of fans and dampers, all located at one end of the tunnel. When a train moves through the tunnel, ventilation air for locomotive cooling is generated by the piston effect of the train moving toward (or away from) the closed portal door. This effect often creates a sufficient flow of air past the train for self-cooling.

Under certain conditions, when the piston effect cannot provide required airflow, fans supplement the flow and cool the tunnel. When the train exits at the portal, the tunnel is purged of residual smoke and diesel contaminants by running the fans (with the door closed) to move fresh air from one end of the tunnel to the other. Because the airflow and pressure required for cooling and purge modes may be substantially different, multiple fan systems or variable-volume fans may be required for the two operations. Also, dampers are provided to relieve the pressure across the door, which facilitates its operation while the train is in the tunnel.

Application of this basic ventilation concept varies depending on the length and grade of the tunnel, type and speed of the train, environmental and structural site constraints, and train traffic flow. One design, for a 14.5 km long tunnel (Levy and Danziger 1985), extended the basic concept by including a mid-tunnel door and a partitioned shaft, which was connected to the tunnel on both sides of the mid-tunnel door. The combination of mid-tunnel door and partitioned shaft divided the tunnel into two segments, each with its own ventilation system. Thus, the ventilation requirement of each segment was satisfied independently. The need for such a system was dictated by the length of the tunnel, relatively low speed of the trains, and traffic pattern.

Locomotive Cooling Requirements. A breakdown of the heat emitted by a locomotive to the surrounding air can be determined by performing an energy balance. Starting with the fuel consumption rate (as a function of the throttle position), the heat release rates (as provided by the engine manufacturer) at the engine exhaust stack and radiator discharge, and the gross power delivered by the engine shaft (as determined from manufacturer's data), the amount of miscellaneous heat radiated by a locomotive can be determined as follows:

$$q_M = FH - q_S - q_R - P_G \tag{9}$$

where

q_M = miscellaneous heat radiated from locomotive engine, W
F = locomotive fuel consumption, kg/s
H = heating value of fuel, J/kg
q_S = heat rejected at engine exhaust stack, W
q_R = heat rejected at radiator discharge, W
P_G = gross power at engine shaft, W

Because locomotive auxiliaries are driven off the engine shaft, with the remaining power used for traction power through the main engine generator, heat released by the main engine generator can be determined as follows:

$$q_G = (P_G - L_A)(1 - \varepsilon_G) \tag{10}$$

where

q_G = main generator heat loss, W
L_A = power driving locomotive auxiliaries, W
ε_G = main generator efficiency

Heat loss from the traction motors and gear trains can be determined as follows:

$$q_{TM} = P_G - L_A - q_G - P_{TE} \tag{11}$$

where

q_{TM} = heat loss from traction motors and gear trains, W
P_{TE} = locomotive tractive effort power, W

The total locomotive heat release rate q_T can then be determined:

$$q_T = q_S + q_R + q_m + L_A + q_G + q_{TM} \tag{12}$$

For a train with N locomotives, the average air temperature approaching the last locomotive is determined from

$$t_{AN} = t_{AT} + \frac{q_T(N-1)}{\rho c_p Q_R} \tag{13}$$

where

t_{AN} = average tunnel air temperature approaching Nth locomotive, °C
t_{AT} = average tunnel air temperature approaching locomotive consist, °C
ρ = density of tunnel air approaching locomotive consist, kg/m³
c_p = specific heat of air, J/(kg·°C)
Q_R = tunnel airflow rate relative to train, m³/s

The inlet air temperature to the locomotive radiators is used to judge the adequacy of the ventilation system. For most locomotives running at maximum throttle position, the maximum inlet air temperature recommended by manufacturers is about 46°C. Field tests in operating tunnels (Aisiks and Danziger 1969; Levy and Elpidorou 1991) showed, however, that some units can operate continuously with radiator inlet air temperatures as high as 57°C. The allowable inlet air temperature for each locomotive type should be obtained from the manufacturer when contemplating a design.

To determine the airflow rate required to prevent a locomotive from overheating, the relationship between the average tunnel air temperature approaching the last unit and the radiator inlet air temperature must be known or conservatively estimated. This relationship depends on variables such as the number of locomotives in the consist, air velocity relative to the train, tunnel cross-sectional area/configuration, type of tunnel lining, and locomotive orientation (i.e., facing forward or backward). For trains traveling under 32 km/h, Levy and Elpidorou (1991) showed that a reasonable estimate is to assume the radiator inlet air temperature to be about 6 K higher than the average air temperature approaching the unit. For trains moving at 50 km/h or more, a reasonable estimate is to assume that the radiator inlet air temperature equals the average air temperature approaching the unit. When the last unit of the train consist faces forward, thereby putting the exhaust stack ahead of its own radiators, the stack heat release rate must be included when evaluating the radiator inlet air temperature.

Tunnel Aerodynamics. When designing a ventilation system for a railroad tunnel, airflow and pressure distribution throughout the tunnel (as a function of train type, train speed, and ventilation system operating mode) must be determined. This information is required to determine (1) whether sufficient ventilation is provided for locomotive cooling, (2) the pressure that the fans are required to deliver, and (3) the pressure that the structural and ventilation elements of the tunnel must be designed to withstand.

The following equation, from DOT (1997a), relates the piston effect of the train, steady-state airflow from fans to the tunnel, and pressure across the tunnel door. This expression assumes that air leakage across the tunnel door is negligible. Figure 13 shows the dimensional variables on a schematic of a typical tunnel.

$$\frac{\Delta p}{\rho} = \frac{(p_A - p_B)}{\rho} - \frac{Hg}{g_C} + \left(\frac{(A_V^2 + A_V A_T C_{DVB})}{(A_T - A_V)^2} + \frac{A_V C_{DVF}}{A_T}\right)\frac{(A_T V + Q_S)^2}{2A_T^2 g_C} + \frac{f_T L_V P_T (A_V V + Q_S)^2}{8(A_T - A_V)^3 g_C} + \frac{\lambda_V L_V P_V (A_T V + Q_S)^2}{8(A_T - A_V)^3 g_C} + \frac{f_T (L_T - L_V) P_T Q_S^2}{8A_T^3 g_C} + \frac{K Q_S^2}{2A_T^2 g_C} \qquad (14)$$

where

Δp = static pressure across tunnel door, Pa
ρ = density of air, kg/m^3
p_A = barometric pressure at portal A, Pa
p_B = barometric pressure at portal B, Pa
H = difference in elevation between portals, m
g = acceleration of gravity = 9.81 m/s^2
g_C = gravitational constant = 1.0 (m·kg)/N·s^2
A_V = train cross-sectional area, m^2
A_T = tunnel cross-sectional area, m^2

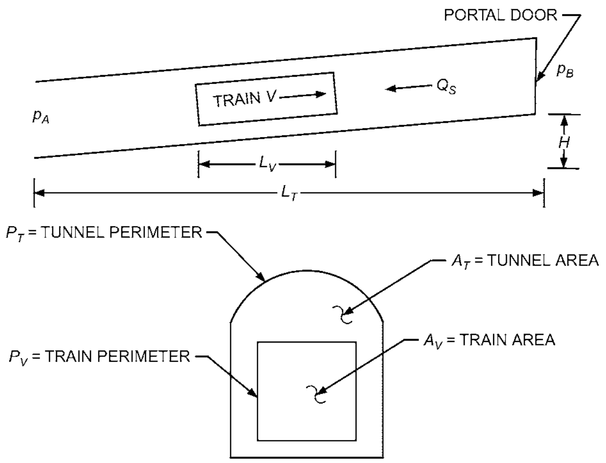

Fig. 13 Railroad Tunnel Aerodynamic Related Variables

C_{DVB} = drag coefficient at back end of train
C_{DVF} = drag coefficient at front end of train
V = velocity of train, m/s
Q_S = airflow delivered by fan, m^3/s
f_T = tunnel wall friction factor
L_T = tunnel length, m
L_V = train length, m
P_T = tunnel perimeter, m
P_V = train perimeter, m
λ_V = train skin friction factor
K = miscellaneous tunnel loss coefficient

The pressure across the tunnel door generated only by train piston action is evaluated by setting Q_S equal to zero. The airflow rate, relative to the train, required to evaluate locomotive cooling requirements is

$$Q_{rel} = A_T V + Q_S \qquad (15)$$

where Q_{rel} is the airflow rate relative to the train, m^3/s.

Typical values for C_{DVB} and C_{DVF} are about 0.5 and 0.8, respectively. Because trains passing through a railroad tunnel are often more than 1.6 km long, the parameter that most affects the generated air pressure is the train skin friction coefficient. For dedicated coal or grain trains, which essentially use uniform cars throughout, a value of 0.09 for the skin friction coefficient results in air pressure predictions that conform closely to those observed in various railroad tunnels. For trains with non-uniform car distribution, the skin friction coefficient may be as high as 1.5 times that for a uniform car distribution.

The wall surface friction factor corresponds to the coefficient used in the Darcy-Weisbach equation for friction losses in pipe flow. Typical effective values for tunnels constructed with a formed concrete lining and having a ballasted track range from 0.015 to 0.017.

Tunnel Purge. The leading end of a locomotive must be exposed to an environment that is relatively free of smoke and diesel contaminants emitted by preceding trains. Railroad tunnels are usually purged by displacing contaminated tunnel air with fresh air by mechanical means after a train has left the tunnel. With the tunnel door closed, air is either supplied to or exhausted from the tunnel, moving fresh air from one end of the tunnel to the other. Observations at the downstream end of tunnels have found that an effective purge time is usually based on displacing 1.25 times the tunnel volume with outdoor air.

The time required for purging is primarily determined by operations schedule needs. A long purging time limits traffic; a short purging time may necessitate very high ventilation airflow rates and result in high electrical energy demand and consumption. Consequently, multiple factors must be considered, including the overall ventilation concept, when establishing the purge rate.

2. PARKING GARAGES

Automobile parking garages (car parks) can be either fully enclosed or partially open. Fully enclosed parking areas are often underground and require mechanical ventilation. Partially open parking garages are generally above-grade structural decks having open sides (except for barricades), with a complete deck above. Natural ventilation, mechanical ventilation, or a combination can be used for partially open garages.

Parking garages provide a unique set of challenges because there is a continuous influx of potentially harmful contaminants on a regular basis. In addition, smoke from any fire must be controlled properly to ensure the safety of occupants. The ventilation system should (1) remove toxic gases during nonemergency operation (CO and NO_x) and (2) control smoke and hot gases in the event of a fire.

Nonemergency operation of automobiles in parking garages presents two concerns. The more serious is emission of CO, with its known risks. The other concern is oil and gasoline fumes, which may cause nausea and headaches and also represent potential fire hazards. Additional concerns about NO_x and smoke haze from diesel engines may also require consideration. However, the ventilation rate required to dilute CO to acceptable levels is usually satisfactory to control the level of other contaminants as well, provided the percentage of diesel vehicles does not exceed 20%.

For many years, the various model codes, ASHRAE *Standard* 62.1, and its predecessor standards recommended a flat exhaust rate of either 0.0038 $m^3/(s \cdot m^2)$ or 6 ach for enclosed parking garages. But because vehicle emissions have been reduced over the years, ASHRAE sponsored a study to determine ventilation rates required to control contaminant levels in enclosed parking facilities (Krarti and Ayari 1998). The study found that, in some cases, much less ventilation than 0.0075 $m^3/(s \cdot m^2)$ was satisfactory. The study's methodology for determining whether a reduced ventilation rate would be effective is included below. However, the current ASHRAE *Standard* 62.1 and the International Code Council's *International Mechanical Code*® (ICC 2009a) allow 0.0038 $m^3/(s \cdot m^2)$ ventilation, whereas NFPA *Standard* 88A recommends a minimum of 0.005 $m^3/(s \cdot m^2)$, so the engineer must understand the specific codes and standards that apply. The engineer may be required to request a variation, or waiver, from authorities having jurisdiction before implementing a lesser ventilation system design.

If larger fans are installed to meet code requirements, they will not necessarily increase overall power consumption; with proper CO level monitoring and ventilation system control, fans will run for shorter time periods to maintain acceptable CO levels. With increased attention on reducing energy consumption, CO-based ventilation system control can provide substantial cost savings in the operation of parking garages.

Ventilation Requirements and Design

ASHRAE research project RP-945 (Krarti and Ayari 1998) found that the design ventilation rate required for an enclosed parking facility depends chiefly on four factors:

- Acceptable level of contaminants in the parking facility
- Number of cars in operation during peak conditions
- Length of travel and the operating time for cars in the garage
- Emission rate of a typical car under various conditions

Contaminant Level Criteria. ACGIH (1998) recommends a threshold CO limit of 29 mg/m^3 (25 ppm) for an 8 h exposure, and the U.S. EPA (2000) determined that exposure, at or near sea level, to a CO concentration of 40 mg/m^3 (35 ppm) for up to 1 h is acceptable. For parking garages more than 1000 m above sea level, more stringent limits are required.

In Europe, an average concentration of 40 mg/m^3 (35 ppm) and a maximum level of 230 mg/m^3 (200 ppm) are usually maintained in parking garages.

Various agencies and countries differ on the acceptable level of CO in parking garages, but a reasonable solution is a ventilation rate designed to maintain a CO level of 40 mg/m^3 (35 ppm) for 1 h exposure, with a maximum of 29 mg/m^3 (25 ppm) for an 8 h exposure. Because the time associated with driving in and parking, or driving out of a garage, is on the order of minutes, 40 mg/m^3 (35 ppm) is probably an acceptable level of exposure. However, Figure 14 provides nomographs for 15 and 25 ppm maximum exposures as well, to allow the designer to conform to more stringent regulations.

Number of Cars in Operation. The number of cars operating at any one time depends on the type of facility served by the parking garage. For distributed, continuous use, such as an apartment building or shopping area, the variation is generally 3 to 5% of the total vehicle capacity. The operating capacity could reach 15 to 20% in other facilities, such as sports stadiums or short-haul airports.

Table 8 Predicted CO Emissions in Parking Garages

	Hot Emission (Stabilized), g/min		Cold Emission, g/min	
Season	1991	1996	1991	1996
Summer, 32°C	2.54	1.89	4.27	3.66
Winter, 0°C	3.61	3.38	20.74	18.96

Results from EPA MOBILE3, version NYC-2.2 (1984); sea level location.
Note: Assumed vehicle speed is 8 km/h.

Length of Time of Operation. The length of time that a car remains in operation in a parking garage is a function of the size and layout of the garage, and the number of cars attempting to enter or exit at a given time. The operating time could vary from as much as 60 to 600 s, but on average usually ranges from 60 to 180 s. Table 7 lists approximate data for average vehicle entrance and exit times; these data should be adjusted to suit the specific physical configuration of the facility.

Car Emission Rate. Operating a car in a parking garage differs considerably from normal vehicle operation, including that in a road tunnel. Most car movements in and around a parking garage occur in low gear. A car entering a garage travels slowly, but the engine is usually hot. As a car exits from a garage, the engine is usually cold and operating in low gear, with a rich fuel mixture. Emissions for a cold start are considerably higher, so the distinction between hot and cold emission plays a critical role in determining the ventilation rate. Motor vehicle emission factors for hot- and cold-start operation are presented in Table 8. An accurate analysis requires correlation of CO readings with the survey data on car movements (Hama et al. 1974); the data should be adjusted to suit the specific physical configuration of the facility and the design year.

Step 1. Collect the following data:

- Number of cars N in operation during peak hour use
- Average CO emission rate E for a typical car, g/h
- Average length of operation and travel time θ for a typical car, s
- Acceptable CO concentration CO_{max} in the garage, ppm
- Total floor area of parking facility A_f, m^2

Step 2. Evaluate CO generation rate:

(1) Determine the peak CO generation rate per unit floor area G, in g/(h·m²), for the parking garage:

$$G = NE/A_f \tag{16}$$

(2) Normalize the peak CO generation rate using the reference value $G_0 = 26.7$ g/(h·m²) and Equation (17). This reference value is based on an actual enclosed parking facility (Krarti and Ayari 1998):

$$f = 100G/G_0 \tag{17}$$

Step 3. Determine the minimum required ventilation rate Q per unit floor area using Figure 14, or the correlation presented by Equation (18), depending on CO_{max}:

$$Q = Cf\theta \tag{18}$$

where

$C = 1.204 \times 10^{-6}$ (m³/s)/(m²·s) for $CO_{max} = 15$ ppm
$= 0.692 \times 10^{-6}$ (m³/s)/(m²·s) for $CO_{max} = 25$ ppm
$= 0.481 \times 10^{-6}$ (m³/s)/(m²·s) for $CO_{max} = 35$ ppm

Example 1. Consider a two-level enclosed parking garage with a total capacity of 450 cars, a total floor area of 8360 m², and an average height of 2.75 m. The total length of time for a typical car operation is 2 min (120 s). Determine the required ventilation rate for the enclosed parking garage in m³/(s·m²) and in air changes per hour so that the CO level never exceeds 25 ppm. Assume that the number of cars in operation during peak use is 40% of the total vehicle capacity.

Solution:

Step 1. Garage data:

$N = 450 \times 0.4 = 180$ cars
$E = 11.67$ g/min = 700 g/h, the average of all values of emission rate for a winter day, from Table 8
$CO_{max} = 25$ ppm
$\theta = 120$ s

Step 2. Calculate the normalized CO generation rate:

$G = (180 \times 700 \text{ g/h})/8360 \text{ m}^2 = 15.1$ g/(h·m²)
$f = 100 \times (15.1 \text{ g/h·m}^2)/26.7 \text{ g/(h·m}^2) = 56.6$

Step 3. Determine the ventilation requirement, using Figure 14 or the correlation of Equation (18) for $CO_{max} = 25$ ppm.

$Q = 0.692 \times 10^{-6}$ (m³/s)/(m²·s) × 56.6 × 120 s = 0.0047 m³/(s·m²)

Or, for air changes per hour,

$$(0.0047 \text{ (m}^3\text{/s)/m}^2 \times 3600 \text{ s/h})/2.74 \text{ m} = 6.2$$

Notes:

1. If the average vehicle CO emission rate is reduced to $E = 6.60$ g/min, because of, for instance, better emission standards or better maintained cars, the required minimum ventilation rate decreases to 0.0027 m³/(s·m²) or 3.5 ach.

2. Once calculations are made and a decision reached to use CO demand ventilation control, increasing airflow through a safety margin does not increase operating costs; larger fans work for shorter periods to sweep the garage and maintain satisfactory conditions.

CO Demand Ventilation Control. A parking garage ventilation system should meet applicable codes and maintain acceptable contaminant levels. If permitted by local codes, the ventilation airflow rate should be varied according to CO levels to conserve energy. For example, the ventilation system could consist of multiple fans, with single- or two-speed motors, or variable-pitch blades. In multilevel parking garages or single-level structures of extensive area, independent fan systems with individual controls are preferred. The *International Mechanical Code*® (ICC 2009a) allows ventilation system operation to be reduced from 0.0038 to 0.00025 m³/(s·m²) with the use of a CO monitoring system that restores full ventilation when CO levels of 29 mg/m³ (25 ppm) are detected.

Figure 15 shows the maximum CO level in a tested parking garage (Krarti and Ayari1998) for three car movement profiles and the following ventilation control strategies:

- Constant-volume (CV), where the ventilation system is kept on during the entire occupancy period
- On/off control, with fans stopped and started based on input from CO sensors
- Variable-air-volume (VAV) control, using either two-speed fans or axial fans with variable-pitch blades, based on input from CO sensors

Figure 15 also shows typical fan energy savings achieved by on/off and VAV systems relative to constant-volume systems. Signifi-

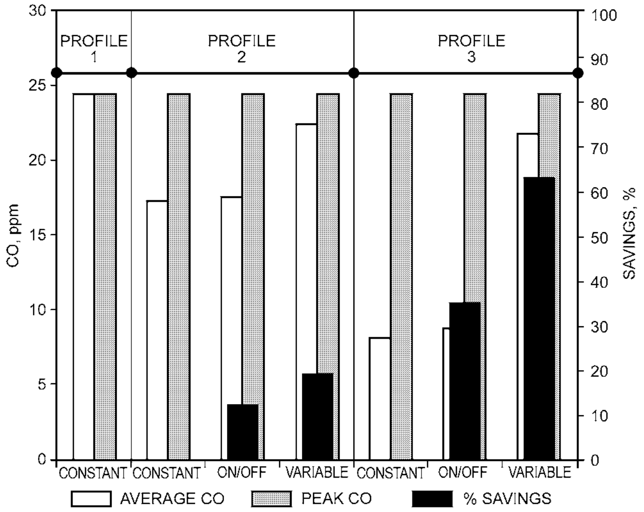

Fig. 15 Typical Energy Savings and Maximum CO Level Obtained for Demand CO-Ventilation Controls

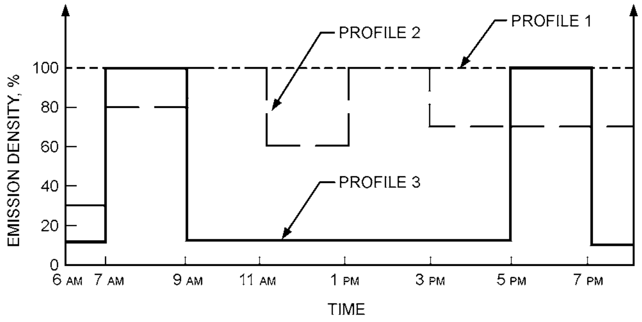

Fig. 16 Three Car Movement Profiles

cant fan energy savings can be obtained using a CO-based demand ventilation control strategy to operate the ventilation system, maintaining CO levels below 29 mg/m^3 (25 ppm). Wear and tear and maintenance on mechanical and electrical equipment are reduced with a CO-based demand strategy.

Figure 16 is based on maintaining a 29 mg/m^3 (25 ppm) CO level. With most systems, actual energy usage is further reduced if 40 mg/m^3 (35 ppm) is maintained. The actual ppm level should follow local codes and standards.

In cold climates, the additional cost of heating makeup air is also reduced with a CO-based demand strategy. Energy stored in the mass of the structure usually helps maintain the parking garage air temperature at an acceptable level. If only outdoor air openings are used to draw in ventilation air, or if infiltration is allowed, the stored energy is lost to the incoming cold air.

Types of Ventilation Systems for Enclosed Parking Garages

Natural ventilation is not an option for enclosed vehicular facilities, but there are two mechanical options available: ducted and ductless. Both options can be effective at controlling contaminants and smoke. However, one method may be more desirable than the other when considering the needs of a particular space.

Ducted Systems. Enclosed vehicular facilities require mechanical ventilation. In the United States, this is traditionally done with ducts across the parking structure. Figure 17 shows a typical design. Intakes are both high and low and distributed across the parking structure.

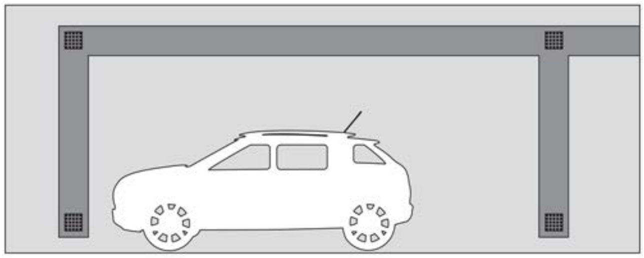

Fig. 17 Section View of Typical Ducted System

Design Considerations/Issues. Typical design considerations for ducted systems include the following:

- Appropriate duct sizing to ensure proper supply and exhaust throughout the space
- Clearance height requirements to allow traffic flow underneath duct
- Distribution strategy through parking garage to keep cost at a minimum
- Areas of higher contaminant injection that may require a nonuniform exhaust

Ductless Systems. Like some tunnel ventilation systems designs, ductless designs use jet fans to dilute and remove contaminants and control smoke. Ductless ventilation systems are considered acceptable to many global AHJs and continue to grow in popularity. However, the corresponding design methodologies and requirements vary substantially across the globe.

Tunnel ventilation projects have used jet fans for many years to induce flow and move pollutants and smoke through the tunnel. Research projects like the Memorial Tunnel Fire Ventilation Test program (1995) proved that jet fans have the capability to induce air movement to create a tenable environment for occupant egress. In the late 1990s, jet fan systems for enclosed parking garages began to spread across Europe and continue to grow in the Middle East, Asia, and America. In the United States, example projects include the Children's Hospital of Philadelphia and the Ikea Merriam in Kansas.

There are several basic components required in a ductless system: (1) a supply and exhaust fan system, which is required to provide the primary air changes for the space; (2) jet fans used to mix the air and eliminate any dead spots in the system (but do not impact the air changes per hour); and (3) control panels combined with contaminant sensors to save energy by controlling the contaminant levels only as needed (demand based). High-temperature cabling is also required in most regions, which can be a significantly high portion of total system cost.

Finally, a computational fluid dynamic analysis (CFD) is required in many regions to validate the placement of the fans. This is the case in the United Kingdom and India, as referenced in BS *Standard* 7346 and National Building Code of India (NBC; BIS 2015), respectively. The project is then completed with installation, commissioning, and, in some regions, a cold or hot smoke test used as another visual indication of the system performance.

Design Considerations/Issues. There are several design considerations when designing ductless systems:

- When conducting the CFD analysis, it is important to identify appropriate contaminant levels, and ensure that simulations accurately represent the space. This requires a three-dimensional model of the area. Parameters should be evaluated carefully when comparing different simulations.
- Height clearance requirements must be evaluated to ensure traffic can safely pass beneath the equipment.

- If designing a demand-based system, the designer must consider where the sensors are placed, along with which sensors correspond to which jet fans.
- When designing for smoke control, the designer must consider how fan placement directs smoke away from pedestrian exits.
- Cabling cost can make up a significant cost of the system. Jet fan placement and corresponding control panels can have a significant impact on cabling cost.

Ductless Design Methodology

Smoke Control. The role of parking garage ventilation systems during a fire event varies around the world. Specifically, some requirements dictate that the ventilation system to be turned off, whereas others require the ventilation system to continuously operate to control the spread and purge smoke. Where mechanical ventilation is used for smoke control, it is important to distinguish between emergency ventilation mode (when the fire is active), and smoke purge mode (when the fire is extinguished). Local codes and standards provide the proper design requirements.

For example, the U.K. standard BS7346-7:2013 cites two potential purposes for smoke ventilation design for a ductless system. The simplest goal is to assist firefighters clearing smoke during and after the fire. This method does not necessarily control the smoke in any particular manner and operates the same regardless of the fire location. A ducted system is typically designed this way to purge smoke by operating in exhaust. It is conceivable to create a ducted system with control dampers that target the smoke-filled areas. However, the cost of the system would increase due to the additional controls and dampers.

The other potential goal is to create a smoke-free access point for firefighters and to maintain a tenable path of egress. The fire department needs to enter the building to set up their equipment and extinguish the fire. Similarly, the means of egress for building occupants should be tenable to ensure that there is at least one exit available independent of the fire location.

An optimal smoke-control system accomplishes both of these goals. The ductless design, along with a grid-based fire detection system, allows the designer to create smoke control zones and only operate the necessary jet fans.

Smoke Control Zones. The purpose of a smoke control zone is to limit the spread of smoke from one area to another. Requirements for the sizing of these areas vary greatly, depending on the AHJ and on what other fire suppression systems are installed. For example, India requires a smoke zone to be 3000 m^2, per NBC 2015. The United Kingdom requires 2000 m^2 per zone.

For the smoke control zone to work properly, it must have separate supply and exhaust locations in each zone, and the jet fans must be placed so that smoke does not cross between zones in the event of a fire. Also, the control panels are separated so if one panel is damaged from the fire, the other areas in the system still operate. Requirements for smoke zone control add redundancy and safety to the system, but can significantly drive up initial cost for ductless systems. In contrast, ducted systems already clear smoke locally due to the fully distributed duct network, so they typically do not require any additional equipment to satisfy a smoke control zone requirement.

Supply and Exhaust Placement

Once the contaminant levels and purpose of smoke control are designed, the next step is to determine how many supply and exhaust shafts are required, and where they are placed. This is a critical design step that can significantly impact the number of jet fans required and the overall ventilation performance.

Figure 18 shows two common design examples. Both designs have louvers and dampers on each level. However, the design on the left has a single, larger exhaust fan placed at the top of the shaft, whereas the other has smaller fans placed at each level. When there is a fire, dampers on the nonfire floor typically close to prevent smoke from entering. The method on the left is preferred, because in the case of a fire on the second floor as indicated, the dampers will close. If there is a damper failure on Basement 1, then the smoke will still be pulled up by the fan. In the design on the right, the smoke may push back into Basement 1 if there is a damper failure.

Additionally, some regions require that the exhaust shafts are dedicated to each floor, as shown in Figure 19, to eliminate the possibility of smoke entering nonfire floors. This is the safest approach but adds initial cost to the building by requiring a larger footprint for the exhaust shafts.

Often, designers attempt to save cost by using the ramps as fresh air supply with no additional mechanical supply. This may work if there are only one or two levels maximum. However, this usually requires significantly more jet fans due to the contaminated air from the other levels. Thus, it typically involves both lower initial and operating cost to have forced air supply on all levels of the parking garage, because fewer total fans are usually initially installed and fewer fans operate. The ramps are a source for fresh air and should be considered, and placing an additional mechanical supply helps.

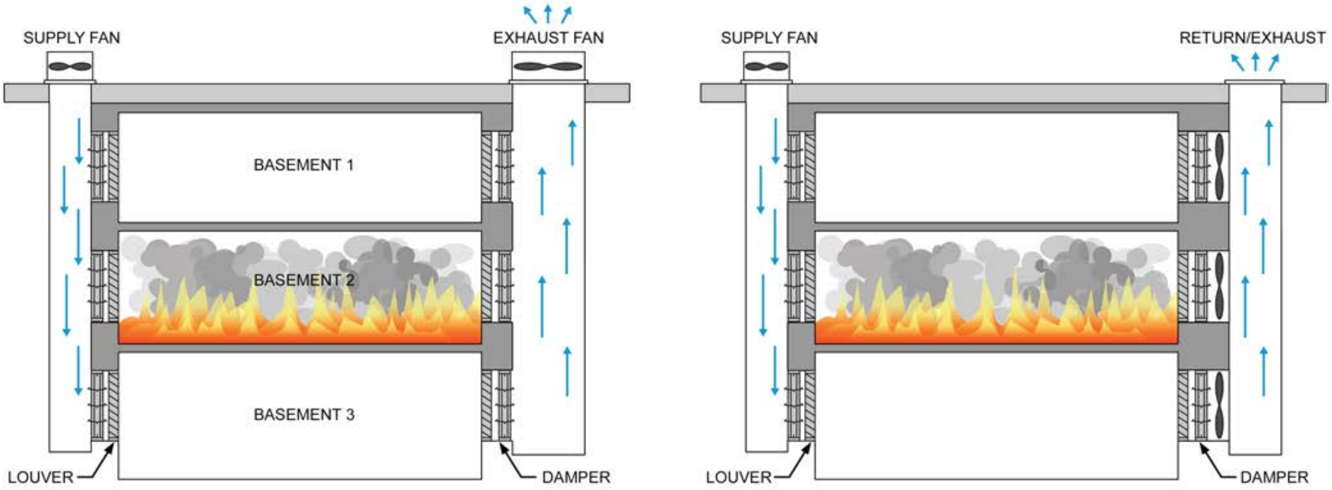

Fig. 18 Typical Three-Level Underground Parking Garage with Shared Supply and Exhaust System

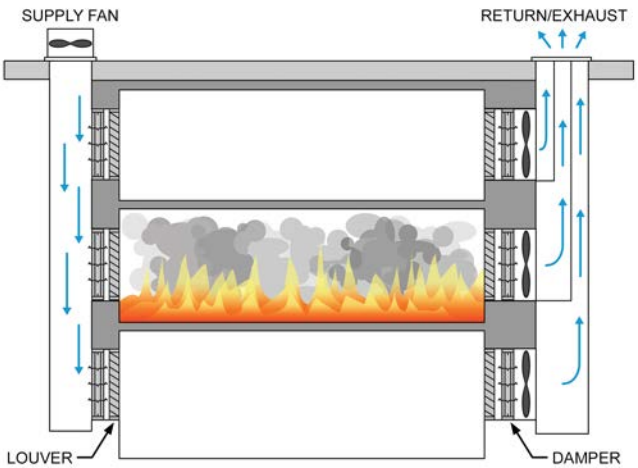

Fig. 19 Typical Three-Level Underground Parking Garage with Separate Exhaust

Jet Fan Design and Placement

Two primary types of jet fans are used in parking garage design: (1) axial (impulse), the most common, and (2) centrifugal (induction). The number of jet fans can be greatly reduced with a proper supply and exhaust design. Initial jet fan quantity is typically determined by rule of thumb, which may vary depending on the designer. For example, a common axial jet fan is 315 mm and generates about 25 N thrust. A typical rule of thumb states that a jet fan with 1 N of thrust can cover an area of 10 to 15 m^2. Therefore, a 25 N fan could cover 2250 to 375 m^2. The range depends on the layout of the space and the locations of the supply and exhaust. If the supply and exhaust are opposite each other, creating a longitudinal flow across the floor, then the fans could cover an even greater area. However, if the placement creates a lot of dead spots and short circuiting of air, more jet fans could be required.

The initial jet fan placement is done in a way conducive to moving fresh air into areas that would not otherwise be reached. To minimize the number of jet fans, this placement is typically not uniform across the parking structure. The goal is to mix the air and guide fresh air from the supply to the exhaust. Throw diagrams can help determine the distance between fans. A throw diagram shows the velocity of the air as it exits a jet fan. Generally, it is desirable to keep the air moving at 0.2 to 0.5 m/s.

CFD Analysis

Once the initial placement is complete, a CFD analysis is recommended. The CFD analysis can assist with the following:

- Optimizing the number and placement of fans
- Simulating the space in normal and fire-mode operation
- Determining the visibility, smoke, contaminate levels, and temperature throughout the garage

When performing a CFD analysis, some important input parameters to consider are design fires size, method of pollutant injection, boundary conditions, meshing strategy, and physics models. Ensure that these parameters are the same when comparing different CFD models, as they may give conflicting results.

Control Sequencing

Once the design is finalized, the control sequencing is relatively straightforward. The following sequence is an example for a normal ventilation, demand-based sequence. This example measures CO, but for other contaminants the appropriate levels should be chosen.

- 0 ppm: only supply and exhaust fans on (if required to maintain minimal ACH)
- CO > 15 ppm: supply and exhaust fans on
- 15 < CO < 35 ppm: select jet fans on
- CO > 35 ppm: all jet fans on
- CO > 100 ppm: all fans on high speed

An example sequence in the case of a fire is as follows:

1. Heat or smoke sensor triggers.
2. Waiting period to confirm fire or timeout (in case of sensor failure).
3. Fire alarm goes off.
4. Turn on supply/exhaust fans on fire floor to maintain negative pressure. Close exhaust dampers on nonfire floors. If local codes allow ventilation system operation during a fire event.
5. Wait an evacuation delay period.
6. Turn on all jet fans at full speed.
7. Run system until the fire department turns it off.

The jet fans are not turned on immediately because the smoke has not had sufficient time to accumulate and cause harm to occupants. Turning the fans on immediately may unnecessarily spread the smoke. For example, BS *Standard* 7346-7 recommends a waiting period, with the length based on building type, size, and number and type of occupants. Also note that the above operation may require a control panel for the fire department, to allow for individual fan control.

High-Temperature Product Requirements

In some areas, ductless parking garage ventilation designs are intended to be both a normal-mode and smoke-control system to optimize cost. Therefore, the equipment must be selected to operate during a fire. High-temperature fans and cabling, or some other fire protection method such as concrete encasement, are required. As with other requirements, the temperature requirement varies across the globe. The United States typically designs for 250°C for four hours. India varies regionally from 250°C to 300°C for two hours. United Arab Emirates and other Middle Eastern countries are transitioning to even higher temperatures, requiring 400°C for two hours. High-temperature cabling must similarly be selected to ensure the equipment will run in the case of fire.

Other Considerations

Access tunnels or long, fully enclosed ramps should be designed in the same way as road tunnels. When natural ventilation is used, wall openings or free area should be as large as possible. Part of the free area should be at floor level.

For parking levels with large interior floor areas, a central emergency smoke exhaust system should be considered for removing smoke (in conjunction with other fire emergency systems) or vehicle fumes under normal conditions.

Noise. In general, parking garage ventilation systems move large quantities of air through large openings without extensive ductwork. These conditions, and the highly reverberant nature of the space, contribute to high noise levels, so sound attenuation should be considered in the ventilation system design. This is a pedestrian safety concern, as well, because high fan noise levels in a parking garage may mask the sound of an approaching vehicle.

Ambient Standards and Contaminant Control. Air exhausted from a parking garage should meet state and local air pollution control requirements.

3. AUTOMOTIVE REPAIR FACILITIES

Automotive repair activities are defined as any repair, modification, service, or restoration activity to a motor vehicle. This includes, but is not limited to, brake work, engine work, machining operations, and general degreasing of engines, motor vehicles, parts, or tools.

ASHRAE *Standard* 62.1 recommends a ventilation rate of 0.0075 $m^3/(s \cdot m^2)$ for automotive service stations; the *International Mechanical Code*® (ICC 2009a) allows 0.00375 $m^3/(s \cdot m^2)$. The designer must determine which code is applicable. The high ventilation rate indicates that contaminants are not related to the occupants, but are produced by the variety of tasks and materials used in the facility. Outdoor ventilation is introduced into the space, and an approximately equal quantity is exhausted through a dedicated exhaust system.

As repairs or maintenance are performed on vehicles, it may be necessary to operate the vehicle inside the facility to test and validate the work. Additional mechanical ventilation is required to exhaust combustion by-products directly outdoors. An independent source capture system that connects directly to the exhaust pipe of the vehicle must be installed in the facility. These systems are available in either an above- or belowground configuration. Flow rates for individual service bays vary from 0.024 to 0.190 m^3/s for automobiles. A large diesel truck will require considerably more airflow per service bay than an automobile.

The above-grade system consists of an exhaust fan, associated ductwork, and flexible hoses that attach to the tailpipe of the vehicle in operation. Generally, the system is installed at a high elevation to maintain maximum clearances above floor level. The hose connections are stored in reels positioned near each service bay. The service technician pulls the hose down and attaches it to the tailpipe by a proprietary connection.

The below-grade system is similar in design to an overhead exhaust system. Care must be taken to select an appropriate corrosion-resistant material to be installed underground, because the condensing products of combustion are corrosive to traditional duct materials. The flexible tailpipe exhaust connectors are stored inside the underground duct. After sliding the flex back inside the duct, a hinged cover plate covers the opening flush to the floor.

Although there is a diversity factor in the system capacity calculations, both systems must be designed to operate at 100% capacity. A constant-volume fan is used, with all air being exhausted from the space. With a single outlet in use, some means of relief is provided to maintain constant flow through the fan. This equipment can be set up to run continuously or intermittently. Intermittent use requires the general exhaust system to vary between the maximum supply air delivered to the space when the capture system is in use and a lower exhaust flow rate reduced by the amount of air exhausted through the capture system.

4. BUS GARAGES

Bus garages generally include a maintenance and repair area, service lane (where buses are fueled and cleaned), storage area (where buses are parked), and support areas such as offices, stock room, lunch room, and locker rooms. The location and layout of these spaces can depend on factors such as local climate, size of the bus fleet, and type of fuel used by the buses. Bus servicing and storage areas may be located outside in a temperate region, but are often inside in colder climates. However, large bus fleets cannot always be stored indoors; for smaller fleets, maintenance areas may double as storage space. Local building and/or fire codes may also prohibit dispensing certain types of fuel indoors.

In general, bus maintenance or service areas should be ventilated using 100% outdoor air with no recirculation. Therefore, using heat recovery devices should be considered in colder climates.

Tailpipe emissions should be exhausted directly from buses at fixed inspection and repair stations in maintenance areas. Offices and similar support areas should be kept under positive pressure to prevent infiltration of bus emissions.

Maintenance and Repair Areas

ASHRAE *Standard* 62.1 recommends a minimum ventilation of 0.0075 $m^3/(s \cdot m^2)$ and the *International Mechanical Code*® (ICC 2009a) recommends 0.00375 $m^3/(s \cdot m^2)$ of floor area in vehicle repair garages, with no recirculation. The designer should determine which code is applicable. However, because the interior ceiling height may vary greatly from garage to garage, the designer should consider making a volumetric analysis of contaminant generation and air exchange rates. The section on Bus Terminals contains information on diesel engine emissions and ventilation airflow rates needed to control contaminant concentrations in areas where buses are operated.

Maintenance and repair areas often include below-grade inspection and repair pits for working underneath buses. Because vapors produced by conventional bus fuels are heavier than air, they tend to settle in these pit areas, so a separate exhaust system should be provided to prevent their accumulation. NFPA *Standard* 30A recommends a minimum of 0.005 $m^3/(s \cdot m^2)$ in pit areas and the installation of exhaust registers near the floor of the pit.

Fixed repair stations, such as inspection/repair pits or hydraulic lift areas, should include a direct exhaust system for tailpipe emissions. Such direct exhaust systems have a flexible hose and coupling attached to the bus tailpipe; emissions are discharged to the outdoors by an exhaust fan. The system may be of the overhead reel, overhead tube, or underfloor duct type, depending on the tailpipe location. For heavy diesel engines, a minimum exhaust rate of 0.28 m^3/s per station is recommended to capture emissions without creating excessive backpressure in the vehicle. Fans, ductwork, and hoses should be able to receive vehicle exhaust at temperatures exceeding 260°C without degradation.

Bus garages often include areas for battery charging, which can produce potentially explosive concentrations of corrosive, toxic gases. There are no published code requirements for ventilating battery-charging areas, but DuCharme (1991) suggested using a combination of floor and ceiling exhaust registers to remove gaseous by-products. The recommended exhaust rates are 0.0114 $m^3/(s \cdot m^2)$ of room area at floor level to remove acid vapors and 0.0038 $m^3/(s \cdot m^2)$ of room area at ceiling level to remove hydrogen gases. The associated supply air volume should be 10 to 20% less than exhaust air volume, but designed to provide a minimum terminal velocity of 0.5 m/s at floor level. If the battery-charging space is located in the general maintenance area rather than in a dedicated space, an exhaust hood should be provided to capture gaseous by-products. Chapter 33 contains specific information on exhaust hood design. Makeup air should be provided to replace that removed by the exhaust hood.

Garages may also contain spray booths, or rooms for painting buses. Most model codes reference NFPA *Standard* 33 for spray booth requirements; this standard should be reviewed when designing heating and ventilating systems for such areas.

Servicing Areas

For indoor service lanes, ASHRAE *Standard* 62.1 recommends a minimum ventilation of 0.0075 $m^3/(s \cdot m^2)$ and the *International Mechanical Code*® (ICC 2009a) recommends 0.00375 $m^3/(s \cdot m^2)$ of floor area in vehicle repair garages, with no recirculation. The designer should determine which code is applicable. However, because the interior ceiling height may vary greatly from garage to garage, the designer should consider making a volumetric analysis of contaminant generation and air exchange rates. The section on Bus Terminals contains information on diesel engine emissions and ventilation airflow rates needed to control contaminant concentrations in areas where buses are operated.

Because of the increased potential for concentrations of flammable or combustible vapor, HVAC systems for bus service lanes should not be interconnected with systems serving other parts of the bus garage. Service-lane HVAC systems should be interlocked with fuel-dispensing equipment, to prevent operation of the latter if the former is shut off or fails. Exhaust inlets should be located both at ceiling level and 75 to 300 mm above the finished floor, with supply and exhaust diffusers/registers arranged to provide air movement across all planes of the dispensing area. A typical equipment arrangement is shown in Figure 20.

Another feature in some service lanes is the cyclone cleaning system: these devices have a dynamic connection to the front door(s) of the bus, through which a large-volume fan vacuums dirt and debris from inside the bus. A large cyclone assembly then removes dirt and debris from the airstream and deposits it into a large hopper for disposal. Because of the large volume of air involved, the designer should consider the discharge and makeup air systems required to complete the cycle. Recirculation and energy recovery should be considered, especially during winter. To aid in contaminant and heat removal during summer, some systems discharge the cyclone air to the outdoors and provide untempered makeup air through relief hoods above the service lane.

Storage Areas

Where buses are stored inside, the minimum ventilation standard is based upon the applicable code: 0.00375 $m^3/(s \cdot m^2)$ for the *International Mechanical Code*®, or 0.0075 $m^3/(s \cdot m^2)$ for ASHRAE *Standard* 62.1, subject to volumetric considerations. The designer should also consider the increased contaminant levels present during peak traffic periods.

One example is morning pullout, when the majority of the fleet is dispatched for rush-hour commute. It is common practice to start and idle a large number of buses during this period to warm up the engines and check for defects. As a result, the emissions concentration in the storage area rises, and additional ventilation may be required to maintain contaminant levels in acceptable limits. Using supplemental purge fans is a common solution to this problem. These purge fans can either be (1) interlocked with a timing device to operate during peak traffic periods, (2) started manually on an as-needed basis, or (3) connected to an air quality monitoring system that activates them when contaminant levels exceed some preset limit.

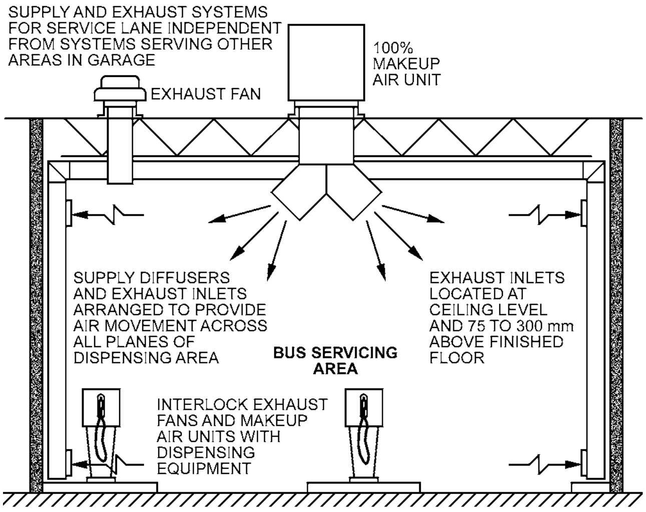

Fig. 20 Typical Equipment Arrangement for Bus Garage

Design Considerations and Equipment Selection

Most model codes require that open-flame heating equipment, such as unit heaters, be located at least 2.4 m above the finished floor or, where located in active trafficways, 0.6 m above the tallest vehicle. Fuel-burning equipment outside the garage area, such as boilers in a mechanical room, should be installed with the combustion chamber at least 460 mm above the floor. Combustion air should be drawn from outside the building. Exhaust fans should be nonsparking, with their motors located outside the airstream.

Infrared heating systems and air curtains are often considered for bus repair garages because of the size of the facility and amount of infiltration through the large doors needed to move buses in and out of the garage. However, infrared heating must be used cautiously in areas where buses are parked or stored for extended periods, because the buses may absorb most of the heat, which is then lost when the buses leave the garage. This is especially true during morning pullout. Infrared heating can be applied with more success in the service lane or at fixed repair positions. Air curtains should be considered for high-traffic doorways to limit both heat loss and infiltration of cold air.

Where air quality monitoring systems control ventilation equipment, maintainability is a key factor in determining success of the application. The high concentration of particulate matter in bus emissions can adversely affect monitoring equipment, which often has filtering media at sampling ports to protect sensors and instrumentation. The location of sampling ports, effects of emissions fouling, and calibration requirements should be considered when selecting monitoring equipment to control ventilation systems and air quality of a bus garage. NO_2 and CO exposure limits published by OSHA and the EPA should be consulted to determine contaminant levels at which exhaust fans should be activated.

Effects of Alternative Fuel Use

Because of legislation limiting contaminant concentrations in diesel bus engine emissions, the transportation industry has begun using buses that operate on alternative fuels, including methanol, ethanol, hydrogen (and fuel cells), compressed natural gas (CNG), liquefied natural gas (LNG), and liquefied petroleum gas (LPG). Flammability, emission, and vapor dispersion characteristics of these fuels differ from those of conventional fuels, for which current code requirements and design standards were developed. Thus, established ventilation requirements may not be valid for bus garage facilities used by alternative-fuel vehicles. The designer should consult current literature on HVAC system design for these facilities rather than relying on conventional practices. One source is the Alternative Fuels Data Center at the U.S. Department of Energy in Washington, D.C; their web site (www.eere.energy.gov/afdc) includes design recommendations for various alternative fuels. The DOT (1996a, 1996b, 1996c, 1997b, 1998) Volpe Transportation Center has also issued several guidelines for alternative-fuel bus facilities, which can be consulted for additional suggestions.

CNG Vehicle Facilities. For CNG bus facilities, NFPA *Standard* 52 recommends a separate mechanical ventilation system providing at least 0.017 m^3/s per 12 m^3, or 5 ach, for indoor fueling and gas processing/storage areas. The ventilation system should operate continuously or be activated by a continuously monitoring natural gas detector when a gas concentration of not more than 20% of the lower flammability limit (LFL) is present. The fueling or fuel-compression equipment should be interlocked to shut down if the mechanical ventilation system fails. Supply inlets should be located near floor level; exhaust outlets should be located high in the roof or exterior wall structure. The *International Mechanical Code*® (ICC 2009a) has identical requirements, except that it requires activation of the ventilation system at 25% of the LFL, and the requirements apply to maintenance and repair areas as well as indoor fueling facilities.

DOT (1996a) guidelines for CNG facilities address bus storage and maintenance areas, as well as bus fueling areas. DOT recommendations include (1) minimizing potential for dead-air zones and gas pockets (which may require coordination with architectural and structural designers); (2) using a normal ventilation rate of 6 ach, with provisions to increase that rate by an additional 6 ach in the event of a gas release; (3) using nonsparking exhaust fans rated for use in Class 1, Division 2 areas (as defined by NFPA *Standard* 70); and (4) increasing the minimum ventilation rate in smaller facilities to maintain dilution levels similar to those in larger facilities. Open-flame heating equipment should not be used, and the surface temperature of heating units should not exceed 425°C. In the event of a gas release, deenergizing supply fans that discharge near the ceiling level should be considered, to avoid spreading the gas plume.

LNG Vehicle Facilities. NFPA *Standard* 52 includes requirements for LNG bus facilities. The standard recommends a separate mechanical ventilation system providing at least 0.017 m^3/s per 12 m^3, or 5 ach, for indoor fueling areas. The ventilation system should operate continuously or be activated by a continuously monitoring natural gas detection system when a gas concentration of not more than 20% of the LFL is present. Fueling equipment should be interlocked to shut down in case the mechanical ventilation system fails. DOT (1997b) provides further information on LNG fuel.

LPG Vehicle Facilities. NFPA *Standard* 58 and the *International Fuel Gas Code*® (ICC 2009d) contain similar provisions relating specifically to LPG-fueled vehicles. Both standards prohibit indoor fueling of all LPG vehicles, allowing only an adequately ventilated weather shelter or canopy for fueling operations. However, the term "adequately ventilated" is not defined by any prescriptive rate. Vehicles are permitted to be stored and serviced indoors under NFPA *Standard* 58, provided they are not parked near sources of heat, open flames (or similar sources of ignition), or "inadequately ventilated" pits. That standard does not recommend a ventilation rate for bus repair and storage facilities, but it does recommend a minimum of 0.005 $m^3/(s \cdot m^2)$ in buildings and structures housing LPG distribution facilities. DOT (1996b) provides additional information on LPG fuel.

Hydrogen Vehicle Facilities. NFPA *Standard* 52 includes requirements for gaseous and liquid hydrogen bus facilities. The standard recommends a separate mechanical ventilation system providing at least 0.017 m^3/s per 12 m^3, but not less than 0.005 $m^3/(s \cdot m^2)$, or 5 ach, for indoor gaseous hydrogen fueling areas. The ventilation system should operate continuously or be activated by a continuously monitoring natural gas detection system when a gas concentration of not more than 25% of the LFL is present. Fueling equipment should be interlocked to shut down in case the mechanical ventilation system fails. Liquid hydrogen fueling facilities are prohibited indoors. The *International Mechanical Code*® (ICC 2009a) has the same requirements, which apply to maintenance and repair areas as well as indoor fueling facilities.

DOT (1998) provides additional information on hydrogen fuel.

5. BUS TERMINALS

The physical configuration of bus terminals varies considerably. Most terminals are fully enclosed spaces containing passenger waiting areas, ticket counters, and some retail areas. Buses load and unload outside the building, generally under a canopy for weather protection. In larger cities, where space is at a premium and bus service is extensive or integrated with subway service, bus terminals may have comprehensive customer services and enclosed (or semienclosed) multilevel structures, busway tunnels, and access ramps. Waiting rooms and consumer spaces should have controlled environments in accordance with normal HVAC system design practices for public terminal occupancies. In addition to providing the recommended ventilation air rate in accordance with ASHRAE *Standard* 62.1, the space should be pressurized against infiltration from the busway environment. Pressurized vestibules should be installed at each doorway to further reduce contaminant migration and to maintain acceptable air quality. Waiting rooms, passenger concourse areas, and platforms are typically subjected to a highly variable people load. The average occupant density may reach 1.0 m^2 per person and, during periods of extreme congestion, 0.3 to 0.5 m^2 per person.

The choice between natural and mechanical ventilation should be based on the physical characteristics of the bus terminal and the airflow required to maintain acceptable air quality. When natural ventilation is selected, the individual levels of the bus terminal should be open on all sides, and the slab-to-ceiling dimension should be sufficiently high, or the space contoured, to allow free air circulation. Jet fans can be used to improve natural airflow in the busway, with relatively low energy consumption. Mechanical systems that ventilate open platforms or gate positions should be configured to serve bus operating areas, as shown in Figures 21 and 22.

Platforms

Platform design and orientation should be tailored to expedite passenger loading and unloading, to minimize both passenger exposure to the busway environment and dwell time of an idling bus in an enclosed terminal. Naturally ventilated drive-through platforms may expose passengers to inclement weather and strong winds. An enclosed platform (except for an open front), with the appropriate mechanical ventilation system, should be considered. Partially enclosed platforms can trap contaminants and may require mechanical ventilation to achieve acceptable air quality.

Multilevel bus terminals have limited headroom, which restricts natural ventilation system performance. These terminals should have mechanical ventilation, and all platforms should be either partially or fully enclosed. The platform ventilation system should not induce contaminated airflow from the busway environment. Supply air velocity should also be limited to 1.3 m/s to avoid drafts on the platform. Partially enclosed platforms require large amounts of outdoor air to hinder fume penetration; experience indicates that a minimum of 0.086 $m^3/(s \cdot m^2)$ of platform area is typically required during rush hours, and about half this rate is required during other

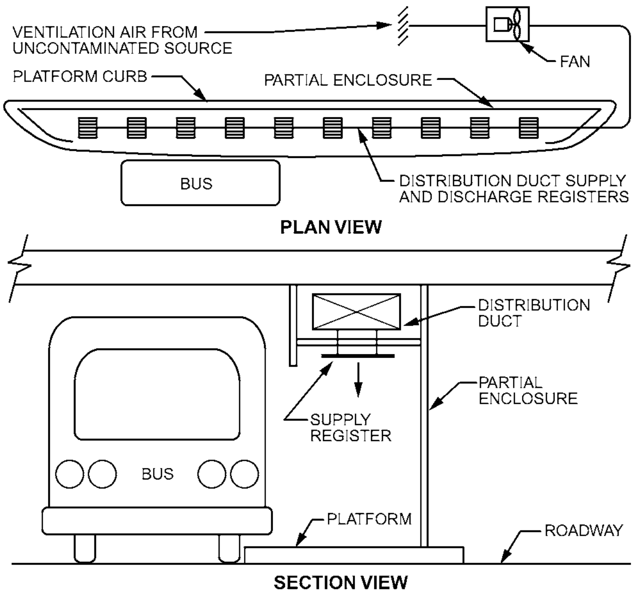

Fig. 21 Partially Enclosed Platform, Drive-Through Type

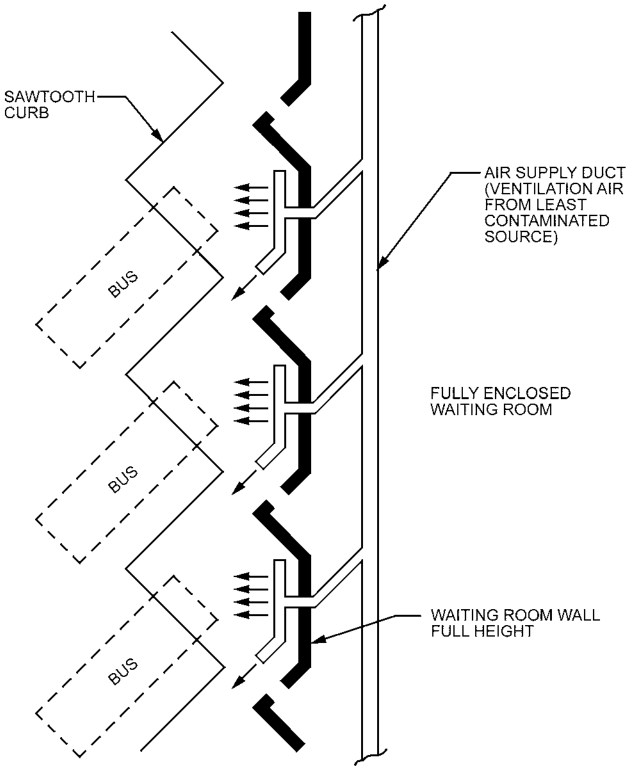

Fig. 22 Fully Enclosed Waiting Room with Sawtooth Gates

periods. Figure 21 shows a partially enclosed drive-through platform with an air distribution system.

Platform air quality should remain essentially the same as that of the ventilation air introduced. Because of the piston effect, however, some momentarily high concentrations of contaminants may occur on the platform. Separate ventilation systems with two-speed fans (for each platform) allow operational flexibility, in both fan usage frequency and supply airflow rate for any one platform. Fans should be controlled automatically to conform to bus operating schedules. In cold climates, mechanical ventilation may need to be reduced or heated during extreme winter weather conditions.

For large terminals with heavy bus traffic, fully enclosed platforms are strongly recommended. Fully enclosed platforms can be adequately pressurized and ventilated with normal heating and cooling air quantities, depending on the construction tightness and number of boarding doors and other openings. Conventional air distribution can be used; air should not be recirculated. Openings around doors and in the enclosure walls are usually adequate to relieve air pressure, unless the platform construction is extraordinarily tight. Figure 22 shows a fully enclosed waiting room with sawtooth gates.

Doors between sawtooth gates and the waiting room should remain closed, except for passenger loading and unloading. The waiting room ventilation system should provide positive pressurization to minimize infiltration of contaminants from the busway environment. Supply air from a suitable source should be provided at the passenger boarding area to dilute local contaminants to acceptable levels.

Bus Operation Areas

Ventilation for bus operation areas should be designed and evaluated to maintain engine exhaust contaminant concentrations within the limits set by federal and local regulations and guidelines. With the proliferation of alternative fuels, such as biodiesel, ethanol, methanol, compressed natural gas (CNG), and liquefied natural gas (LNG), a bus terminal ventilation system should not only be designed for maintaining acceptable air quality, but should also consider the safety risks associated with potential leakage from buses operating with alternative fuel loads. In an enclosed or semi-enclosed area, a comprehensive risk assessment should be performed for the specific types of buses operating in the bus terminal. The nature of the bus engines should be determined for each project.

Table 9 8 h TWA Exposure Limits for Gaseous Pollutants from Diesel Engine Exhaust, ppm

Substance	OSHA PEL	ACGIH TLV
Carbon monoxide (CO)	50	25
Carbon dioxide (CO_2)	5000	5000
Nitric oxide (NO)	25	25
Nitrogen dioxide (NO_2)	5.0*	3.0
Formaldehyde (HCHO)	0.75	0.30*
Sulfur dioxide (SO_2)	5	2.0

*Ceiling value
Note: For data on diesel bus and truck engine emissions, see Watson et al. (1988).

Contaminants. Of all the different types of buses in operation, engine exhaust from diesel buses has the most harmful quantities of contaminants. Some diesel buses also have small auxiliary gasoline engines to drive the vehicle air-conditioning system. Excessive exposure to diesel exhaust can cause adverse health effects, ranging from headache and nausea to cancer and respiratory disease. Tests on the volume and composition of exhaust gases emitted from diesel engines during various traffic conditions indicate large variations depending on the (1) local air temperature and humidity; (2) manufacturer, size, and adjustment of the engine; and (3) type of fuel used.

Components of diesel engine exhaust gases that affect the ventilation system design are NO_x, hydrocarbons, formaldehyde, odor constituents, aldehydes, smoke particles, sulfur dioxide, and a relatively small amount of CO. Diesel engines operating in enclosed spaces also reduce visibility, and generate both odors and particulate matter.

Table 9 lists major health-threatening contaminants found in diesel engine exhaust and the exposure limits set by OSHA and ACGIH.

OSHA permissible exposure limits (PEL) are legally enforceable limits, whereas the ACGIH threshold limit values (TLV) are industrial hygiene recommendations. All the limits are time-weighted averages (TWAs) for 8 h exposure, unless noted as a ceiling value.

NO_x occurs in two basic forms: nitrogen dioxide (NO_2) and nitric oxide (NO). NO_2 is the major contaminant considered in bus terminal ventilation system design. Prolonged exposure to NO_2 concentrations of more than 5 ppm causes health problems. Furthermore, NO_2 affects light transmission and thereby reduces visibility. NO_2 is intensely colored and absorbs light over the entire visible spectrum, especially at shorter wavelengths. Odor perception of NO_2 is immediate at 0.42 ppm, but can be perceived by some at levels as low as 0.12 ppm.

Bus terminal operations also affect the quality of surrounding ambient air. The ventilation airflow rate, contaminant levels in exhaust air, and location and design of the air intakes and discharges determine the effect of the bus terminal on local ambient air quality.

State and local regulations, which require consideration of local atmospheric conditions and ambient contaminant levels in bus terminal ventilation system design, must be followed.

Calculation of Ventilation Rate

To calculate the ventilation rate, the total amount of engine exhaust gases should be determined using the bus operating schedule and amount of time that the buses are in various modes of operation (i.e., cruising, decelerating, idling, and accelerating). The designer must

Table 10 EPA Emission Standards for Urban Bus Diesel Engines

Model Year	Emissions, g/(h·kW)			
	Hydrocarbons (HC)	Carbon Monoxide (CO)	Oxides of Nitrogen (NO_x)	Particulate Matter (PM)
1991	1.74	20.8	6.72	0.335
1993	1.74	20.8	6.72	0.135
1994	1.74	20.8	6.72	0.094
1996	1.74	20.8	6.72	0.067*
1998 to 2003	1.74	20.8	5.37	0.067*
2004 to 2006	1.74	20.8	2.68 to 3.35	0.067*
2007 and later	0.198	20.8	0.027	0.014

*In-use PM standard 0.094 g/(h·kW)

ascertain the grade (if any) in the terminal, and whether platforms are drive-through, drive-through with bypass lanes, or sawtooth. Bus headway, bus speed, and various platform departure patterns must also be considered. For instance, with sawtooth platforms, the departing bus must accelerate backward, brake, and then accelerate forward. The drive-through platform requires a different pattern of departure.

Certain codes prescribe a maximum idling time for bus engines, usually 3 to 5 min. Normally, 1 to 2 min of engine operation is required to build up brake air pressure. EPA emission standards for urban bus engines are summarized in Table 10 (bus emission standards in the state of California are more restrictive). The latest version of the EPA emission factor algorithm should be used to estimate bus tailpipe emissions. MOBILE6.2 (EPA 2002) has been replaced by MOVES2010 (EPA 2009, 2010). Input parameters (e.g., local vehicular inspection and maintenance requirements) suitable for a specific facility should be obtained from the appropriate air quality regulatory agency.

Discharged contaminant quantities should be diluted by natural and/or mechanical ventilation to accepted, legally prescribed levels. To maintain odor control and visibility, exhaust gas contaminants should be diluted with outdoor air in the proportion 75 to 1.

Where urban-suburban bus operations are involved, the ventilation rate varies considerably throughout the day and also between weekdays and weekends. Fan speed or blade pitch control should be used to conserve energy. The required ventilation airflow may be reduced by removing contaminant emissions as quickly as possible. This can be achieved by mounting exhaust capture hoods in the terminal ceiling, above each bus exhaust stack. Exhaust air collected by the hoods is then discharged outside of the facility through a dedicated exhaust system.

Effects of Alternative Fuel Use. As discussed in the section on Bus Garages, alternative fuels are being used more widely in lieu of conventional diesel fuel, especially for urban-suburban bus routes, as opposed to long-distance bus service.

Current codes and design standards developed for conventional fuels may not be valid for alternative-fuel buses. Comprehensive design guidelines are not yet available; there is a lack of design standards and long-term safety records for the alternative-fuel buses and their components. Special attention should be given to both risk assessment and design of HVAC and electrical systems for these facilities with regard to a fuel tank or fuel line leak. Research is continuing in this application; further information may be available from the DOT Volpe Transportation Center and NFPA *Standards* 52 and 58.

Bus terminal design should include a risk assessment to review terminal operations and identify potential hazards from alternative fuel buses. Facility managers should adopt safety principles to determine the acceptability of these hazards, based on severity and frequency of occurrence. All hazards deemed undesirable or unacceptable should be eliminated by system design or by modifications to operations.

Natural Gas (NG) Buses. Fuel burned in LNG and CNG buses has a composition of up to 98% methane (CH_4). Methane burns in a self-sustained reaction only when the volume percentage of fuel and air is in specific limits. The lower and upper flammability, or explosive, limits (LEL and UEL) for methane are 5.3% and 15.0% by volume, respectively. At standard conditions, the fuel/air mixture burns only in this range and in the presence of an ignition source, or when the spontaneous ignition temperature of 540°C is exceeded.

Electrical and mechanical systems in a bus terminal facility should be designed to minimize the number of ignition sources at locations where an explosive natural gas mixture can accumulate.

Although emissions from an NG bus engine include unburned methane, design of the bus terminal ventilation system must be based on maintaining facility air quality below the LEL in the event of a natural gas leak. A worst-case scenario for natural gas accumulation in a facility is a leak from the bus fuel line or fuel tank, or a sudden high-pressure release of natural gas from a CNG bus fuel tank through its pressure relief device (PRD). For instance, a typical CNG bus may have multiple fuel tanks, each holding gas at 25 MPa and 21°C. If the PRD on a single tank were to open, the tank contents would escape rapidly. After 1 min, 50% of the fuel would be released to the surroundings, after 2 min, 80% would be released, and 90% would be released after 3 min.

Because such a large quantity of fuel is released so quickly, prompt activation of a ventilation purge mode is essential. Where installed, a methane detection system should activate a ventilation purge and an alarm at 20% of the LEL. Placement of methane detectors is very important; stagnant areas, bus travel lanes, and bus loading areas must be considered. In addition, although methane is lighter than air (the relative density of CH_4 is 0.55), some research indicates that it may not rise immediately after a leak. In a natural gas release from a PRD, the rapid throttle-like flow through the small-diameter orifice of the device may actually cool the fuel, making it heavier than air. Under these conditions, the fuel may migrate toward the floor until reaching thermal equilibrium with the surrounding environment; then, natural buoyancy forces drive the fuel/air mixture to the ceiling. Thus, the designer may consider locating methane detectors at both ceiling and floor levels of the facility.

Although no specific ventilation criteria have been published for natural gas vehicles in bus terminals, NFPA *Standard* 52 recommends a blanket rate of 5 ach in fueling areas. DOT (1996a) guidelines for CNG transit facility design recommend a slightly more conservative 6 ach for normal ventilation rates in bus storage areas, with capability for 12 ach ventilation purge rate (on activation by the methane sensors). The designer can also calculate a ventilation purge rate based on the volumetric flow rate of methane released, duration of the release, and size of the facility.

The size of the bus terminal significantly affects the volume flow of ventilation air required to maintain the average concentration of methane below 10% of the LEL. The larger the facility, the lower the number of air changes required. However, a methane concentration that exceeds the LEL can be expected in the immediate area of the leak, regardless of the ventilation rate used. The size of the plume and location/duration of the unsafe methane concentration may be determined using comprehensive modeling analysis, such as computational fluid dynamics.

Source of Ventilation Air. Because dilution is the primary means of contaminant level control, the ventilation air source is extremely important. The cleanest available ambient air should be used for ventilation; in an urban area, the cleanest air is generally above roof level. Surveys of contaminant levels in ambient air should be conducted, and the most favorable source of ventilation air should be used. The possibility of short-circuiting exhaust air, because of prevailing winds and/or building airflow patterns, should also be evaluated.

If the only available ambient air has contaminant levels exceeding EPA ambient air quality standards, the air should be treated to control offending contaminants. Air-cleaning systems for removing gases, vapors, and dust should be installed to achieve necessary air quality.

Control by Contaminant Level Monitoring. Time clocks are one of the most practical means of controlling a bus terminal ventilation system. Time-clock-based ventilation control systems are typically coordinated with both bus movement schedules and installed smoke monitoring devices (i.e., obscurity meters). A bus terminal ventilation system can also be controlled by monitoring levels of individual gases, such as CO, CO_2, NO_2, methane, or other toxic or combustible gases.

Dispatcher's Booth. The bus dispatcher's booth should be kept under positive air pressure to prevent infiltration of engine exhaust fumes. Because the booth is occupied for sustained periods, both normal interior comfort conditions and minimized gas contaminant levels must be maintained during the hours of occupancy.

6. TOLLBOOTHS

Toll plazas for vehicular tunnels, bridges, and toll roads generally include a series of individual tollbooths. An overhead weather canopy and a utility tunnel (located below the roadway surface) are frequently provided for each toll plaza. The canopy allows installation of roadway signs, air distribution ductwork, and lighting. The utility tunnel is used to install electrical and mechanical systems; it also provides access to each tollbooth. An administration building is usually situated nearby. The current trend in toll collection facility design favors automatic toll collection methods that use magnetic tags. However, new and retrofit toll plazas still include a number of manual toll collection lanes with individual tollbooths.

Toll collectors and supervisors are exposed to adverse environmental conditions similar to those in bus terminals and underground parking garages. Automotive emission levels are considerably higher at a toll facility than on a highway because of vehicle deceleration, idling, and acceleration. Increased levels of CO, NO_x, diesel particulates, gasoline fumes, and other automotive emissions have a potentially detrimental effect on health.

Toll collectors cannot totally rely on physical barriers to isolate them from automotive emissions, because open windows are necessary for collecting tolls. Frequent opening and closing of the window makes the heating and cooling loads of each booth fluctuate independently. Heat loss or gain is extremely high, because all four sides (and frequently the ceiling) of the relatively small tollbooth are exposed to the outdoor ambient air temperature.

HVAC air distribution requirements for a toll facility should be carefully evaluated to maintain an acceptable environment inside the tollbooth and minimize the adverse ambient conditions to which toll-collecting personnel are exposed.

Air Quality Criteria

Workplace air quality standards are mandated by local, state, and federal agencies. Government health agencies differ on acceptable CO levels. ACGIH (1998) recommends a threshold limit of 29 mg/m^3 (25 ppm) of CO for an 8 h exposure. OSHA (2001a) regulations are for 55 mg/m^3 (50 ppm) for repeated daily 8 h exposure to CO in the ambient air. The U.S. National Institute for Occupational Safety and Health (NIOSH 2005) recommends maintaining an average of 40 mg/m^3 (35 ppm) and a maximum level of 230 mg/m^3 (200 ppm). Criteria for maximum acceptable CO levels should be developed with the proper jurisdiction. As a minimum, the ventilation system should be designed to maintain CO levels below the threshold limit for an 8 h exposure. Deceleration, idling, and acceleration of vehicles, and varying traffic patterns make it difficult to estimate CO levels around specific toll-collecting facilities without using computer programs.

Longitudinal tunnel ventilation systems with jet fans or Saccardo nozzles are increasingly popular for vehicular tunnels with unidirectional traffic flow. These longitudinal ventilation systems discharge air contaminants from the tunnel through the exit portal. If toll plazas are situated near the exit portal, resultant CO levels around the facilities may be higher than for other toll facilities.

If a recirculating HVAC system were used for a toll collection facility, any contaminants entering a particular tollbooth would remain in the ventilation air. Therefore, tollbooth ventilation systems should distribute 100% outdoor air to each booth to prevent both intrusion and recirculation of airborne contaminants.

Design Considerations

The toll plaza ventilation system should pressurize booths to keep out contaminants emitted by traffic. Opening the window during toll collection varies depending on booth design and the habits of the individual toll collector. The amount of ventilation air required for pressurization varies accordingly.

Variable-air-volume (VAV) systems that are achievable with controls now available can vary the air supply rate based on either the pressure differential between the tollbooth and the outdoor environment, or the position of the tollbooth window. A fixed (maximum/minimum) volume arrangement may also be used at toll plazas with a central VAV system.

Because the area of the window opening varies with individual toll collector habits and booth architecture, the design air supply rate may be determined based on an estimated average window open area. The minimum air supply (when the booth window is closed) should be based on the amount of air required to meet the heating/cooling requirements of the booth and that required to prevent infiltration of contaminants through the door and window cracks. Where the minimum supply rate exceeds the exfiltration rate, provisions to relieve excess air should be made to prevent overpressurization.

The space between the booth roof and the overhead canopy may be used to install individual HVAC units, fan-coil units, or VAV boxes. Air ducts and HVAC piping may be installed on top of the plaza canopy or in the utility tunnel. The ducts or piping should be insulated as needed.

The amount of ventilation air is typically high compared to the size of the booth; the resulting rate of air change is also high. Supply air outlets should be sized and arranged to deliver air at low velocity. Air reheating should be considered where the supply air temperature is considered too low.

In summer, the ideal air supply location is the ceiling of the booth, which allows cooler air to descend through the booth. In winter, the ideal air supply location is from the bottom of the booth, or at floor level. It is not always possible to design ideal distribution for both cooling and heating. When air is supplied from the ceiling, other means for providing heat at floor level (e.g., electric forced-air heaters, electric radiant heating, heating coils in the floor) should be considered.

The supply air intake should be located so that air drawn into the system is as free as practicable of vehicle exhaust fumes. The prevailing wind should be considered when locating the intake, which should be as far from the roadway as is practicable to provide better-quality ventilation air. Particle filtration of supply air for booths should be carefully evaluated. The specific level and type of filtering should be based on the ambient level of particulate matter and the desired level of removal. See Chapter 11 of the 2017 *ASHRAE Handbook—Fundamentals* and Chapter 29 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information.

Equipment Selection

Individual HVAC units and central HVAC are commonly used for toll plazas. Individual HVAC units allow each toll collector to choose between heating, cooling, or ventilation modes. Maintenance of individual units can be performed without affecting HVAC units in other booths. In contrast, a central HVAC system should have redundancy to avoid a shutdown of the entire toll plaza system during maintenance operations.

The design emphasis on booth pressurization requires using 100% outdoor air; high-efficiency air filters should therefore be considered. When a VAV system is used to reduce operating cost, varying the supply rate of 100% outdoor air requires a complex temperature control system that is not normally available for individual HVAC units. Individual HVAC units should be considered only where the toll plaza is small or where the tollbooths are so dispersed that a central HVAC system is not economically justifiable.

Where hot-, chilled-, or secondary water service is available from an adjacent administration building, an individual fan-coil for each tollbooth and a central air handler for supplying the total volume of ventilation air may be economical. When the operating hours for the booths and administration building are significantly different, separate heating and cooling for the toll-collecting facility should be considered. Central air distribution system selection should be based on the maximum number of open traffic lanes during peak hours and the minimum number of open traffic lanes during off-peak hours.

The HVAC system for a toll plaza is generally required to operate continuously. Minimum ventilation air may be supplied to unoccupied tollbooths to prevent infiltration of exhaust fumes. Otherwise, consideration should be given to remotely flushing the closed tollbooths with ventilation air before their scheduled occupancy.

7. DIESEL LOCOMOTIVE FACILITIES

Diesel locomotive facilities include shops where locomotives are maintained and repaired, enclosed servicing areas where supplies are replenished, and overbuilds where locomotives routinely operate inside an enclosed space and where railroad workers and/or train passengers may be present. In general, these areas should be kept under slightly negative air pressure to help removal of fumes and contaminants. Ventilation should use 100% outdoor air. However, recirculation may be used to maintain space temperature when a facility is unoccupied or when engines are not running. Heat recovery devices should be considered for facilities in colder climates, though they may require additional maintenance.

Historically, ventilation guidelines for locomotive facilities have recommended simple exhaust rates, usually based on the volume of the facility. These were developed over many years of experience and were based on the assumption of nitrogen dioxide as the most critical contaminant. Because contaminant limits for constituents of diesel exhaust have been and are likely to continue changing, ASHRAE sponsored research project RP-1191 (Musser and Tan 2004), which included field measurements in several facilities and a parametric study of design options using computational fluid dynamics. The study resulted in a simplified contaminant-based design procedure that allows designers flexibility to adapt to other critical contaminants or concentrations. Both the traditional and RP-1191 approaches are discussed here.

Ventilation Guidelines and Facility Types

Maintenance and Repair Areas. ASHRAE *Standard* 62.1 and most model codes require a minimum outdoor air ventilation rate of 0.0075 $m^3/(s \cdot m^2)$ in vehicle repair garages, with no recirculation recommended. Because the ceiling is usually high in locomotive repair shops, the designer should consider making a volumetric analysis of contaminant generation and air exchange rates rather than using the 0.0075 $m^3/(s \cdot m^2)$ ventilation rate as a blanket standard. The sections on Contaminant Level Criteria and Contaminant Emission Rate have more information on diesel engine exhaust emissions.

Information in the section on Bus Garages also applies to locomotive shops, especially for below-grade pits, battery charging areas, and paint spray booths. However, diesel locomotives generally have much larger engines (ranging to over 4500 kW) than buses. Ventilation is needed to reduce crew and worker exposure to exhaust gas contaminants, and to remove heat emitted from engine radiators. Where possible, diesel engines should not be operated in shops. Shop practices should restrict diesel engine activity and engine operating speeds/intervals; however, some shops require that locomotives be load-tested at high engine speeds. This should be done outdoors if possible, both to reduce indoor contaminants and to avoid problems associated with high heat (sprinkler activation, fire risk, etc.).

A dedicated area should be established for diesel engine operations; hoods should be used to capture engine exhaust in this area. If hoods are impractical because of physical obstructions, then dilution ventilation must be used.

In designing hoods, the location of each exhaust point on each type of locomotive must be identified so that each hood can be centered and located as close as possible to each exhaust point. Local and state railroad clearance regulations must be followed, along with occupational safety requirements. In some cases, high ceilings or overhead cranes may limit hood use. Some newer systems attempt to avoid this problem by using a flexible connection that attaches to the exhaust.

The hood design should not increase backpressure on locomotive exhaust; the throat velocity should be kept less than twice the exhaust discharge velocity. The associated duct design should include access doors and provisions for cleaning oily residue, which increases the risk of fire. Fans and other ventilation equipment in the airstream should be selected with regard to the elevated temperature of the exhaust air and the effects of the oily residue in the emissions.

Sometimes high ceilings or overhead cranes limit the use of hoods. The *Manual for Railway Engineering* (AREMA 2007) notes that 6 air changes per hour are usually sufficient to provide adequate dilution for both idling locomotives and short engine runs at high speed. This guideline was developed with nitrogen dioxide as the critical contaminant, with an allowable maximum concentration of 5 ppm(v). Even dilution systems can and should take advantage of thermal buoyancy by removing exhaust air at the ceiling level or a high point in the shop and introducing makeup air at floor level. If exhaust gases are allowed to cool and drop to floor level, locomotive radiator fans (if operating) can cause further mixing in the occupied zone, making removal less effective.

Shops in colder climates should be heated both for worker comfort and to prevent freezing of facility equipment and piping. The heating system may consist of a combination of perimeter convectors to offset building transmission losses, underfloor slab or infrared radiation for comfort, and makeup air units for ventilation. Where natural gas is available and local codes allow, direct-fired gas heaters can be an economical compromise to provide a high degree of worker comfort. Air curtains or door heaters are not needed in shops where doors are opened infrequently.

Enclosed Servicing Areas. Although most locomotive servicing is done outside, some railroads use enclosed servicing areas for protection from weather and extreme cold. Servicing operations include refilling fuel tanks, replenishing sand (used to aid traction), draining toilet holding tanks, checking lubrication oil and radiator coolant levels, and performing minor repairs. Generally, a locomotive spends less than 1 h in the servicing area. Ventilation is needed to reduce personnel exposure to exhaust gas contaminants and remove heat emitted from engine radiators. The designer should also consider the presence of vapors from fuel oil dispensing and silica dust from sanding. Heating may also be included in the design, depending on the need for worker comfort and the operations performed.

Ventilation for servicing areas should be similar to that for maintenance and repair areas. Where possible, hoods should be used in lieu of dilution ventilation. However, coordinating hood locations with engine exhaust points may be difficult because different types of locomotives may be coupled together in consists. Elevated sanding towers and distribution piping may also interfere. Contaminant levels might be higher in servicing areas than in the shops because of constantly idling locomotives and occasional higher-speed movements in servicing areas. For dilution ventilation, the designer should ascertain the type of operations planned for the facility and make a volumetric analysis of expected rates of contaminant generation and air exchange.

Infrared radiation should be considered for heating. As with maintenance and repair areas, direct-fired gas heaters may be economical. Door heaters or air curtains may be justified because of frequent opening of doors or a lack of doors.

Overbuilds. With increasing real estate costs, the space above trackways and station platforms is commonly built over to enclose the locomotive operation area. Ventilation is needed in overbuilds to reduce crew and passenger exposure to exhaust gases and to remove heat emitted from engine radiators and vehicle air-conditioning systems. Overbuilds are generally not heated.

Exhaust emissions from a diesel passenger locomotive operating in an overbuild are greater than those from an idling locomotive because of head-end power requirements. The designer should determine the types of locomotives to be used and the operating practices in the overbuild. As with locomotive repair shops and servicing areas, hoods are recommended to capture engine exhaust. According to the *Overbuild of Amtrak Right-of-Way Design Policy* (Amtrak 2005), the air temperature at the exhaust source will be between 175 and 510°C. A typical ventilation design could have hoods approximately 5.5 to 7 m above the top of the rail, with throat velocities between 9 and 11 m/s. For dilution ventilation, the designer should perform a volumetric analysis of contaminant generation and air exchange rates.

Contaminant Level Criteria

In most locations, diesel exhaust is not regulated specifically, although concentrations of many substances found in diesel exhaust are regulated. The U.S. Occupational Safety and Health Administration (OSHA 2001a, 2001b) identifies carbon dioxide (CO_2), carbon monoxide (CO), nitrogen dioxide (NO_2), nitric oxide (NO), diesel particulate matter (DPM), and sulfur dioxide (SO_2) as major components of diesel exhaust. Thirty-one additional substances are identified as minor components, with seventeen of these being polycyclic aromatic hydrocarbons (PAH). These minor components are elements of DPM.

Federal OSHA requirements establish limits for these compounds in the United States, although a few states may set more restrictive requirements. Also, the American Council of Governmental and Industrial Hygienists (ACGIH) publishes guideline values for use in industrial hygiene that are not legally enforceable, but may evolve more quickly than OSHA requirements (ACGIH 2001). Other countries set their own contaminant limits, though these may draw heavily from the ACGIH and other U.S. publications.

When no regulations exist for DPM, nitrogen dioxide (NO_2) is present in diesel exhaust emissions at the highest levels relative to its published limits. In these circumstances, systems designed to control nitrogen dioxide will maintain other exhaust-related contaminants well below their respective limits. Table 11 shows published exposure limits in parts per million (ppm). Federal OSHA, ACGIH, and NIOSH limits are current as of at least February 2003. Other limits are taken primarily from an international database of participating countries (ILO 2003; Lu 1993). Contaminant limits are often expressed in mg/m^3, even in regions where I-P units are used.

Table 11 Contaminant Exposure Limits for NO_2
(For information only; check updated local regulations)

Entity	NO_2, mg/m^3 8 h	15 min	Ceiling
OSHA: USA (PEL)			9
ACGIH: USA (TLV)	6	9

Switzerland	6	11	
United Kingdom	6	9	
China			5

*Limit specifically for NO_2 from exhaust fumes.

Most authorities do not currently distinguish DPM from other particulates; however, this may change. The ACGIH has added DPM measured as elemental carbon to its TLVs (ACGIH 2003). A 0.1 mg/m^3 limit for elemental carbon in diesel environments has been established in Germany. Laws enacted by the Mine Safety and Health Administration are targeted toward limiting DPM in mining environments (MSHA 2001a, 2001b). These changes may foreshadow action by OSHA. In this changing environment, designers must check local regulations in the time and place of construction for applicable limits.

Contaminant Emission Rate

Locomotive contaminant emissions have been measured primarily for environmental reasons, and data for some models have been published in the environmental literature (Table 12). These data are classified for different duty-cycles of operation and different throttle settings, and were obtained from controlled tests conducted under steady-state operation. Engine speed, engine power, fuel rate, and engine airflow are typically reported. Emissions are usually reported for carbon monoxide (CO), oxides of nitrogen (NO_x), hydrocarbons, sulfur dioxide (SO_2), and particulates. Manufacturers can provide this information for specific engine models and should be consulted for current and specific data for design projects.

Note that passenger locomotives consume a greater amount of power when idling with head-end power (HEP) to serve passenger-related needs. A passenger train idle at HEP can produce five times the amount of NO_x emissions as the same train idling with no HEP effects (Fritz 1994). Thus, this is an important distinction between passenger railway stations, where HEP is likely to be required, and repair facilities, where HEP is not likely to be needed.

Available emissions data have been targeted toward outdoor pollution concerns, which imposes some limitations in application to indoor settings. Only recent tests document exhaust temperatures, a quantity useful to design engineers concerned with sprinkler systems. Emissions data come from steady-state tests on engines whose operation has been allowed to stabilize for an hour or more, so a safety factor is suggested to allow for higher emissions related to cold start and transient operation. Also, the data include only a combined NO_x emissions value. Field measurements in locomotive facilities found that about 13% (by mass) of ambient NO_x could be attributed to NO_2 (Musser and Tan 2004). This factor can be used estimate NO_2 source emissions from avail-

able data. The applicability of these data to design applications is supported by comparisons of CFD models based on published emissions data and field measurements taken in repair shops that showed reasonable agreement between the measured and predicted values (Musser and Tan 2004).

Locomotive Operation

Designers need to anticipate locomotive operation during the design phase, particularly when estimating source strength based on published locomotive emissions data. Some important parameters include the number of operating locomotives and the location, duration, and throttle position at which they operate. The number of locomotives likely to be operating can be estimated based on shop or station schedules. Although it is important to remember that a locomotive could idle at any location inside a facility, there are often practical cues to identify the most common or likely locations. These include platforms, facility layout, location of equipment for servicing toilets, fuel stations, or other service equipment. In small shops, the layout may create one or two convenient positions in which locomotives are very likely to be parked.

Other operating parameters may be more difficult to estimate, particularly in shops. Field observations for ASHRAE research project RP-1191 recorded locomotive operation in several shops varying from a few minutes to an hour in duration, usually at idle and low throttle settings (Musser and Tan 2004). Operation was influenced by shop rules, practices, and conventions, which are valuable to consider during the design phase. The cooperation and involvement of shop employees in the design stage can help integrate these practices so that the design conforms to the needs of the facility, rather than the other way around.

Design Methods

General Exhaust Systems. A contaminant-based procedure using a simplified equation developed with computational fluid dynamics can be used to design general exhaust systems using the steps below. The simplified equation was developed to flexibly adapt to changes in contaminant limits. Figures 23 and 24 show schematic drawings of such a system.

Step 1: Verify that design parameters to be used in the simplified equation fall within the ranges for which the equation is valid.

- Ceiling height Z must be 6 to 13.7 m.
- Fan spacing X must be 6 to 18 m.
- Exhaust fan flow Q must provide 5 to 12 air changes per hour (ach).

Step 2: Verify that other facility characteristics show reasonable agreement with the assumptions of the parametric study:

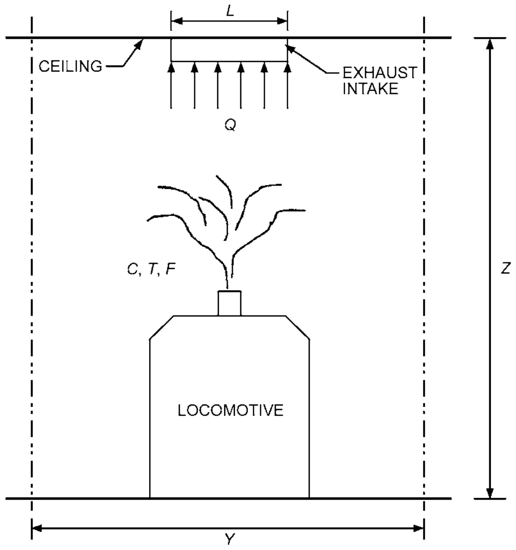

Fig. 23 Section View of Locomotive and General Exhaust System

- Fan dimensions L: Exhaust fan or duct dimensions are 1.5 by 1.5 m.
- Fan placement: Exhaust fans or duct openings are centered above each track.
- Locomotive exhaust temperature T: 177°C.
- Locomotive exhaust flow rate F: 1 m^3/s.
- Radiator fans: For many locomotive models, radiator fans do not operate when the locomotive is idling, and no radiator fan flow was modeled in this study. If radiator fans will be operating, they may alter the indoor airflow patterns.
- Operating time: The equation is based on steady state conditions, so it is not necessary to assume a maximum operating time.
- Concurrent operation: The equation allows for concurrent operation on different tracks. However, it does not include concurrent operation of more than one locomotive on the same track.
- Track-to-track spacing Y: 7.6 m.
- Ambient temperature: 32°C. This was selected because warmer ambient temperatures tend to reduce the upward buoyancy of warm exhaust gases.

Step 3: Obtain emissions data for critical contaminants and determine the design indoor concentration limit for the critical contaminant.

- Emissions data for some locomotive models are published in the environmental literature, and data for specific locomotives can be obtained from the manufacturer. The emissions rate for a given locomotive model depends on throttle position and whether head-end power is used.
- Acceptable indoor concentration limits can be determined from legal requirements at the location and time of construction. The designer may also wish to consider recommended limits from organizations such as ACGIH. To allow a safety margin, a designer might choose a contaminant limit that is lower than the published legal limit.

Contaminant limits are often expressed in mg/m^3, even in regions where I-P units are used. A contaminant limit in ppm(v) can be converted to mg/m^3 for use in the simplified equation as follows (ASHRAE *Standard* 62.1):

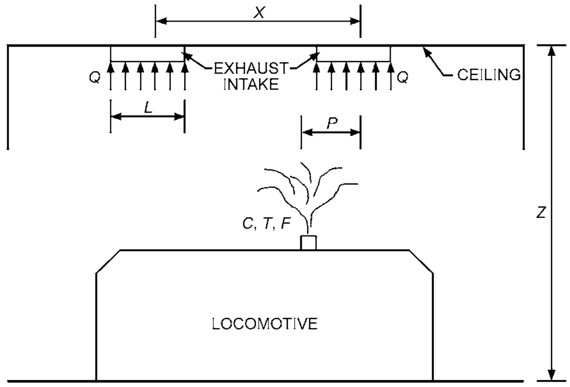

Fig. 24 Elevation View of Locomotive and General Exhaust System

Table 13 Constants for Equation (20)

Constant	No Platform	With 1.7 m Platform
a	20.0	22.5
b	–0.551	–0.773
c	–3.32	–2.09
d	–0.106	–0.109
e	–0.308	–0.346
f	0.0119	0.0159
g	0.235	0.236
h	0.0792	0.0407
i	0.00191	0.00190
j	–0.00505	–0.00499

$$\text{ppm(v)} \times \frac{\text{Molecular mass}}{24.45} = \text{mg/m}^3 \qquad (19)$$

Step 4: Select a fan flow rate and calculate the maximum concentration to which occupants would be exposed using Equation (20). Table 13 gives values for constants a to j whether occupants will be standing on the floor or a 1.2 m high platform.

$$C_{occ} = 10^{-3} C_{emissions}(a + bQ + cP + dX + eZ + fQZ + gPX + hPZ + iXZ + jPXZ) \qquad (20)$$

where

C_{occ} = maximum time-averaged concentration of critical contaminant to which occupants could be exposed, mg/m^3

$C_{emissions}$ = concentration of critical contaminant in exhaust emissions, mg/m^3

a to j = constants found in Table 13

Q = total exhaust fan flow rate required, ach; must be between 5 and 12 ach

Z = ceiling height; must be 6 to 13.7 m

X = fan spacing; must be 6 to 18 m

P = locomotive offset position, dimensionless; $P = 0$ under fan and $P = 1$ between fans. Other values for P can be calculated based on the distance of locomotive stack from the nearest exhaust fan d and fan spacing X:

$$P = 2\frac{d}{X} \qquad (21)$$

Step 5: Compare C_{occ} obtained in step 4 with the concentration limit C_{limit} determined in step 3. If $C_{occ} < C_{limit}$, the selected flow rate is adequate. If $C_{occ} > C_{limit}$, repeat step 4 with a higher flow rate until a concentration less than the limit is obtained.

Step 6: Verify that the result is between 5 and 12 ach.

- If the flow rate obtained is between 5 and 12 ach, this is the system size.
- If the flow rate obtained is less than 5 ach, the designer could
  - Design for 5 ach.
  - Perform a more detailed analysis to verify that less than 5 ach will provide acceptable contaminant control. For rates less than the 0.0075 $m^3/(s \cdot m^2)$ recommended by ASHRAE *Standard* 62.1 or in the case of unusual sources, the presence of contaminants other than those from diesel exhaust in the space (e.g., liquid fuel) should also be considered.
- If the flow rate obtained is greater than 12 ach, the designer could
  - Adjust the other parameters to attempt to reduce the air change requirement.
  - Perform a more detailed analysis to verify the necessary air flow requirement.

Example 2. Perform design calculations for a passenger locomotive repair shop.

Step 1: Verify design parameters. The planned facility ceiling height is 9.1 m, which falls within the 6 to 13.7 m range for which the simplified equation is valid. The planned fan spacing is 15.2 m, which also falls within the required range of 6 to 18 m.

Step 2: Verify other facility characteristics.

- Exhaust fans: Exhaust openings with an area of approximately 2.3 m^2 will be used, and fans will be centered above each track.
- Locomotive: Operating locomotives are usually high idle or lower. When moving in, they will not exceed throttle position 1. Information obtained from the manufacturer of the locomotive most commonly serviced in this facility indicates an exhaust flow rate of 1.085 m^3/s, an exhaust temperature of 190°C, and NO_x generation of 3.475 kg/h. Radiator fans will not operate in the high idle position for this locomotive.
- Track-to-track spacing is 8.3 m. Locomotives may operate concurrently on adjacent tracks, but concurrent operation on the same track is not planned.
- These characteristics are reasonably similar to the assumptions upon which the simplified equation is based.

Step 3: Obtain emissions data and determine the design limit.

- The critical contaminant for this design is nitrogen dioxide (NO_2). Emission data from the manufacturer state that the NO_x generation rate is 3.475 kg/h. Field measurements conducted for ASHRAE research project RP-1191 (Musser and Tan 2004) showed that ambient NO_2 concentrations were about 13% of ambient NO_x levels. Therefore, the NO_2 generation rate is estimated to be 13% of the total, or 452 g/h. For an exhaust flow rate of 1.085 m^3/s, the concentration of NO_2 in the exhaust is 116 mg/m^3.

$$C_{emissions} = \left(\frac{452 \text{ g/h}}{1.085 \text{ m}^3/\text{s}}\right)\left(\frac{1}{3600 \text{ s/h}}\right)(1000 \text{ mg/g})$$

$$= 116 \text{ mg/m}^3$$

- OSHA currently requires a 5 ppm(v) ceiling for NO_2, but NIOSH and other sources recommend a 1 ppm(v) 15 min short-term exposure limit (STEL). The designer decides to select the lower 1 ppm(v) limit and to design for 0.5 ppm(v) (i.e., 0.94 mg/m^3) to allow for a safety factor for variations in emissions or operation.

$$\frac{0.5 \text{ ppm(v)} \times 46}{24.45} = 0.94 \text{ mg/m}^3$$

Step 4: Select a flow rate and solve for the contaminant concentration. Ceiling height is 9.1 m, and fan spacing is 15.2 m. Based on the placement of services in the shop, expect that the stack of an operating locomotive will be at most 3.8 m from the nearest exhaust fan, so P = 0.5. The shop does have a 1.2 m high platform where workers may stand,

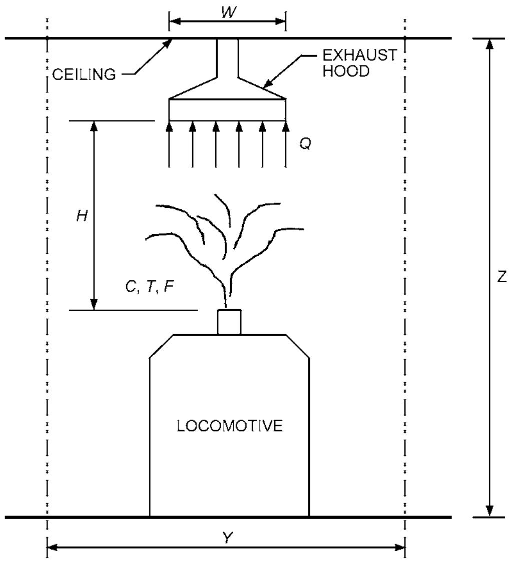

Fig. 25 Section View of Locomotive and Exhaust Hood System

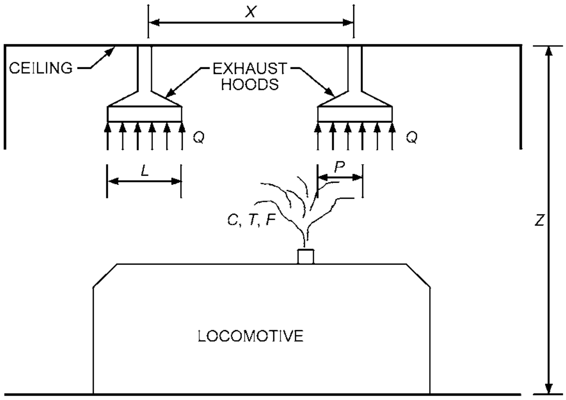

Fig. 26 Elevation View of Locomotive and Exhaust Hood System

so Equation (20) is solved using a platform. First, try fans that provide 5 ach:

$$C_{occ} = 10^{-3}(116 \text{ mg/m}^3)(22.5 - 0.773Q - 2.09P - 0.109X$$
$$- 0.346Z + 0.0159QZ + 0.236PX + 0.0407PZ$$
$$+ 0.00190XZ - 0.00499PXZ) = 1.13 \text{ mg/m}^3$$

- Iterate between steps 5 and 4. With 5 ach, C_{occ} = 1.13 mg/m^3. This is greater than the desired limit of 0.94 mg/m^3. If the fan flow rate is increased to provide 10.5 ach, C_{occ} decreases to 0.94 mg/m^3. This meets the design criterion.

Step 5: Verify that the fan flow rate is between 5 and 12 ach. No further analysis is needed.

Exhaust Hood Design. A similar equation was also developed for design of exhaust hood systems. However, results from the parametric set of computational fluid dynamics simulations performed to develop the equation were shown to be highly specific to the situation and geometry shown in Figures 25 and 26. Therefore, these equations should not be used unless the given assumptions are exactly matched. For further information on hood design, see ACGIH (1998).

Step 1: Verify that the design parameters to be used in the simplified equation fall within the ranges for which it is valid.

- Hood mounting height H must be 0.9 to 2.4 m.
- Hood length L must be 1.5 to 3.4 m.
- Exhaust fan flow Q must provide 5 to 12 ach.

Step 2: Verify that other facility characteristics agree with the assumptions of the parametric study. These assumptions are as follows:

- Hood width W: 1.5 m.
- Hood placement: Hoods are centered above each track at 18.3 m intervals.
- Hood operation: All hoods switched on together.
- Ceiling height Z: 7.6 m.
- Locomotive exhaust temperature T: 177°C.
- Locomotive exhaust flow rate F: 0.944 m^3/s.
- Radiator fans: Radiator fans do not operate.
- Operating time: The results of the study are based on steady-state conditions, so it is not necessary to assume a maximum operating time.
- Concurrent operation: The study allows for concurrent operation on different tracks, but not for concurrent operation of more than one locomotive on the same track.
- Track-to-track spacing Y: 7.6 m.
- Ambient temperature: 32°C.

Step 3: Obtain emissions data for critical contaminants and determine the design indoor concentration limit for the critical contaminant. This can be done using the procedure described for general exhaust systems.

Step 4: Select a fan flow rate and calculate the maximum concentration to which occupants would be exposed using Equation (22). Table 14 gives values for constants a to l for occupants standing on the floor or on a 1.2 m high platform.

$$C_{occ} = 10^{-3} C_{emissions}(a + bQ + cP + dH + eL + fQP + gQH + hQL + iPH + jHL + kQPH + lQHL) \quad (22)$$

where

C_{occ} = maximum time-averaged concentration of critical contaminant to which occupants could be exposed, mg/m^3
$C_{emissions}$ = concentration of critical contaminant in exhaust emissions, mg/m^3
a to l = constants in Table 14
Q = total exhaust fan flow rate required, ach; must be 5 to 12 ach
H = hood mounting height; must be 0.9 to 2.4 m
L = fan spacing; must be 1.5 to 3.4 m
P = locomotive offset position; dimensionless; $P = 0$ centered under hood and $P = 1$ under edge of hood. Other values for P can be calculated based on distance d of locomotive stack from center of nearest exhaust hood and hood length L:

$$P = \frac{2d}{L} \quad (23)$$

Step 5: Compare C_{occ} obtained in step 4 with the concentration limit C_{limit} determined in step 3. If $C_{occ} < C_{limit}$, the selected flow rate is adequate. If $C_{occ} > C_{limit}$, repeat step 4 with a higher flow rate until a concentration less than the limit is obtained.

Step 6: Verify that the result is between 5 and 12 ach.

- If the flow rate obtained is between 5 and 12 ach, this is the system size.
- If the flow rate obtained is less than 5 ach, the designer could
  - Design for 5 ach.
  - Perform a more detailed analysis to verify that less than 5 ach will provide acceptable contaminant control. For rates less than the 0.0075 $m^3/(s \cdot m^2)$ recommended by ASHRAE *Standard* 62.1 or in the case of unusual sources, the presence of contaminants other than those from diesel exhaust in the space should also be considered (e.g., liquid fuel).
- If the flow rate obtained is greater than 12 ach, the designer could
  - Adjust other parameters to attempt to reduce the air change requirement.
  - Perform a more detailed analysis to verify the necessary airflow requirement.

Table 14 Constants for Equation (22)

8. EQUIPMENT

An enclosed vehicular facility's ability to function depends mostly on the effectiveness and reliability of its ventilation system, which must operate effectively under the most adverse environmental, climatic, and vehicle traffic conditions. A tunnel ventilation system should also have more than one dependable power source, to prevent interruption of service.

Fans

Fan manufacturers should be prequalified and should be responsible under one contract for furnishing and installing the fans, bearings, drives (including any variable-speed components), motors, vibration devices, sound attenuators, discharge/inlet dampers, actuators, and limit switches. Other ventilation-related equipment, such as ductwork, may be provided under a subcontract.

The primary concerns in selecting the type, size, and number of fans include the total theoretical ventilation airflow capacity required and a reasonable comfort margin. Fan selection is also influenced by how reserve ventilation capacity is provided either when a fan is inoperative, or during maintenance or repair of either the equipment or the power supply.

Selection (i.e., number and size) of fans needed to meet normal, emergency, and reserve ventilation capacity requirements of the system is based on the principle of parallel fan operation. Actual airflow capacities can be determined by plotting fan performance and system curves on the same pressure-volume diagram.

Fans selected for parallel operation may be required to operate in a particular region of their performance curves, so that airflow capacity is not transferred back and forth between fans. This is done by selecting a fan size and speed such that the duty-point total pressure, no matter how many fans are operating, falls below the minimum total pressure characterized by the bottom of the stall dip or unstable performance range. This may require consultation with the fan manufacturer, because this information is not typically available from published fan performance data. Fans operating in parallel should be of equal size and have identical performance curves. If airflow is regulated by speed control, all fans should operate at the same speed. If airflow is regulated by dampers or by inlet vane controls, all dampers or inlet vanes should be set at the same angle. For axial-flow fans, blades on all fans should be set at the same pitch or stagger angle.

Jet fans can be used for longitudinal ventilation to provide a positive means of smoke and air temperature management in tunnels. This concept was proven as part of the Memorial Tunnel Fire Ventilation Test Program (MHD/FHWA 1995). Although jet fans deliver relatively small air quantities at high velocity, the momentum produced is transferred to the entire tunnel, inducing airflow in the desired direction. Jet fans are normally rated in terms of thrust rather than airflow and pressure, and can be either unidirectional or reversible.

Number and Size of Fans. The number and size of fans should be selected by comparing several fan arrangements based on the feasibility, efficiency, and overall economy of the arrangement, and the duty required. Factors that should be studied include (1) annual power cost for operation, (2) annual capital cost of equipment (usually capitalized over an assumed equipment life of 30 years for mass transit tunnel fans, or 50 years for highway and railroad tunnel fans), and (3) annual capital cost of the structure required to house the equipment (usually capitalized over an arbitrary structure life of 50 years).

Two views are widely held regarding the proper number and size of fans: the first advocates a few high-capacity fans and the second prefers numerous low-capacity fans. In most cases, a compromise arrangement produces the greatest efficiency. The number and size of the fans should be selected to build sufficient flexibility into the system to meet the varying ventilation demands created by daily and seasonal traffic fluctuations and emergency conditions. Consideration should be given to satisfying emergency conditions during fan outages for maintenance or unplanned downtime.

In general, when selecting the number of fans, several issues may need to be considered, ranging from redundancy and space allocation, to design issues such as determining the number of control boxes, dampers, silencers, and similar equipment. In tunnel ventilation, the required fan airflow capacity is typically very large. If one fan is installed, the fan must be large, and this design provides zero redundancy in case of failure or maintenance. However, if many fans are installed, more space is required than for a single fan. Designs need to balance space allocation with an acceptable level of redundancy.

Jet fan sizing is usually limited by space available for installation in the tunnel. Typically mounted on the tunnel ceiling (above the vehicle traffic lanes) or on the tunnel walls (outside the vehicle traffic lanes), jet fans are sometimes placed in niches to minimize the height or width of the entire tunnel boundary. However, niches must be adequately sized to avoid reducing the thrust of the fans. A typical jet fan niche arrangement is provided in Figure 27.

For longitudinal ventilation using jet fans, the required number of fans is defined (once fan size and tunnel airflow requirements have been determined) by the total thrust required to overcome the tunnel resistance (pressure loss), divided by the individual jet fan

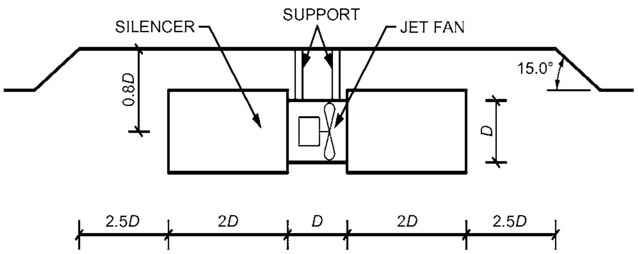

Fig. 27 Typical Jet Fan Arrangement in Niche

thrust, which is a function of the mean air velocity in the tunnel. Jet fans installed longitudinally should be at least 7 to 10 tunnel hydraulic diameters apart so that the jet velocity does not affect the performance of downstream fans. Jet fans installed side by side should be at least two fan diameters (centerline to centerline) apart.

Type of Fan. Normally, ventilating an enclosed vehicular facility requires a large volume of air at relatively low pressure. Some fans have low efficiencies under these conditions, so the choice of a suitable fan type is often limited to a centrifugal, vaneaxial, or jet fan.

Special Considerations. Special attention must be given to a fan installed where **airflow and pressure transients** are caused by vehicle passage. If the transient tends to increase airflow through the fan (i.e., positive flow in front of the vehicle toward an exhaust fan, or negative flow behind the vehicle toward a supply fan), blade loading must not become high enough to produce long-term fatigue failures. If the disturbance tends to decrease airflow through the fan (i.e., negative flow behind the vehicle toward an exhaust fan or positive flow in front of the vehicle toward a supply fan), the fan performance characteristic must have adequate comfort margins to prevent an aerodynamic stall.

If the pressure pulses are large relative to the fan's total pressure capability, at either full or planned reduced-speed operation, it can result in an overblown condition. Motors, power, and mechanical systems should be designed for overblown operation if the motor needs to operate under these conditions.

The ability to **rapidly reverse** the rotation of a tunnel ventilation fan is important during an emergency. This requirement must be considered in selection and design of the fan and drive system.

Fan Design and Operation. Fans and fan components (e.g., blade-positioning mechanisms, drives, bearings, motors, controls, etc.) that must operate in the exhaust airstream during a fire or smoke emergency should be capable of operating at maximum speed under the temperatures specified by the following standards or calculation procedures:

- NFPA *Standard* 130 for mass transit and passenger rail tunnels
- NFPA *Standard* 502 for road tunnels
- Computer simulations or other calculations for the maximum expected temperatures, in railroad tunnels and other enclosed vehicular facilities

Fans and dampers that are operated infrequently or for emergency service only should be activated and tested at least once every month to ensure that all rotating elements are in good condition and properly lubricated. The period of activity should be long enough to achieve stabilized temperatures in fan bearings and motor windings.

Inlet boxes can be used to protect centrifugal fan bearings and drives from high temperatures, corrosive gases, and particulate matter in exhaust air during emergency operating mode. This arrangement requires special attention to fan shaft design because of overhung drive loads (see the section on Fan Shafts).

Reversible axial flow fans should be able to be rapidly reversed from the maximum design speed in one direction to the maximum design speed in the opposite direction in less than 60 s. Fan design should include the effects of temperature changes associated with reversing airflow direction. All components of reversible fans should be designed for a minimum of 5000 cycles without damage.

Housings for variable-pitch axial flow fans should be furnished with instruments to measure airflow in both directions. Capped connections should be provided for measuring the pressure developed across the fan. The fan should also be protected from operating in a stall region.

To minimize blade failure in axial flow fans, the following precautions should be taken:

- Blades should be secured to the hub by positive locking devices.
- The fan inlet (and discharge, if reversible) should be protected against entry of foreign objects that could damage the rotating assembly.
- The natural frequency (static and rotating) of the blade and the maximum stress on the blade surface (for all operating points on the fan characteristic curve) should be measured during factory testing.
- For mass transit and rail systems, fans subjected to airflow and air pressure reversals caused by train passage should be designed (and tested, for verification) to withstand 4 000 000 cycles of airflow reversals.

When a fan includes a variable-frequency drive (VFD), factory testing with a production version of the VFD should be done to ensure adequate operation and compatibility with the fan system. Fans that are run by VFDs should have an installed static blade with a first bending natural frequency at least four times higher than the maximum intended running speed (e.g., an 1180 rpm fan's first bending frequency should be at least 79 Hz). If installed blades have a first bending frequency below this value, the VFD should be programmed to avoid speeds that are potentially problematic.

Jet fan blades should be strong enough to withstand the air temperatures created by a fire. Design calculations for jet fans should consider that the fire might destroy the fan(s) at the fire location, and that the jet fans downstream of the fire will operate under high temperatures and reduced thrust.

Fan Shafts. Fan shafts should be designed so that the maximum deflection of assembled fan components, including forces associated with the fan drive, does not exceed 0.42 mm per metre of shaft length between centers of the bearings. For centrifugal fans where the shaft overhangs the bearing, the maximum deflection at the centerline of the fan drive pulley should not exceed 0.42 mm per metre of shaft length between the center of the bearing and the center of the fan drive pulley.

Good practice suggests that the fundamental bending mode frequency of the assembled shaft, wheel, or rotor be more than 50% higher than the highest fan speed. The first resonant speed of all rotational components should be at least 125% above the maximum speed. The fan assembly should be designed to withstand, for at least 3 min, all stresses and loads from an overspeed test at 110% of maximum design fan speed.

Bearings. Fan and motor bearings should have a minimum equivalent L10 rated life of 10 000 h, as defined by the American Bearing Manufacturers Association (ANSI/ABMA 2000). Special attention must be given to belt-driven fans, because improper tensioning or overtensioning of belts can drastically reduce the bearing life, belt life, and possibly shaft life.

For **axial-flow fans** and **jet fans**, each fan motor bearing and fan bearing should have a monitoring system that senses individual bearing vibrations and temperatures, and provides a warning alarm if either rises above the manufacturer-specified range. Jet fan motors should have an industrial protection class (IP rating) of 55 or higher, which has bearings with washdown-rated seals.

Because of their low speed (generally less than 450 rpm), **centrifugal fans** are not always provided with bearing vibration sensors, but they do require temperature sensors with warning alarm and automatic fan shutdown. Bearing pedestals for centrifugal fans should provide rigid support for the bearings with negligible impediments to airflow. Static and dynamic loading of the shaft and the impeller, and the maximum force from tension in the belts, should be considered.

Corrosion-Resistant Materials. Choosing a particular material or coating to protect a ventilation fan from corrosive gas is a matter of economics. Selection of the material and/or coating should be based on the installation environment, fan duty, and an expected service life of 50 years.

Sound. For ventilation fan sound attenuator design, construction documents should specify the following:

- Speed and direction of airflow, and number of operating fans
- Maximum dBA rating or NC curve(s) acceptable under installed conditions, and locations of fan supply inlet and exhaust outlet where these requirements apply
- OSHA or local requirements for jet-fan-generated noise limits, which may require silencers of 1 to 2 fan diameters in length
- The dBA rating required at certain specific locations, such as intake louvers, discharge louvers, or discharge stacks, may not exceed OSHA or local requirements
- That the fan manufacturer must furnish and install the acoustical treatment needed to bring the sound level down to an acceptable value if measured sound values exceed the specified maximum values at the defined boundaries of the fan manufacturer's scope of supply
- NFPA-recommended maximum noise levels for emergency fan operations

Dampers

Dampers play a major role in overall tunnel safety and the successful operation of a tunnel ventilation system. Dampers regulate airflow into and out of the tunnel, through either natural or forced ventilation, to maintain acceptable temperatures. Dampers also relieve pressure: opening and closing dampers allows tunnel air to be driven out of ventilation shafts located in front of moving vehicles, and for fresh air to be drawn into tunnels by ventilation shafts located behind moving vehicles. Dampers are also used with fans to dilute or remove carbon monoxide (CO), flammable gases, or other toxic fumes from tunnels. However, the most important function of dampers is to direct ventilation air and smoke flow during a fire emergency. In this function, fans and dampers operate in conjunction to exhaust smoke and control its flow in the tunnel in support of passenger evacuations and firefighter ingress.

Damper Design. Tunnel ventilation damper design requires a thorough understanding of design criteria, installation methods, environmental surroundings, equipment life expectancy, maintenance requirements, and operating system. Damper construction varies, but the general construction is based on the following design criteria:

- Maximum fan operating pressure
- Normal and rogue tunnel air pressures
- Maximum air temperature
- Maximum air velocity
- Corrosion protection
- Maintainability and life expectancy of equipment
- Maximum damper module size
- Maximum air leakage

Fan Pressure. The maximum operating pressure that the damper will withstand during normal or emergency ventilation operations is typically the maximum pressure that the fan can generate at shutoff. This air pressure is generally 1.0 to 12.5 kPa.

Normal and Rogue Tunnel Pressures. Some dampers in the track area of a train tunnel see much higher positive- and negative-pressure pulses than the maximum pressure generated by the fan. These high-pressure pulses are caused by the piston action of trains moving through the tunnel. A closed damper is subjected to positive pressures as trains approach, and to negative pressures as trains pass. This pressure reversal subjects damper blades and related components to reverse bending loads that must be considered to prevent premature fatigue failures. The magnitude of the pulsating pressure depends on factors such as maximum train speed, unidirectional or bidirectional traffic, tunnel length, blockage ratio, clearance between train and tunnel walls, and amount of air pushed through the dampers.

Pulsating pressure is part of normal tunnel operation. However, a rogue train condition (e.g., a train operating at high speed during an emergency or a runaway train) could occur once or twice during the lifetime of a tunnel ventilation system. Dampers must be designed for both day-to-day fatigue and for maximum train-speed conditions.

Design specifications should require that the damper and its components meet reverse bending load criteria for 1 to 6 million reverse bending cycles for normal, day-to-day train operations. This number equates to a train passing a damper once every 5 to 20 min for 30 to 50 years. The number of cycles can be adjusted for each application. In addition, the specifying engineer should indicate the pressure that could result from a (once or twice in a lifetime) rogue train condition.

Typically, actuators for tunnel dampers must be selected to operate against the maximum fan pressure. Because reversing pressures only occur briefly, and because normal train operations cease during an emergency, actuators are not expected to operate under either reverse pressure or rogue train conditions.

Temperature. The maximum temperature can vary for each tunnel project; some specifying engineers use the temperature limits recommended by NFPA. Typical equipment specifications state that dampers, actuators, and accessories should meet the operational requirements of the emergency ventilation fan system described in NFPA *Standard* 130: "Emergency ventilation fans, their motors, and all related components exposed to the exhaust airflow shall be designed to operate in an ambient atmosphere of 250°C for a minimum of 1 h with actual values to be determined by design analysis. In no case shall the operating temperatures be less than 150°C."

Some tunnel design engineers have specified higher air temperature criteria based on additional design considerations. A few road tunnels have been designed for the possibility of two tanker trucks carrying flammable liquids exploding from an accident in the tunnel, which would subject tunnel dampers to very high temperatures. Dampers for projects of this type, or other projects with special considerations, have been designed for maximum temperatures up to 425°C. The specifying engineer must evaluate design conditions for each project and determine what the maximum temperature could be.

Dampers, and especially damper actuators, must be specially constructed to operate reliably in high-temperature conditions for extended periods. It is important to verify that the proposed equipment can provide this required safety function. Because standard testing procedures have not been developed, a custom high-temperature test of a sample damper and actuator should be considered for inclusion in the equipment specifications.

Air Velocity. The maximum air velocity for a tunnel damper design is determined from the maximum airflow expected through the damper during any operating condition. Maximum airflow could be generated from more than one fan, depending on the system design. Actuators for tunnel dampers are typically selected to operate against the maximum airflow that dampers will be exposed to in a worst-case scenario. Thus, the maximum airflow must be specified. It is important that the engineer understands the effect of damper free area on expected airflow and pressure loss. Air velocity through a damper can vary significantly depending on damper construction and the installation configuration used.

A multiple-panel damper assembly usually has less free area than a single panel damper because of the additional blockage caused by its vertical and/or horizontal mullions. A multiple-panel damper assembly with 60 to 70% free area can have two to four times the pressure loss of a single-panel damper with 80% free area. Therefore, airflow through the multiple-panel damper assembly can be significantly lower than that through a comparable single-panel damper.

The configuration of the damper installation can also affect free area, airflow, and pressure loss. For example, a damper can either be mounted to the face of an opening or in the opening itself. The damper mounted in the opening has a smaller free area because of the additional blockage of the damper frame, resulting in lower airflow and higher pressure loss. Damper performance also depends on where the damper is mounted (e.g., in a chamber, at one or the other end of a duct). AMCA *Standard* 500-D has more information on damper mounting configurations.

Corrosion Protection. Construction materials for tunnel projects vary considerably; their selection is usually determined based on one or more of the following reasons:

- Initial project cost
- Environmental conditions
- Life expectancy of the equipment
- Success or failure of previous materials used on similar projects
- Engineer's knowledge of and/or experience with the materials required to provide corrosion protection
- Design criteria (e.g., tunnel air pressure, temperature, velocity)

The corrosion resistance of a damper should be determined by the environment in which it will operate. A damper installation near a saltwater or heavy industrial area may need superior corrosion protection compared to one in a rural, non-industrialized city. Underground or indoor dampers may need less corrosion protection. However, many underground dampers are also exposed to rain, snow, and sleet. These and other factors must be evaluated by the engineer before a proper specification can be written.

Tunnel dampers have been made from commercial-quality galvanized steel, hot-dipped galvanized steel, anodized aluminum, aluminum with a duranodic finish, carbon steel with various finishes, and stainless steel, including types 304, 304L, 316, 316L, and 317.

Maintainability and Life Expectancy of Equipment. These issues are of great concern when specifying dampers that may be difficult to access regularly for servicing, inspection, or maintenance. In addition, the equipment may be difficult to replace if it fails prematurely because it was marginally designed for the pressures, temperatures, corrosion resistance, etc., required for the application.

Thus, some specifying engineers purposely design dampers with a more robust construction. Dampers may be specified with heavier and/or more corrosion-resistant materials than may be required for the application, in hopes of reducing operational problems and maintenance costs and extending the life expectancy of the product. Typical methods used to design dampers of more robust construction include the following:

- Limiting blade, frame, and linkage deflections to a maximum of *L*/360
- Selecting actuators for 200 to 300% of the actual damper torque required
- Using large safety factors for stresses and deflections of high stress components
- Specifying heavier material sizes and gages than necessary
- Using more corrosion-resistant materials and finishes than required
- Using slower damper activation times (from full-close to full-open and vice versa)

Many damper specifications include a quality assurance (QA) or system assurance program (SAP) to ensure that required performance levels are met. Others include an experience criterion that requires damper manufacturers to have five installations with five or more years of operating experience; a list of projects and contact names must be submitted so the current customer can communicate with past customers regarding the product performance. These requirements help ensure that reliable products are supplied.

Module Size. The maximum damper module size is one of the most important initial-cost factors. Many dampers can be made as a single-module assembly, or in several sections that can be field assembled into a single-module damper. However, some damper openings are very large and it may not be practical to manufacture the damper in a one-piece frame construction because of shipping, handling, and/or installation problems.

Generally, initial cost is lower with fewer modules because they have fewer blades, frames, jackshafts, actuators, and mullion supports. However, other factors, such as job site access, lifting capabilities, and installation labor costs, must also be included in the initial-cost analysis. These factors vary for each project, so the specifying engineer must evaluate each application separately.

Air Leakage. The specifying engineer must consider air leakage through the damper when evaluating a design. Leakage is usually specified in terms of cubic metres per second per square metre of damper face area, at a specific air pressure. As differential air pressure increases across the damper, so does air leakage. Leakage is, therefore, a function of air pressure and damper crack area, rather than of airflow. To reduce leakage, the number or size of leakage paths must be reduced. The most common method is adding damper blades and/or jamb seals, which can reduce leakage to an acceptable value.

Some specifications note the allowable damper air leakage as a percentage of the normal or maximum airflow. However, it is important to recognize that this is only an acceptable practice if the airflow and associated pressure are known.

Damper Applications and Types. Dampers allow or restrict airflow into a tunnel, and balance airflow in a tunnel. **Fan isolation dampers** can be installed in multiple-fan systems to (1) isolate any parallel, nonoperating fan from those operating, to prevent short-circuiting and airflow/pressure losses through the inoperative fan; (2) prevent serious windmilling of an inoperative fan; and (3) provide a safe environment for maintenance and repair work on each fan. Single-fan installations may also have a fan isolation damper to prevent serious windmilling from natural or piston-effect drafts and facilitate fan maintenance.

Ventilation dampers control the amount of fresh air supplied to and exhausted from the tunnel and station areas. They may also serve as **smoke exhaust dampers** (SEDs), **bypass dampers** (BDs), **volume dampers** (VDs), and **fire dampers** (FDs), depending on their location and design. Two types of ventilation dampers are generally used: (1) trapdoor, which is installed in a vertical duct, such that the door lies horizontal when closed; and, (2) multiblade louver with parallel-operating blades. Both types can be driven by either an electric or pneumatic actuator; the fan controller operates the damper actuator. During normal operation, the damper usually closes when the fan is shut off and opens when the fan is turned on.

The trapdoor damper is simple and works satisfactorily where a vertical duct enters a plenum fan room through an opening in the floor. This damper is usually constructed of steel plate, with welded angle iron reinforcements; it is hinged on one side and closed by gravity against the embedded angle frame of the opening. The opening mechanism is usually a shaft sprocket-and-chain device. The drive motor and gear drive mechanism, or actuator, must develop sufficient force to open the damper door against the maximum (static) air pressure differential that the fan can develop. This pressure can be obtained from the fan performance curves. Limit switches start and stop the gear-motor drive or actuator at the proper position.

Fan isolation and ventilation dampers in places other than vertical ducts should have multiblade louvers. These dampers usually consist of a rugged channel frame, the flanges of which are bolted to the flanges of the fan, duct, wall, or floor opening. Damper blades are assembled with shafts that turn the bearings mounted on the outside of the channel frame. This arrangement requires access outside the duct for bearing and shaft lubrication, maintenance, and linkage operation space. Multiblade dampers should have blade edge and/or end seals to meet air leakage requirements for the application.

The trapdoor damper, properly fabricated, is inherently a low-leakage design because of its weight and the overlap at its edges. Multiblade dampers can also have low air leakage, but they must be carefully constructed to ensure tightness on closing. The pressure drop across a fully opened damper and the air leakage rate across a fully closed damper should be verified by the appropriate test procedure in AMCA *Standard* 500-D. A damper that leaks excessively under pressure can cause the fan to rotate counter to its power rotation, thus making restarting dangerous and possibly damaging to the fan motor drive.

Actuators and Accessory Selections. Tunnel damper specifications typically call for dampers, actuators, and accessories to meet the operational requirements of **emergency ventilation fans**, as described by NFPA *Standard* 130. Damper actuators are normally specified to be electric or pneumatic. Actuator selection is determined by the engineer or the customer and is usually decided by available power or initial and/or long-term operating cost.

Pneumatic Actuators. Pneumatic actuators are available in many sizes and designs; rack and pinion, air cylinder, and Scotch yoke are common configurations. Each can be of either double-action (i.e., air is supplied to operate the damper in both directions) or spring-return construction. A spring-return design uses air to power it in one direction and a spring to drive it in the opposite direction; it is selected when it is desirable to have the damper fail to a set position on loss of air supply. Many manufacturers make pneumatic actuators; several manufacturers make both double-acting and spring-return designs capable of operating at 250°C for 1 h.

Electric Actuators. Electric actuators are also available in a variety of designs and sizes. They can be powered in both directions to open and close the damper; in this case the actuator usually fails in its last position on loss of power. Electric actuators that are powered in one direction and spring-driven in the opposite direction are also available. As with pneumatic actuators, spring return is selected when it is desirable to have the damper fail to a particular position on loss of power. There are fewer manufacturers of electric actuators than pneumatic actuators, and most do not make a spring-return design, especially in larger-torque models. Also, very few electric actuators are capable of operating at 250°C for 1 h, particularly for spring-return designs.

Actuator Selection. Actuators for tunnel dampers are typically sized to operate against the maximum airflow or velocity and pressure that will occur in a worst-case scenario. The maximum air velocity corresponds to the maximum airflow expected through the damper during any of its operating conditions. In addition, the maximum airflow could come from more than one fan, depending on system design. The maximum pressure on the damper during normal or emergency ventilation is typically the maximum pressure that the fan can generate at shutoff.

Actuators are sized and selected to (1) overcome the frictional resistance of blade bearings, linkage pivots, jackshafting assemblies, etc.; and (2) compress the blade and jamb seals to meet specified air leakage requirements. Therefore, the specifying engineer must determine maximum airflow (or air velocity) and pressure conditions, and maximum air leakage criteria.

Other factors in actuator selection are reliability and maintenance requirements. Although pneumatic actuators are considered more reliable than electric ones, the larger number of components in a pneumatic system and the cumulative risk of failure of any one component make the overall reliability of both systems similar.

Safety factors in actuator selection are not always addressed in tunnel damper specifications. This omission can result in operational problems if a manufacturer selects actuators too close to the required operating torque. Tunnel dampers are expected to function for many years when properly maintained. Also, damper manufacturers determine their torque requirements based on square, plumb, and true installations. These factors, plus the fact that dirt and debris build-up can increase damper torque, suggest that a minimum safety factor of at least 50% should be specified. Greater safety factors can be specified for some applications; however, larger actuators require larger drive shafts with higher initial cost.

Supply Air Intake. Supply air intakes require careful design to ensure that air drawn into the ventilation system is of the best quality available. Factors such as recirculation of exhaust air or intake of contaminants from nearby sources should be considered. Louvers or grilles are usually installed over air intakes for aesthetic, security, or safety reasons. Bird screens are also necessary if the openings between louver blades or grilles are large enough to allow birds to enter.

Because of the large volumes of air required in some ventilation systems, it may not be possible for intake louvers to have face air velocities low enough to be weatherproof. Therefore, intake plenums, ventilation shafts, fan rooms, and fan housings often need water drains. Windblown snow can also enter the fan room or plenum, but snow accumulation usually does not prevent the ventilation system from operating satisfactorily, if additional floor drains are located near the louvers.

Sound attenuation devices may be needed in fresh air intakes or exhaust outlets to keep fan-generated noise from disturbing the outdoor environment. If noise reduction is required, the total system (i.e., fans, housings, plenums, ventilation building, and location and size of air intakes and exhaust outlets), should be investigated. Fan selection should be based on the total system, including pressure drop from sound attenuation devices.

Exhaust Outlets. Exhaust air from ventilation systems should be discharged above street level and away from areas with human occupancy. Contaminant concentrations in exhaust air should not be a concern if the system is working effectively. However, odors and entrained particulate matter in exhaust make discharge into occupied areas undesirable. Exhaust stack discharge velocity, usually a minimum of 10 m/s, should be high enough to disperse contaminants into the atmosphere.

Evasé (flared) outlets have been used to regain some static pressure and thereby reduce exhaust fan energy consumption. Unless the fan discharge velocity is over 10 m/s, the energy savings may not offset the cost of the evasé outlets.

In a vertical or near-vertical exhaust fan discharge connection to an exhaust duct or shaft, rainwater runs down the inside of the stack into the fan. This water dissolves material deposited from vehicle exhaust on the inner surface of the stack and becomes extremely corrosive. Therefore, fan housings should be corrosion-resistant or specially coated to protect the metal.

Discharge louvers and gratings should be sized and located so that their discharge is not objectionable to pedestrians or contaminating to nearby air intakes. Airflow resistance across the louver or grating should also be minimized. Discharge air velocities through sidewalk gratings are usually limited to 2.5 m/s. Bird screens should be provided if the exhaust airstream is not continuous (i.e., 24 h/day, 7 days/week), and the openings between louver blades are large enough to allow birds to enter.

Corrosion resistance of the louver or grating should be determined by the corrosiveness of the exhaust air and the installation environment. Pressure drop across the louvers should be verified by the design engineer using the appropriate test procedure in AMCA *Standard* 500-L.

9. NATIONAL AND INTERNATIONAL SAFETY STANDARDS AND GUIDELINES

National Fire Protection Association (NFPA)

NFPA developed fire protection standards for both road tunnels and for rapid transit facilities. The standard for transit systems is known as NFPA *Standard* 130, and the standard for road tunnels, bridges, and other limited-access roads is NFPA *Standard* 502.

In addition to *Standards* 130 and 502, NFPA publishes many standards and codes that are applicable to enclosed vehicular facilities, including the following:

- Standard for Portable Fire Extinguishers, NFPA 10, 2010
- Standard for the Installation of Sprinkler Systems, NFPA 13, 2010
- Standard for the Installation of Standpipe and Hose Systems, NFPA 14, 2010
- Standard for the Installation of Stationary Pumps for Fire Protection, NFPA 20, 2010
- Standard for Water Tanks for Private Fire Protection, NFPA 22, 2008
- Flammable and Combustible Liquids Code, NFPA 30, 2008
- Code for Motor Fuel Dispensing Facilities and Repair Garages, NFPA 30A, 2008
- Standard for Spray Application using Flammable or Combustible Materials, NFPA 33, 2011
- Vehicular Gaseous Fuel Systems Code, NFPA 52, 2010
- Liquefied Natural Gas (LNG) Vehicular Fuel Systems Code, NFPA 57, 2002
- Liquefied Petroleum Gas Code, NFPA 58, 2011
- National Electrical Code®, NFPA 70, 2011
- Recommended Practice for Electrical Equipment Maintenance, NFPA 70B, 2010
- National Fire Alarm and Signaling Code®, NFPA 72®, 2010
- Standard for Fire Doors and Other Opening Protectives, NFPA 80, 2010
- Standard for Parking Structures, NFPA 88A, 2011
- Standard for Repair Garages, NFPA 88B, 1997
- Life Safety Code®, NFPA 101®, 2009
- Standard for Emergency and Standby Power Systems, NFPA 110, 2010
- Standard on Stored Electrical Energy Emergency and Standby Power Systems, NFPA 111, 2010
- Standard for Safeguarding Construction, Alteration, and Demolition Operations, NFPA 241, 2009
- Standard on Emergency Services Incident Management System, NFPA 1561, 2008
- Standard for Fire Hose Connections, NFPA 1963, 2009

World Road Association (PIARC)

PIARC, or the World Road Association (formerly the Permanent International Association of Road Congresses), has for many years published technical reports on tunnels and tunnel ventilation in conjunction with their quadrennial World Road Congresses. The PIARC Technical Committee on Road Tunnel Operation (C3.3) and its working groups published several important specific documents on tunnel ventilation and fire safety:

- Classification of Tunnels, Existing Guidelines and Experiences, Recommendations, 05.03.B, 1995
- Road Tunnels: Emissions, Environment, Ventilation, 05.02.B, 1996
- Fire and Smoke Control in Road Tunnels, 05.05.B, 1999
- Pollution by Nitrogen Dioxide in Road Tunnels, 05.09.B, 2000
- Cross Section Geometry in Unidirectional Tunnels, 05.11.B, 2002
- Cross Section Design of Bidirectional Road Tunnels, 05.12.B, 2004
- Good Practice for the Operation and Maintenance of Road Tunnels, 05.13.B, 2004
- Road Tunnels: Vehicle Emissions and Air Demand for Ventilation, 05.14.B, 2004
- Traffic Incident Management Systems Used in Road Tunnels, 05.15.B, 2004
- Systems and Equipment for Fire and Smoke Control in Road Tunnels, 05.16.B, 2007

- Integrated Approach to Road Tunnel Safety, 2007R07, 2007
- Risk Analysis for Road Tunnels, 2008R02, 2008
- Management of the Operator—Emergency Teams Interface in Road Tunnels, 2008R03, 2008
- Road Tunnels: A Guide to Optimising the Air Quality Impact upon the Environment, 2008R04, 2008
- Road Tunnels: An Assessment of Fixed Fire Fighting Systems, 2008R07, 2008
- Tools for Road Tunnel Safety Management, 2009R08, 2009

Country-Specific Standards and Guidelines

Many countries publish tunnel guidelines and standards primarily for use in their country; however, many of these documents do provide an insight into numerous unique tunnel applications. A partial list of those available is as follows:

- Design Guidelines Tunnel Ventilation, RVS 9.261 & RVS 9.262, Transportation and Road Research Association, National Roads Administration, Austria, 1997
- Regulations on Technical Standards and Conditions for Design and Construction of Tunnels on Roads, Croatia, 1991
- Design of Road Tunnels, *Standard* CSN 73 7507, Czech Republic
- Road Tunnel Equipment, *Guideline* TP 98, Czech Republic
- Inter-Ministerial *Circular* 2000-63: Safety in the Tunnels of the National Highways Network, Ministry of the Establishment, Transport and Housing, France, 2000
- Guidelines for Equipment and Operation of Road Tunnels, Road and Transportation Research Association (RABT), Federal Ministry of Traffic, Germany, 2006
- Safety of Traffic in Road Tunnels with Particular Reference to Vehicles Transporting Dangerous Materials, Italy, 1999
- National Safety Standard of Emergency Facilities in Road Tunnels, Japan Road Association, Japan, 2001
- Recommendations for the Ventilation of Road Tunnels Public Works and Water Management (RWS), the Netherlands, 2005
- *Norwegian Design Guide—Road Tunnels*, Public Roads Administration, Directorate of Public Roads, Norway, 1992
- Ventilation of Road Tunnels, Sub-Committee 61, Nordisk Vejteknisk Forbund (NVF), *Report* 6, 1993
- *Manual for the Design, Construction and Operation of Tunnels*, IOS-98, Spain, 1998
- *Tunnel 2004—General Technical Specification for New Tunnels and Upgrading of Old Tunnels*, Swedish National Road Association, Sweden, 2004
- *Ventilation for Road Tunnels*, Swiss Federal Roads Authority (FEDRO), 2004
- TSI *Technical Specification for Interoperability, Safety in Railway Tunnels*, European Railway Association, 2008
- *Design of Road Tunnels*, the Highways Agency, United Kingdom, 1999
- Road Tunnel Design Guidelines, Federal Highway Administration, FHWA-IF-05-023, United States, 2004

Building and Fire Codes

Often, building and fire codes have supplementary information and requirements applicable to a specific type of facility. For example, ventilation of a vehicle parking garage is also governed by the applicable building code. Some of the commonly used codes are as follows:

- The **International Building Code® (IBC®)** with its own subset of mechanical codes such as the *International Plumbing Code®* (IPC®) and the *International Mechanical Code®* (IMC®), as well as the *International Existing Buildings Code®*, *International Fire Code®*, and *International Fuel Gas Code®*.
- **National building codes** were the Uniform Building Code (UBC), Building Officials Code Association (BOCA), and the Southern Building Code Conference (SBCC), each of which was applicable in different parts of the country but now have been replaced by the IBC.
- Most states have their own **state building and fire codes** with specific modifications to the IBC or other as applicable for the conditions specific to the state, such as seismic requirements.
- Many cities and municipalities have their own **local building and fire codes**. The designer should be aware of the local code governing the facility. Many cities have adopted specific NFPA standards into their codes and some amend these standards. The facility's design is required to conform to the requirements of the amended standard, unless a specific waiver is applied for and obtained.

Ancillary areas of tunnels such as electrical and mechanical equipment rooms, which are often adjacent to the tunnel they serve, are governed by the applicable building codes. For separation requirements between these ancillary spaces and the tunnel, the more stringent of the requirements between the building code and the applicable NFPA standard applies. The authority having jurisdiction should always be consulted when there is any doubt in the application of this separation requirement.

MODERN laboratories require regulated temperature, humidity, relative static pressure, air motion, air cleanliness, sound, and exhaust. This chapter addresses biological, chemical, animal, and physical laboratories. Within these generic categories, some laboratories have unique requirements. This chapter provides an overview of the HVAC characteristics and design criteria for laboratories, including a brief overview of architectural and utility concerns. This chapter does not cover pilot plants, which are essentially small manufacturing units.

The function of a laboratory is important in determining the appropriate HVAC system selection and design. Air-handling, hydronic, control, life safety, and heating and cooling systems must function as a unit and not as independent systems. HVAC systems must conform to applicable safety and environmental regulations.

Providing a safe environment for all personnel is a primary objective in the design of HVAC systems for laboratories. A vast amount of information is available, and HVAC engineers must study the subject thoroughly to understand all the factors that relate to proper and optimum design. This chapter serves only as an introduction to the topic of laboratory HVAC design. HVAC systems must integrate with architectural planning and design, electrical systems, structural systems, other utility systems, and the functional requirements of the laboratory. The HVAC engineer, then, is a member of a team that includes other facility designers, users, industrial hygienists, safety officers, security, operators, and maintenance staff. Decisions or recommendations by the HVAC engineer may significantly affect construction, operation, and maintenance costs.

Laboratories frequently use 100% outdoor air, which broadens the range of conditions to which the systems must respond. They seldom operate at maximum design conditions, so the HVAC engineer must pay particular attention to partial load operations that are continually changing due to variations in internal space loads, exhaust requirements, external conditions, and day/night variances. Most laboratories will be modified at some time. Consequently, the HVAC engineer must also consider to what extent laboratory systems should be adaptable for other needs. Both economics and integration of the systems with the rest of the facility must be considered.

1. GENERAL DESIGN GUIDANCE

1.1 LABORATORY TYPES

Laboratories can be divided into the following general types:

- **Biological laboratories** are those that contain biologically active materials or involve the chemical manipulation of these materials. This includes laboratories that support such disciplines as biochemistry, microbiology, cell biology, biotechnology, genomics, immunology, botany, pharmacology, and toxicology. Both chemical fume hoods and biological safety cabinets are commonly installed in biological laboratories.
- **Chemical laboratories** support both organic and inorganic synthesis and analytical functions. They may also include laboratories in the material and electronic sciences. Chemical laboratories commonly contain a number of fume hoods.
- **Animal laboratories** are areas for manipulation, surgical modification, and pharmacological observation of laboratory animals. They also include animal holding rooms, which are similar to laboratories in many of the performance requirements but have an additional subset of requirements.
- **Physical laboratories** are spaces associated with physics; they commonly incorporate lasers, optics, radioactive material, high- and low-temperature material, electronics, and analytical instruments.

Laboratory Resource Materials

The following are general or specific resource materials applicable to various types of laboratories.

- ACGIH. *Industrial Ventilation: A Manual of Recommended Practice*. American Conference of Governmental Industrial Hygienists, Cincinnati, OH.
- FGI guidelines for design and construction. The Facilities Guideline Institute, American Society of Healthcare Engineering, Chicago, IL.
- ASSE. Laboratory Ventilation. ANSI/AIHA/ASSE *Standard* Z9.5. American Society of Safety Engineers, Des Plaines, IL
- ASHRAE *Laboratory Design Guide*.
- CAP. *Medical Laboratory Planning and Design*. College of American Pathologists, Northfield, IL.
- DHHS. *Biosafety in Microbiological and Biomedical Laboratories*. U.S. Department of Health and Human Services (CDC).
- EEOC. *Americans with Disabilities Act Handbook*. Equal Employment Opportunity Commission.
- I^{2}SL. *I^{2}SL's Electronic Library*. i2sl.org/elibrary/index.html. International Institute for Sustainable Laboratories.
- NFPA. *Fire Protection Guide for Hazardous Materials*. National Fire Protection Association, Quincy, MA.

The preparation of this chapter is assigned to TC 9.10, Laboratory Systems.

- NFPA. Fire Protection for Laboratories Using Chemicals. ANSI/NFPA *Standard* 45. National Fire Protection Association, Quincy, MA.
- NRC. *Biosafety in the Laboratory: Prudent Practices for Handling and Disposal of Infectious Materials*. National Research Council, National Academy Press, Washington, D.C.
- NRC. *Prudent Practices in the Laboratory: Handling and Management of Chemical Hazards,* updated version. National Research Council, National Academy Press, Washington, D.C.
- NSF. Class II Biosafety Cabinetry. NSF/ANSI *Standard* 49.
- OSHA. *Occupational Exposure to Chemicals in Laboratories*. Appendix VII, 29 CFR 1910.1450. www.ecfr.gov.
- SEFA. *Laboratory Fume Hoods Recommended Practices*. Scientific Equipment and Furniture Association, Garden City, NY.

Other regulations and guidelines may apply to laboratory design. All applicable institutional, local, state, and federal requirements should be identified before design begins.

1.2 HAZARD ASSESSMENT

Laboratory operations potentially involve some hazard; nearly all laboratories contain some type of hazardous materials. Before the laboratory is designed, the owner's designated safety officers should perform a comprehensive hazard assessment. These safety officers include, but are not limited to, the chemical hygiene officer, radiation safety officer, biological safety officer, and fire and loss prevention officials. The hazard assessment should be incorporated into the chemical hygiene plan, radiation safety plan, and biological safety protocols.

Hazard study methods such as hazard and operability analysis (HAZOP) can be used to evaluate design concepts and certify that the HVAC design conforms to the applicable safety plans. Nature and quantity of the contaminants, types of operations, and degree of hazard dictate the types of containment and local exhaust devices. For functional convenience, operations posing less hazard potential are conducted in devices that use directional airflow for personnel protection (e.g., laboratory fume hoods and biological safety cabinets). However, these devices do not provide absolute containment. Operations having a significant hazard potential are conducted in devices that provide greater protection but are more restrictive (e.g., sealed glove boxes).

The design team should visit similar laboratories to assess successful design approaches and safe operating practices. Each laboratory is somewhat different. Design must be evaluated using appropriate, current standards and practices as well, rather than simply duplicating existing (and possibly outmoded) facilities.

1.3 DESIGN PARAMETERS

The following ventilation system design parameters must be established for a laboratory space:

- Temperature and humidity, both indoor and outdoor
- Air quality, from both process and safety perspectives, including the need for air filtration and special treatment (e.g., charcoal, HEPA, or other filtration of supply or exhaust air)
- Equipment and process heat gains, both sensible and latent
- Minimum allowable air change rates
- Equipment and process exhaust quantities
- Exhaust and air intake locations
- Style, capture velocities, and usage factors of the exhaust device
- Need for standby equipment and emergency power
- Alarm requirements.
- Potential changes in the size and number of laboratory hoods
- Anticipated increases in internal heat loads
- Isolation and room pressurization requirements
- Biological containment provisions
- Decontamination provisions

It is important to (1) review design parameters with the safety officers and scientific staff, (2) determine limits that should not be exceeded, and (3) establish the desirable operating conditions. For areas requiring variable temperature or humidity, these parameters must be carefully reviewed with the users to establish a clear understanding of expected operating conditions and system performance.

Because laboratory HVAC systems often incorporate 100% outdoor air systems, the selection of design parameters has a substantial effect on capacity, first cost, and operating costs. The selection of proper and prudent design conditions is very important.

Internal Thermal Considerations

In addition to the heat gain from people and lighting, laboratories frequently have significant sensible and latent loads from equipment and processes. Often, data for equipment used in laboratories are unavailable or the equipment has been custom built. Information for some common laboratory equipment is listed in the appendix of the *ASHRAE Laboratory Design Guide* (ASHRAE 2002). Data on heat release from animals that may be housed in the space can be found in Table 2 of this chapter and in Alereza and Breen (1984).

Careful review of the equipment to be used, a detailed understanding of how the laboratory will be used, and prudent judgment are required to obtain good estimates of the heat gains in a laboratory. The convective portion of heat released from equipment located within exhaust devices can be discounted. Heat from equipment that is directly vented or heat from water-cooled equipment should not be considered part of the heat released to the room. Any unconditioned makeup air that is not directly captured by an exhaust device must be included in the load calculation for the room. In many cases, additional equipment will be obtained by the time a laboratory facility has been designed and constructed. The design should allow for this additional equipment.

Internal load as measured in watts per square metre is the average continuous internal thermal load discharged into the space. It is not a tabulation of the connected electrical load because it is rare for all equipment to operate simultaneously, and most devices operate with a duty cycle that keeps the average electrical draw below the nameplate information. When tabulating the internal sensible heat load in a laboratory, the duty cycle of the equipment should be obtained from the manufacturer. This information, combined with the nameplate data for the item, may provide a more accurate assessment of the average thermal load.

The HVAC system engineer should evaluate equipment nameplate ratings, applicable use and usage factors, and overall diversity. Review use, usage factors, and diversity with lab occupants. Much laboratory equipment includes computers, automation, sample changing, or robotics; this can result in high levels of use even during unoccupied periods. The HVAC engineer must evaluate internal heat loads under all anticipated laboratory operating modes. Because of highly variable equipment heat gain, individual laboratories should have dedicated temperature controls. See Chapter 18 in the 2017 *ASHRAE Handbook—Fundamentals* for more information on load calculation.

Two cases encountered frequently are (1) building programs based on generic laboratory modules and (2) laboratory spaces that are to be highly flexible and adaptive. Both situations require the design team to establish heat gain on an area basis. The values for area-based heat gain vary substantially for different types of laboratories. Heat gains of 50 to 270 W/m^2 or more are common for laboratories with high concentrations of equipment.

Architectural Considerations

Integrating utility systems into the architectural planning, design, and detailing is essential to providing successful research facilities. The architect and the HVAC system engineer must seek an early understanding of each other's requirements and develop integrated solutions. HVAC systems may fail to perform properly if the architectural requirements are not addressed correctly. Quality assurance of the installation is just as important as proper specifications. The following play key roles in the design of research facilities:

Modular Planning. Most laboratory programming and planning is based on developing a module that becomes the base building block for the building layout. Laboratory planning modules are frequently 3 to 3.5 m wide and 6 to 9 m deep. The laboratory modules may be developed as single work areas or combined to form multiple-station work areas. Utility systems should be arranged to reflect the architectural planning module, with services provided for each module, or pair of modules, as appropriate.

Development of Laboratory Units or Control Areas. National Fire Protection Association (NFPA) *Standard* 45 requires that laboratory units be designated. Similarly, the *International Building Code*® (ICC 2015) requires the development of control areas. Laboratory units or control areas should be developed, and the appropriate hazard levels should be determined early in the design process. The HVAC designer should review the requirements for maintaining separations between laboratories and note requirements for exhaust ductwork to serve only a single laboratory unit or control area.

Additionally, NFPA *Standard* 45 requires that no fire dampers be installed in laboratory exhaust ductwork. Building codes offer no leeway on maintaining required floor-to-floor fire separations. Review these criteria and the proposed solutions early in the design process with the appropriate building code officials. The combination of the two requirements commonly necessitates the construction of dedicated fire-rated shafts from each occupied floor to the penthouse or building roof.

Provisions for Adaptability and Flexibility. Research objectives frequently require changes in laboratory operations and programs. Thus, laboratories must be flexible and adaptable, able to accommodate these changes without significant modifications to the infrastructure. For example, the utility system design can be flexible enough to supply ample cooling to support the addition of heat-producing equipment without requiring modifications to the HVAC system. Adaptable designs should allow programmatic research changes that require modifications to the laboratory's infrastructure within the limits of the individual laboratory area and/or interstitial and utility corridors. For example, an adaptable design would allow addition of a fume hood without requiring work outside that laboratory space. Further, the HVAC designer should consider the consequences of future programmatic changes on the sizing of main ductwork and central system components. The degree of flexibility and adaptability for which the laboratory HVAC system is designed should be determined from discussion with the researchers, laboratory programmer, and laboratory planner. The HVAC designer should have a clear understanding of these requirements and their financial impact.

Early Understanding of Utility Space Requirements. The amount and location of utility space are significantly more important in research facility design than in that of most other buildings. The available ceiling space and the frequency of vertical distribution shafts are interdependent and can significantly affect architectural planning. The HVAC designer must establish these parameters early, and the design must reflect these constraints. The designer should review alternative utility distribution schemes, weighing advantages and disadvantages.

High-Quality Envelope Integrity. Laboratories that have stringent requirements for control of temperature, humidity, relative static pressure, and background particle count generally require architectural features to allow the HVAC systems to perform properly. The building envelope may need to be designed to handle relatively high levels of humidification and slightly negative building pressure without moisture condensation in the winter or excessive infiltration. Some of the architectural features that the HVAC designer should evaluate include

- Vapor and air barriers: position, location, and kind
- Insulation: location, thermal resistance, and kind
- Window frames and glazing
- Caulking
- Internal partitions: their integrity in relation to air pressure, vapor barriers, and insulation value
- Finishes: vapor permeability and potential to release particles into the space
- Doors
- Air locks

Air Intakes and Exhaust Locations. Mechanical equipment rooms and their outdoor air intakes and exhaust stacks must be located to avoid intake of fumes into the building. As with other buildings, air intake locations must be chosen to minimize fumes from loading docks, cooling tower discharge, vehicular traffic, adjacent structures and processes, etc.

2. LABORATORY EXHAUST AND CONTAINMENT DEVICES

2.1 FUME HOODS

The Scientific Equipment and Furniture Association (SEFA 2010) defines a laboratory fume hood as a "safety device specifically designed to carry undesirable effluents (generated . . . during a laboratory procedure) away from laboratory personnel and out of the building, when connected to a properly designed laboratory ventilation system." The hood can be mounted on a bench, a pedestal, or the floor. Materials should mainly be flame resistant. The face opening has a sash and an optional additional protective shield, and usually has an airfoil to reduce reverse airflow on the lower surface. The hood should have a baffle, and usually a bypass system to control airflow patterns in the hood and distribute air evenly at the opening. For variable-air-volume (VAV) systems, the bypass system may be partially blocked. Figure 1 shows the basic elements of a general-purpose benchtop fume hood.

Fume hoods may be equipped with a variety of accessories, including internal lights, service outlets, sinks, air bypass openings, airfoil entry devices, flow alarms, special linings, ventilated base storage units, and exhaust filters. Under-counter cabinets for storage of flammable materials require special attention to ensure safe installation. NFPA *Standard* 30 does not recommend venting these cabinets; however, ventilation is often required to avoid accumulation of toxic or hazardous vapors. Ventilation of these cabinets by a separately ducted supply and exhaust that will maintain the temperature rise of the cabinet interior within the limits defined by NFPA *Standard* 30 should be considered.

Types of Fume Hoods

The following are the primary types of fume hoods and their applications:

Constant Volume (approximately constant-volume airflow with variable face velocity). Hood that meets basic SEFA definition. Sash may be vertical, horizontal, or combination.

Application: Moderate to highly hazardous processes; varying procedures.

Variable Volume (constant face velocity). Hood has an opening or bypass designed to provide a prescribed minimum air intake when sash is closed, and an exhaust system designed to vary airflow in accordance with sash opening. Sash may be vertical, horizontal, or a combination of both.

Application: Moderate to highly hazardous processes; varying procedures.

Auxiliary Air (approximately constant-volume airflow). A plenum above the face receives air from a secondary air supply that provides partially conditioned or unconditioned outdoor air.

Note: Many organizations restrict the use of this type of hood.

Low Velocity or Reduced Flow (approximately constant-volume airflow with variable face velocity or variable volume). These hoods are designed to provide containment at lower average face velocities.

Application: Moderate to highly hazardous processes; varying procedures.

Filtered, Recirculating (approximately constant-volume airflow). Particulate filtration combined with chemical adsorption to remove contaminants.

Application: Moderate process with predictable procedures.

Radioisotope. Hood with special integral work surface, linings impermeable to radioactive materials, and structure strong enough to support high-density shielding materials. The interior must be constructed to prevent radioactive material buildup and allow complete cleaning. Ductwork should have flanged gasketed joints with quick-disconnect fasteners that can be readily dismantled for decontamination. High-efficiency particulate air (HEPA) and/or charcoal filters may be needed in exhaust duct.

Application: Laboratories using radioactive isotopes.

Perchloric Acid. Hood with special integral work surfaces, coved corners, and nonorganic lining materials. Perchloric acid is an extremely active oxidizing agent. Its vapors can form unstable deposits in the ductwork that present a potential explosion hazard. To alleviate this hazard, the exhaust system must be equipped with an internal water washdown and drainage system, and the ductwork must be constructed of smooth, impervious, cleanable materials that are resistant to acid attack. The internal washdown system must completely flush the ductwork, exhaust fan, discharge stack, and fume hood inner surfaces. Ductwork should be kept as short as possible with minimum elbows. Perchloric acid exhaust systems with longer duct runs may need a zoned washdown system to avoid water flow rates in excess of the capacity to drain water from the hood. Because perchloric acid is an extremely active oxidizing agent, organic materials should not be used in the exhaust system in places such as joints and gaskets. Ducts should be constructed of a stainless steel material, with a chromium and nickel content not less than that of 316L stainless steel, or of a suitable nonmetallic material. Joints should be welded and ground smooth. A perchloric acid exhaust system should only be used for work involving perchloric acid.

Application: Process and research laboratories using perchloric acid. Mandatory use because of explosion hazard.

California. Special hood with sash openings on multiple sides (usually horizontal).

Application: For enclosing large and complex research apparatus that require access from two or more sides.

Floor-Mounted Hood (Walk-In). Hood with sash openings to the floor. Sash can be either horizontal or vertical.

Application: For enclosing large or complex research apparatus. Not designed for personnel to enter while operations are in progress.

Distillation. Fume hood with extra depth and 1/3- to 1/2-height benches.

Application: For enclosing tall distillation apparatus.

Process (approximately constant-volume airflow with approximately constant face velocity). Standard hood with a fixed opening and without a sash. Not a fume hood. Considered a ventilated enclosure.

Application: Low-hazard processes; known procedures.

Canopy. Open hood with an overhead capture structure.

Application: Not a fume hood. Useful for heat or water vapor removal from some work areas. Not to be substituted for a fume hood. Not recommended when workers must bend over the source of heat or water vapor.

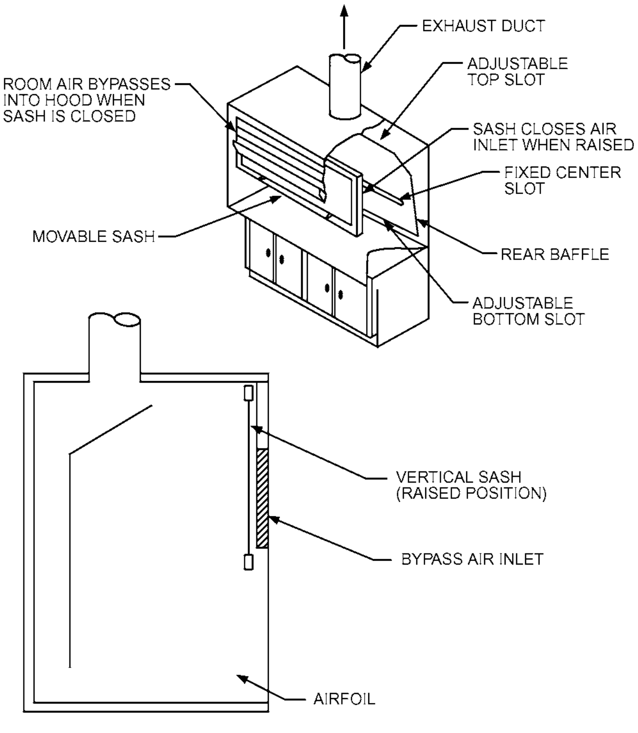

Fig. 1 Bypass Fume Hood with Vertical Sash and Bypass Air Inlet

Fume Hood Sash Configurations

The work opening has operable glass sash(es) for observation and shielding. A sash may be vertically operable, horizontally operable, or a combination of both. A vertically operable sash can incorporate single or multiple vertical panels. A horizontally operable sash incorporates multiple panels that slide in multiple tracks, allowing the open area to be positioned across the face of the hood. The combination of a horizontally operable sash mounted within a single vertically operable sash section allows the entire hood face to be opened for setup. The opening area can then be limited by closing the vertical panel, with only the horizontally sliding sash sections used during experimentation. Both the multiple vertical sash section and combination sash arrangement allow the use of larger fume hoods with limited opening areas, resulting in reduced exhaust airflow requirements. Fume hoods with vertically rising sash sections should include provisions around the sash to prevent the bypass of ceiling plenum air into the fume hood.

Fume Hood Performance

Containment of hazards in a fume hood is based on the principle that a flow of air entering at the face of the fume hood, passing through the enclosure, and exiting at the exhaust port prevents the escape of airborne contaminants from the hood into the room.

The following variables affect the performance of the fume hood:

- Face velocity
- Size of face opening
- Sash position
- Shape and configuration of entrance
- Shape of any intermediate posts
- Inside dimensions and location of work area relative to face area
- Location of service fittings inside the fume hood
- Heat generated in the hood
- Size and number of exhaust ports
- Back baffle and exhaust plenum arrangement
- Bypass arrangement, if applicable.
- Auxiliary air supply, if applicable
- Arrangement and type of replacement supply air outlets
- Air velocities near the hood
- Distance from openings to spaces outside the laboratory
- Movements of the researcher within the hood opening
- Location, size, and type of research apparatus placed in the hood
- Distance from the apparatus to the researcher's breathing zone

Air Currents. Air currents external to the fume hood can jeopardize the hood's effectiveness and expose the researcher to materials used in the hood. Detrimental air currents can be produced by

- Air supply distribution patterns in the laboratory
- Movements of the researcher
- People walking past the fume hood
- Thermal convection
- Opening (or open) doors and windows

Caplan and Knutson (1977, 1978) conducted tests to determine the interactions between room air motion and fume hood capture velocities with respect to the spillage of contaminants into the room. Their tests indicated that the effect of room air currents is significant and of the same order of magnitude as the effect of the hood face velocity. Consequently, improper design and/or installation of the replacement air supply can lower performance of the fume hood.

Disturbance velocities at the face of the hood should be no more than one-half and preferably one-third the face velocity of the hood. This is an especially critical factor in designs that use low face velocities. For example, a fume hood with a face velocity of 0.5 m/s could tolerate a maximum disturbance velocity of 0.25 m/s. If the design face velocity were 0.3 m/s, the maximum disturbance velocity would be 0.15 m/s.

To the extent possible, the fume hood should be located so that traffic flow past the hood is minimal. Also, the fume hood should be placed to avoid any air currents generated from the opening of windows and doors. Air currents from open doors and windows can be significantly higher than acceptable maximum disturbance velocities. To ensure optimum placement of the fume hoods, the HVAC system designer must take an active role early in the design process.

Use of Auxiliary Air Fume Hoods. ASSE *Standard* Z9.5 discourages the use of auxiliary air fume hoods. These hoods incorporate an air supply at the fume hood to reduce the amount of room air exhausted. The following difficulties and installation criteria are associated with auxiliary air fume hoods:

- The auxiliary air supply must be introduced outside the fume hood to maintain appropriate velocities past the researcher.
- The flow pattern of the auxiliary air must not degrade the containment performance of the fume hood.
- The volume of auxiliary air must not be enough to degrade the fume hood's containment performance.
- Auxiliary air must be conditioned to avoid blowing cold air on the researcher; often the air must be cooled to maintain the required temperature and humidity within the hood. Auxiliary air can introduce additional heating and cooling loads in the laboratory.
- Only vertical sash should be used in the hood.
- Controls for the exhaust, auxiliary, and supply airstreams must be coordinated.
- Additional coordination of utilities during installation is required to avoid spatial conflicts caused by the additional duct system.
- Humidity control can be difficult; unless auxiliary air is cooled to the dew point of the specified internal conditions, there is some degradation of humidity control; however, if such cooling is done, the rationale for using auxiliary air has been nullified.

Fume Hood Performance Criteria. ASHRAE *Standard* 110 describes a quantitative method of determining the containment performance of a fume hood. This method requires the use of a tracer gas and instruments to measure the amount of tracer gas that enters the breathing zone of a mannequin; this simulates the containment capability of the fume hood as a researcher conducts operations in the hood. The following tests are commonly used to judge the performance of the fume hood: (1) face velocity test, (2) flow visualization test, (3) tracer gas test, and (4) sash movement test. These tests should be performed under the following conditions:

- Usual amount of research equipment in hood; room air balance fixed
- Doors and windows in normal positions
- Fume hood sash set in varying positions to simulate both static and dynamic performance

All fume hoods should be tested annually, at minimum, to verify their performance. Refer to ASHRAE *Standard* 110 for procedures.

2.2 BIOLOGICAL SAFETY CABINETS

A biological safety cabinet protects the researcher and, in some configurations, the research materials as well. Biological safety cabinets are also referred to as ventilated safety cabinets, laminar flow cabinets, and glove boxes. Biological safety cabinets are categorized into six groups (four of which are shown in Figure 2):

Class I	Similar to chemical fume hood, no research material protection, 100% exhaust through a HEPA filter
Class II	
Type A1	70% recirculation within the cabinet; 30% exhaust through a HEPA filter; common plenum configuration; can be recirculated into the laboratory
Type A2	70% recirculation within the cabinet; 30% exhaust through a HEPA filter; common plenum configuration; can be recirculated to the room or exhausted to the outdoor
Type B1	40% recirculation within the cabinet; 60% exhaust through a HEPA filter; separate plenum configuration, must be exhausted to the outdoor
Type B2	100% exhaust through a HEPA filter to the outdoor
Class III	Special applications; 100% exhaust through a HEPA filter to the outdoors; researcher manipulates material within cabinet through physical barriers (gloves)

The researcher must make several key decisions before selecting a biological safety cabinet (Eagleston 1984). An important difference in biological safety cabinets is their ability to handle chemical vapors properly (Stuart et al. 1983). Of special concern to the HVAC

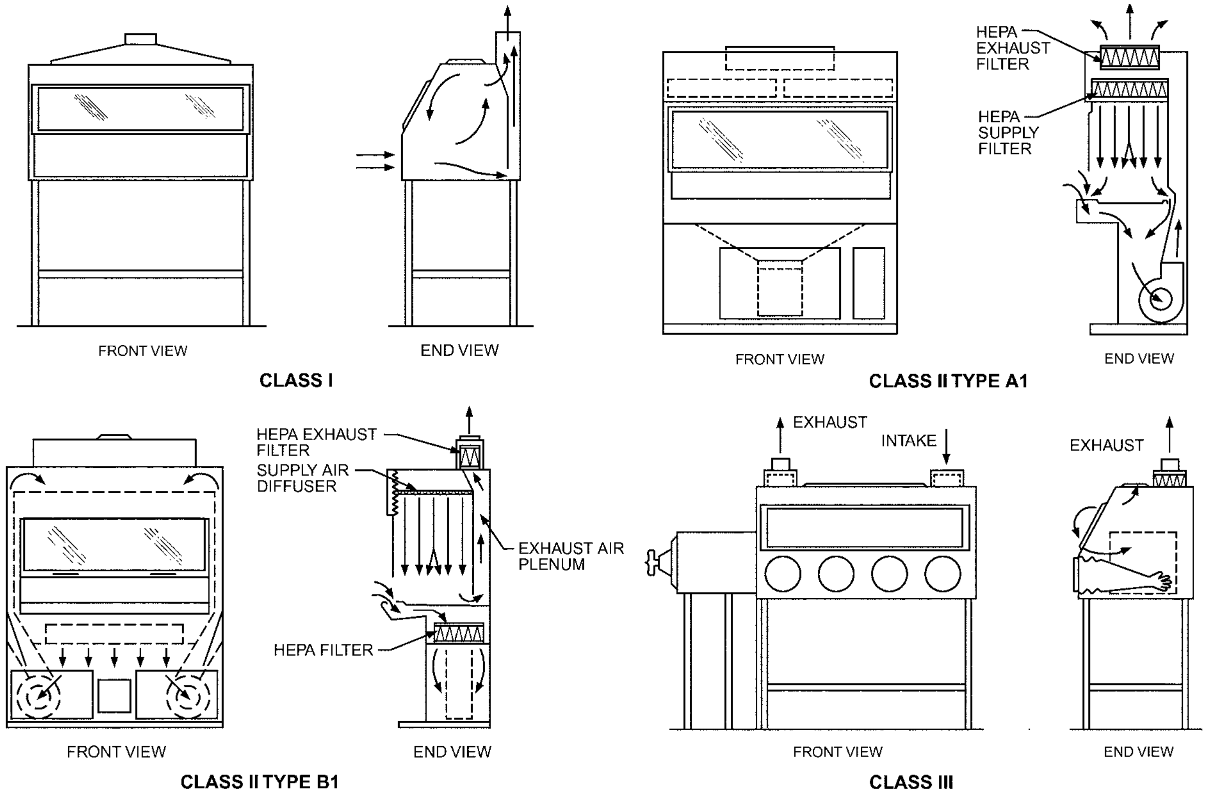

Fig. 2 Types of Biological Safety Cabinets

engineer are the proper placement of the biological safety cabinet in the laboratory and the room's air distribution. Rake (1978) concluded the following:

> A general rule of thumb should be that, if the cross draft or other disruptive room airflow exceeds the velocity of the air curtain at the unit's face, then problems do exist. Unfortunately, in most laboratories such disruptive room airflows are present to various extents. Drafts from open windows and doors are the most hazardous sources because they can be far in excess of 200 fpm [1 m/s] and accompanied by substantial turbulence. Heating and air-conditioning vents perhaps pose the greatest threat to the safety cabinet because they are much less obvious and therefore seldom considered. . . . It is imperative then that all room airflow sources and patterns be considered before laboratory installation of a safety cabinet.

Class II biological safety cabinets should only be placed in the laboratory in compliance with NSF International *Standard* 49, Class II (Laminar Flow) Biohazard Cabinetry. Assistance in procuring, testing, and evaluating performance parameters of Class II biological safety cabinets is available from NSF as part of the standard. The cabinets should be located away from drafts, active walkways, and doors. The air distribution system should be designed to avoid air patterns that impinge on the cabinet.

The different biological safety cabinets have varying static pressure resistance requirements. Generally, Class II Type A1 cabinets have pressure drops ranging between 1 and 25 Pa. Class II Type B1 cabinets have pressure drops in the range of 150 to 300 Pa, and Class II Type B2 cabinets have pressure drops ranging from 370 to 570 Pa. The manufacturer must be consulted to verify specific requirements.

Pressure requirements also vary based on filter loading and the intermittent operation of individual biological safety cabinets. Exhaust systems for biological safety cabinets must be designed with these considerations in mind. Take care when manifolding biological safety cabinet exhausts to ensure that the varying pressure requirements are met.

The manufacturer of the biological safety cabinet may be able to supply the transition to the duct system. The transition should include an access port for testing and balancing and an airtight damper for decontamination. As with any containment ductwork, high-integrity duct fabrication and joining systems are necessary.

Biological safety cabinets may require periodic decontamination before service and filter replacement. During decontamination, the cabinet must be isolated or sealed from the laboratory and the exhaust system. The responsible safety officer should be consulted to determine the need for, and placement of, isolation dampers to facilitate decontamination operations. If provisions for decontamination are necessary, the ventilation system design should maintain laboratory airflow and pressure during the decontamination procedure.

Class I Cabinets

The Class I cabinet is a partial containment device designed for research operations with low- and moderate-risk etiologic agents. It does not provide protection for materials used in the cabinet. Room air flows through a fixed opening and prevents aerosols that may be generated in the cabinet enclosure from escaping into the room. Depending on cabinet usage, air exhausted through the cabinet may be HEPA filtered before being discharged into the exhaust system. The fixed opening through which the researcher works is usually 200 mm high. To provide adequate personnel protection, air velocity through the fixed opening is usually at least 0.4 m/s.

If approved by the appropriate safety officer, the Class I cabinet can be modified to safely contain chemical carcinogens by adding appropriate exhaust air treatment and increasing the velocity through the opening to 0.5 m/s. Large pieces of research equipment can be placed in the cabinet if adequate shielding is provided.

The Class I cabinet is not appropriate for containing systems that are vulnerable to airborne contamination because the air flowing into the cabinet is untreated. Also, the Class I cabinet is not recommended for use with highly infectious agents because an interruption of the inward airflow may allow aerosolized particles to escape.

Class II Cabinets

Class II cabinets provide protection to personnel, product, and the environment. The cabinets feature an open front with inward airflow and HEPA-filtered recirculated and exhaust air. Microbiological containment, product protection, and cross-contamination performance is established for certain cabinets by NSF International's *Standard* 49. Measurement techniques in NSF *Standard* 49 vary from those often used by building system testing and balancing agencies; therefore, it is important to coordinate activities of the biological safety cabinet (BSC) certification agency and the testing and balancing agency.

The Class II Type A1 cabinet has a fixed opening with a minimum inward airflow velocity of 0.4 m/s. The average downward velocity is established by the manufacturer and is typically 0.25 to 0.4 m/s. The Class II Type A1 cabinet is suitable for use with agents meeting Biosafety Level 2 criteria (DHHS 1999), and, if properly certified, can meet Biosafety Level 3. However, because approximately 70% of the airflow is recirculated, the cabinet is not suitable for use with flammable, toxic, or radioactive agents.

The Class II Type A2 cabinet maintains an inward airflow velocity of 0.5 m/s and is similar in performance to the Class II Type A1.

The Class II Type B1 cabinet has a vertical sliding sash and maintains an inward airflow of 0.5 m/s at a sash opening of 200 mm. The average downward velocity of the internal airflow is typically in the range of 0.25 to 0.4 m/s. The Class II Type B1 cabinet is suitable for use with agents meeting Biosafety Level 3. Approximately 60% of the internal airflow is exhausted through HEPA filters; this allows the use of biological agents treated with limited quantities of toxic chemicals and trace amounts of radionuclides, provided the work is performed in the direct exhaust area of the cabinet.

The Class II Type B2 cabinet maintains an inward airflow velocity of 0.5 m/s through the work opening. The cabinet is 100% exhausted through HEPA filters to the outdoors; all downward-velocity air is drawn from the laboratory or other supply source and is HEPA filtered before being introduced into the workspace. The Class II Type B2 cabinet may be used for the same level of work as the Class II Type B1, and is used when the primary consideration is protection of the material in the hood. In addition, the design allows use of small quantities of toxic chemicals and radionuclides in microbiological studies.

In Class II Type A2 cabinets, exhaust air delivered to the outlet of the cabinet by internal blowers must be handled by the laboratory exhaust system. This arrangement requires a delicate balance between the cabinet and the laboratory's exhaust system, and it may incorporate a thimble connection between the cabinet and the laboratory exhaust ductwork. Thimble (or canopy) connections incorporate an air gap between the biological safety cabinet and the exhaust duct. The purpose of the air gap is to buffer the effect of any exhaust system fluctuations on the biological safety cabinet airflow. The exhaust system must pull more air than is exhausted by the biological safety cabinet to make airflow in through the gap. The designer should confirm the amount of air to be drawn through the air gap. A minimum flow is required to provide the specified level of containment, and a maximum flow cannot be exceeded without causing an imbalance through aspiration. In the event of an exhaust system failure, the air gap allows the cabinet to maintain safe intake velocity by exhausting HEPA-filtered air through the air gap.

Class II Type B1 and Type B2 cabinets rely on the building exhaust system to pull the air from the cabinet's workspace and through the exhaust HEPA filters. The pressure resistance that must be overcome by the building exhaust system can be obtained from the cabinet manufacturer. In a fire or smoke condition, exhaust flow should continue through the cabinet, as for a fume hood; therefore, fire and smoke dampers should not be installed in the exhaust ductwork. The cabinet should be provided with a gastight damper to isolate it from the downstream ductwork to allow for decontamination. Because containment in this type of cabinet depends on the building's exhaust system, the exhaust fan(s) should have redundant back-ups and the proper controls to maintain required flow rates.

Class III Cabinets

The Class III cabinet is a gastight, negative-pressure containment system that physically separates the agent from the worker. These cabinets provide the highest degree of personnel protection. Work is performed through arm-length rubber gloves attached to a sealed front panel. Room air is drawn into the cabinet through HEPA filters. The American Glovebox Society (AGS 2007) indicates that Class III cabinets should be maintained at 125 Pa below ambient pressure. Exhaust flow rate should provide a minimum of 0.5 m/s inward containment velocity through a glove port opening in the event of a glove being inadvertently removed. HEPA filtration or incineration before discharge to the atmosphere removes or destroys particulate material entrained in the exhaust air. A Class III system may be designed to enclose and isolate incubators, refrigerators, freezers, centrifuges, and other research equipment. Double-door autoclaves, liquid disinfectant dunk tanks, and pass boxes are used to transfer materials into and out of the cabinet.

Class III systems can contain highly infectious materials and radioactive contaminants. Although there are operational inconveniences with these cabinets, they are the equipment of choice when a high degree of personnel protection is required. Note that explosions have occurred in Class III cabinets used for research involving volatile substances.

2.3 MISCELLANEOUS EXHAUST DEVICES

Snorkels are used in laboratories to remove heat or nontoxic particles that may be generated from benchtop research equipment. Snorkels usually have funnel-shaped inlet cones connected to 75 to 150 mm diameter flexible or semi-flexible ductwork extending from the ceiling to above the benchtop level.

Benchtop slots are used to remove nontoxic particles or fumes that may be generated by benchtop equipment.

Often, hoods are installed over weigh stations to contain and minimize disturbances from room air currents.

2.4 LAMINAR FLOW CLEAN BENCHES

Laminar flow clean benches are available in two configurations: horizontal (crossflow) and vertical (downflow). Both configurations filter the supply air and usually discharge the air out the front opening into the room. Clean benches protect the experiment or product but do not protect the researcher; therefore, they should not be used with any potentially hazardous or allergenic substances. Clean benches are not recommended for any work involving hazardous biological, chemical, or radionuclide materials.

2.5 COMPRESSED GAS STORAGE AND VENTILATION

Gas Cylinder Closets

Most laboratory buildings require storage closets for cylinders of compressed gases, which may be inert, flammable, toxic, corrosive, or poisonous. The requirements for storage and ventilation are covered in building codes and NFPA standards and codes. Water sprinklers are usually required, but other types of fire suppression may be needed based on the gases stored. Explosion containment requires a separate structural study, and closets generally require an outer wall for venting. One design used by a large chemical manufacturer to house gases with explosion potential specifies a completely welded 6 mm steel inner liner for the closet, heavy-duty door latches designed to withstand the force of an internal explosion, and venting out the top of the closet.

Closet temperature should not exceed 52°C per NFPA *Standard* 55. Ventilation for cylinder storage is established in NFPA *Standard* 55 at a minimum of 5 L/(s·m^2). Ventilation rates can be calculated by determining both the amount of gas that could be released by complete failure of the cylinder outlet piping connection and the time the release would take, and then finding the dilution airflow required to reduce any hazard below the maximum allowable limit.

Ventilation air is usually exhausted from the closet; makeup air comes from the surrounding space through openings in and around the door or through a transfer duct. That makeup air must be considered for the building air balance. Ventilation for a closet containing materials with explosion potential must be carefully designed, with safety considerations taken into account. See NFPA *Standard* 68 for information on explosion venting.

Cylinder closet exhausts should be connected through a separate duct system to a dedicated exhaust fan or to a manifold system in which constant volume can be maintained under any possible manifold condition. A standby source of emergency power should be considered for the exhaust system fan(s).

Gas Cylinder Cabinets

Compressed gases that present a physical or health hazard are often placed in premanufactured gas cylinder cabinets. Gas cylinder cabinets are available for single-, dual-, or triple-cylinder configurations and are commonly equipped with valve manifolds, fire sprinklers, exhaust connections, access openings, and operational and safety controls. The engineer must fully understand safety, material, and purity requirements associated with specific compressed gases when designing and selecting cylinder cabinets and the components that make up the compressed gas handling system.

Exhaust from the gas cylinder cabinets is provided at a high rate. Air is drawn into the gas cylinder cabinet from the surrounding space through a filtered opening, usually on the lower front of the cylinder cabinet. Depending on the specific gas stored in the cabinet, the exhaust system may require emission control equipment and a source of emergency power.

3. LABORATORY VENTILATION

The total airflow rate for a laboratory is dictated by one of the following:

- Total amount of exhaust from containment and exhaust devices
- Cooling required to offset internal heat gains
- Minimum ventilation rate requirements
- Airflow required to maintain pressure relationships

Fume hood exhaust requirements (including evaluation of alternate sash configurations as described in the section on Fume Hoods) must be determined in consultation with the safety officers. The HVAC engineer must determine the expected heat gains from the laboratory equipment after consulting with the laboratory staff (see the section on Internal Thermal Considerations).

Minimum ventilation rates should be established to provide a safe and healthy environment under normal and expected operating conditions. The dilution ventilation provided by this airflow is no substitute for the containment performance of a laboratory fume hood or other primary containment device, regardless of the room ventilation rate. The appropriate ventilation rate for clearing a room of fugitive emissions or spills varies significantly based on the amount of release, the chemical's evaporation rate and hazard level, and ventilation system effectiveness.

Fixed minimum airflow rates of 4 to 12 air changes per hour (ach) when the space is occupied have been used in the past. Recent university research (Klein et al. 2009) has shown a significant increase in dilution and clearing performance by increasing the air change rate from 6 to 8 ach with diminishing returns above 12 ach. Similarly, CFD research (Schuyler 2009) found that increasing the lab's dilution ventilation rate from 4 to 8 ach reduced the background contaminant level by greater than a factor of 10. This indicates that minimum ventilation rates at the lower end of the 4 to 12 ach range may not be appropriate for all laboratories. Minimum ventilation rates should be established on a room-by-room basis, considering the hazard level of materials expected to be used in the room and the operation and procedures to be performed. As the operation, materials, and hazard level of a room change, evaluate the prospect of increasing or decreasing the minimum ventilation rate.

Active sensing of air quality in individual laboratories (Sharp 2010) is an alternative approach for dealing with the variability of appropriate ventilation rates, particularly when energy efficiency is important or when hazard level is less established. With this approach, the minimum airflow rate is varied based on sensing the laboratory's actual air quality level or air cleanliness. Sensors used to determine air quality should be evaluated for their ability to detect chemicals being used in the space. When air contaminants are sensed in the laboratory above a given threshold, the minimum air change rate is increased proportionally to an appropriate level to purge the room. When the air is clean and contaminants are below the threshold, lower minimum airflow rates may be appropriate. Extensive studies of lab room environmental conditions (Sharp 2010) have shown that the air in labs is typically clean over 98% of the time.

The maximum airflow rate for the laboratory should be reviewed to ensure that supply air delivery methods are appropriate and that supply airflows do not impede performance of the exhaust devices. Laminar-flow (nonaspirating) supply air outlets can be used to create predictable air flow patterns in the laboratory, generating directional flows toward exhaust and containment device locations. Laboratory ventilation systems can be arranged for either constant-volume or variable-volume airflow. The specific type should be selected with the research staff, safety officers, and maintenance personnel. Special attention should be given to unique areas such as glass washing areas, hot and cold environmental rooms and labs, fermentation rooms, and cage washing rooms. Emergency power systems to operate the laboratory ventilation equipment should be considered based on hazard assessment or other specific requirements. Ensure that an adequate amount of makeup air is available whenever exhaust fans are operated on emergency power. Additional selection criteria are described in the sections on Hazard Assessment and Operation and Maintenance.

Usage Factor

When considering an overall facility, all laboratory personnel, scientific equipment, and exhaust devices are seldom, if ever, present or in use simultaneously. Accordingly, the system designer should consider the impact of nonsimultaneous use on the sizing and selection of building systems. Many variables influence usage factors, including

- Type and size of facility
- Total number of fume hoods
- Number of fume hoods per researcher
- Scientific equipment use diversity
- Type of fume hood controls
- Fume hood sash configuration and minimum airflow required
- Type of laboratory ventilation systems
- Number of devices that must operate continuously due to chemical storage requirements or contamination prevention
- Number of current and projected research programs

Apply usage factors carefully when sizing equipment. For example, teaching laboratories may have a usage factor of 100% when occupied by students.

If the usage factor is too low, design airflow and containment performance cannot be maintained. It is usually expensive and disruptive to add capacity to an operating laboratory's supply or exhaust system. Detailed discussions with research staff are required to ascertain maximum usage factors as well as potential future requirements.

Noise

Noise level in the laboratory should be considered at the beginning of the design so that the sound levels do not interfere with scientific work. Sound generated by the building HVAC equipment should also be evaluated to ensure that excessive levels do not escape to the outdoors. Remedial correction of excessive sound levels can be difficult and expensive. See Chapter 48 for more information.

3.1 SUPPLY AIR SYSTEMS

Supply air systems for laboratories provide the following:

- Thermal comfort for occupants
- Minimum and maximum airflow rates
- Replacement for air exhausted through fume hoods, biological safety cabinets, or other exhaust devices
- Space pressurization control
- Environmental control to meet process or experimental criteria

The design parameters must be well defined for selection, sizing, and layout of the supply air system. Installation and setup should be verified as part of the commissioning process. Design parameters are covered in the section on Design Parameters, and commissioning is covered in the section on Commissioning. Laboratories in which chemicals and compressed gases are used generally require nonrecirculating air supply systems. The selection of 100% exhaust air systems versus return air systems should be made as part of the hazard assessment process, which is discussed in the section on Hazard Assessment. A 100% outdoor air system must have a very wide range of heating and cooling capacity, which requires special design and control.

Filtration

Filtration for the air supply depends on the requirements of the laboratory. Conventional chemistry and physics laboratories commonly use minimum efficiency reporting value (MERV) 13 filters (see ASHRAE *Standard* 52.2-2012 for more on MERVs). Biological and biomedical laboratories usually require MERV 14 or 15 filtration. HEPA filters should be provided for spaces where research materials or animals are particularly susceptible to contamination from external sources. HEPA filtration of the supply air is necessary for such applications as environmental studies, studies involving specific pathogen-free research animals or nude mice, dust-sensitive work, and electronic assemblies. In many instances, biological safety cabinets or laminar flow clean benches (which are HEPA filtered) may be used rather than HEPA filtration for the entire laboratory.

Air Distribution

Air supplied to a laboratory must be distributed to keep temperature gradients and air currents to a minimum. Air outlets (preferably nonaspirating diffusers) must not discharge into the face of a fume hood, a biological safety cabinet, or an exhaust device. Acceptable room air velocities are covered in the sections on Fume Hoods and Biological Safety Cabinets. Special techniques and diffusers are often needed to introduce the large air quantities required for a laboratory without creating disturbances at exhaust devices or on work surfaces.

3.2 EXHAUST SYSTEMS

Laboratory exhaust systems remove air from containment devices and from the laboratory itself. The exhaust system must be controlled and coordinated with the supply air system to maintain correct pressurization. Additional information on the control of exhaust systems is included in the section on Control. Design parameters must be well defined for selection, sizing, and layout of the exhaust air system. Installation and setup should be verified as part of the commissioning process. See the sections on Design Parameters and Commissioning. Laboratory exhaust systems should be designed for high reliability and ease of maintenance. This can be achieved by providing multiple exhaust fans and by sectionalizing equipment so that maintenance work may be performed on an individual exhaust fan while the system is operating. Another option is to use predictive maintenance procedures to detect problems prior to failure and to allow for scheduled shutdowns for maintenance. To the extent possible, components of exhaust systems should allow maintenance without exposing maintenance personnel to the exhaust airstream. Access to filters and the need for bag-in, bag-out filter housings should be considered during the design process.

Depending on the effluent of the processes being conducted, the exhaust airstream may require filtration, scrubbing, or other emission control to remove environmentally hazardous materials. Any need for emission control devices must be determined early in design so that adequate space can be provided and cost implications can be recognized.

Types of Exhaust Systems

Laboratory exhaust systems can be constant-volume, variable-volume, or high-low volume systems with low-, medium-, or high-pressure ductwork, depending on the static pressure of the system. Each fume hood may have its own exhaust fan, or fume hoods may be manifolded and connected to one or more common central exhaust fans. Maintenance, functional requirements, and safety must be considered when selecting an exhaust system. Part of the hazard assessment analysis is to determine the appropriateness of variable-volume systems and the need for individually ducted exhaust systems. Laboratories with a high hazard potential should be analyzed carefully before variable-volume airflow is selected, because minimum air flow requirements could affect the design criteria.Airflow monitoring and pressure-independent control may be required even with constant-volume systems. In addition, fume hoods or other devices in which extremely hazardous or radioactive materials are used should receive special review to determine whether they should be connected to a manifolded exhaust system.

It is rare for all exhaust devices installed in a laboratory to be used simultaneously at full capacity, so it is possible to conserve energy and potentially to reduce equipment capacities by installing a variable-volume system that includes an overall system usage factor. Selection of an appropriate usage factor is discussed in the section on Usage Factor.

Manifolded Exhaust Systems. These can be classified as pressure dependent or independent. **Pressure-dependent systems** are constant volume only and incorporate manually adjusted balancing dampers for each exhaust device. If an additional fume hood is added to a pressure-dependent exhaust system, the entire system must be rebalanced, and the speed of the exhaust fans may need to be adjusted. Because pressure-independent systems are more flexible, pressure-dependent systems are not common in current designs.

A **pressure-independent system** can be constant-volume, variable-volume, or a mix of the two. It incorporates pressure-independent volume regulators with each device. The system offers two advantages: (1) flexibility to add exhaust devices without having to rebalance the entire system and (2) variable-volume control.

The volume regulators can incorporate either direct measurement of the exhaust airflow rate or positioning of a calibrated pressure-independent air valve. The input to the volume regulator can be (1) a manual or timed switch to index the fume hood airflow from minimum to operational airflow, (2) sash position sensors, (3) fume hood cabinet pressure sensors, or (4) velocity sensors. The section on Control covers this topic in greater detail. Running many exhaust devices into the manifold of a common exhaust system offers the following potential benefits:

- Lower ductwork cost
- Fewer pieces of equipment to operate and maintain
- Fewer roof penetrations and exhaust stacks
- Opportunity for energy recovery
- Centralized locations for exhaust discharge
- Ability to take advantage of exhaust system diversity
- Ability to provide a redundant exhaust system by adding one spare fan per manifold
- Higher stack momentum, which can be beneficial for exhaust dispersion

Individually Ducted Exhaust Systems. These comprise a separate duct, exhaust fan, and discharge stack for each exhaust device or laboratory. The exhaust fan can be single-speed, multiple-speed, or variable-speed and can be configured for constant volume, variable volume, or a combination of the two. Potential benefits include the following:

- Provision for installation of special exhaust filtration or treatment systems
- Customized ductwork and exhaust fan corrosion control for specific applications
- Provision for selected emergency power backup
- Simpler initial balancing
- Failure of an individual fan may affect smaller areas of the facility
- Suitability for smaller laboratories

Maintaining correct flow at each exhaust fan requires (1) periodic maintenance and balancing and (2) consideration of flow rates with the fume hood sash in different positions. One problem encountered with individually ducted exhaust systems occurs when an exhaust fan is shut down. In this case, air can be drawn in reverse flow through the exhaust ductwork into the laboratory because the laboratory is maintained at a negative pressure.

A challenge in designing independently ducted exhaust systems for multistory buildings is to provide extra vertical ductwork, extra space, and other provisions for future installation of additional exhaust devices. In multistory buildings, dedicated fire-rated shafts may be required from each floor to the penthouse or roof level. This issue should be evaluated in conjunction with requirements of the relevant fire code. As a result, individually ducted exhaust systems (or vertically manifolded systems) consume greater floor space than horizontally manifolded systems. However, less height between floors may be required.

Ductwork Leakage

Ductwork should have low leakage rates and should be tested to confirm that the specified leakage rates have been attained. Leaks from positive-pressure exhaust ductwork can contaminate the building. The design goal should be zero leakage from any positive-pressure exhaust ductwork. Designs that minimize the amount of positive-pressure ductwork are desirable. It is recommended (and required by some codes) that positive-pressure ductwork transporting potentially hazardous materials be located outside of the building; if these ducts must be inside the building, they should be of the highest possible integrity. The fan discharge should connect directly to the vertical discharge stack. Careful selection and proper installation of airtight flexible connectors at the exhaust fans are essential. Some feel that flexible connectors should be used on the exhaust fan inlet only. If flexible connectors are used on the discharge side of the exhaust fan, they must be of high quality and included on a preventative maintenance schedule, because a connector failure could result in the leakage of hazardous fumes into the equipment room. Another viewpoint contends that the discharge side of the exhaust fan should be hard connected to the ductwork, without using flexible connectors. The engineer should evaluate these details carefully. The potential for vibration and noise transmission must also be considered. Machine rooms that house exhaust fans should be ventilated to minimize exposure to exhaust effluent (e.g., leakage from the shaft openings of exhaust fans).

Containment Device Leakage

Leakage of the containment devices themselves must also be considered. For example, in vertical sash fume hoods, the clearance to allow sash movement creates an opening from the top of the fume hood into the ceiling space or area above. Air introduced through this leakage path also contributes to the exhaust airstream. The amount that such leakage sources contribute to the exhaust airflow depends on the fume hood design. Edge seals can be placed around sash tracks to minimize leaks. Although the volumetric flow of air exhausted through a fume hood is based on the actual face opening, appropriate allowances for air introduced through paths other than the face opening must be included.

Materials and Construction

The selection of materials and the construction of exhaust ductwork and fans depend on the following:

- Nature of the effluents
- Ambient temperature
- Ambient relative humidity
- Effluent temperature
- Length and arrangement of duct runs
- Constant or intermittent flow
- Flame spread and smoke developed ratings
- Duct velocities and pressures

Effluents may be classified generically as organic or inorganic chemical gases, vapors, fumes, or smoke; and qualitatively as acids, alkalis (bases), solvents, or oils. Exhaust system ducts, fans, dampers, flow sensors, and coatings are subject to (1) corrosion, which destroys metal by chemical or electrochemical action; (2) dissolution, which destroys materials such as coatings and plastics; and (3) melting, which can occur in certain plastics and coatings at elevated temperatures.

Common reagents used in laboratories include acids and bases. Common organic chemicals include acetone, ether, petroleum ether, chloroform, and acetic acid. The HVAC engineer should consult with the safety officer and scientists, because the specific research to be conducted determines the chemicals used and therefore the necessary duct material and construction.

The ambient temperature in the space housing the ductwork and fans affects the condensation of vapors in the exhaust system. Condensation contributes to the corrosion of metals, and the chemicals used in the laboratory may further accelerate corrosion.

Ducts are less subject to corrosion when runs are short and direct, flow is maintained at reasonable velocities, and condensation is avoided. Horizontal ductwork may be more susceptible to corrosion if condensate accumulates in the bottom of the duct. Applications with moist airstreams (cage washers, sterilizers, etc.) may require condensate drains. The design should include provisions to minimize joint or seam corrosion problems.

If flow through the ductwork is intermittent, condensate may remain for longer periods because it will be unable to reevaporate into the airstream. Moisture can also condense on the outside of ductwork exhausting cold environmental rooms.

Flame spread and smoke developed ratings, which are specified by codes or insurance underwriters, must also be considered when selecting duct materials. In determining the appropriate duct material and construction, the HVAC engineer should

- Determine the types of effluents (and possibly combinations) handled by the exhaust system
- Classify effluents as either organic or inorganic, and determine whether they occur in the gaseous, vapor, or liquid state
- Classify decontamination materials
- Determine the concentration of the reagents used and the temperature of the effluents at the hood exhaust port (this may be impossible in research laboratories)
- Estimate the highest possible dew point of the effluent
- Determine the ambient temperature of the space housing the exhaust system
- Estimate the degree to which condensation may occur
- Determine whether flow will be constant or intermittent (intermittent flow conditions may be improved by adding time delays to run the exhaust system long enough to dry the duct interior prior to shutdown)
- Determine whether insulation, watertight construction, or sloped and drained ductwork are required
- Select materials and construction most suited for the application

Considerations in selecting materials include resistance to chemical attack and corrosion, reaction to condensation, flame and smoke ratings, ease of installation, ease of repair or replacement, and maintenance costs.

Appropriate materials can be selected from standard references and by consulting with manufacturers of specific materials. Materials for chemical fume exhaust systems and their characteristics include the following:

Galvanized steel. Subject to acid and alkali attack, particularly at cut edges and under wet conditions; cannot be field welded without destroying galvanization; easily formed; low in cost.

Stainless steel. Subject to acid and chloride compound attack depending on nickel and chromium content of the alloy; relatively high in cost. The most common stainless steel alloys used for laboratory exhaust systems are 304L and 316L. Cost increases with increasing chromium and nickel content.

Asphaltum-coated steel. Resistant to acids; subject to solvent and oil attack; high flame and smoke rating; base metal vulnerable when exposed by coating imperfections and cut edges; cannot be field welded without destroying coating; moderate cost.

Epoxy-coated steel. Epoxy phenolic resin coatings on mild black steel or fluoropolymer coatings on stainless steel can be selected for particular characteristics and applications; they have been successfully applied for both specific and general use, but no one compound is inert or resistive to all effluents. Requires sand blasting to prepare the surface for a shop-applied coating, which should be specified as pinhole free, and field touch-up of coating imperfections or damage caused by shipment and installation; cannot be field welded without destroying coating; cost is moderate.

Plastic-coated galvanized steel. Subject to corrosion at cut edges; cannot be field welded; easily formed; moderate in cost.

Fiberglass. When additional glaze coats are used, this is particularly good for acid applications, including hydrofluoric acid. May require special fire-suppression provisions. Special attention to hanger types and spacing is needed to prevent damage.

Plastic materials. Have particular resistance to specific corrosive effluents; limitations include physical strength, flame spread and smoke developed rating, heat distortion, and high cost of fabrication. Special attention to hanger types and spacing is needed to prevent damage.

Borosilicate glass. For specialized systems with high exposure to certain chemicals such as chlorine.

3.3 FIRE SAFETY FOR VENTILATION SYSTEMS

Fire safety for ventilation systems is addressed in the different model building codes and in NFPA *Standard* 45. The HVAC designer needs to understand which codes apply based on project-specific requirements. The hazard classification of the exhaust air stream, requirements for fail-safe operation of dampers, system response on the detection of fire or smoke, appropriateness of installing fire dampers in exhaust air ductwork, and placement of fume hoods away from traffic and egress paths are some of the many factors that must be understood and addressed.

3.4 CONTROL

Laboratory controls must regulate temperature and humidity, control and monitor laboratory safety devices that protect personnel, and control and monitor secondary safety barriers used to protect the environment outside the laboratory from laboratory operations. Reliability, redundancy, accuracy, and monitoring are important factors in controlling the lab environment. Many laboratories require precise control of temperature, humidity, and airflows. Components of the control system must provide the necessary accuracy and corrosion resistance if they are exposed to corrosive environments. Laboratory controls should provide fail-safe operation, which should be defined jointly with the safety officer. A fault tree can be developed to evaluate the impact of the failure of any control system component and to ensure that safe conditions are maintained.

Thermal Control

Temperature in laboratories with a constant-volume air supply is generally regulated with a room temperature sensor and controller that positions control valve on a reheat coil in the supply air. In laboratories with a variable-volume ventilation system, room exhaust device(s) are generally regulated as well. The room exhaust device(s) are modulated to handle greater airflow in the laboratory when additional cooling is needed. The exhaust device(s) may determine the total supply air quantity for the laboratory.

Most microprocessor-based laboratory control systems can use proportional-integral-derivative (PID) algorithms to eliminate the error between the measured temperature and the temperature set point. Anticipatory control strategies increase accuracy in temperature regulation by recognizing the increased reheat requirements associated with changes in the ventilation flow rates and adjusting the position of reheat control valves before the thermostat measures space temperature changes (Marsh 1988).

Constant-Air-Volume (CAV) Versus Variable-Air-Volume (VAV) Room Airflow Control

Several factors can influence the decision of whether VAV or CAV airflow control in a laboratory is most appropriate, including required air change rates, density of exhausted containment devices, and the potential hazards related to the lab operations.

Many laboratories that are considered CAV systems are not truly constant. Even when the fume hoods operate continuously and are of the bypass type, considerable variations in airflow may occur. Variations in airflow result from

- Static pressure changes due to filter loading
- Wet or dry cooling coils
- Wear of fan belts that change fan speed
- Position of chemical fume hood sash or sashes
- Outdoor wind speed and direction
- Position of doors and windows

Current controls can achieve good conformance to the requirements of a CAV system, subject to normal deviations in control performance (i.e., the dead band characteristics of the controller and the hysteresis present in the control system). The same is true for VAV systems, although they are more complex. Systems may be either uncontrolled or controlled. An uncontrolled CAV system can be designed with no automatic controls for airflow other than two-speed fan motors to reduce flow during unoccupied periods. These systems are balanced by manual dampers and adjustable drive pulleys. They provide reasonable airflow rates relating to design values but do not provide true CAV under varying conditions, maintain constant fume hood face velocity, or maintain relative static pressures in the spaces. For laboratories that are not considered hazardous and do not have stringent safety requirements, uncontrolled CAV may be satisfactory.

For laboratories housing potentially hazardous operations (i.e., involving toxic chemicals or biological hazards), a true CAV or VAV system ensures that proper airflow and room pressure relationships are maintained at all times. A true CAV system requires volume controls on the supply and exhaust systems.

The principal advantage of using a VAV system is its ability to (1) ensure that face velocities of chemical fume hoods are maintained within a set range and (2) reduce energy use by reducing laboratory airflow. The appropriate safety officer and the users should concur with the choice of VAV or CAV with reduced airflow during unoccupied periods. Consider giving laboratory users the ability to reset VAV systems to full airflow volume in the event of a chemical spill. Education of the laboratory occupants in proper use of the system is essential. The engineer should recognize that the use of variable-volume exhaust systems may result in higher concentrations of contaminants in the exhaust airstream, which may increase corrosion, which influences the selection of materials.

Room Pressure Control

In most experimental work, the laboratory apparatus, fume hood, or biological safety cabinet is considered to be the primary method of containment. The facility is considered the secondary level of containment.

The laboratory envelope acts as the secondary containment barrier. It is important that the walls surrounding, and door openings into, the laboratory be of appropriate construction. Because maintaining an airtight seal is rarely practical, air pressure in the laboratory must be maintained slightly negative with respect to adjoining areas. Exceptions are sterile facilities or clean spaces that may need to be maintained at a positive pressure with respect to adjoining spaces. Positively pressurized spaces in which hazardous materials are used should have an anteroom or vestibule to maintain overall negative pressurization.

Proper isolation is accomplished through the air balance/pressure relationship to adjacent areas. The pressure relationship is

- Negative, for hazardous isolation of hazardous or toxic operations (dirty operations), or
- Positive, for protective isolation of precious or delicate operations (clean operations)

Common methods of room pressure control include manual balancing, direct pressure control, volumetric flow tracking, and cascade control. All methods manipulate airflow into or out of the space; however, each method measures a different variable. Regardless of the method of space pressure control, the goal is to maintain an inward flow of air through small gaps in the secondary barrier (room envelope). In critical applications, airlocks (entry vestibules) may be required to ensure that pressure relationships are maintained as personnel enter or leave the laboratory. The airlocks have an outer and inner door, with a vestibule in between, allowing personnel to enter or exit the lab without a direct, open passage between the laboratory and the adjoining space. Normal operation, by practice or through interlocks, keeps one door closed as the second door is opened. If interlocks are necessary, take care to prevent personnel from being trapped in the vestibule in a system malfunction. The airlocks also serve as a buffer space between the laboratory and adjoining spaces, allowing personal protective equipment (PPE) to be donned or doffed, and also provide a convenient location for storing lab coats and for hand wash sinks.

Direct Pressure Control. This method measures the pressure differential across the room envelope and adjusts the amount of supply air into the laboratory to maintain the required differential pressure. Challenges encountered include (1) maintaining the pressure differential when the laboratory door is open, (2) finding suitable sensor locations, (3) maintaining a well-sealed laboratory envelope, and (4) obtaining and maintaining accurate pressure sensing devices. The direct pressure control arrangement requires tightly constructed and compartmentalized facilities and may require a vestibule on entry/exit doors. Engineering parameters pertinent to envelope integrity and associated flow rates are difficult to predict.

Because direct pressure control works to maintain the pressure differential, the control system automatically reacts to transient disturbances. Entry/exit doors may need a switch to disable the control system when they are open. Pressure controls recognize and compensate for unquantified disturbances such as stack effects, infiltration, and influences of other systems in the building. Expensive, complex controls are not required, but the controls must be sensitive and reliable. In noncorrosive environments, controls can support a combination of exhaust applications, and they are insensitive to minimum duct velocity conditions. Successful pressure control provides the desired directional airflow but cannot guarantee a specific volumetric flow differential.

Factors that favor direct pressure control include the following:

- High pressurization level (>10 Pa) and very tight construction
- Complex set of relative pressurization requirements
- Slow disturbances only (e.g., stack effect, filter loading)
- Poor conditions for airflow measurement

Volumetric Flow Tracking Control. This method measures both exhaust and supply airflow and controls the amount of supply air to maintain the desired pressure differential. Volumetric control requires controlling air at each supply and exhaust point. It does not recognize or compensate for unquantified disturbances such as stack effects, infiltration, and influences of other systems in the building. Flow tracking is essentially independent of room door operation. Engineering parameters are easy to predict, and extremely tight construction is not required. Balancing is critical and must be addressed across the full operating range. The flow offset required should be greater than the accuracy of the flow measurement and associated control error. The error in offset airflow should be evaluated to ensure that the space remains under proper offset control.

Controls may be located in corrosive and contaminated environments; however, the controls may be subject to fouling, corrosive attack, and/or loss of calibration. Flow measurement controls are sensitive to minimum duct velocity conditions. Volumetric control may not guarantee directional airflow.

Factors that favor volumetric flow tracking include the following:

- Low pressurization level (usually 2 to 10 Pa), less tight construction
- Fast disturbances (e.g., VAV fume hoods)
- Simple set of relative pressurization levels (one or two levels)

Cascade Control. This method measures the pressure differential across the room envelope to reset the flow tracking differential set point. Cascade control includes the merits and shortcomings of both direct pressure control and flow tracking control; however, first cost is greater, and the control system is more complex to operate and maintain. It is used less often than the two preceding methods, but its popularity is increasing. The trend toward tighter envelope construction makes it more challenging to select effective flow offset values in pressurized suites, but using cascade control makes this selection easier.

Factors that favor cascade control include fast disturbances and a complex set of relative pressurization levels.

Fume Hood Control

Criteria for fume hood control differ depending on the type of hood. The exhaust volumetric flow is kept constant for standard, auxiliary air, and air-bypass fume hoods. In variable-volume fume hoods, exhaust flow is varied to maintain a constant face velocity. The fume hood control method should be selected in consultation with the safety officer. Regardless of control decisions, fume hoods must be equipped with an airflow indicator for the hood user.

Constant-volume fume hoods can further be split into pressure-dependent or pressure-independent systems. Although simple in configuration, the pressure-dependent system is unable to adjust the damper position in response to any fluctuation in system pressure across the exhaust damper.

Variable-volume fume hood control strategies can be grouped into two categories. The first either measures the air velocity entering a small sensor in the wall of the fume hood or determines face velocity by other techniques. The measured variable is used to infer the average face velocity based on an initial calibration. This calculated face velocity is then used to modulate the exhaust flow rate to maintain the desired face velocity.

The second category of variable-volume fume hood control measures the fume hood sash opening and computes the exhaust flow requirement by multiplying the sash opening by the face velocity set point. The controller then adjusts the exhaust device (e.g., by a variable-frequency drive on the exhaust fan or a damper) to maintain the desired exhaust flow rate. The control system may measure the exhaust flow for closed-loop control, or it may not measure exhaust flow in an open-loop control by using linear calibrated flow control dampers.

3.5 STACK HEIGHTS AND AIR INTAKES

Laboratory exhaust stacks should release effluent to the atmosphere without producing undesirable high concentrations at fresh air intakes, operable doors and windows, and locations on or near the building where access is uncontrolled. Three primary factors that influence the proper disposal of effluent gases are stack/intake separation, stack height, and stack height plus momentum (plume height). Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals* and Chapter 45 of this volume cover the criteria and formulas to calculate the effects of these physical relationships. For complex buildings or buildings with unique terrain or other obstacles to the airflow around the building, either scale model wind tunnel testing or computational fluid dynamics should be considered. However, standard *k*-ℳ computational fluid dynamics methods as applied to airflow around buildings need further development (Castro 2003; Murakami et al. 1996; Zhou and Stathopoulos 1996). HVAC system designers who do not have the analytical skills required to undertake a dispersion analysis should consider retaining a specialized consultant.

Stack/Intake Separation

Separation of the stack discharge and air intake locations allows the atmosphere to dilute the effluent. Separation is simple to calculate with the use of short to medium-height stacks; however, to achieve adequate atmospheric dilution of the effluent, greater separation than is physically possible may be required, and the building roof near the stack will be exposed to higher concentrations of the effluent. However, when stacks are much taller than the intake, the best location for the intake may be very close to the stack but this should evaluated on a case-by-case basis.

Stack Height

Chapter 45 describes a geometric method to determine the stack discharge height high enough above the turbulent zone around the building so that little or no effluent gas impinges on air intakes of the emitting building. This technique is conservative and generally requires tall stacks that may be visually unacceptable or fail to meet building code or zoning requirements. Also, this technique does not ensure acceptably low concentrations of effluents at air intakes (e.g., if there are large releases of hazardous materials or elevated intake locations on nearby buildings). A minimum stack height of 3 m is required by ASSE *Standard* Z9.5 and is recommended by Appendix A of NFPA *Standard* 45 to protect rooftop maintenance workers. However, a taller stack height may be necessary to ensure that harmful contaminants are not reentrained into nearby air intakes.

Stack Height plus Vertical Momentum

Concentrations at downwind locations are directly related to the height of the centerline of the plume. Plume height is a function of the physical stack height and plume rise (vertical momentum). To increase the plume height, increase the volumetric flow and/or the discharge velocity to increase the discharge momentum (Momentum flow = Density × Volumetric flow rate × Velocity), or increase the physical stack height. The momentum of a large vertical flow lifts the plume above the stack top, thereby potentially reducing the necessary physical height of the stack and making it easier to screen from view. This technique is particularly suitable when (1) many small exhaust streams can be clustered together or manifolded prior to the exhaust fan to provide the large volumetric flow and (2) outdoor air can be added through automatically controlled dampers to provide constant exhaust vertical momentum under variable load. The drawbacks to the second arrangement are the amount of energy consumed to achieve the constant high vertical momentum and the added complexity of the controls to maintain constant volumetric flow rates. Dilution equations in Chapter 45 can be used to predict the performance of a particular stack design, or performance can be validated through wind tunnel testing. Current numerical procedures tend to have a high degree of uncertainty, and the results should be judged accordingly.

Architectural Screens

Rooftop architectural screens around exhaust stacks are known to adversely affect exhaust dispersion. In general, air intakes should not be placed within the same screen enclosure as laboratory exhausts. Petersen et al. (1997) describe a method of adjusting dilution predictions of Chapter 45 using a stack height adjustment factor, which is essentially a function of screen porosity.

Criteria for Suitable Dilution

An example criterion based on Halitsky (1988) dictates that the release of 7.5 L/s of pure gas through any stack in a moderate wind (5 to 30 km/h), from any direction with a near-neutral atmospheric stability (Pasquill Gifford Class C or D), must not produce concentrations exceeding 3 mg/kg at any air intake. This criterion is meant to simulate an accidental release such as would occur in a spill of an evaporating liquid or after the fracture of the neck of a small lecture bottle of gas in a fume hood.

The intent of this criterion is to limit the concentration of exhausted gases at the air intake locations to levels below the odor thresholds of gases released in fume hoods, excluding highly odorous gases such as mercaptans. Laboratories that use extremely hazardous substances should conduct a chemical-specific analysis based on published health limits. A more lenient limit may be justified for laboratories with low levels of chemical usage. Project-specific requirements must be developed in consultation with the safety officer. The equations in Chapter 45 are presented in terms of dilution, defined as the ratio of stack exit concentration to receptor concentration. The exit concentration, and therefore the dilution required to meet the criterion, varies with the total volumetric flow rate of the exhaust stack. For the preceding criterion, with the emission of 7.5 L/s of a pure gas, a small stack with a total flow rate of 500 L/s will have an exit concentration of 7.5/500 or 15 000 mg/kg. A dilution of 1:5000 is needed to achieve an intake concentration of 3 mg/kg. A larger stack with a flow rate of 5000 L/s will have a lower exit concentration of 7.5/5000 or 1500 mg/kg and would need a dilution of only 1:500 to achieve the 3 mg/kg intake concentration.

The preceding criterion is preferred over a simple dilution standard because a defined release scenario (7.5 L/s) is related to a defined intake concentration (3 mg/kg) based on odor thresholds or health limits. A simple dilution requirement may not yield safe intake concentrations for a stack with a low flow rate.

Adjacent Building Effects

The influence of adjacent building effects was studied under ASHRAE research project RP-897 (Wilson et al. 1998). Several guidelines were developed from this project:

- Avoid locating stacks near the edge of a roof.
- With the emitting building upwind, an adjacent building will always have higher dilution on a lower roof than would occur on a roof at the emitting building's height. Ignoring the step-down in roof level will produce conservative designs.
- If the lower adjacent building is upwind of the emitting building, it will block flow approaching the emitting building, producing lower velocities and recirculation cavities on the emitting building roof and increasing dilution by factors of 2 to 10 on the emitting building.
- Designers should increase either the physical stack height or the vertical momentum of the exhaust when the plume will be trapped in the recirculation cavity from a high upwind adjacent building.
- When the adjacent building is higher than the emitting building, designers should try to avoid placing air intakes on the adjacent building at heights above the roof level of the emitting building.

Also see Chapter 45 for more information.

4. APPLICATIONS

4.1 LABORATORY ANIMAL FACILITIES

Laboratory animals must be housed in comfortable, clean, temperature- and humidity-controlled rooms. Animal welfare must be considered in the design; the air-conditioning system must provide the macroenvironment (for the animal room) and microenvironment (in the animal's primary enclosure or cage) specified by the facility's veterinarian (Besch 1975; ILAR 2011; Woods 1980). Early and detailed discussions with the veterinarian regarding airflow patterns, cage layout, and risk assessment help ensure a successful animal room HVAC design. The elimination of research variables (fluctuating temperature and humidity, drafts, and spread of airborne diseases) is another reason for a high-quality air-conditioning system. See Chapter 24 for additional information on environments for laboratory animals.

Primary Uses of Animal Housing Facilities

Primary uses of animal facilities include the following:

- **Acute (short-term) studies:** generally less than 90 days in length, although the animal species and particular experiments involved could affect duration. Most frequently found in pharmaceutical, medical, or other life science laboratories, and includes
  - Assays and screens
  - Immune-suppressed animals
  - Pharmacology and metabolism
  - Infectious disease
- **Chronic (long-term) studies:** generally more than 90 days in length, although the species and experiment involved could affect the length. Includes
  - Toxicology
  - Teratology
  - Neurological
  - Quality control
- **Long-term holding of animals,** including
  - Production of materials used primarily in pharmaceuticals
  - Breeding
  - Laboratory animals
  - Companion animals
  - Food and fiber animals
- **Agricultural studies,** including food and fiber animals

Regulatory Environment

There are a number of regulations and guidelines that pertain to the housing of laboratory animals. Additional regulations cover the housing of animals that may be used in some way in the production of pharmaceuticals, testing for agricultural products, or used for quality control. Pertinent regulations, as found in the United States, are outlined below. Other countries have similar regulations that should be consulted when designing animal facilities located in that country. Regulations and guidelines include the following:

- Code of Federal Regulations (CFR) 21
  - Part 58; Good Laboratory Practices for Nonclinical Laboratory Studies
  - Part 210; Current Good Manufacturing Practice in Manufacture, Processing, Packing or Holding of Human and Veterinary Drugs
- *Guide for the Care and Use of Laboratory Animals*, National Research Council
- *Biosafety in Microbiological and Biomedical Laboratories*, Centers for Disease Control (CDC).
- The Animal Welfare Act of 1966 and as subsequently amended. Regulatory authority is vested in the Secretary of the U.S. Department of Agriculture (USDA) and implemented by the USDA's Animal and Plant Health Inspection Service.
- American Association for Accreditation of Laboratory Animal Care (AAALAC), a nonprofit organization to which many institutions and corporations belong. This group provides accreditation based upon inspections and reports from member groups. Many

Table 1 Recommended Dry-Bulb Microenvironmental Temperatures for Common Laboratory Animals

Animal	Temperature, °C
Mouse, rat, hamster, gerbil, guinea pig*	20 to 26
Rabbit	16 to 22
Cat, dog, nonhuman primate	18 to 29
Farm animals and poultry	16 to 27

Source: ILAR (2011). Reprinted with permission.
* Dry-bulb room temperature settings for rodents are typically set below the animals' lower critical temperature (LCT) to avoid heat stress, and should reflect different species-specific LCT values. Animals should be provided with adequate resources for thermoregulation (nesting material, shelter) to avoid cold stress.
Note: These ranges permit scientific personnel who will use the facility to select optimum conditions (set points). The ranges do not represent acceptable fluctuation ranges.

Table 2 Heat Generated by Laboratory Animals

Species	Mass, kg	Heat Generation, W per Normally Active Animal		
		Sensible	Latent	Total
Mouse	0.021	0.325	0.158	0.484
Hamster	0.118	1.18	0.58	1.76
Rat	0.28	2.28	1.12	3.40
Guinea pig	0.41	2.99	1.47	4.45
Rabbit	2.45	11.5	5.66	17.1
Cat	3.00	13.4	6.59	20.0
Nonhuman primate	5.44	20.9	10.3	31.1
Dog	10.3	30.8	16.5	47.2
Dog	22.7	67.7	36.3	104.0

organizations that build or maintain animal facilities adhere to AAALAC programs and HVAC engineers are expected to design to their guidelines.

Local ordinances or user organization requirements may also apply. HVAC engineers should confirm which regulations are applicable for any project.

Temperature and Humidity

Due to the nature of research programs, air-conditioning design temperature and humidity control points may be required. Research animal facilities require more precise environmental control than farm animal or production facilities (as covered in Chapter 24) because variations affect the experimental results. A totally flexible system permits control of the temperature of individual rooms to within ±1 K for any set point in a range of 18 to 29°C. This flexibility requires significant capital expenditure, which can be mitigated by designing the facility for selected species and their specific requirements.

Table 1 lists dry-bulb temperatures recommended by ILAR (2011) for several common species. In the case of animals in confined spaces, the range of daily temperature fluctuations should be kept to a minimum. Relative humidity should also be controlled. ILAR (2011) suggests the acceptable range of relative humidity is 30 to 70%.

Ventilation

Providing 10 to 15 fresh air changes per hour in animal housing rooms is an acceptable guideline to maintain macroenvironmental air quality by constant-volume systems, and may also ensure microenvironmental air quality (NRC 2011). Although this range is effective in many animal housing settings, it does not take into account the range of possible heat loads; species, size, and number of animals involved; type of primary enclosure and bedding; frequency of cage changing; room dimensions; or efficiency of air distribution both in the macroenvironment and between the macro- and microenvironments. In some situations, using such a broad guideline might overventilate a macroenvironment containing few animals, thereby wasting energy, or underventilate a microenvironment containing many animals, allowing heat, moisture, and pollutants to accumulate.

VAV systems allow ventilation rates to be set in accordance with heat load and other variables. These systems offer considerable advantages in flexibility and energy conservation, but should always provide a minimum amount of air exchange, as recommended for general-use laboratories. Active sensing of contaminants in the secondary enclosure and varying the air change rates based on the room environmental conditions is one approach that can be considered to meet these requirements more energy efficiently.

For small-animal caging systems, studies suggest that room conditions have very little influence on the cage environments. ASHRAE research project RP-730 (Maghirang et al. 1995; Riskowski et al. 1996) found the following:

- No relationship between room ventilation rate and cage microenvironments for shoebox and microisolator cages exists. In fact, 5 ach provided the same cage ventilation rates for shoebox cages as did 10 and 15 ach. Memarzadeh (2000) also found this lower air change rate satisfactory.
- Diffuser type (perforated square versus radial) had only a small effect on shoebox cage ventilation rates. The radial diffuser provided higher wire cage ventilation rates.
- One high return provided the same cage ventilation rates as four high returns or as one low return.
- Room size had no effect on cage ventilation rates.

This research is further discussed in Chapter 24.

In certain types of animal rooms, usually those used for long-term studies involving high-value work or animals, the outdoor air change rate is maintained at 10 to 15 per hour, but the total airflow in the rooms ranges from 90 to 150 ach (mass flow spaces similar to clean rooms). The air supply is generally terminal HEPA filtered to reduce the potential for disease. These rooms are energy intensive, and may not be required with newer filter capability and caging systems.

The air-conditioning load and flow rate for an animal room should be determined by the following factors:

- Desired animal microenvironment (Besch 1975, 1980; ILAR 2011)
- Species of animal(s)
- Animal population
- Recommended ambient temperature (Table 1)
- Heat produced by motors on special animal housing units (e.g., laminar flow racks or HEPA-filtered air supply units for ventilated racks)
- Heat generated by the animals (Table 2)

Additional design factors include method of animal cage ventilation; operational use of a fume hood or a biological safety cabinet during procedures such as animal cage cleaning and animal examination; airborne contaminants (generated by animals, bedding, cage cleaning, and room cleaning); and institutional animal care standards (Besch 1980; ILAR 2011). Note that ambient conditions of the animal room might not reflect the actual conditions within a specific animal cage.

Animal Heat Production

Air-conditioning systems must remove the sensible and latent heat produced by laboratory animals. The literature concerning the metabolic heat production appears to be divergent, but new data are consistent. Current recommended values are given in Table 2. These values are based on experimental results and the following equation:

$$ATHG = 2.5M$$

where

ATHG = average total heat gain, W per animal

M = metabolic rate of animal, W per animal = $3.5W^{0.75}$
W = mass of animal, kg

Conditions in animal rooms must be kept constant. This may require year-round availability of refrigeration and, in some cases, dual/standby chillers and emergency electrical power for motors and control instrumentation. Storing critical spare parts is one alternative to installing a standby refrigeration system.

Design Considerations

If the entire animal facility or extensive portions of it are permanently planned for species with similar requirements, the range of individual adjustments may be reduced. Each animal room or group of rooms serving a common purpose should have separate temperature and humidity controls. The animal facility and human occupancy areas should be conditioned separately. The human areas may use a return air HVAC system and may have unoccupied mode setback on weekends for energy conservation. Separation prevents exposure of personnel to biological agents, allergens, and odors from animal rooms.

Control of air pressure in animal housing and service areas is important to ensure directional airflow. For example, quarantine, isolation, soiled equipment, and biohazard areas should be kept under negative pressure, whereas clean equipment and pathogen-free animal housing areas and research animal laboratories should be kept under positive pressure.

Supply air outlets should not cause drafts on research animals. Efficient air distribution for animal rooms is essential; this may be accomplished effectively by supplying air through ceiling outlets and exhausting air at floor level (Hessler and Moreland 1984). Supply and exhaust systems should be sized to minimize noise.

A study by Neil and Larsen (1982) showed that predesign evaluation of a full-size mock-up of the animal room and its HVAC system was a cost-effective way to select a system that distributes air to all areas of the animal-holding room. Wier (1983) describes many typical design problems and their resolutions. Evaluate room air distribution using ASHRAE *Standard* 113 procedures to evaluate drafts and temperature gradients.

HVAC ductwork and utility penetrations must be minimized and sealed. Exposed ductwork is not generally recommended; however, if constructed of 316 stainless steel, in a fashion to facilitate removal for cleaning, it can provide a cost-effective alternative. Joints around diffusers, grilles, and the like should be sealed. Exhaust air grilles with 25 mm washable or disposable filters are normally used to prevent animal hair and dander from entering the ductwork. Noise from the HVAC system and sound transmission from nearby spaces should be evaluated. Sound control methods such as separate air-handling systems or sound traps should be used as required.

Multiple-cubicle animal rooms enhance the operational flexibility of the animal room (i.e., housing multiple species in the same room, quarantine, and isolation). Each cubicle should be treated as if it were a separate animal room, with air exchange/balance, temperature, and humidity control.

Caging Systems

Animal facilities use a number of different caging systems that can significantly affect the environment within the cage or the total heat load in the room. The purpose of the caging systems is to

- Protect the health and wellbeing of the animals
- Protect support staff from antigens released or shed by the animals
- Minimize exposure of animals to pheromones released by other animals in the space

To provide the appropriate design, the HVAC engineer must be aware of the type of caging system to be used. Some common caging systems include the following:

- Cage boxes made of sheet metal, plastic, or wire mesh, with the space inside the cage open to the room so the room's macroenvironment is essentially identical to the cage's microenvironment.
- Cage boxes made primarily of plastic, with the top shielded from the room by a filter material to provide some level of isolation from the room. The filter is usually not sealed to the cage, so some open space between the room and the interior of the cage remains. Exchange of air, vapors, particulates, and gases between the room and the cage interior does occur, but the rate of exchange is reduced by the filter. The microenvironment of the interior of the cage is usually different from that of the room.
- Plastic and wire cages that are part of a cage rack assembly, which provides varying degrees of isolation from the room. These usually provide filtered (generally HEPA-filtered) air directly to each individual or shelf of cage boxes. In some cases, both a fan-powered supply and an exhaust unit are used. In other cases, cage units are connected to the facility exhaust system to provide airflow. Facilities with this kind of caging system must be designed to accommodate the heat gain in the space if the exhaust is released in the room. Some heat gain may be excluded if the caging assembly is connected directly to the facility exhaust system. When the facility is used to provide the exhaust by direct connection to the caging assembly, the design must include provisions to control the airflow to ensure that the overall proper airflow and relative static pressure of the room and each cage rack assembly is maintained, especially when caging and rack connections may be changed over time. The temperature and specific humidity in each cage will be higher than the ambient conditions of the room.

4.2 ANCILLARY SPACES FOR ANIMAL LABORATORIES

In addition to animal holding rooms, a facility intended to provide for an animal colony generally requires other areas, such as

- **Cage washer:** Usually provided with some temperature control to minimize heat stress for occupants. In addition, specific exhaust hoods and separate exhaust ductwork should be considered for the space and equipment.
- **Feed storage:** Usually provided with temperature and humidity control to protect quality and shelf life of feed.
- **Diagnostic laboratory:** Usually provided with laboratory-quality air conditioning.
- **Treatment laboratory:** Usually provided with laboratory-quality air conditioning.
- **Quarantine spaces:** To separate incoming animals from the remainder of the colony until their health can be evaluated. These rooms are frequently located near the receiving location. Animal-room-quality air conditioning is provided.
- **Surgery suite:** Sterile-quality air conditioning is provided. The suites frequently have provisions to exhaust anesthetic gases.
- **Necropsy laboratory:** Usually provided with laboratory-quality air conditioning and frequently fitted with special exhaust tables or other means of protecting laboratory workers from exposure to chemical preservatives or biological contamination. For high-risk or high-hazard work, Type III biological safety cabinets may be provided.
- **Waste-holding room:** Usually only provided with heating and ventilation, but maintained at negative pressure relative to adjacent areas. When used to store carcasses, a refrigerated storage unit of appropriate size should be provided.

4.3 CONTAINMENT LABORATORIES

With the initiation of biomedical research involving recombinant DNA technology, federal guidelines on laboratory safety were published that influence design teams, researchers, and others.

Containment describes safe methods for managing hazardous chemicals and infectious agents in laboratories. The three elements of containment are laboratory operational practices and procedures, safety equipment, and facility design. Thus, the HVAC design engineer helps decide two of the three containment elements during the design phase.

In the United States, the U.S. Department of Health and Human Services (DHHS), Centers for Disease Control and Prevention (CDC), and National Institutes of Health (NIH) classify biological laboratories into four levels (Biosafety Levels 1 to 4) listed in DHHS (1999). The USDA Agricultural Research Service (ARS) *Manual* 242.1 (ARS 2012) similarly classifies biological laboratories, and also identifies a BSL 3Ag containment level.

Biosafety Level 1

Biosafety Level 1 is suitable for work involving well-known agents not thought to consistently cause disease in healthy adult humans, and of minimal potential hazard to laboratory personnel and the environment. The laboratory is not necessarily separated from the general traffic patterns in the building. Work is generally conducted on open benchtops using standard microbiological practices. Special containment equipment is neither required nor generally used. The laboratory can be cleaned easily and contains a sink for washing hands. Federal guidelines for these laboratories contain no specific HVAC requirements.

Biosafety Level 2

Biosafety Level 2 is suitable for work involving agents of moderate potential hazard to personnel and the environment. Laboratory access is limited when certain work is in progress. The laboratory can be cleaned easily and contains a sink for washing hands. Biological safety cabinets (Class I or IIA2) are used when

- Procedures with a high potential for creating infectious aerosols are conducted. These include centrifuging, grinding, blending, vigorous shaking or mixing, sonic disruption, opening containers of infectious materials, inoculating animals intranasally, and harvesting infected tissues or fluids from animals or eggs.
- High concentrations or large volumes of infectious agents are used. Federal guidelines for these laboratories contain minimum facility standards.

At this level of biohazard, most research institutions have a full-time safety officer (or safety committee) who establishes facility standards. The federal guidelines for Biosafety Level 2 contain no specific HVAC requirements; however, typical HVAC design criteria can include the following:

- 100% outdoor air systems
- 6 to 15 air changes per hour
- Directional airflow into the laboratory rooms
- Site-specified hood face velocity at fume hoods (many institutions specify 0.4 to 0.5 m/s)
- An assessment of research equipment heat load in a room.
- Inclusion of biological safety cabinets

Most biomedical research laboratories are designed for Biosafety Level 2. However, the laboratory director must evaluate the risks and determine the correct containment level before design begins.

Biosafety Level 3

Biosafety Level 3 applies to facilities in which work is done with indigenous or exotic agents that may cause serious or potentially lethal disease as a result of exposure by inhalation. The Biosafety Level 3 laboratory uses a physical barrier of two sets of self-closing doors to separate the laboratory work area from areas with unrestricted personnel access. This barrier reinforces biological containment to within the laboratory work area.

The ventilation system must be single-pass, nonrecirculating, and configured to maintain the laboratory at a negative pressure relative to surrounding areas. Audible alarms and visual monitoring devices are recommended to notify personnel if the laboratory pressure relationship changes from negative to positive. The user may wish to have alarms reported to a remote, constantly monitored location. Gastight dampers are required in the supply and exhaust ductwork to allow decontamination of the laboratory. Ductwork between these dampers and the laboratory must also be gastight. All penetrations of the Biosafety Level 3 laboratory envelope must be sealable for containment and to facilitate gaseous decontamination of the work area.

All procedures involving the manipulation of infectious materials are conducted inside biological safety cabinets. The engineer must ensure that the connection of the cabinets to the exhaust system does not adversely affect performance of either cabinets or exhaust system. Refer to the section on Biological Safety Cabinets for further discussion.

Exhaust air from biological safety cabinets and/or the laboratory work area may require HEPA filtration. Review the need for filtration or special exhaust handling from any scientific equipment with the appropriate safety officers. If required, HEPA filters should be equipped with provisions for bag-in, bag-out filter handling systems and gastight isolation dampers for biological decontamination of the filters.

Biosafety Level 4

Biosafety Level 4 is required for work with dangerous and exotic agents that pose a high risk of aerosol-transmitted laboratory infections and life-threatening disease. HVAC systems for these areas have stringent design requirements that must be determined by the biological safety officer. Design of Level 4 laboratories requires significant specialization and understanding of best practices.

Biosafety Level 3Ag

Biosafety Level 3Ag is required for work with certain biological agents in large animal species. Using the containment features of the standard BSL 3 facility as a starting point, BSL 3Ag facilities are specifically designed to protect the environment by including almost all of the features ordinarily used for BSL 4 facilities as enhancements. All BSL 3Ag containment spaces must be designed, constructed, and certified as primary containment barriers.

4.4 SCALE-UP LABORATORIES

Scale-up laboratories are defined differently depending on the nature and volume of work being conducted. For laboratories performing recombinant DNA research, large-scale experiments generally involve vessels between 10 and 100 L or more. A chemical or biological laboratory is defined as scale-up when the principal holding vessels are glass or ceramic. When the vessels are constructed primarily of metals, the laboratory is considered a pilot plant, which this chapter does not address. The amount of experimental materials present in scale-up laboratories is generally significantly greater than the amount found in the small-scale laboratory. Experimental equipment is also larger and therefore requires more space; these may include larger chemical fume hoods or reaction cubicles that may be of the walk-in type. Significantly higher laboratory airflow rates are needed to maintain the face velocity of the chemical fume hoods or reaction cubicles, although their size frequently presents problems of airflow uniformity over the entire face area. Walk-in hoods are sometimes entered during an experimental run, so provisions for breathing-quality air stations and other forms of personnel protection should be considered. Environmental containment or the ability to decontaminate the laboratory, the laboratory exhaust airstream, or other effluent may be needed in the event of an accidental discharge. Scale-up laboratories may be in operation for sustained periods.

For large walk-in hoods or reaction cubicles, the large volume of exhaust air required and the simultaneous requirement for supply air can result in temperature gradient problems in the space.

Large hoods, similar to what sometimes are called “California hoods,” may also be provided in scale-up laboratories. These hoods are large in volume and height, provide access on multiple sides, and can be customized using standard components. Before beginning any custom hood design, the HVAC engineer, working with the user, should first determine what activities will be conducted. Then the HVAC engineer can develop a custom hood design that considers

- What access is required for setup of experimental apparatus
- How the hood is expected to function during experimental runs
- Which doors or sashes should be open during a run
- Safety and ergonomic issues
- What features should be incorporated
- Airflow required to achieve satisfactory containment

Testing and balancing criteria should also be defined early in the design process. Mockups and factory testing of prototypes should be considered to avoid problems with installed hoods.

4.5 TEACHING LABORATORIES

Laboratories in academic settings can generally be classified as either those used for instruction or those used for research. Research laboratories vary significantly depending on the work being performed; they generally fit into one of the categories of laboratories described previously.

The design requirements for teaching laboratories also vary based on their function. The designer should become familiar with the specific teaching program, so that a suitable hazard assessment can be made. For example, the requirements for the number and size of fume hoods vary greatly between undergraduate inorganic and graduate organic chemistry teaching laboratories. Unique aspects of teaching laboratories include the need of the instructor to be in visual contact with the students at their work stations and to have ready access to the controls for the fume hood operations and any safety shutoff devices and alarms. Frequently, students have not received extensive safety instruction, so easily understood controls and labeling are necessary. Because the teaching environment depends on verbal communication, sound from the building ventilation system is an important concern. See Lewis (2007) for additional considerations.

4.6 CLINICAL LABORATORIES

Clinical laboratories are found in hospitals and as stand-alone operations. Work in these laboratories generally consists of handling human specimens (blood, urine, etc.) and using chemical reagents for analysis. Some samples may be infectious; because it is impossible to know which samples may be contaminated, good work practices require that all be handled as biohazardous materials. The primary protection of the staff at clinical laboratories depends on the techniques and laboratory equipment (e.g., biological safety cabinets) used to control aerosols, spills, or other inadvertent releases of samples and reagents. People outside the laboratory must also be protected.

The building HVAC system can provide additional protection with suitable exhaust, ventilation, and filtration. The HVAC engineer is responsible for providing an HVAC system that meets the biological and chemical safety requirements. The engineer should consult with appropriate senior staff and safety professionals to ascertain what potentially hazardous chemical or biohazardous conditions will be in the facility and then provide suitable engineering controls to minimize risks to staff and the community. Appropriate laboratory staff and the design engineer should consider using biological safety cabinets, chemical fume hoods, and other specific exhaust systems.

4.7 RADIOCHEMISTRY LABORATORIES

In the United States, laboratories located in Department of Energy (DOE) facilities are governed by DOE regulations. All other laboratories using radioactive materials are governed by the Nuclear Regulatory Commission (NRC), state, and local regulations. Other agencies may be responsible for the regulation of other toxic and carcinogenic materials present in the facility. Laboratory containment equipment for nuclear processing facilities are treated as primary, secondary, or tertiary containment/confinement zones, depending on the level of radioactivity anticipated for the area and the materials to be handled. Chapter 28 has additional information on nuclear laboratories.

4.8 OPERATION AND MAINTENANCE

During long-term research studies, laboratories may need to maintain design performance conditions, with no interruptions, for long periods. Even when research needs are not so demanding, systems that maintain air balance, temperature, and humidity in laboratories must be highly reliable, with a minimal amount of downtime. The designer should work with operation and maintenance personnel, as well as users, early in the design of systems to gain their input and agreement.

System components must be of adequate quality to achieve reliable HVAC operation, and they should be reasonably accessible for maintenance. Laboratory work surfaces should be protected from possible leakage of coils, pipes, and humidifiers. Changeout of supply and exhaust filters should require minimum downtime.

Centralized monitoring of laboratory variables (e.g., pressure differentials, face velocity of fume hoods, supply flows, and exhaust flows) is useful for predictive maintenance of equipment and for ensuring safe conditions. For their safety, laboratory users should be instructed in the proper use of laboratory fume hoods, safety cabinets, ventilated enclosures, and local ventilation devices. They should be trained to understand the operation of the devices and the indicators and alarms that show whether they are safe to operate. Users should request periodic testing of the devices to ensure that they and the connected ventilation systems are operating properly.

Personnel who know the particular nature of the contaminants in a given laboratory should be responsible for decontamination of equipment and ductwork before they are turned over to maintenance personnel for work.

Maintenance personnel should be trained to keep laboratory systems in good operating order and should understand the critical safety requirements of those systems. Schedule preventive maintenance of equipment and periodic checks of air balance. High-maintenance items should be placed outside the actual laboratory (in service corridors or interstitial space) to reduce disruption of laboratory operations and exposure of the maintenance staff to laboratory hazards. Maintenance personnel must be aware of and trained in procedures for maintaining good indoor air quality (IAQ) in laboratories. Many IAQ problems have been traced to poor maintenance due to poor accessibility (Woods et al. 1987).

4.9 ENERGY

Because of the nature of the functions they support, laboratory HVAC systems consume large amounts of energy (high flow rates; high static pressure filtration; critical cooling, heating, and humidification). Efforts to reduce energy use must not compromise standards established by safety officers. Typically, HVAC systems supporting laboratories and animal areas use 100% outdoor air and operate continuously. All HVAC systems serving laboratories can benefit from energy reduction techniques that are either an integral part of the original design or added later. Energy reduction techniques should be analyzed in terms of both appropriateness to the facility and economic payback.

Energy-efficient design is an iterative process that begins with establishing communication among all members of the design team. Each design discipline has an effect on the energy load. On a macro scale, air change rate, building orientation, window shading devices, and high-performance envelopes offer opportunity for energy use reduction. On a micro scale, for example, the choice of a lighting system can affect sensible heat gain. Energy-efficient designs should recognize the variability of exhaust, envelope, and equipment loads and use systems that respond appropriately and perform efficiently during partial-load conditions.

The HVAC engineer must understand and respond to the scientific requirements of the facility. Research requirements typically include continuous control of temperature, humidity, relative static pressure, and air quality. Energy reduction systems must maintain required environmental conditions during both occupied and unoccupied modes.

Energy Efficiency

Energy can be used more efficiently in laboratories by reducing exhaust air requirements. One way to achieve this is to use variable-volume control of exhaust air through the fume hoods to reduce exhaust airflow when the fume hood sash is not fully open. Recent changes in ASSE *Standard* Z9.5 allow a much lower fume hood minimum flow rate with variable-volume hoods, depending on system design and aspects of laboratory operations. Any airflow control must be integrated with the laboratory control system, described in the section on Control, and its setting and operation must not jeopardize the safety and function of the laboratory.

Fume hood selection also affects exhaust airflow requirements and energy consumption. Modern fume hood designs use several techniques to reduce airflow requirements, including reduced-face-opening sashes and specially designed components that allow operation with reduced inflow velocities. These reduced-face-opening sash hoods or low-capture-velocity hoods may reduce overall airflow requirements to the degree that additional variable-volume controls may not be justifiable. When considering these features, it is important to obtain approval of laboratory occupants and safety personnel.

Energy efficiency in laboratories and other buildings depends on many examples of dynamically adjusting consumption to match changing needs, rather than simply running systems at constant output. Laboratory ventilation is part of this trend.

Ventilation designers and safety professionals attempt to take scientific, quantitative approach to setting airflow levels, but they face many unknown factors. They are forced to make assumptions and exercise judgment. This leads to conservatively selected ventilation rates. **Dynamic ventilation** eliminates some of the uncertainty by using real-time information, making it possible to lower ventilation rates without sacrificing a conservative approach. It is not necessary to set one constant ventilation rate, based only on information available at design time: a range of rates can be selected, with the specific value determined according to information gained in operation (e.g., presence or absence of lab workers [ventilation setback], or measured concentration of selected contaminants in the room air [demand-controlled ventilation]; these two example strategies are completely complementary, and can deliver benefits when used together or separately).

Reducing ventilation requirements in laboratories and vivariums based on real-time sensing of contaminants in the room environment offers opportunities for energy conservation. This approach can potentially safely reduce lab air change rates to as low as 2 ach when the lab air is clean and the fume hood exhaust or room cooling load requirements do not require higher airflow rates. Sharp (2010) showed that lab rooms are on average clean of contaminants about 98% of the time. With fixed ventilation rates, engineers are forced to design for the 2% of the time when high flow is needed; dynamic ventilation takes advantage of the 98% of the time that it is not.

Using a reduced ventilation rate when the laboratory is unoccupied can save significant amounts of energy. The savings potential that justifies a ventilation setback depends on the amount that the ventilation can be reduced and the amount of reliably unoccupied operating time. To use it properly, ventilation designers need to confirm that premise applies: that is, when the workers cease their activities and leave the laboratory, the contamination hazard is significantly reduced.

The following design steps should be considered when designing unoccupied setback ventilation systems:

- Determine whether the unoccupied period presents an opportunity to reduce ventilation. This depends on how the lab is used and its condition at the end of the day. The designer should work with the responsible health and safety professional and the lab users to establish that their work practices lead to reduced hazard when the room is unoccupied. Lab processes that continue unattended or erratic occupancy patterns may eliminate the opportunity.
- When using an unoccupied setback approach, select the minimum flow rates that apply during occupied and unoccupied periods. This step still requires making assumptions. Combining contaminant sensing with setback can allow lower values for both periods.
- A trigger approach also needs to be selected to inform the control system when to switch between occupied and unoccupied settings. This is a common BAS function implemented in many familiar ways: schedules, occupancy sensors, or manual switches. It is important to select the trigger or combination of triggers that work effectively for the space.
- Consider an indicator for users so that anyone in the room or entering the room knows that the ventilation system is in the correct mode. Train workers on the meaning of the airflow indicator and the procedure to follow if the wrong mode is indicated.
- Consider connecting room HVAC operation with access control to reduce the chance of low ventilation rates when a worker is present.
- Consider coordinating HVAC operation with lighting controls and temperature setback to maximize the value of occupancy-sensing components.

Laboratory exhaust systems often use constant-speed fans to discharge exhaust air at a constant velocity to prevent cross contamination with supply air intakes. Alternative approaches to reduce the considerable energy consumption of exhaust fans include using taller stacks, and real-time reduction of exhaust exit velocity based on sensing either wind direction, velocity, or reduced contaminant levels in the exhaust fan plenum.

Room cooling approaches, such as hydronic cooling using local fan-coil units or noncondensing, chilled radiant ceiling panels, passive chilled beams, or active chilled beams offer opportunities for energy conservation. These approaches decouple the room cooling function from the ventilation air requirements, potentially reducing outdoor air needs, overall HVAC capacity, and reheat energy. Less energy is needed to pump chilled water than to provide the equivalent amount of airflow required for a given level of cooling. Note that some form of dew-point sensing and possibly condensation monitoring is recommended (Rumsey and Weale 2007) for noncondensing hydronic cooling approaches. Chapter 5 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* and Chapter 47 of this volume offer more information on controlling chilled beams.

Often, offices spaces have recirculating air-handling systems, and laboratory spaces have separate 100% outdoor-air-handling systems. Significant energy savings can be achieved by using combined air-handling systems to serve both offices and laboratories: air supplied to offices can be recirculated, and air supplied to the laboratory spaces exhausted. This approach, on both a peak and annual basis, reduces the amount of outdoor air that must be processed and the associated heating and cooling energy.

Energy Recovery

Energy can often be recovered economically from the exhaust airstream in laboratory buildings with large quantities of exhaust air. Many energy recovery systems are available, including rotary air-to-air energy exchangers or heat wheels, coil energy recovery loops (runaround cycle), twin tower enthalpy recovery loops, heat pipe heat exchangers, fixed-plate heat exchangers, and thermosiphon heat exchangers, many of which can be coupled with direct evaporative cooling. Some of these technologies can be combined with indirect evaporative cooling for further energy recovery. See Chapters 26 and 41 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information.

Concerns about using energy recovery devices in laboratory HVAC systems include (1) the potential for cross-contamination of chemical and biological materials from exhaust air to the intake airstream, and (2) the potential for corrosion and fouling of devices located in the exhaust airstream. It is important to understand the potential hazard of the exhaust air stream and to select the style and materials of the energy recovery equipment appropriately.

Energy recovery is also possible for hydronic systems associated with HVAC. Rejected heat from centrifugal chillers can be used to produce low-temperature reheat water. Potential also exists in plumbing systems, where waste heat from washing operations can be recovered to heat makeup water.

Sustainable Design

Laboratories present unique challenges and opportunities for energy efficiency and sustainable design. Laboratory systems are complex, use significant energy, have health and life safety implications, need long-term flexibility and adaptability, and handle potentially hazardous effluent with associated environmental impacts. Therefore, before implementing energy-efficiency and sustainable-design protocols, the engineer must be aware of the effects of these measures on the laboratory processes, which affect the safety of the staff, environment, and scientific procedures.

Several laboratory facilities have achieved high recognition for energy efficiency and sustainable design. Sustainable design features specific to laboratory facilities include all aspects of design, construction, and operations. These features include (1) managing air and water effluent on the site; (2) reducing water used by laboratory processes; (3) rightsizing equipment and improving its energy efficiency; (4) hazardous material handling; (5) ventilation system enhancements, including modeling airflow patterns, fume hood testing, and additional safety alarming; and (6) laboratory-specific opportunities for innovation.

4.10 COMMISSIONING

In addition to HVAC systems, electrical systems and chemical handling and storage areas should be commissioned. Training of technicians, scientists, and maintenance personnel is a critical aspect of the commissioning process. Users should understand the systems and their operation.

It should be determined early in the design process whether any laboratory systems must comply with Food and Drug Administration (FDA) regulations because these systems have additional design, commissioning, and potential validation requirements. Commissioning is defined in Chapter 43; the process is outlined in ASHRAE *Guidelines* 0 and 1.1, and further defined in ANSI/ASHRAE/IES *Standard* 202. Laboratory commissioning can be more demanding than that described in ASHRAE guidelines and includes systems that are not associated with other occupancies. Requirements for commissioning should be clearly understood by all participants, including the contractors and the owner's personnel. Roles and responsibilities should be defined, and responsibilities for documenting results should be established.

Laboratory commissioning starts with the intended use of the laboratory, as described in the owner's project requirements (OPR), and should include development of a commissioning plan, as outlined in the ASHRAE guidelines. The start-up and prefunctional testing of individual components should come first; after individual components are successfully tested, the entire system should be functionally tested. This requires verification and documentation that the design meets applicable codes and standards and that it has been constructed in accordance with the design intent and owner's project requirements. Most facilities require integrated systems testing to verify that the HVAC system is properly coordinated with other systems, such as fire alarm or emergency power systems. Before general commissioning begins, obtain the following data:

- Owner's project requirements
- Basis of design (BOD) that includes the intent of system operation
- Definition of the use of the laboratory and an understanding of the work being performed
- Complete set of the laboratory utility drawings
- Equipment requirements
- All start-up and prefunctional test results

For HVAC and associated integrated system commissioning, the following should be verified and documented:

- Manufacturer's requirements for airflow for biological safety cabinets and laminar flow clean benches have been met.
- Exhaust system configuration, damper locations, and performance characteristics, including any required emission equipment, are correct.
- Approved test and balance report.
- Control system operates as specified. Controls include fume hood alarm; miscellaneous safety alarm systems; fume hood and other exhaust airflow regulation; laboratory pressurization control system; laboratory temperature control system; and main ventilation unit controls for supply, exhaust, and heat recovery systems. Control system performance verification should include speed of response, accuracy, repeatability, turndown, and stability.
- Desired laboratory pressurization relationships are maintained throughout the laboratory, including entrances, adjoining areas, air locks, interior rooms, and hallways. Balancing terminal devices within 10% of design requirements will not provide adequate results. Additionally, internal pressure relationships can be affected by airflow around the building. See Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals* for more information.
- Fume hood containment performance is within specification. ASHRAE *Standard* 110 provides criteria for this evaluation.
- Dynamic response of the laboratory's control system is satisfactory. One method of testing the control system is to open and shut laboratory doors during fume hood performance testing.
- System fault tree and failure modes are as specified, including life safety fan system shutdown impact on proper provisions for egress from the building within allowable limits of door-opening force requirements
- Standby electrical power systems function properly.
- Design noise criterion (NC) levels of occupied spaces have been met.

Training of facilities staff and laboratory occupants should also be considered part of the commissioning and design process. Training should address both the operation of individual system components and the overall system.

4.11 ECONOMICS

In laboratories, HVAC systems make up a significant part (often 30 to 50%) of the overall construction budget. The design criteria and system requirements must be reconciled with the budget allotment for HVAC early in the planning stages and continually throughout the design stages to ensure that the project remains within budget.

Every project must be evaluated on both its technical features and its economics. The following common economic terms are discussed in Chapter 37 and defined here as follows:

Initial cost: Costs to design, install, and test an HVAC system such that it is fully operational and suitable for use.

Operating cost: Cost to operate a system (including energy, maintenance, and component replacements) such that the total system can function until the end of its normal useful life.

Life-cycle cost: Cost related to the total cost over the life of the HVAC system, including initial capital cost, considering the time value of money.

Mechanical and electrical costs related to HVAC systems are commonly assigned a depreciation life based on current tax policies. This depreciation life may be different from the projected functional life of the equipment, which is influenced by the quality of the system components and of the maintenance they receive. Some parts of the system, such as ductwork, could last the full life of the building. Other components, such as air-handling units, may have a useful life of 15 to 30 years, depending on their original quality and ongoing maintenance efforts. Estimated service life of equipment is listed in Chapter 37.

Engineering economics can be used to evaluate life-cycle costs of configuration (utility corridor versus interstitial space), systems, and major equipment. The user or owner makes a business decision concerning the quality and reliability of the system and its ongoing operating costs. The HVAC engineer may be asked to provide an objective analysis of energy, maintenance, and construction costs, so that an appropriate life-cycle cost analysis can be made. Other considerations that may be appropriate include economic influences related to the long-term use of energy and governmental laws and regulations.

Many technical considerations and the great variety of equipment available influence the design of HVAC systems. Factors affecting design must be well understood to ensure appropriate comparisons between various systems and to determine the impact on either first or operating costs.

Gas-Turbine Test Cells 18.3
Chassis Dynamometer Rooms 18.3
Ventilation 18.4
Combustion Air Supply 18.4
Cooling Water Systems 18.4
Noise 18.4

INDUSTRIAL testing of turbines and internal combustion engines is performed in enclosed test spaces to control noise and isolate the test for safety or security. These spaces are ventilated or conditioned to control the facility environment and fumes. Isolated engines are tested in test cells; engines inside automobiles are tested on chassis dynamometers. The ventilation and safety principles for test cells also apply when large open areas in the plant are used for production testing and emissions measurements.

Enclosed test cells are normally found in research or emissions test facilities. Test cells may require instruments to measure cooling system water flow and temperature; exhaust gas flow, temperature, and emission concentrations; fuel flow; power output; and combustion air volume and temperature. Changes in the temperature and humidity of the test cell affect these measurements. Accurate control of the testing environment is becoming more critical. For example, the U.S. Environmental Protection Agency requires tests to demonstrate control of automobile contaminants in both hot and cold environments.

Air conditioning and ventilation of test cells must (1) supply and exhaust proper quantities of air to remove heat and control temperature; (2) exhaust sufficient air at proper locations to prevent buildup of combustible vapors; (3) supply and modulate large quantities of air to meet changing conditions; (4) remove exhaust fumes; (5) supply combustion air; (6) prevent noise transmission through the system; (7) provide for human comfort and safety during setup, testing, and tear-down; and (8) treat the exhaust effluent. Supply and exhaust systems for test cells may be unitary, central, or a combination of the two. Mechanical exhaust is necessary in all cases.

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

1. ENGINE HEAT RELEASE

The special air-conditioning requirements of an engine test facility stem from burning the fuel used to run the engine. For internal combustion engines at full load, 10% of the total heat content of the fuel is radiated and convected into the room or test cell atmosphere, and 90% is fairly evenly divided between the shaft output (work), exhaust gas heating, and heating of the jacket cooling water.

Air-cooled engines create a forced convection load on the test space equal to the jacket water heat that it replaces. For turbine engines, the exhaust gas carries double the heat of the internal combustion engine exhaust and there is no jacket water to heat. The engine manufacturer can provide a more precise analysis of heat release characteristics at various speeds and power outputs.

Test facilities use dynamometers to determine the power supplied by the engine shaft. The dynamometer converts shaft work into heat that must be accounted for by a cooling system or as heat load into the space. Often, shaft work is converted into electricity through a generator and the electric power is dissipated by a resistance load bank or sold to the local utility. Inefficiencies of the various pieces of equipment add to the load of the space in which they are located.

Heat released into the jacket water must also be removed. If a closely connected radiator is used, the heat load is added to the room load. Many test facilities include a heat exchanger, and a secondary cooling circuit transfers the heat to a cooling tower. Some engines require an oil cooler separate from the jacket water. Whichever system is used, the cooling water flow, temperature, and pressure are usually monitored as part of the test operation, and heat from these sources needs to be accommodated by the facility's air conditioning.

Exhaust systems present several challenges to engine test cell design. Exhaust gases can exit the engine at 800°C or higher. Commonly, the exhaust gas is augmented by inserting the exhaust pipe into a larger-bore exhaust system (laboratory fixed system), which draws room air into the exhaust to both cool the gas and ventilate the test cell. Both the exhausted room air and combustion air must be supplied to the room from the HVAC or from the outdoors.

Radiation and convection from exhaust pipes, catalytic converter, muffler, etc., also add to the load. In most cases, the test cell's HVAC system should account for an engine that can fully load the dynamometer, and have capacity control for operation at partial and no load.

Large gas turbine engines have unique noise and airflow requirements; therefore, they usually are provided with dedicated test cells. Small gas turbines can often be tested in a regular engine test cell with minor modifications.

2. ENGINE EXHAUST

Engine exhaust systems remove combustible products, unburned fuel vapors, and water vapor. Flow loads and operating pressure need to be established for design of the supporting HVAC.

Flow loads are calculated based on the number of engines, the engine sizes and loads, and use factors or diversity.

Operating pressure is the engine discharge pressure at the connection to the exhaust. Systems may operate at positive pressure using available engine tail-pipe pressure to force the flow of gas, or at negative pressure with mechanically induced flow.

The simplest way to induce engine exhaust from a test cell is to size the exhaust pipe to minimize variations in pressure on the engine and to connect it directly outdoors (Figure 1A). Exhausts directly connected to the outdoor are subject to wind currents and air pressure, however, and can be hazardous because of positive pressure in the system.

Mechanical engine exhausts are either unitary or central. A **unitary exhaust** (Figure 1B) serves only one test cell, and can be closely regulated to match the engine's operation. A **central exhaust** (Figure 1D) serves multiple test cells with one or more exhaust fans and a

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

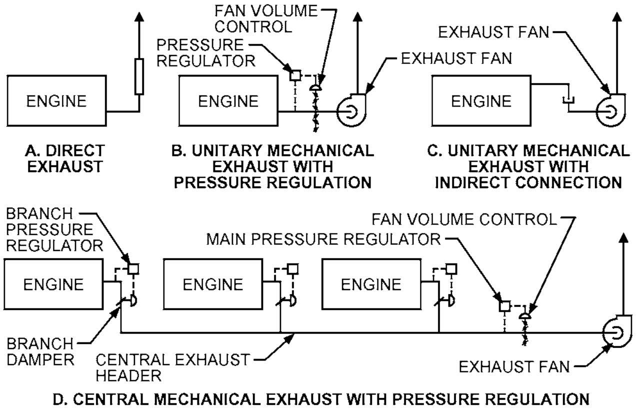

Fig. 1 Engine Exhaust Systems

duct system with branch connections to the individual test cells. Relief of a possible explosion in the ductwork should be considered.

Engine exhaust pressures fluctuate with changes in engine load and speed. Central exhausts should be designed to minimize effects of load variations in individual test cells on the system. Engine characteristics and diversity of operation determine the maximum airflow to be handled. Dampers and pressure regulators may be required to keep pressures within test tolerances.

An indirect connection between the engine exhaust pipe and mechanical exhaust gas removal (Figure 1C) eliminates variation in back pressure and augments exhaust gas flow by inducing room air into the exhaust stream. In this system, the engine exhaust pipe terminates by being centered and inserted about 75 mm into the augmentation pipe, which is at least 25 mm larger in diameter. The induced room air is mixed with the exhaust gases, yielding a much cooler exhaust flow. However, the potential for increased corrosion in a cooler exhaust must be considered when selecting construction materials. The engine muffler should be located upstream of the augmentation connection to control noise. The indirect connection should be considered a potential point of ignition if the exhaust is fuel rich and the tail pipe reaches temperatures above 370°C.

Exhaust pipes and mufflers run very hot. A ventilated heat shield or a water-jacketed pipe reduces cell heat load, and some exhausts are equipped with direct water injection. Thermal expansion, stress, and pressure fluctuations must also be considered in the design of the exhaust fan and ducting. The equipment must be adequately supported and anchored to relieve the thermal expansion.

Exhaust systems for chassis dynamometer installations must capture high-velocity exhaust from the tail pipe to prevent fume buildup in the room. An exhaust flow rate of 330 L/s has been used effectively for automobiles at a simulated speed of 100 km/h.

Engine exhaust should discharge through a stack extending above the roof to an elevation sufficient to allow the fumes to clear the building. Chapter 46 has further details about exhaust stacks. Codes or air emission standards may require that exhaust gases be cleaned before being discharged to atmosphere.

3. INTERNAL COMBUSTION ENGINE TEST CELLS

Test Cell Exhaust

Ventilation for test cells is based on exhaust requirements for (1) removal of heat generated by the engine, (2) emergency purging (removal of fumes after a fuel spill), and (3) continuous cell scavenging during nonoperating periods. Heat is transferred to the test cell by convection and radiation from all of the heated surfaces, such as the engine and exhaust system. At a standard air density of $\rho = 1.2$ kg/m^3 and specific heat $c_p = 1.0$ kJ/(kg·K),

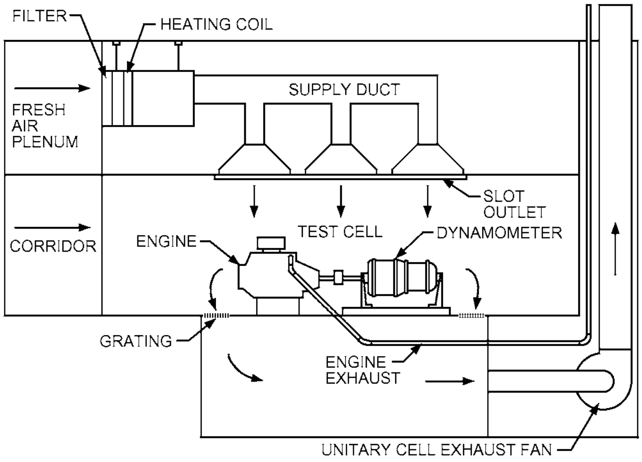

Fig. 2 Engine Test Cell Showing Direct Engine Exhaust: Unitary Ventilation System

$$Q = \frac{q}{\rho c_p (t_e - t_s)} = \frac{q}{1.2(t_e - t_s)}$$

where

Q = airflow, m^3/s
q = engine heat release, kW
t_e = temperature of exhaust air, °C
t_s = temperature of supply air, °C

The constant (1.2) should be corrected for other temperatures and pressures.

Heat radiated from the engine, dynamometer, and exhaust piping warms surrounding surfaces, which release heat to the air by convection. The value for $(t_e - t_s)$ in the equation cannot be arbitrarily set when a portion of q is radiated heat. The section on Engine Heat Release discusses other factors required to determine the overall q.

Vapor Removal. The exhaust should remove vapors as quickly as possible. Emergency purging, often 50 L/s per square metre of floor area, should be controlled by a manual overriding switch for each test cell. In case of fire, provisions need to be made to shut down all equipment, close fire dampers at all openings, and shut off the fuel-flow solenoid valves.

Cell Scavenging. Exhaust air is the minimum amount of air required to keep combustible vapors from fuel leaks from accumulating. In general, the NFPA *Standard* 30 requirement of 5 L/s per square metre of floor area is sufficient. Because gasoline vapors are heavier than air, exhaust grilles should be low, even when an overhead duct is used. Exhausting close to the engine minimizes the convective heat that escapes into the cell.

In some installations, all air is exhausted through a floor grating surrounding the engine bed plate and into a cubicle or duct below. In this arrangement, slots in the ceiling over the engine supply a curtain of air to remove the heat. This scheme is particularly suitable for a central exhaust (Figure 2). Water sprays in the underfloor exhaust lessen the danger of fire or explosion in case of fuel spills.

Trenches and pits should be avoided in test cells. If they exist, as in most chassis dynamometer rooms, they should be mechanically exhausted at all times. Long trenches may require multiple exhaust takeoffs. The exhaust should sweep the entire area, leaving no dead air spaces. Because of fuel spills and vapor accumulation, suspended ceilings or basements should not be located directly below the engine test cell. If such spaces exist, they should be ventilated continuously and have no fuel lines running through them. Detection of

Table 1 Exhaust Quantities for Test Cells

	Minimum Exhaust Rates per Square Metre of Floor Area	
	L/s	ach[a]
Engine testing: cell operating	50	60[b]
Cell idle	5	6
Trenches[c] and pits	50	—
Accessory testing	20	24
Control rooms and corridors	5	6

[a] Air changes per hour, based on cell height of 3 m.
[b] For chassis dynamometer rooms, this quantity is usually set by test requirements.
[c] For large trenches, use 0.5 m/s across the cross-sectional area of the trench.

exhaust in the test cell should be considered (per ACGIH) for a time-weighted average (TWA) of 25 mg/kg.

Table 1 lists exhaust quantities used in current practice; the exhaust should be calculated for each test cell on the basis of heat to be removed, evaporation of possible fuel spills, and the minimum ventilation needed during downtime.

4. TEST CELL SUPPLY

The air supply to a test cell should be balanced to yield a slightly negative pressure This is accomplished by having either an exhaust airflow 10% greater than the supply air or a differential pressure of the test cell at least 12.5 Pa less than the surrounding space. Test cell air should not be recirculated. Air taken from nontest areas can be used if good ventilation practices are followed, such as using air that is free of unacceptable contaminants, is sufficient for temperature control, and can maintain the proper test cell pressure.

Ventilation air should keep heat released from the engine away from cell occupants. Slot outlets with automatic dampers to maintain a constant discharge velocity have been used with variable-volume systems.

A variation of systems C and D in Figure 3 includes a separate air supply sized for the minimum (downtime) ventilation rate and for a cooling coil with room thermostat to regulate the coil to control the temperature in the cell. This system is useful in installations where much time is devoted to the setup and preparation of tests, or where constant temperature is required for complicated or sensitive instrumentation. Except for production and endurance testing, the actual engine operating time in test cells may be surprisingly low. The average test cell is used approximately 15 to 20% of the time.

Air should be filtered to remove particulates and insects. The degree of filtration is dictated by the type of tests. Facilities in relatively unpolluted areas sometimes use unfiltered outdoor air.

Heating coils are needed to temper supply air if there is danger of freezing equipment or if low temperatures adversely affect tests. For low-temperature applications, a desiccant wheel with pre- and post-cooling may be needed (with qualified environmentally safe refrigerants). If desiccant wheels are used, consider placing the fan in a self-contained unit outside of the air stream with nonsparking components, to reduce the risk of ignition source from the fan if the airstream could contain combustible components.

5. GAS-TURBINE TEST CELLS

Large gas-turbine test cells must handle large quantities of air required by the turbine, attenuate the noise generated, and operate safely with a large flow of fuel. These cells are unitary and use the turbine to draw in untreated air and exhaust it through noise attenuators.

Small gas turbine engines can generally be tested in a conventional test cell with relatively minor modifications. The test-cell ventilation air supply and exhausts are sized for turbine-generated heat as for a conventional engine. The combustion air supply for the turbine is

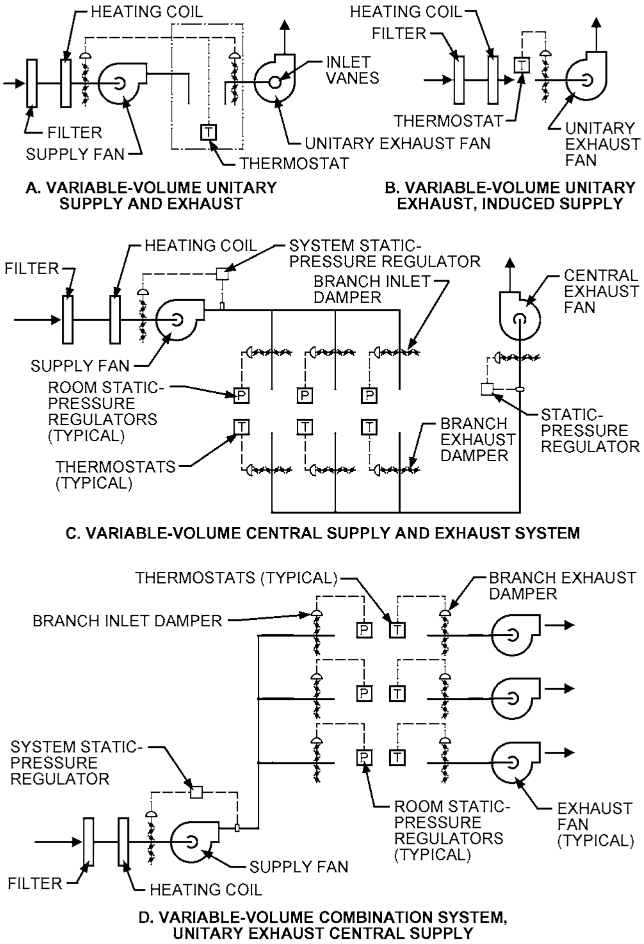

Fig. 3 Heat Removal Ventilation Systems

considerable; it may be drawn from the cell, from outdoors, or through separate conditioning units that handle only combustion air.

Exhaust quantities are higher than from internal combustion engines and are usually ducted directly to the outdoors through muffling devices that provide little restriction to airflow. Exhaust air may be water-cooled, as temperature may exceed 700°C.

6. CHASSIS DYNAMOMETER ROOMS

A chassis dynamometer (Figure 4) simulates road driving and acceleration conditions. The vehicle's drive wheels rest on a large roll, which drives the dynamometer. Air quantities, which are calibrated to correspond to air velocity at a particular road speed, flow across the front of the vehicle for radiator cooling and to approximate the effects of air speed on the body of the vehicle. Additional refinements may vary air temperature within prescribed limits from –40 to 55°C, control relative humidity, and/or add shakers to simulate road conditions. Air is usually introduced through an area approximating the frontal area of the vehicle. A duct with a return grille at the rear of the vehicle may be lowered so that air remains near the floor rather than cycling through a ceiling return air grille. Air is recirculated to air-handling equipment above the ceiling.

Chassis dynamometers are also installed in

- Cold rooms, where temperatures may be as low as –70°C.
- Altitude chambers, where elevations up to 3700 m can be simulated.
- Noise chambers for sound evaluation.
- Electromagnetic cells for evaluation of electrical components.

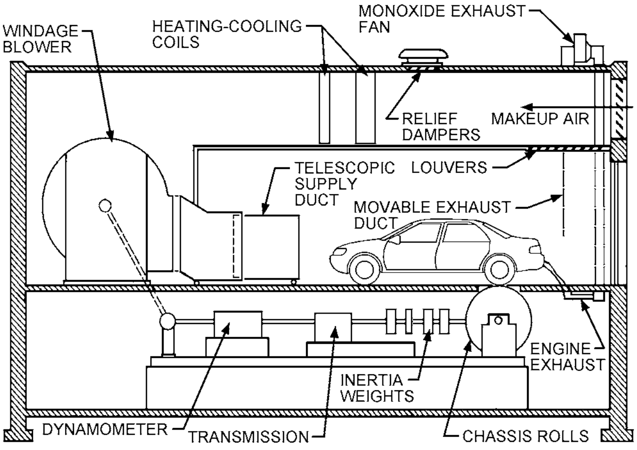

Fig. 4 Chassis Dynamometer Room

- Environmental chambers.
- Full-sized wind tunnels with throat areas much larger than the cross-sectional area of the vehicle. Combustion air is drawn directly from the room, but the engine exhaust must be installed in a way that will preserve the low temperature and humidity.

Where ultralow-temperature refrigeration is required for a cold room, direct cooling with toxic refrigerants is not recommended. Consider secondary cooling loops using safe low-temperature heat transfer fluids (LTHTFs) that, if released into the atmosphere of the cold test cell, do not present a significant health risk to occupants or require mitigation resources.

A temperature soak space is often placed near chassis dynamometer rooms having a controlled temperature. This space is used to cool or heat automobiles scheduled to enter the room. Generally, 18 to 24 h is required before the temperature of the vehicle stabilizes to the temperature of the room. The soak space and the temperature-controlled room are often isolated from the rest of the facility, with entry and egress through an air lock.

7. VENTILATION

Constant-volume systems with variable supply temperatures can be used; however, variable-volume, variable-temperature systems are usually selected. Ventilation is generally controlled on the exhaust side (see Figure 3). Unitary variable-volume systems (Figure 3A) use an individual exhaust fan and makeup air supply for each cell. Supply and exhaust fans are interlocked, and their operation is coordinated with the engine, usually by sensing the temperature of the cell. Some systems have exhaust only, with supply induced directly from outdoors (Figure 3B). The volume is varied by changing fan speed or damper position.

Ventilation with central supply fans, central exhaust fans, or both (Figure 3C) regulates air quantities by test cell temperature control of individual dampers or by two-position switches actuated by dynamometer operations. Air balance is maintained by static pressure regulation in the cell. Constant pressure in the supply duct is obtained by controlling supply fan inlet vanes, modulating dampers, or varying fan speed.

In systems with individual exhaust fans and central supply air, exhaust is controlled by cell temperature or a two-position switch actuated by dynamometer operation. The central supply system is controlled by a static pressure device in the cell to maintain room pressure (Figure 3D). Variable-volume exhaust airflow should not drop below minimum requirements. Exhaust requirements should override cell temperature requirements; thus, reheat may be needed.

Table 2 Typical Noise Levels in Test Cells

	Sound Level 0.9 m from Engine, dBA			
Type and Size of Engine	63 Hz	124 Hz	500 Hz	2000 Hz
Diesel				
Full load	105	107	98	99
Part load	70	84	56	49
Gasoline engine, 7.2 L at 5000 rpm				
Full load	107	108	104	104
Part load	75	—	—	—
Rotary engine, 75 kW				
Full load	90	90	83.5	86
Part load	79	78	75	72

Ventilation should be interlocked with fire protection to shut down the supply to and exhaust from the cell in case of fire. Exhaust fans should be nonsparking, and makeup air should be tempered.

8. COMBUSTION AIR SUPPLY

Combustion air is usually drawn from the test cell or introduced directly from the outdoors. Separate dedicated units can be used if combustion air must be closely regulated and conditioning of the entire test cell is impractical. These units filter, heat, and cool the supply air and regulate its humidity and pressure; they usually provide air directly to the engine air intake. Combustion air systems may be central units or portable packaged units.

9. COOLING WATER SYSTEMS

Dynamometers absorb and measure the useful output of an engine or its components. In a water-cooled dynamometer, engine work is converted to heat, which is absorbed by circulating water. Electrical dynamometers convert engine work to electrical energy, which can be used or dissipated as heat in resistance grids or load banks or sold to the local utility. Grids should be located outdoors or adequately ventilated.

Heat loss from electric dynamometers is approximately 8% of the measured output, plus a constant load of about 5 kW for auxiliaries in the cell. Recirculating water absorbs heat from the engine jacket water, oil coolers, and water cooled dynamometers through circulating pumps, cooling towers, or atmospheric coolers and hot- and cold-well collecting tanks.

10. NOISE

Noise generated by internal combustion engines and gas turbines must be considered in the design of a test cell air-handling system. Part of the engine noise is discharged through the tail pipe. If possible, internal mufflers should be installed to attenuate this noise at its source. Any ventilation ducts or pipe trenches that penetrate the cells must be insulated against sound transmission to other areas or to the outdoors. Attenuation equivalent to that provided by the cell structure should be applied to duct penetrations. Table 2 lists typical noise levels in test cells during engine operations.

Noise and Vibration Control 19.27
Space Construction and Operation 19.27
Cleanroom Installation and Test Procedures 19.28
Integration of Cleanroom Design and Construction 19.30
Life and Property Safety 19.31

CLEAN SPACES are defined as areas in which particle concentration and environmental conditions are controlled at or within specified limits. Design of clean spaces (or cleanrooms) covers much more than traditional control of air temperature and humidity. Additional factors may include control of particle, microbial, electrostatic discharge (ESD), molecular, and gaseous contamination; airflow patterns; air pressurization; sound and vibration; environmental health; life safety; industrial engineering aspects; and manufacturing equipment layouts. The objective of good cleanroom design is to maintain effective contamination control while ensuring required levels of reliability, productivity, installation, and operating costs.

1. TERMINOLOGY

Acceptance Criteria. Upper and lower limits of a pharmaceutical critical parameter required for product or process integrity. If the measured conditions are not within the allowable limits, the pharmaceutical product may be considered adulterated.

ach. Air changes per hour.

Air Lock. A small transitional space between two adjacent spaces of different cleanliness classification and air pressure set points.

As-built Cleanroom. A cleanroom that is completely constructed, with all services connected and functional, but not containing production equipment, materials, or personnel in the space.

Aseptic Space. A space controlled such that bacterial growth is contained within acceptable limits. This is not a sterile space, in which absolutely no life exists.

At-rest Cleanroom. A cleanroom that is complete with production equipment and materials installed and operating, but without personnel in the room.

CFU (colony-forming unit). A measure of bacteria present in a pharmaceutical processing space, measured by sampling as part of performance qualification or routine operational testing.

Challenge. An airborne dispersion of particles of known sizes and concentration used to test filter integrity and filtration efficiency.

Cleanroom. A specially constructed enclosed space with environmental control of particulates, temperatures, humidity, air pressure, airflow patterns, air motion, vibration, noise, viable organisms, and lighting.

Clean Space. A defined area in which particle concentration and environmental conditions are controlled at or within specified limits.

Contamination. Any unwanted material, substance, or energy, including vibration, noise, lighting, radiation, etc.

Commissioning. A quality-oriented process for achieving, verifying, and documenting that the performance of facilities, systems, and assemblies meets defined objectives and criteria, usually beginning at the user requirements specification (URS) generation stage.

Conventional-flow Cleanroom. A cleanroom with non-unidirectional or mixed airflow patterns and velocities.

Critical Parameter. A space variable (e.g., temperature, humidity, air changes, space pressure, particulates, viable organisms) that, by law or per product development data, affects product strength, identity, safety, purity, or quality (SISPQ).

Critical Surface. The part of the work surface to be protected from particulate contamination.

Design conditions. The environmental conditions for which the clean space is designed.

DOP. Dioctyl phthalate: an aerosol formerly used for testing efficiency and integrity of HEPA filters.

ESD. Electrostatic discharge.

EU GMP. European Union guidelines for GMP (defined in following text) pharmaceutical manufacturing.

Electrically Enhanced Filtration (EEF). System that reduces fan energy requirements by using an electrical ionizing device to charge incoming particles and a high-voltage electrical field across the air filter to enhance filtration efficiency of the filter media.

Exfiltration. Air leakage from a space of higher pressurization to one of lower pressurization through material transfer openings; gaps between personnel/pass-through access doors and their respective jambs, window frame/glass interfaces; wall/ceiling and wall/floor interfaces; electrical/data outlets and other room boundary penetrations.

FDA. U.S. Food and Drug Administration.

First Air. Air supplied directly from the HEPA filter before it passes over any work location.

GMP. Good manufacturing practice, as defined by *Code of Federal Regulations* (CFR) 21 CFR 210, 211 (also, CGMP = current GMP).

High-efficiency Particulate Air (HEPA) Filter. A filter with a minimum efficiency of 99.97% of 0.3 μm particles.

IEST. Institute of Environmental Sciences and Technology.

Infiltration. Air leakage into a space from adjoining areas, such as interstitial spaces, of higher pressurization. Moisture leakage from a space of higher partial vapor pressure to one of lower partial vapor pressure may also be described as infiltration, even when one space is at a lower static pressure.

ISPE. International Society for Pharmaceutical Engineering.

ISO. International Organization for Standardization.

ISO 14644-1. Specifies classification of air cleanliness by particle concentration. Only particle populations having cumulative distributions based on threshold (lower limit) particle sizes ranging from 0.1μm to 5 μm are considered for classification purposes. ISO (International Organization for Standardization) *Standard* 14644-1 is an international standard for cleanrooms. Table 1 and Figure 1 summarize the ISO standard classes.

The preparation of this chapter is assigned to TC 9.11, Clean Spaces.

Table 1 Airborne Particle Concentration Limits by Cleanliness Class per ISO *Standard* 14644-1 (2015)

ISO 14644 Class	0.1 µm	0.2 µm	0.3 µm	0.5 µm	1.0 µm	5.0 µm
	Particles per m^3					
1	10					
2	100	24	10			
3	1000	237	102	35		
4	10 000	2370	1020	352	83	
5	100 000	23 700	10 200	3520	832	
6	1 000 000	237 000	102 000	35 200	8320	293
7				352 000	83 200	2930
8				3 520 000	832 000	29 300
9				35 200 000	8 320 000	293 000

Source: ISO *Standard* 14644-1.
Note: Maximum concentration limits (particles/m^3 of air) for particles equal to and larger than considered sizes shown in table. All concentrations in table are cumulative (e.g., for ISO Class 5, the 10 200 particles shown at 0.3 µm include all particles equal to and greater than this size).
$C_n = 10^N(0.1/D)^{2.08}$ where C_n = concentration limits in particles/m^3, N = ISO class, and D = particle diameter in µm

ISO 14644-2. Specifies monitoring to provide evidence of cleanroom performance related to air cleanliness by particle concentration.

ISO 14644-3. Specifies test methods.

ISO 14644-8. Specifies classification of air cleanliness by chemical concentration (ACC).

Laminar Flow. Air flowing in parallel paths, without mixing between paths.

Leakage. The movement of air into or out of a space due to uncontrolled enclosure leaks and its pressure relationship to surrounding space(s).

Makeup Air. Outdoor air introduced to the air system for ventilation, pressurization, and replacement of exhaust air.

Minienvironment/Isolator. A barrier, enclosure, or glove box that isolates products from production personnel and other contamination sources to control or improve process consistency while reducing resource consumption.

Monodispersed Particles. An aerosol with a narrow band of particle sizes, generally used for challenging and rating HEPA and UPLA air filters.

Most Penetrating Particle Size (MPPS). The particle size that has the highest rate of filter penetration, or the particle size for which a filter has the least removal efficiency. Most penetrating particle size is a function of the filter media, construction, aerosol density, and air velocity.

Non-unidirectional Flow Workstation. A workstation without unidirectional airflow patterns and velocities.

Offset Flow. The sum of all space leakage airflows; the net flow difference between supply airflow rate minus the exhaust and return airflow rates.

Operational Cleanroom. A cleanroom in normal operation mode with all specified services, production equipment, materials, and personnel present and performing their normal work functions.

Oral Product. A pharmaceutical product to be taken by mouth by the patient.

OP. Operating parameter.

PAO. Polyalphaolefin, a substitute for DOP in testing HEPA filters.

Parenteral Product. A pharmaceutical product to be injected into the patient. Parenterals are manufactured under aseptic conditions or are terminally sterilized to destroy bacteria and meet aseptic requirements.

Particle Concentration. The number of individual particles per unit volume of air (e.g., number per cubic meter per ISO 14644 or number per cubic foot for non ISO).

Particle Size. The apparent maximum linear dimension of a particle in the plane of observation.

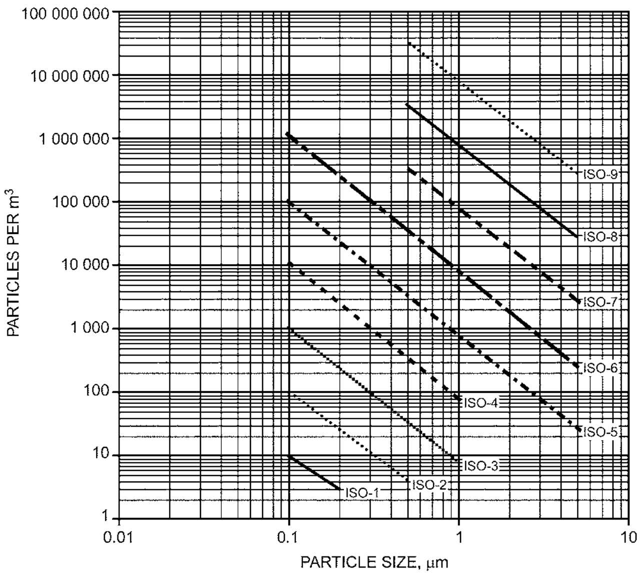

Fig. 1 Air Cleanliness Classifications in ISO *Standard* 14644-1

Polydispersed Particles. An aerosol with a broad band of particle sizes, generally used to leak-test filters and filter framing systems.

Qualification. Formal, quality-driven, thoroughly documented pharmaceutical commissioning activities undertaken to demonstrate that utilities and equipment are suitable for their intended use, and perform properly and consistently. These activities necessarily precede manufacturing drug products at the commercial scale, and usually consist of installation, operational, and performance testing procedures generated by engineering and quality teams.

Qualification Protocol (QP). A written description of activities necessary to qualify a specific cleanroom and its systems, with required approval signatures.

Room Classification. Room air cleanliness class (Figure 1, Table 1).

SOP. Standard operating procedure.

Topical Product. A pharmaceutical product to be applied to the skin or soft tissue as a liquid, cream, or ointment, which therefore does not need to be aseptic. Sterile ophthalmic products, though, are usually manufactured aseptically.

ULPA (Ultralow-penetration Air) Filter. A filter with a minimum of 99.999% efficiency at 0.12 µm particle size.

Unidirectional Flow. Air flowing in a constant direction uniformly over a defined space or region (different from laminar flow).

Validation. A systematic, quality-driven approach for verifying and documenting that a pharmaceutical process is designed, installed, functions, and is maintained properly, involving sequential executions of installation qualification, operational qualification, and performance qualification activities.

Workstation. An open or enclosed work surface with direct air supply.

2. CLEAN SPACES AND CLEANROOM APPLICATIONS

Use of clean space environments in manufacturing, packaging, and research continues to grow as technology advances and the need for control and containment of airborne particles in work environments increases. This chapter focuses on state-of-the-art facility design and operations to improve quality and resource efficiency in a worldwide industry that provides great benefits and consumes significant energy. The following major industries use clean spaces for their products:

- **Pharmaceuticals/Biotechnology.** Preparations of pharmaceutical, biological, and medical products require clean spaces to control viable (living) and nonviable particles that could impact product sterility.
- **Microelectronics/Semiconductors.** Advances in semiconductor microelectronics drive cleanroom design. Semiconductor facilities are a significant percentage of all cleanrooms in operation in the United States, with most newer semiconductor cleanrooms being ISO *Standard* 14644-1 Class 5 or cleaner.
- **Flat Panel Display.** FPD factories are some of the largest cleanrooms, with some cleanrooms greater than 200 000 m^2, requiring adherence to ISO 14644-1 Classes 5 to 8 throughout the factory. They typically change cleanliness requirements by process area and risk of exposure to the product. These facilities may produce liquid crystal, light-emitting diodes (LEDs), and organic light-emitting diodes based displays.
- **Aerospace.** Cleanrooms were first developed for aerospace applications to manufacture and assemble satellites, missiles, and aerospace electronics. Most applications involve large-volume spaces with cleanliness levels of ISO *Standard* 14644-1 Class 8 or cleaner.
- **Hospitals.** Operating rooms may be classified as cleanrooms, but their primary function is more to limit particular types of contamination than to control the quantity of particles present. Cleanrooms are used in patient isolation and surgery where risks of infection and cross contamination must be controlled, and in hospital pharmacies, where compounding sterile pharmaceuticals requires stringent control of the immediate and surrounding environments. For more information, see Chapter 9.
- **Miscellaneous Applications.** Cleanrooms are also used in aseptic food processing and packaging, microelectronic and nanotech applications, medical device manufacturing, automotive paint booths, crystal, laser/optic industries, and advanced materials research.

3. AIRBORNE PARTICLES AND PARTICLE CONTROL

Airborne particles occur in nature as pollen, bacteria, miscellaneous living and dead organisms, and windblown dust and sea spray. Industry generates particles from combustion, chemical vapors, manipulation of material, and friction in moving equipment. Personnel working in the cleanrooms are a prime source of particle generation (e.g., skin flakes, hair, clothing lint, cosmetics, respiratory emissions, bacteria from perspiration). Sizes of airborne particles vary from 0.001 to several hundred micrometres (μm). Although it is common for airborne particles of sizes larger than 5.0 μm to settle quickly due to gravity, it may take days for some forms of airborne particles smaller than 1.0 μm to settle (barring intervention and control mechanisms applied to the space). In many manufacturing processes, airborne particles are a source of contamination or facilitate spread of biological contaminants. Cleanroom designs must accommodate particulate sources and focus on particulate control to maintain acceptable environmental conditions. Locations and sizes of return and exhaust registers are important considerations, as are layouts of equipment and locations and sizes of supply registers.

Particle Sources in Clean Spaces

In general, the origins of cleanroom particles are described as either external or internal.

- **External Sources.** Externally sourced particles enter the clean space from the outside via infiltration through doors, windows, wall penetrations, surface contamination on personnel, material and equipment entering the space, and outdoor makeup air entering through the HVAC system. In a typical cleanroom, external particle sources normally have little effect on overall cleanroom particle concentration because HEPA filters remove particulates from the supply air and the cleanroom is operated at a higher pressure than surrounding spaces to prevent infiltration. However, the particle concentration in clean spaces at rest relates directly to ambient particle concentrations. Particles from external sources are controlled primarily by air filtration, room pressurization, and sealing space penetrations.
- **Internal Sources.** People, cleanroom surface shedding, process equipment, and the manufacturing process itself can generate particles in clean spaces. Cleanroom personnel, if not properly gowned, may be the largest source of internal particulate generation, generating several thousand to several million particles per minute. Personnel-generated particles are controlled with proper gowning procedures, including new cleanroom garments, and airflow designed to continually shower critical areas with clean air and direct less-clean airstreams toward the return/exhaust registers. As personnel work in the cleanroom, their movements may reentrain airborne particles from other sources by creating turbulent air movement, eddies, and vortexes. Other activities, such as writing, printing, or moving and bumping equipment may also cause higher particle concentrations. Door swings or equipment challenges can produce strong additional transient differential pressure excursions, which may lead to particle infiltration through crack and crevices.

Though particle concentrations in the cleanroom air may be used to define its cleanliness class, actual particle deposition on the product critical surface is of greater concern. In addition to the ISO 14644-1 standard covering classification by airborne particle concentration, ISO 14644-8 specifies classification of air cleanliness by chemical concentration (ACC), which is critical to many organic-based processes, and ISO 14644-9 and 14644-10 cover classification of surface cleanliness by particle and chemical concentration. The sciences of aerosols, filter theory, and fluid motions are the primary sources of understanding nonvolatile residue deposition and contamination control (IEST *Recommended Practice* RP CC016). Cleanroom designers may not be able to control or prevent internal particle generation completely, but they may anticipate internal sources and design control mechanisms and airflow patterns to limit their effect on the product. Particle counters are used to measure particle counts and concentrations for selected locations in the cleanroom and provide control feedback. They should be well calibrated to ensure accuracy and reliability of contamination control (ISO 21501).

Fibrous Air Filters

Proper air filtration prevents most externally generated particles from entering the cleanroom via the HVAC system. High-efficiency air filters come in two types: high-efficiency particulate air (HEPA) filters and ultralow-penetration air (ULPA) filters. HEPA or Group H filters (ISO 29463) are individually tested, and their efficiency is between 99.95 and 99.995% at most penetrating particle size (MPPS), in accordance with ISO 29463-5. ULPA or Group U (ISO 29463) filters are individually tested, and their efficiency is between 99.999 and 99.999995% at MPPS, in accordance with ISO 29463-5. HEPA and ULPA filters use glass fiber paper technology; laminates and nonglass media for special applications also have been developed. HEPA and ULPA filters are usually constructed in a minipleat form with aluminum, coated string, filter paper, or hot-melt adhesives as pleating separators. Filters pleat depths are available from 25 to 300 mm; available filter media surface area increases with deeper-pleated filters and closer pleat spacing, which reduces filter pressure drop and increases dirt holding capacity.

There are four common mechanisms by which HEPA and ULPA filters capture particulate: (1) straining, (2) inertia, (3) interception, and (4) diffusion. In addition, some systems use electromagnetic forces to enhance HEPA and ULPA filter performance (see the section on Sustainability and Energy Conservation in Cleanrooms for details). In **straining** capture, sometimes called sieving, particles enter passages between two or more fibers that have dimensions less than the particle diameter (most of these particles are captured in prefilters). In **inertia** capture, particles traveling in airstream through fiber material have too much mass to stay in the airstream as it bends through the filter fibers; particles leave the airstream and attach to filter fibers. In **interception** capture, particles with mass small enough to stay in the airstream nevertheless touch the filter fiber and are attached. In **diffusion** capture, very small particles move randomly through Brownian motion; they touch and subsequently attach to filter fibers. Theories and models verified by empirical data indicate that interception and diffusion are the more effective capture mechanisms for smaller particles in HEPA and ULPA filters. In general, fibrous filters' lowest removal efficiency corresponds to the most penetrating particle size, which is determined by filter fiber diameter, volume fraction or packing density, and air velocity. For most HEPA and ULPA filters, the MPPS is between 0.1 to 0.3 μm. Group H (HEPA) and Group U (ULPA) filter efficiency is calculated using the MPPS per ISO 29463. Table 2 provides the ISO 29463 efficiency values and typical applications for Group H and U filters.

4. AIR PATTERN CONTROL

Air turbulence in the clean space may be detrimental to environmental quality. Turbulence is strongly influenced by air supply and return configurations, air balancing adjustments, foot traffic, buoyancy effects from hot surfaces, and process equipment layout. Specifying and optimizing airflow patterns to meet operational requirements are the first steps of good cleanroom design. User requirements for cleanliness level, process equipment layout, available space for installing air pattern control device and systems (air handlers, clean workstations, environmental control components, types of recirculation air system, etc.), and project financial considerations all affect air pattern design selection.

Numerous airflow pattern configurations are possible, but they fall into two general categories: non-unidirectional airflow (commonly called turbulent or mixed flow), and unidirectional airflow (previously, often mistakenly, called laminar flow).

Non-unidirectional Airflow

Non-unidirectional airflow has either multiple-pass circulating characteristics or nonparallel flow streamlines. Variations are based primarily on the location of supply and return/exhaust air registers and the associated airflow rates. Examples of non-unidirectional airflow of cleanroom systems are shown in Figures 2 and 3. Air is typically supplied to the space through supply diffusers with integral HEPA filters (Figure 2) or with HEPA filters in the supply diffuser ductwork or air handler (Figure 3). In a mixed flow configuration, air is prefiltered in the supply and then HEPA filtered at workstations in the clean space (see the left side of Figure 3).

Non-unidirectional airflow may provide satisfactory contamination control for ISO *Standard* 14644-1 Classes 6 to 8. Attaining desired cleanliness classes with designs similar to Figures 2 and 3 requires terminal or in-line mounted HEPA filters to remove airborne particulates from the supply air, which improves the interior particulate concentration levels through mixing. Selected air diffusers should introduce air with least amount of induction (to promote mixing) and maximize space flushing effect. Supply terminals with perforated sheet or low induction swirl diffusers are preferred, with low level extract or return for rooms with high process dust generation.

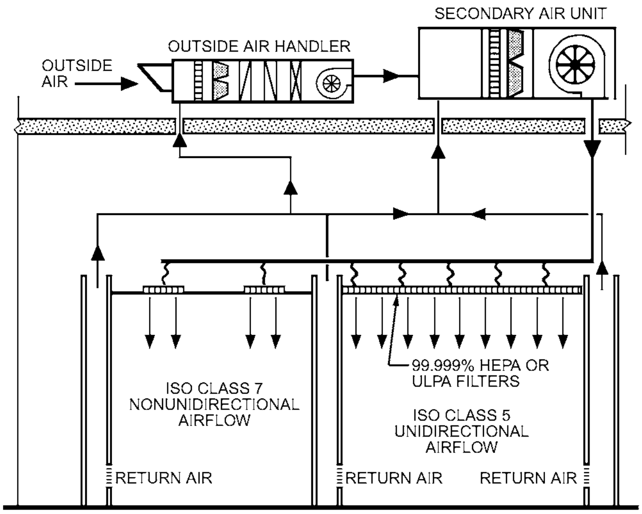

Fig. 2 ISO Class 7 Non-unidirectional Cleanroom with Ducted HEPA Filter Supply Elements and ISO Class 5 Unidirectional Cleanroom with Ducted HEPA or ULPA Filter

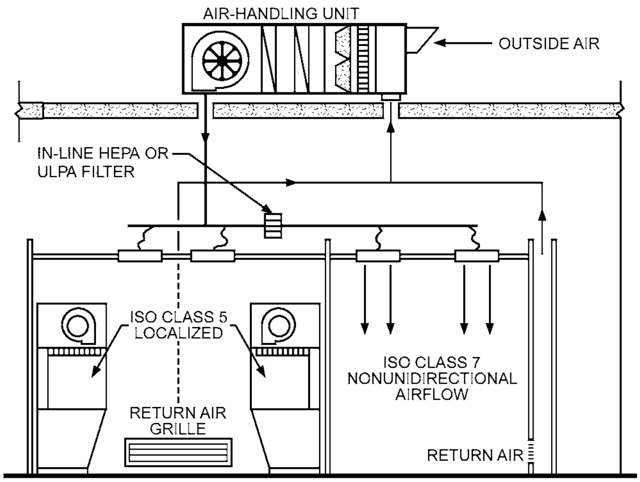

Fig. 3 ISO Class 7 Non-unidirectional Cleanroom with HEPA Filters Located in Supply Duct and ISO Class 5 Local Workstations

Table 2 Filter Classification, per ISO 29463, of High-Efficiency Filters and Filter Media for Removing Particles in Air

Filter Class and Group	Overall Value Efficiency, %	Overall Value Penetration, %	Filter Application
ISO 15 E	≥95	≤5	General
ISO 20 E	≥99	≤1	Industrial, hospital, food
ISO 25 E	≥99.5	≤0.5	
ISO 30 E	≥99.90	≤0.1	
ISO 35 H	≥99.95	≤0.05	
ISO 40 Hd	≥99.99	≤0.01	Unidirectional flow (semiconductor, pharmaceuticals)
ISO 45 Hd	≥99.995	≤0.005	Nanotechnology Applications
ISO 50 U	≥99.999	≤0.001	
ISO 55 U	≥99.9995	≤0.0005	
ISO 60 U	≥99.9999	≤0.0001	
ISO 65 U	≥99.99995	≤0.00005	
ISO 70 U	≥99.99999	≤0.00001	
ISO 75 U	≥99.999995	≤0.000005	

When internally generated particles are of primary concern, clean workstations can be used effectively in the clean space.

Unidirectional Airflow

Unidirectional airflow, though not truly laminar, is characterized as air flowing in a single pass in a single direction through a cleanroom with generally parallel streamlines. Ideally, flow streamlines would be uninterrupted; although personnel and equipment in the airstream distort the streamlines, a state of constant velocity is approximated. Most particles that encounter an obstruction in unidirectional airflow continue around it as the airstream reestablishes itself downstream of the obstruction. Hot surfaces and abrupt changes in flow streamlines may occur and create internal circulating paths. Identifying these phenomena during the design stage by using CFD modeling can help avoid high particle concentration areas.

Air patterns are optimized and air turbulence is minimized in unidirectional airflow. In a **unidirectional-flow space**, air is typically introduced through ceiling HEPA or ULPA filters and returned through a raised access floor or at the base of sidewalls. For pharmaceutical and life sciences applications, this method is not recommended because of the potential for biological growth under raised floors. Instead, judicial placement of supply filters and room returns allows unidirectional flow. Often, computational fluid dynamics (CFD) is used to determine these locations before construction; see Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals* for details on CFD. Because air enters from the entire ceiling area, this configuration produces nominally parallel airflow. In a horizontal-flow cleanroom, air enters one wall and returns on the opposite wall.

A **downflow cleanroom** has a ceiling with HEPA filters. As the space cleanliness classification becomes more stringent, the space air change rate and the number of HEPA filters may increase. Typically, for an ISO Class 5 or cleaner space, the ceiling has 70 to 100% HEPA filter coverage. Ideally, a grated or perforated floor serves as the air return/exhaust. In this configuration, clean air flows downward past a contamination source, sweeping away the contamination particles, and removes them directly down through the floor to prevent the particles from contacting the critical surface of a product. However, this type of floor is inappropriate for pharmaceutical cleanroom applications, which typically have solid floors and low-level wall returns. Raised-floor configurations may not be appropriate where there is concern for contamination under the floor.

Special attention should be given to ceiling HEPA and ULPA filter design, selection, and installation to ensure a leakproof ceiling system. Properly sealed filters in the ceiling can provide the cleanest air presently available in a cleanroom. HEPA and ULPA filters may be leak tested before installation, looking for filter defects, and again after installation, looking for leaks in the system used to seal the filter into the ceiling system.

In a **horizontal-flow cleanroom**, the supply wall consists entirely of HEPA or ULPA filters supplying air at approximately 0.45 m/s or less across the entire cross section of the space. Due to higher turbulence, the use of higher velocities may be necessary to address high particle generation rates, but note that 0.45 m/s may be too high for some applications, and velocities above 0.36 m/s may increase particle reentrainment and particle residence time. Return/exhaust air exits through the return wall at the opposite end of the space. As with the downflow cleanroom, the horizontal-flow cleanroom removes contamination generated in the space and minimizes cross contamination perpendicular to airflow. However, a major limitation is that downstream air particle concentration increases from entry plane to exit plane. Air leaving the filter wall is the cleanest; it then becomes contaminated by the process as it flows past the first workstation. Process activities should be arranged to have the most critical operations at the clean end of the space, with progressively less critical operations located toward the return or dirty end of the space.

ISO *Standard* 14644-1 does not specify velocity requirements, so the actual velocity is as specified by the owner or owner's agent. IEST published rule-of-thumb air change rates for various cleanliness classes (IEST RP CC012.3), which should be reviewed by the owner; however, the scientific basis for the ranges is unclear. Acceptable cleanliness class has been demonstrated with much lower air change rates (Xu 2003, 2004), suggesting that the actual particle concentration and cleanliness level may also depend on filter efficiency, filter coverage, and particle generation rates, in addition to air change rates. ISO *Standard* 14644-2 requires an owner to understand the risk to maintaining clean spaces' cleanliness and to prepare a monitoring plan to ensure cleanliness levels are maintained. Monitoring plans should take into account the level of air cleanliness required, critical locations, and performance attributes of the cleanroom that may affect performance of the space. These attributes should be identified during the risk assessment and may include room pressurization, room air velocity, HEPA filter leak testing, air change rates, etc. Any reduced air change rate design should be factored into risk assessment and monitoring plans.

Unidirectional airflow systems have a predictable airflow path that airborne particles tend to follow. Without good filtration practices, unidirectional airflow only indicates a predictable path for particles. However, superior cleanroom performance may be obtained with, in addition to other measures, a good understanding of unidirectional airflow, which remains parallel to below the normal work surface height of 760 to 915 mm, but deteriorates when it encounters obstacles (e.g., process equipment, work benches) or over excessive distances. Personnel movement also disturbs airflow patterns, resulting in a cleanroom with areas of good unidirectional airflow and areas of turbulent airflow.

Turbulent zones have countercurrents of air with high velocities, reverse flow, or no flow at all (stagnancy). Countercurrents can produce stagnant zones where small particles may cluster and settle onto surfaces or product; they may also lift particles from contaminated surfaces and deposit them on product surfaces.

Cleanroom mockups may help designers minimize and avoid turbulent airflow zones and countercurrents. Smoke, neutral-buoyancy helium-filled soap bubbles, and nitrogen vapor fogs can make air streamlines visible in the mockup.

Computational Fluid Dynamics (CFD)

Air is the primary carrier of heat, moisture, contaminants, and particles in cleanroom facilities. The distribution of supply air determines the resulting air velocities, temperatures, and concentration of particles at various locations in a cleanroom. Such distribution in turn determines thermal comfort and air quality. Satisfactory thermal comfort for occupants, higher energy efficiency, and maintaining the desired cleanliness are mutually competing goals. Obtaining these goals by optimizing various design and operating parameters of cleanroom air distribution systems is a daunting task.

Airflow patterns, temperature, and particle distribution in a cleanroom can depend on several interrelated factors, including location of supply diffusers, supply air flow rates (air change rates) and associated diffuser throws, supply air temperature, size and locations of room return, leakage areas and associated airflow rates, locations and strengths of various heat sources in a room, location and size of obstructions to airflow, and relative location and strength of particle-generating entities in a cleanroom. Physical testing and measurements to study the influence of all these factors on the thermal comfort, energy efficiency, and level of cleanliness are time consuming and labor intensive, if not impossible. In this situation, analysis of various realistic scenarios through computational fluid dynamics (CFD) simulations is an attractive alternative. In critical applications, it is good practice to verify the CFD predicted results.

Computational fluid dynamics analysis can predict airflow patterns, resulting temperature distribution, particle concentration, relative humidity distribution, and resulting thermal comfort of occupants in confined spaces such as cleanrooms. In addition, CFD is routinely used to predict wind patterns around buildings to evaluate impact of wind on environmental dispersion, wind pressure on building facade, and pedestrian comfort. In cleanroom design analysis, it is used to predict the effects of room pressurization (i.e., relative supply and return airflow rates, locations of supply and returns, particle generation rate on the distribution of cleanliness in a room). CFD analysis can help provide deep insight into real-life operation of cleanroom at the conceptual design stage, which in turn can help in optimizing the operating parameters and in reducing the first and operating costs of HVAC systems.

CFD involves solving and analyzing transport equations of fluid flow, heat transfer, mass transfer, and turbulence. The transport of mass, momentum, energy, and chemical species are governed by a generalized conservation principle that can be described in the form of a general differential equation. During this CFD procedure, the calculation domain (extent of space) is divided into a number of nonoverlapping control volumes, such that there is one control volume surrounding each grid point. Then, each governing differential equation is iteratively balanced over each control volume to conserve the mass, momentum, energy, and other similar physical entities. During iteration, the residual error for each governing equation is monitored and reduced. This process continues until the overall balance in the conservation of all the governing entities reaches the acceptable or desired level. Finally, such converged numerical solutions reveal a detailed distribution of pressure, velocities, turbulence parameters, temperature, concentration of chemical species, etc., in the calculation domain.

CFD results can be presented in color contour plots showing three-dimensional distributions of temperature and particle concentrations in cleanrooms. Flow path lines and vectors plots are used to reveal airflow patterns in a room. Flow animations also help in visualizing air and particle movement in a room.

CFD models of particle trajectories, transport mechanisms, and contamination propagation are commercially available. Flow analysis with computer models may compare flow fields associated with different process equipment, work benches, robots, building exterior envelope, personnel, and building structural design. Flow patterns and air streamlines are analyzed by computational fluid dynamics for laminar and turbulent flow where incompressibility and uniform thermophysical properties are assumed. Using CFD modeling in actual cleanroom design and layout planning, design parameters may be modified and optimized to determine the effect of airflow control and space or equipment layouts on particle transport, flow streamlines, and contamination concentrations, thus reducing or avoiding the cost of mockups (Tung et al. 2010; Yang et al. 2009).

Major features and benefits associated with most computer flow models are

- Two- or three-dimensional modeling of cleanroom configurations, including people and equipment
- Modeling of unidirectional airflows
- Multiple air inlets and outlets of varying sizes and velocities
- Allowances for varying boundary conditions associated with walls, floors, and ceilings
- Aerodynamic and buoyancy effects of process equipment, workbenches, and people
- Prediction of specific airflow patterns, velocities, and temperature gradients of all or part of a cleanroom
- Simulation of space pressures by arranging supply, return, exhaust, and planned exfiltration and infiltration airflows
- Reduced cost associated with new cleanroom design verification
- Identifying particle deposition risks to open wafers in some metrology tools
- Recognition of temperature hot spots
- Projection of particulate loading in the air spaces
- Calculation of flow fields and their effect on particulate control
- Use of chemical dispersion to aid airborne molecular contaminant (AMC) mitigation strategies
- Identification of recirculation zones and design features that may lead to detrimental airflow
- Raised-floor damper balancing
- Determining preliminary raised floor damper position settings
- Graphical representation of flow streamlines and velocity vectors to assist in flow analysis (Figures 4, 5, and 7)

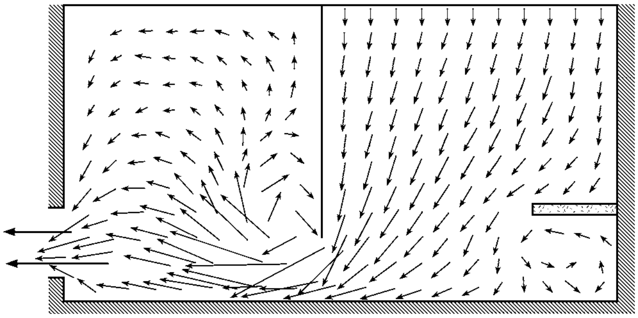

Fig. 4 Cleanroom Airflow Velocity Vectors Generated by Computer Simulation

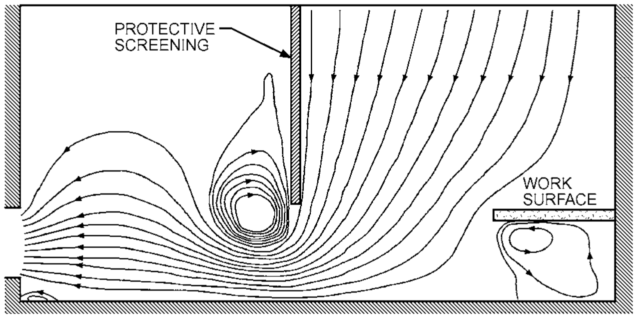

Fig. 5 Computer Modeling of Cleanroom Airflow Streamlines

- Graphical representation of simulated particle trajectories and propagation (Figures 6 and 8)

Research has shown good agreement between flow modeling by computer and physical experimentation done in simple mockups. However, computer flow modeling software should not be considered a panacea for cleanroom design because of the variability of individual project conditions.

For more information on CFD, see Chapter 13 of the 2017 *ASHRAE Handbook—Fundamentals*.

Air Change Rate Determination

Cleanroom HVAC systems are highly energy intensive (Lowell et al. 1999), and can have an energy use index of between 2543 kWh/m^2 and 3819 kWh/m^2 (Boyd 2011) for pharmaceutical factories and greater than 10 000 kWh/m^2 for semiconductor factories. Airflow rates in cleanrooms must meet not only the heating and cooling loads, but also the contaminant dilution requirements to reduce room particle concentration. It is critical to realize that particle contaminants generated in a cleanroom are not from HEPA-filtered supply air, but from activities inside the cleanroom. A very high air change rate is not typically needed for cooling, heating, or ventilation loads but mainly for controlling and diluting particle concentrations. There is a precedent of cleanroom design engineers using conservative, simplified rule-of-thumb values for air change rates published in IEST RP-12.3, supplier literature, or guidance documents from various government or industry sources. This approach uses the required room cleanliness class alone to suggest an air change per hour (ach) value, often arbitrarily, from a wide range specified in older documents and therefore ignores many critical variables that could significantly affect the room particle concentration in terms of air change rate requirements. Such variables include room internal particle size and generation rate, particle surface deposition, particle entry through filtered supply air, particle exit through return and exhaust air, air leakage (particle loss or gain) under pressurization or depressurization, layout of processes, and locations of supply, return, and exhaust registers. Intuitively, for example, activities that generate higher levels of particle concentration would need a higher air change rate to dilute particle concentration than those that generate lower levels of particle concentration, but existing practices use an oversimplified approach that ignores such differences.

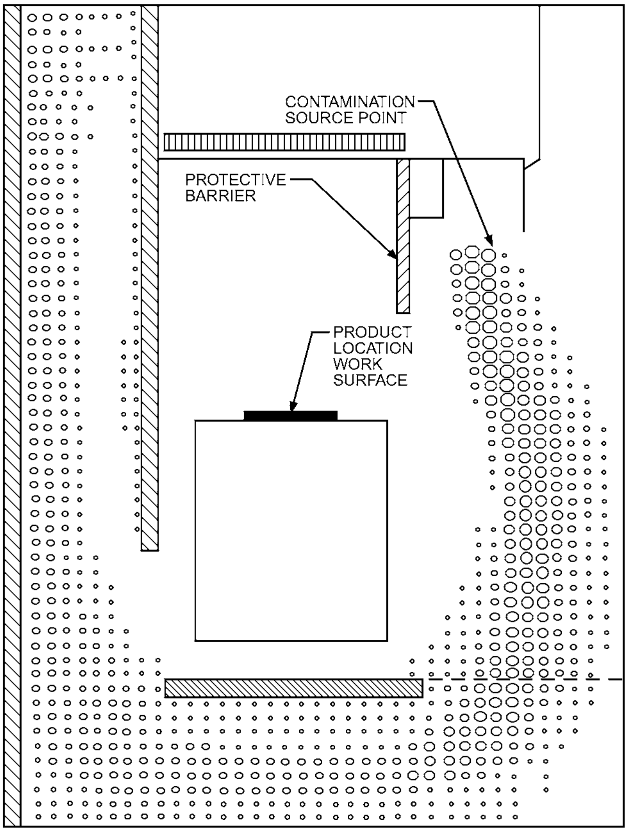

Fig. 6 Computer Simulation of Particle Propagation in Cleanroom

Each cleanroom facility is unique; its location, building construction, production or process activities, space configurations, HVAC systems, room cleanliness requirements, etc., can impact the air change requirement for each room. Using a rough, oversimplified approach without considering all these variables could cause either significant energy waste or poorly designed HVAC systems. Xu (2003, 2004) found that airflow rates or air velocities for cleanrooms in actual operation exhibited lower values than those described in IEST RP CC012.3.

In attempts to offset expected contamination generation rates, some operating cleanrooms may be overdesigned and may operate at higher airflow rates or airflow velocities than necessary, resulting in significant energy waste. To save fan and thermal energy in cleanroom HVAC systems, modeling technologies have been developed and published that provide more scientifically based, quantitative design tools (rather than rule-of-thumb values) (Sun 2008; Sun et al. 2010). Figure 9 shows the measured airflow rates and airflow velocities of actual ISO Class 5 and Class 6 cleanrooms in the United States in comparison with the typical ranges exhibited in IEST RP CC012.3.

Demand Control Airflow

Demand control is used in many applications such as variable-air-volume systems to control room temperature, variable water flow to control a coil's capacity, and demand control ventilation to decrease airflow to spaces during low occupancy. Additionally, demand-based control has been widely applied to research laboratory spaces to vary lab room air change rates in real time based on active sensing of both particulate and chemical containment levels. Extensive studies of lab room environmental conditions (Sharp 2010) have shown that the air quality in labs is typically acceptable over 98% of the time, which can allow significant savings in HVAC energy costs by reducing airflow to as low as 2 ach during these time periods. For the 1 or 2% of the time that chemical or particulate contaminants are sensed in the lab the air flow is raised to a high level to rapidly purge the lab of these contaminants.

Although less commonly used, this same technology and approach can also be applied to control cleanroom airflows. ASHRAE research project RP-1604, Demand Based Control for Cleanrooms (Sun [in progress]), is examining this concept and will provide qualitative data on the effectiveness of this approach. Lawrence Berkeley National Laboratory has also demonstrated the concept of demand based control in cleanrooms and shown its feasibility (Faulkner et al. 1996, 2008).

The benefit of demand control in a cleanroom is a significant reduction in the average airflow rate and thus a large reduction in energy use. Typically, a room is actually challenged with particle emissions only for a small amount of time. Consequently, the best approach for controlling cleanroom air change rates is to vary the rate as needed based on the real-time quality of the cleanroom's air. When the cleanroom is clean of particles and other potential contaminants, the air change rate can be dropped significantly: perhaps one-half to one-quarter the nominal operating air change rate. When particles or other contaminants are detected, the air change rate can be increased to the nominal rates or beyond, to provide a faster purge of the contaminants.

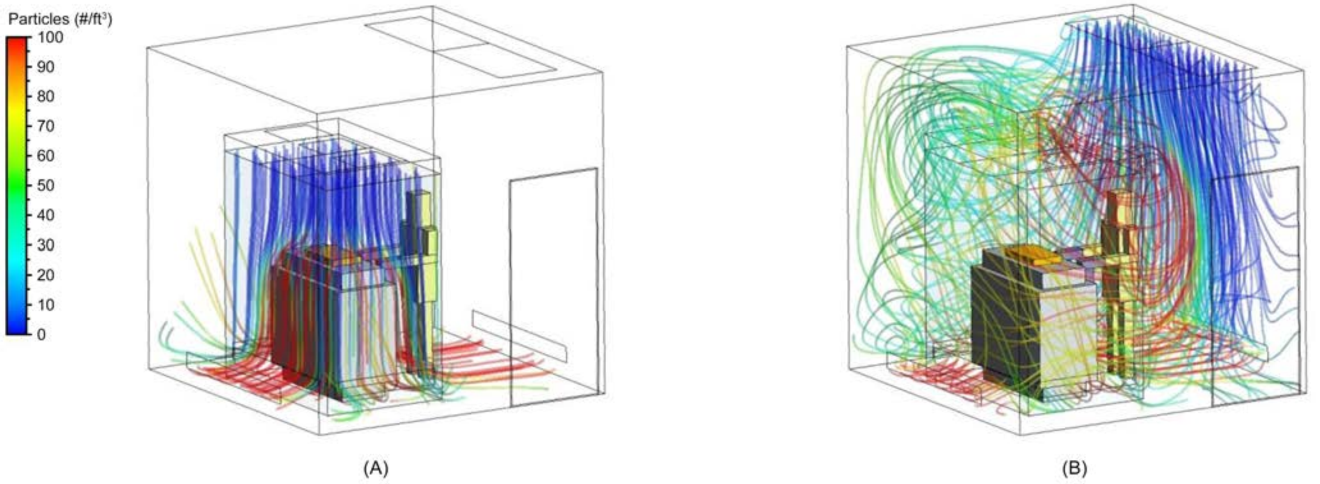

Fig. 7 Computer Simulated Airflow Patterns in Minienvironment Cleanroom: (A) Unidirectional Flow and (B) Mixed Flow
(CFD analysis provided by Kishor Khankari, Ph.D., President, AnSight LLC, Ann Arbor, MI)

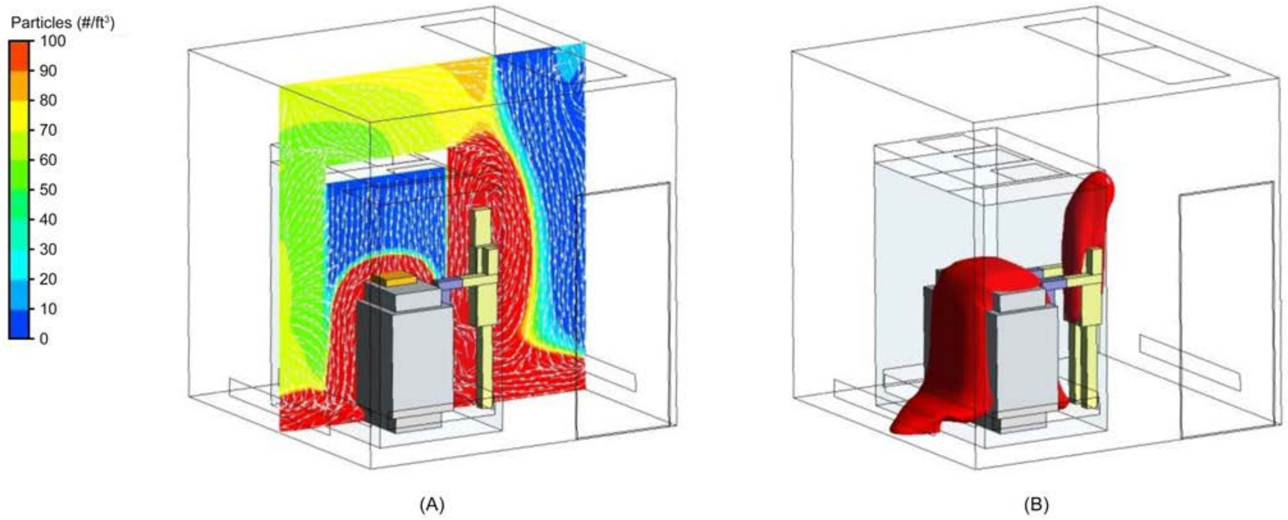

Fig. 8 Computer Simulated Particle Concentration in Minienvironment Cleanroom Showing (A) Lower Particle Concentration in Minienvironment and Higher Concentration near Person because of Recirculation of Air around Occupant and (B) Particle Cloud of 35 311 particles/m^3 with Higher Particle Concentration near Occupant's Face
(CFD analysis provided by Kishor Khankari, Ph.D., President, AnSight LLC, Ann Arbor, MI)

Implementing a dynamic approach to controlling minimum air change rates requires the ability to continuously measure particles in the cleanroom, but other parameters of interest (e.g., total volatile organic compounds [TVOCs], carbon dioxide, humidity) may be desirable as well. This information may then be integrated with the building management system for control purposes.

Different sensing approaches may be used to implement this concept. Individual sensors may be deployed in the cleanrooms of interest, or a manifolded sensing system may be used for a potentially more cost-effective deployment. With this latter approach, one central set of sensors is used in a multiplexed fashion to sense not one, but many different rooms or areas. With this system, packets of air are sequentially drawn down to the central sensor for individual measurement on a periodic basis.

5. AIRFLOW DIRECTION CONTROL BETWEEN CLEAN SPACES

Airflow direction control between clean spaces having different cleanliness classifications is complex but critical to prevent airborne cross contamination. Particulate contaminants could infiltrate a cleanroom through doors, cracks, pass-throughs, and other penetrations for pipes, ducts, conduits, etc. An effective method of contamination control is control of space pressurization: air moves from spaces with higher pressures to adjacent spaces with lower pressures. Normally, the cleanest cleanroom(s) with the most critical operations should be designed with the highest pressure, having decreasing pressures correspond to lower cleanliness classifications. The desired flow path should be from the area of cleanest, most critical environmental requirements to less clean

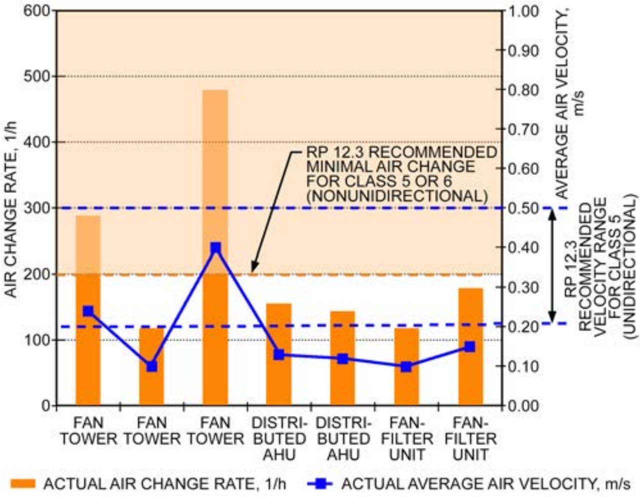

Fig. 9 Actual versus Recommended Cleanroom Airflow Rates
(Based on data from Xu 2004 and IEST RP CC012.3)

areas, progressively cascading down through less clean areas, and finally down to uncontrolled (dirty) areas.

Space Pressurization

Controlling contaminants in cleanrooms requires controlling the direction of airflow between adjacent spaces that have various levels of cleanliness classification(s). This is achieved by establishing and maintaining a pressure differential between the spaces. The pressurization set point for a space can be used to prevent contamination from entering the space by being positive relative to all surrounding spaces or to prevent contamination of other spaces by being negative relative to all surrounding spaces. Air pressure differences are created mechanically between spaces to introduce intentional air movement paths through space leakage or openings (Sun 2003, 2005). These openings could be designated (e.g., doorways, material transfer tunnel) or undesignated (e.g., air gaps around doorframes, other cracks). Pressurization resists infiltration of unfiltered external sources of contaminants. It can be achieved by arranging controlled flow rates of supply, return, and exhaust airstreams to each space based on the following rules:

- *Positive Pressurization*: entering (supply) airflow rate is higher than leaving (exhaust and/or return) airflow rate in the space.
- *Negative Pressurization*: entering (supply) airflow rate is lower than leaving (exhaust and/or return) airflow rate in the space.

A cleanroom envelope (including doors) is a natural barrier to contain airborne contaminants' (e.g., particle, microbial, chemical gas) migration. However, when a door is opened for traffic, the initial pressure differential across the door/envelope disappears much more quickly (typically in less than 0.25 s) than a door operation cycle (typically 6 to 10 s) closes the door, and is also much quicker than any airflow control devices (e.g., air valves) to modulate from prior flow positions to the new positions (1 to 2 s). The magnitude of particle migration is much higher at the door-in-operation (dynamic) condition than at the door-closed (static) condition. Additional treatment is required and associated design criteria need to be considered for the door-in-operation condition.

An effective mechanism to tackle this issue is to install a two-door airlock with a proper time delay. A time delay between two doors can allow the airlock room air to be fully or partially replaced by filtered clean air. Airlock can reduce particle migration not only during door operations, but also in closed door conditions.

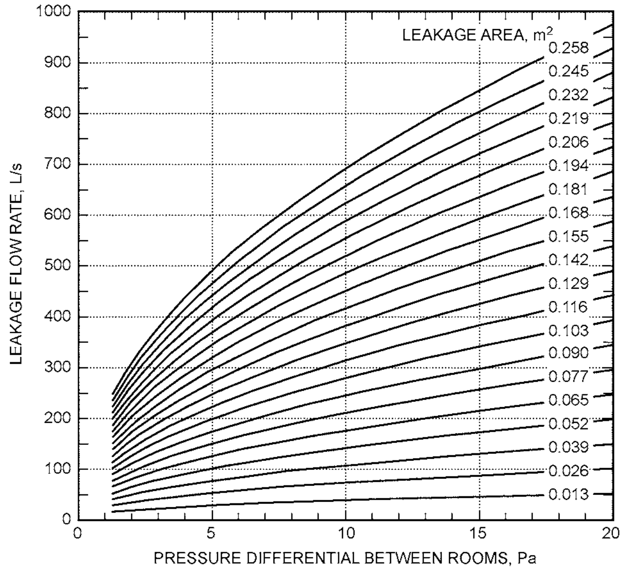

Fig. 10 Flow Rate Through Leakage Area under Pressure Differential

Recommended minimum pressure differentials (ΔP) across cleanroom envelopes are based on findings from ASHRAE research project RP-1431 (Sun et al. 2011). The static (door closed) ΔP requirement is the same for adjacent rooms of all class differences: 10 Pa ΔP across a cleanroom door in respect to adjacent areas is required to minimize particle migration. When an adjacent area across the door is two classes (or more) dirtier than the cleanliness class of the cleanroom, installation of an airlock (see Figure 12) may be required to maintain acceptable pressurization conditions when doors are opened/dynamic (depending on the daily frequency of the door operation). This requirement does vary with the respective ISO class of adjacent rooms. For a difference of only one class between rooms, no airlock installation is required. For a two-class difference, airlock installation is required only when door operation is frequent (more than 30 times daily). For a difference of three classes (or more) and cleanrooms surrounded by noncleanroom areas, airlock installation is required regardless of door use frequency.

When airlock installation is necessary,

- A two-door airlock should replace a single door separating the two areas.
- A minimum pressure of 5 Pa is necessary across each door of the airlock.
- There should be a time delay between the two doors in the airlock.

Detailed information can be found in ASHRAE (2017).

Differential pressure between any two spaces is normally designed at 12.5 Pa or less.

A space's differential airflow rate is often called **offset flow**, which is the sum of all mechanically driven airflows (in or out, which correlates with space leakage). Figure 10 shows the relationship between leakage flow rates at a specific pressure differential across an opening. Each curve on the chart represents a different leakage area. Once a leakage area along a doorframe is estimated, then the air leakage rate through the door cracks while the door is closed can be calculated based on the pressure difference across the door.

Space airtightness (sealing of the facility, fixtures, and penetrations) is the key element in the relationship between the space's flow offset value and the resulting pressure differential, and each space's airtightness is unique and unknown unless tested. Treatment of a space's offset value defines a pressurization control strategy. Typical pressurization control techniques include the following:

- **Direct pressure-differential control (DP)** uses a pressure differential sensor to measure the pressure difference between a controlled space and an adjacent space (e.g., a corridor). DP is suitable for a tightly constructed space with airlocks and/or limited traffic. It basically ignores the specific offset value as required; instead, it directly controls the airflow control devices to achieve the required pressure differential between the controlled space and an adjacent space. A door switch is recommended to trigger a reduced pressure-differential set point if the door opens or the DP control is based on average readings over a period of time (e.g., polling every 10 seconds and averaging over a minute).
- **Differential flow tracking control (DF)** assumes an offset value and refines it through commissioning; this value is then used as a volumetric or mass flow difference between supply and return/exhaust airflows through their airflow control devices. This method is suitable for open-style spaces or spaces with frequent traffic. DF normally maintains the same airflow offset value throughout operation to maintain constant space pressurization. A constant-percentage airflow offset value is sometimes used, but this creates a lower space pressurization at lower flow and may cause space pressurization reversal in facilities having multiple pressurization cascades.
- **Hybrid control (DF+DP)** (or **cascaded control**) combines the pressure accuracy of DP and the stability of DF. The offset value is resettable based on the pressure differential reading. The offset value reset schedule is predetermined, and the controller's parameters are adjusted or calibrated manually in the field.

Multiple-Space (Suite) Pressurization

Pressurization for a suite of clean manufacturing spaces is more complex. In practice, unforeseen air leakage interactions between spaces can lead to facility operational challenges. Because most of the air leaking out of one space leaks into another, adjusting one space's offset value often affects adjacent spaces' pressurization and can result in ripple effects. HVAC automation systems must provide stable control over supply, return, and exhaust to maintain the facility and environmental operational requirements. Careful facility designs and space layout arrangements are needed to minimize operational space pressurization challenges; overlooking this can cause difficulties in commissioning and operation. Properly designed facilities and control systems can avoid pressurization challenges such as sporadic, unstable, or unachievable pressurization requirements. For more information and procedures, consult the sources in the Bibliography.

A space pressure and flow (P&F) diagram for the controlled area (suite, zone, or floor) is often provided in design documents, and can be used as the basis of continuous quality control of cleanroom environmental parameters.

The system flow diagrams should indicate

- Airflow design settings (values) of all supply, return, and exhausts for each space inside the controlled area
- Desired space pressure value with an acceptable tolerance in each pressure-controlled space
- Resulting leakage flow directions (due to space pressure differentials) and their estimated leakage flow values through doors at closed-door conditions
- Room particulate classifications

The three traditional pressure-control methods (DP, DF, and DF+DP) require field adjustments of airflow offset values to achieve the differential pressurization values specified during design. A robust strategy is to control all spaces' pressures together as an optimized system, instead of independently. **Adaptive DF+DP** directly accounts for variable leakage flows between spaces, and actively adjusts each space's airflow offset to maintain required pressurizations continuously. It uses airflow and pressure differential measurements to estimate characteristics of leakage between spaces and adjust flow offsets automatically. This adaptive approach can be more effective for complex suite pressurization strategies. For design procedures and control strategies, see the related literature in the Bibliography.

6. TESTING CLEAN AIR AND CLEAN SPACES

The first standard written for a clean manufacturing room, or cleanroom, was published by the U.S. Air Force in March 1961. *Technical Order* (TO) 00-25-203 (USAF 1961) was the first standard with wide appeal to science and industry.

In 1963, a group of experts chaired by J. Gordon King created the first U.S. federal standard: U.S. General Services Administration (GSA) *Federal Standard* (FS) FED-STD-209, "Cleanroom and work station requirements, controlled environments." In 1966, it was released as FED-STD-209A, "Air-borne particulate cleanliness classes in cleanrooms and clean zones," and was revised several times over the years. Other cleanroom standards had been issued by many other countries, including Australia, France, Germany, Holland, Japan, and the United Kingdom. With the evolution of the global economy, the need for an international standard for cleanrooms became apparent. In 1993, International Organization for Standardization (ISO) Technical Committee TC 209 produced the first international cleanroom standard: ISO 14644, "Cleanrooms and associated controlled environments." Finally, in 2001, FS 209 was canceled and superseded by the ISO 14644 standards, and other countries around the world followed suit.

Three basic test conditions are used to evaluate a facility: (1) as built, (2) at rest, and (3) operational. **As-built** condition is the stage in which the cleanroom is built, but with none of the equipment or fixtures installed. **At-rest** condition refers to the state of having equipment and fixtures installed and operational, but without personnel. **Operational** condition is where the equipment and fixtures are all installed and operational, and personnel are present. A cleanroom cannot be fully evaluated until it is tested in operational condition. Thus, techniques for conducting initial performance tests and operational monitoring must be similar.

Although cleanroom classification by particle concentration is the prevalent method of evaluation, additional cleanroom attributes may also be tested based on operations and products specific to a given clean space. ISO 14644 standards provide several different attribute testing methods and classification criteria. The test or tests applied are determined by the cleanliness attributes of interest. The following cleanliness attribute tests can be chosen:

- Air pressure difference test
- Airflow test
- Airflow direction test and visualization
- Recovery test
- Temperature test
- Humidity test
- Installed filter system leakage test
- Containment leak test
- Electrostatic and ion generator tests
- Particle deposition test
- Segregation test

The ISO 14644 standards also provide for certification by chemical concentration for clean spaces concerned with chemicals in the air, such as organic light-emitting diode (OLED) display manufacturing or photolithographic areas in a semiconductor facility.

As noted previously, sources of contamination can be generated within the space or infiltrate into the space from an external source. The level of space contamination can be monitored using discrete particle counters or aerosol photometers, which use laser or light-scattering principles for detecting particles of 0.01 to 5 µm. For particles 5 µm and larger, microscopic counting can be used, with particles collected on a membrane filter through which a specific volume of sample air has been drawn.

HEPA filters in unidirectional flow and ISO *Standard* 14644-1 Class 5 (or cleaner) should be tested for pinhole leaks at the filter media, sealant between media and filter frame, filter frame gasket, and filter bank supporting frames. The filter frame interface with the wall or ceiling should also be tested. A filter bank pinhole leak can be extremely critical, because the leakage rate varies inversely as the square of the pressure drop across the hole (the industry term *pinhole* used to describe the leak site is a misnomer; the size is almost never that of a hole formed by a pin, but is actually many times smaller).

IEST testing procedures describe 12 tests for cleanrooms. The tests that are applicable to each specific cleanroom project must be determined based on the specific cleanroom's criteria.

7. PHARMACEUTICAL AND BIOMANUFACTURING CLEAN SPACES

Pharmaceutical product manufacturing facilities require careful assessment of many factors, including HVAC, controls, room finishes, process equipment, room operations, and utilities. Flow of equipment, personnel, and product must also be considered along with system flexibility, redundancy, and maintenance shutdown strategies. It is important to involve designers, operators, commissioning staff, quality control, maintenance, constructors, validation personnel, and the production representative during the conceptual stage of design. Critical variables for room environment and types of controls vary greatly with the clean space's intended purpose. It is particularly important to determine critical parameters with quality assurance to set limits and safety factors for temperature, humidity, room pressure, and other control requirements.

In the United States, regulatory requirements and specification documents such as current good manufacturing practice (CGMP) for finished pharmaceuticals (FDA 2008) and for sterile products (FDA 2004), ISPE guidelines (ISPE 2001, 2009, 2011), and National Fire Protection Association (NFPA) standards describe CGMP requirements. The goal of CGMP is to achieve a proper and repeatable method of producing therapeutic, medical, and similar products free from microbial and particle contaminants.

One factor that differentiates pharmaceutical processing suites from other clean spaces (e.g., for electronic and aerospace) is the requirement to meet government regulations and inspection for product licensing (e.g., U.S. Food and Drug Administration [FDA]). It is important to include the appropriate regulatory arms, such as the FDA's Center for Biologics Evaluation and Research (CBER) or the Center for Drug Evaluation and Research (CDER), early in the concept design process.

Design Process

It is important to develop a qualification plan (QP) early in the design process. Functional requirement specifications (FRS), critical parameters and acceptance criteria, installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ) in the cleanroom suites are all required to ensure proper process performance and validation. IQ, OQ, and PQ protocols, in part, set the acceptance criteria and control limits for critical environmental parameters such as temperature, humidity, room pressurization, air change rates, and operating particle counts (or air classifications). These protocols must receive defined discipline approvals in compliance with the owner's quality policies. The qualification plan must also address master document updates, SOPs, preventive maintenance (PM), and operator and maintenance personnel training.

The quality of pharmaceutical products depends on the proper establishment of critical validation parameters and protocols. This ensures that the pharmaceutical manufacturing operations are executed properly and consistently, and maintained such that any deviations from the critical control parameters are identified, addressed, and mitigated. The pharmaceutical process must remain under control throughout the entire product life cycle, so it is important for engineers and designers to avoid including tangential or non-process-impacting parameters on the list of validated parameters. For example, while processing room temperature and relative humidity may be critical to a product's production, the associated air handler's chilled water flow rate and/or temperature are not, as long as the critical parameters are maintained within the requirements of the pharmaceutical process. The same logic often justifies not validating the facility's electrical supply or the drainage system if they do not have a direct impact on the product or process quality. Over validating can create a lot of additional paperwork in the original validation plan submittal, and a lot of unnecessary monitoring and reporting on deviations or excursions that don't impact the operations directly. It is wise to limit the systems, sequences, and equipment in the validation plan to only the essential items that impact the pharmaceutical product or process.

The technical design process often begins with **piping and instrumentation diagrams (P&IDs)** depicting the relationships between process equipment, utility systems, and control instrumentation. It is critical to document the physical sequence of equipment and systems throughout the design and installation processes, as well as how these systems interconnect, to ensure drug product quality and consistency. During design, these diagrams also provide the basis for developing system control schemes, process work and material flows, and further safety and operational investigations, such as the hazard and operability study (HAZOP).

Piping and instrument diagrams are necessary early in the facility design process to ensure design goals are achieved, with two types playing a central role in HVAC system design:

- **Room classification and pressurization diagrams** typically consist of a facility room layout plan drawing visually coded to indicate required pharmaceutical room classifications. Room pressurization values and directions often are shown on this diagram because differential pressure between rooms is critical to maintain required the environmental quality.
- **Air handler zoning layout diagrams** show the service area of each air handler system (or subsystem) on a plan view of the facility room layout. This diagram is used to optimize HVAC system layouts to minimize cross contamination issues, and to enhance facility operational responses to equipment failure and maintenance service outages. It is often necessary to segregate the exhaust and return HVAC system paths from other HVAC systems to prevent cross contamination.

System flow and room pressurization diagrams are used throughout the facility design process, and can be used as the basis of continuous quality control of cleanroom environmental parameters. It is critical to develop HVAC system layouts in conjunction with environmental quality requirements (room classifications) to minimize process contamination risks, promote stable facility pressurization strategies, and minimize facility operational challenges during equipment servicing.

Biomanufacturing and pharmaceutical aseptic clean spaces are typically arranged in operational suites based on specific process and formulation requirements. For example, common convention positions an aseptic core (ISO *Standard* 14644-1 Class 5) filling area in the innermost room, which is at the highest pressure, surrounded by areas of descending pressure and increasing particulate classes and bacterial levels (see Figure 11).

In aseptic processing facilities, the area of highest cleanliness is intentionally placed with lower-cleanliness areas surrounding it, separated by airlocks and room pressure differentials. A positive pressure difference of 10 to 15 Pa between air cleanliness classifications is common (FDA 2004), with the higher-cleanliness space having the higher pressure. Lower pressure differences may be acceptable if they are proven effective. A pressure differential is generally accepted as good manufacturing practice to inhibit particles from entering a clean suite.

Where there are spaces adjoined in series that all have different cleanliness classifications, a multiple-step pressurization cascade should be implemented, which should have air flow from the cleanest spaces to the least clean spaces. Normally, three pressure steps are used for ISO Class 6, 7, or 8 applications; four pressure steps are desirable for Class 5 or cleaner applications. Air locks are effective at minimizing potential particle contamination from surrounding nonclassified or less-clean areas; selection depends on the type of cleanroom (Figure 12), because some that involve fume or biological agent operations may have a containment provision. For biological agent operations, the U.S. Centers for Disease Control and Prevention (CDC) and National Institutes of Health (NIH) define four biosafety levels (BSL-1 to BSL-4), discussed in more detail in Chapter 16.

An air lock is a transitional room between adjacent rooms to prevent airborne cross contamination. Based on relative space pressure levels, air locks can be classified as follows:

- **Cascading:** Air lock pressure is between pressures in cleanroom and corridor
- **Bubble:** Air lock pressure is above pressures in cleanroom and corridor

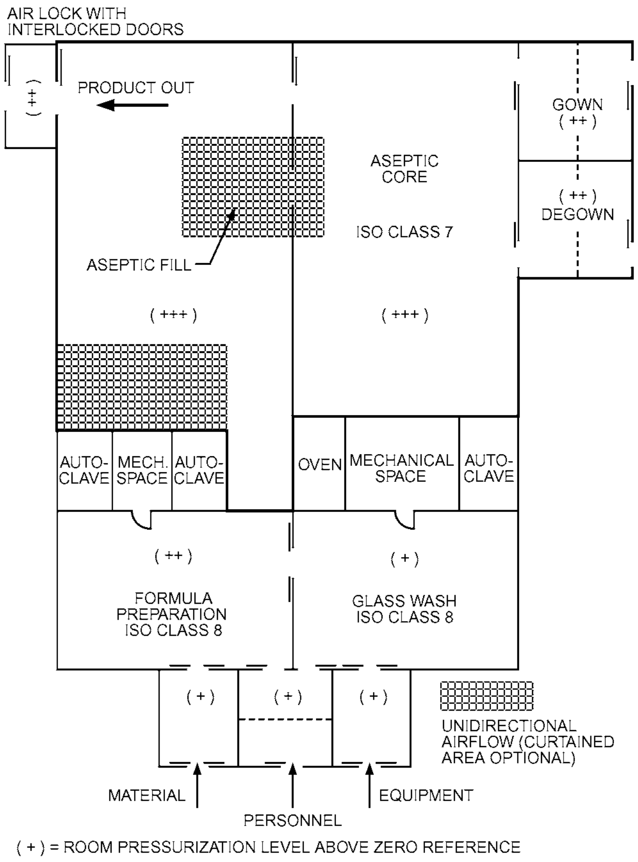

Fig. 11 Typical Aseptic Suite

- **Sink:** Air lock pressure is below pressures in cleanroom and corridor
- **Dual-compartment:** A bubble and a sink air lock are connected

Double-door air locks are often used at cleanroom entrances and exits. A **required time delay (RTD)** needs to be specified between door openings, so both are not open simultaneously, to minimize possible contamination opportunities. The RTD should be long enough for HEPA-filtered clean supply air to partially or fully replace the entire air volume of the air lock room at least once before the second door is allowed to open. RTD operational procedures often use hard interlocks (i.e., the second door cannot be opened until after the required time delay) or soft interlocks, in which procedures are supplemented by lights or alarms.

Design Concerns for Pharmaceutical Cleanrooms

Proper design and qualification of a manufacturing facility is required under part 211, subpart C, of the CGMP regulations on Buildings and Facilities. Section 501(a)(2)(B) of the Act (21 U.S.C. 351[a][2][B]) states the following:

> A drug . . . shall be deemed to be adulterated . . . if . . . the methods used in, or the facilities or controls used for, its manufacture, processing, packing, or holding do not conform to or are not operated or administered in conformity with current good manufacturing practice to assure that such drug meets the requirements of this Act as to safety and has the identity and strength, and meets the quality and purity characteristics, which it purports or is represented to possess. . . . CGMP regulations require that manufacturing processes be designed and controlled to assure that in-process materials and the finished product meet predetermined quality requirements and do so consistently and reliably.

Qualification of utilities and equipment is critical to demonstrate and document compliance with all requirements, and generally includes the following activities:

- Selecting utilities and equipment construction materials, operating principles, and performance characteristics based on whether they are appropriate for their specific uses.
- Verifying that utility systems and equipment are built as designed and installed in compliance with the design specifications, with proper materials, capacity, and functions, and properly connected and calibrated.
- Verifying that utility systems and equipment operate in accordance with the process requirements in all anticipated operating ranges. This should include challenging the equipment or system functions while under load comparable to that expected during routine production. It should also include the performance of interventions, stoppage, and start-up as is expected during routine production. Operating ranges should be shown capable of being held as long as would be necessary during routine production.

Before any batch from the process is commercially distributed for use by consumers, a manufacturer should have a high degree of confidence in the performance of the manufacturing process and that it will consistently produce APIs and drug products meeting requirements relating to identity, strength, quality, purity, and potency. Assurance should be obtained from objective information and data that demonstrates that the commercial manufacturing process is capable of consistently producing acceptable quality.

Manufacturers must establish control procedures that monitor the output and validate the performance of manufacturing processes to prevent variability in the in-process material and the drug product. Engineering responsibility includes identifying any and all variables that may foreseeably affect product or process quality, and assessing these potential problems during quality-driven risk analysis. Careful identification and control of variables that can affect product and process quality is necessary to ensure system performance and compliance. Utility system designs emphasizing performance stability and consistency through appropriate controls, alarms, and routine maintenance and inspections are required for compliance with pharmaceutical regulations. A lack of compensation for HEPA filter loading is a common HVAC system qualification challenge; if airflow or pressure controls are not used, appropriate alternative controls or alarms are required for documentation of continuous compliance. For most cleanroom applications, a routine environmental monitoring program verifies that the critical parameter of room cleanliness is being maintained. For holding rooms and other specialized applications, ensuring the stability of HVAC system performance through air filter loading compensation is usually the most effective way to support consistent facility operations.

The owner and designer must define the tolerable range of variable value (acceptance criterion) for each critical parameter. The product's safety, identity, strength, purity, and quality must be demonstrated to be unadulterated in that range. The owner should define **action alarm** points at the limits of acceptance criteria, beyond which exposed product may be adulterated. The designer should select tighter (but achievable) target design values for critical parameters (in the range of acceptance criteria), along with appropriate critical parameter monitoring strategies and values for warning alerts and actionable alarms.

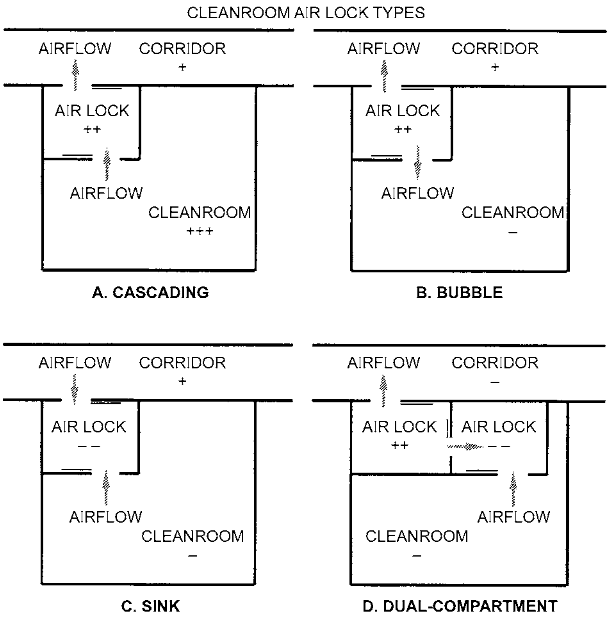
Facilities manufacturing penicillin or similar antibiotics (e.g., cephalosporins) must be physically isolated from other manufacturing areas and served by a dedicated HVAC system. Other processes also require dedicated HVAC systems, including high-potency formulas and formulas that must have dedicated production facilities.

Facilities manufacturing aseptic/sterile products derived from chemical synthesis may have different requirements than those manufacturing biological or biotechnological products. The owner must define the inspecting agency's requirements.

The United States Pharmacopoeia (USP) limits temperatures to which finished pharmaceutical products may be exposed to 15 to 25°C. The production facility may need tighter limits than these, based on the owner's observed product data. Personnel comfort is also a factor in design. Personnel perspiring in their protective overgarments can increase particulate and microbial counts, so lower temperatures and tighter temperature control may be advantageous.

Relative humidity may be critical to the product's integrity. Some products are processed or packaged cold and need a low room dew point to prevent condensation on equipment and vials. Some products are hygroscopic and require lower humidity than a condensing coil can provide; in that case, consider desiccant dehumidification. Caution must be taken in designing low-humidity (i.e., low-vapor-pressure) spaces to ensure limited moisture migration through walls and ceilings bordering an unclean space. Low-humidity spaces should be provided with air locks to reduce moisture propagation into the low-humidity cleanroom. The importance of positive pressure increases when moisture infiltration potential becomes an element of the design process. Humidification is usually needed for personnel comfort but not usually for product needs; it may also be needed where dust might present an explosion hazard or where low humidity may hinder handling of dry materials. Clean steam (free of chemicals and other additives) is preferred for humidification because it is free of bacteria, but the humidification system should be free of amines or other contaminants if space air might contact the product. Humidification control systems often require careful sensor placement in critical areas and safety shutoff monitors to prevent overhumidification.

Although airborne particles and viable organisms may be minimized by dilution with high air change rates and by supplying filtered air, the most effective control is to minimize release of these contaminants in the space. Personnel and machinery are the most common sources of contamination, and can be isolated from the product by gowning, masks, and isolation barriers. Careful study of how each space operates should reveal the most probable sources of contaminants and help the HVAC designer determine dilution air quantities and locate supply air outlets and return air inlets. Avoid duct liners and silencers in supply air ductwork where contaminants can collect and bacterial and mold spores can accumulate. Ensure special attention is paid to cleaning and degreasing of metal sheeting



CLEANROOM AIR LOCK APPLICATION STRATEGIES

Type of Cleanroom	Air Lock Type	Purpose of Air Lock	Relative Pressure Relationship
• Positive pressure • No fume or bio agent • No containment needed	Cascading	• Prevent cleanroom being contaminated by dirty corridor air • Prevent cleanroom being contaminated from surrounding spaces through cracks	Cleanroom: +++ Air lock: ++ Corridor: +
• Negative pressure • Has fume or bio agent contamination • Containment needed	Bubble	• Prevent cleanroom being contaminated by dirty corridor air • Prevent cleanroom fume or bio agent releasing to corridor	Cleanroom: – Air lock: ++ Corridor: +
• Negative pressure • Has fume or bio agent contamination • Containment needed	Sink	• Provides containment • Prevent cleanroom fume or bio agent releasing to air lock. No personal protective equipment is needed.	Cleanroom: – Air lock: – – Corridor: +
• Negative pressure • Has toxic fume or hazardous bio agent contamination, or has potent compound substances • Containment needed • Personal protection needed	Dual-Compartment	• Prevent cleanroom being contaminated by dirty corridor air • Prevent cleanroom fume or bio agent releasing to corridor • Personal protective equipment (such as pressurized suit and respirator) is required	Cleanroom: – Neg. Air lock: – – Pos. Air lock: ++ Corridor: –

Notes:
1. Excessive negative pressure in cleanroom is not recommended. If it is not surrounded by other clean spaces, untreated dirty air can infiltrate through cracks into cleanroom.
2. A cleanroom service corridor often must be designed slightly positive or neutral pressure. Do not design for negative pressure unless a dual-compartment lock is used.

Fig. 12 Air Lock Types and Applications

and air ductwork before installation. Ensure the cleaning agent will not cause flaking of galvanized ductwork or leave residual soap. Factory-wrapped ducts and components with clean installation and inspection protocols promote cleanroom system cleanliness.

Airborne particle and microbe levels in aseptic processing areas are limited by government regulations, with lower limits for more critical spaces. European and FDA particle limits are for the space in full operational mode, and can also be used conservatively as limits for the space at rest.

Facilities complying with U.S. CGMPS for aseptic processing must meet particle levels with manufacturing under way. (An exception is aseptic powder processing, in which airborne particulate levels at powder filling heads will exceed limits.) There should be no microbial contaminants in the critical-zone airstream, where filling and other critical activities occur; this area should be ISO Class 5. The area immediately around the critical zone should be ISO Class 7. If the critical area is within an isolator, then the area outside the isolator may be ISO Class 8. Less critical support areas can be ISO Class 8. For more detail on facility design, see FDA requirements.

According to the FDA, 20 ach is usually sufficient for ISO Class 8 rooms; ISO Class 7 and 5 areas require significantly higher air change rates. Facility requirements for terminally sterilized products are not defined.

EU GMP (2008) also contains requirements for aseptic processing, and also addresses terminally sterilized products. Note that many facilities are constructed to meet both EU and U.S. GMPs (FDA 2008).

Restricted access barrier systems (RABS) are an alternative to a conventional cleanroom or isolator. Use of RABS should be approved by the manufacturer's quality unit during design.

Once the product is in containers, the need for particulate control and minimum air changes is reduced or eliminated, depending on the degree of protection provided by product packaging. The owner should determine the necessary critical environmental parameters and acceptance criteria for each space and processing step.

Return openings for space HVAC should be low on the walls, to promote downward airflow from supply to return, sweeping contaminants to the floor and away from the product. For ISO Class 8 and lower, ceiling return or exhaust register are common. Room air quality can be improved greatly by optimizing return and exhaust register locations to route air flows away from cleaner areas, which in many cases can resolve problems more effectively than changing supply register locations. In larger spaces, internal return air columns may be necessary. Perforated floors are discouraged because of the difficulty in cleaning them. It is good design practice to avoid returning air from one air-handling unit (AHU) system to another, unless special project considerations justify this decision. Mixing AHU zones through return air pathways may lead to cross-contamination concerns and operational challenges when HVAC maintenance shutdowns affect multiple operations. Combining noncontrolled and controlled areas through return or exhaust air pathways may also lead to operational challenges by expanding controlled-area boundaries into zones with activities that may negatively influence process or product integrity.

Aseptic facilities usually require pinhole-scanned (integrity-tested) HEPA filters (not ULPA) on supply air. Many facilities install HEPA filters in the supply air to nonaseptic production facilities to minimize cross contamination from other manufacturing areas served by the HVAC system. To increase the life of terminal HEPA filters in aseptic facilities, and to minimize the need to rebalance the supply system because of differential loading of terminal HEPA filters, many designers install a high-capacity HEPA bank downstream of the supply air fan, with constant-volume control to compensate for primary filter pressure changes and any dehumidifier airflow. The final HEPA filter is usually in a sealed gel frame or of a one-piece lay-in design that can be caulked to the ceiling frame, maintaining the integrity of the room envelope.

Aseptic product must be protected by pressurizing the space in which it is exposed, to about 12.5 Pa above the next lower cleanliness space classification. To keep the pressure differential from dropping to zero when a door is opened, air locks are often used between spaces of different air pressures, especially at the entrance to the aseptic fill space itself. Space pressure is a function of airflow resistance through cracks, openings, and permeable surfaces in the space shell. Consider all potential openings, slots, electrical outlets, annular spaces around pipe penetrations, and door leakage that could affect the amount of air needed to pressurize the space. Because space offset airflows and space pressure are closely related, outdoor or makeup air requirements are often dictated by space pressures rather than by the number of occupants. The HVAC system should be able to handle more makeup air than needed for commissioning, because door seals can deteriorate over time.

ISO Class 5 unidirectional hoods are commonly used in process-critical applications for aseptic processes, consisting of banks of HEPA (or ULPA) filters, integrity-tested to be pinhole-free. Because it is difficult to maintain unidirectional flow for long distances or over large areas, the hood should be located as closely as possible to product critical surfaces (work surface). Hood-face velocity is usually 0.35 to 0.45 m/s, but the user should specify velocity and uniformity requirements. The velocity measurement is commonly taken at a distance of 150 to 300 mm from the filter face to demonstrate unidirectional airflow via airflow pattern testing. A unidirectional hood usually has clear sidewalls (curtains) to promote downward airflow and prevent entrainment of space particles into the hood's zone of protection. Curtains should extend below the product critical surface and be designed to prevent accidental disruption of airflow patterns by personnel. Many production facilities prefer rigid curtains for easier cleaning and sanitization.

Hood fan heat may become a problem, forcing the designer to overcool the space from which the hood draws its air or to provide sensible cooling air directly into the hood's circulating system.

Decontamination

Cleanrooms used for sterile operations are rarely built clean enough for their intended purpose. Before the initial use of the room or after a shutdown, the cleanroom must be decontaminated or disinfected to ensure bioburden and particulate levels are at or below acceptable limits. For some operations, such as compounding of sterile preparations, surface disinfection is considered adequate. However, larger-scale CGMP sterile manufacturing operations typically use some type of biological decontamination before final occupancy. Cleanrooms for sterile processing should be designed to accommodate decontamination or disinfection.

Having originated from small-volume spaces (i.e., sealed glove boxes), most early large-volume decontamination processes included using formaldehyde gas generated by heating paraformaldehyde in a frying pan or spraying with a mild peracetic acid and wiping all surfaces, which was very labor intensive. Today, most cleanrooms are decontaminated by using either chlorine dioxide (CD) or hydrogen peroxide. Regardless of the type of decontamination process used, the cleanroom should accommodate the process. Factors that should be considered include (1) leaktightness of the cleanroom shell, (2) compatibility of cleanroom finishes to the decontamination process, and ability to (3) remotely control the process and recirculate the gas, (4) maintain appropriate humidity levels during the decontamination process, and (5) evacuate the gas after decontamination is complete.

Sometimes it is economically feasible to integrate the gas-generating equipment with the cleanroom air ducts. This decision is dictated by the intended gassing frequency, or by the need for automated recovery preparedness following any kind of bioevent. Strategically placed, airtight dampers, gas distribution nozzles, a means to agitate the gas within the cleanroom (or suite of rooms), and exhaust equipment for evacuation are some of the components necessary for automated decontamination. As with all decontamination procedures, protocols must be developed to demonstrate efficacy.

Barrier Technology

Cleanrooms designed to meet ISO Class 5 or better require considerable equipment, space, and maintenance. Operating such cleanrooms is expensive. Furthermore, cleanrooms typically need gowned operators inside to manipulate product and adjust machinery. Because the operator can be a major source of particle generation and contamination, it is better to separate the operator from the controlled environment; this allows the volume of the controlled space to be reduced significantly to a point where only the process equipment is enclosed. Using such a separative device can substantially reduce capital and operating costs while meeting required airflow patterns and cleanliness levels (IEST RP CC028.1; Xu 2007a, 2008). Separative devices, including microenvironments, isolators (glove boxes), and restricted access barrier systems (RABs), are thus becoming increasingly popular. These systems are also called **barrier technology** in pharmaceutical applications and **minienvironments** in semiconductor industries.

Barrier technology systems must be designed to fit the specific application and can be highly customized to allow the tasks required to accomplish the process needs. Applications vary widely based on product, process equipment, and throughput volume. Barrier technology systems are typically positive-pressure envelopes around the filling equipment with multiple glove ports for operator access, constructed of polished stainless steel with clear, rigid view ports. Systems can be fully sealed or leak into the support environment via "mouse holes" used to allow passage of vials in and out of the unit. Ancillary systems designed to prevent migration of contaminants are used for passing stoppers, containers, and tools in and out of the barrier systems. These can range from simple lock chambers to highly complex alpha/beta ports fitted with features to allow sanitization of the systems or contents. Important design concerns include accessibility, ergonomics, integration with mating equipment, decontamination or sterilization/sanitization procedures, access to service equipment, filter change, filter certification, process validation, and environmental control.

Extra attention must be paid to product filling, vial, and stopper protection; access to the barrier for sterilized stoppers; interface to the vial sterilization (depyrogenation) device; sterilizing product path, including pumps and tubing; and airflow patterns inside the barrier, especially at critical points. If a vapor-forming sanitizing agent such as hydrogen peroxide is to be used as a surface sanitizer, care must be taken to ensure good circulation and adequate concentration inside the barrier, as well as removal of residual vapor in the required time frame. In addition, because many of the sanitizing agents are strong oxidizers, care must also be taken in selecting construction materials to ensure compatibility and their ability to absorb and retain or potentially outgas the sanitizing agent at a later time.

Barrier technology systems may also be designed for applications requiring operator protection from high-potency and cytotoxic compounds (those that may have an inadvertent therapeutic effect on an operator), while maintaining a sterile internal environment. These tend to be total containment systems with totally contained product transfer ports. All internal surfaces are sealed from the external environment or potential operator exposure. Because of potential chamber leaks, its internal pressure may be kept negative compared to the ambient space via exhaust fans, posing an additional potential risk to the product that must be addressed by the owner.

Other systems, such as a nonsterile powder control booth, may incorporate more passive barrier designs. One such design incorporates a downflow sampling and weighing cubicle. This arrangement takes advantage of unidirectional airflow to wash particles down and away from the operator's breathing zone. Low-wall air returns at the rear of the cubicle capture fugitive dust. An arrangement of roughing and final filters allows air to return to the air handlers and back to the work zone through ceiling-mounted HEPA filters. Products involving noxious or solvent vapors require a once-through air design.

Barrier technology allows installation in environments that might require no special control or particulate classification. Isolators, RABs, and containment chambers are still relatively new to the pharmaceutical industry. As such, installations for sterile products should be in a controlled ambient room condition of ISO Class 8 or better.

Maintainability

A facility that considers maintainability (e.g., accessibility, frequency of maintenance, spare parts, rapid diagnostics and repair, reliability and facility uptime) in its design will be much more reliable and should have fewer operational and regulatory concerns. Many pharmaceutical facilities have been designed so that routine maintenance can be performed from outside the facility's clean space (except for unidirectional and terminal HEPA filters, which must be tested twice a year). Quality of materials is important to reliability, especially where failure can compromise a critical parameter or operation. Consider how much exposure and risk to product and personnel exist during maintenance (e.g., how to clean the inside of a glove box contaminated by a toxic product). Beyond cleanable room surfaces that must be sanitized, consider whether and how HVAC equipment may be decontaminated using the owner's procedures. Determine whether ductwork must be internally cleaned, and how. Reduced- or no-shutdown HVAC system designs require energy-efficient and redundant components. When incorporating redundant components into systems, it is important to consider how both maintenance and removal/replacement of a component would be executed; the effect of redundancy is negated if there is no way to isolate equipment that needs to be replaced. Aligning HVAC system layouts with facility operational areas or suites can save significant operating costs and increase plant availability.

Controls, Monitors, and Alarms

Space pressure may be maintained by passive (fixed offset) HVAC systems if there are limited airflow variables. For example, the HVAC system for a few pressurized spaces may be statically balanced if there is a method of maintaining supply airflow volume to compensate for filter loading to ensure minimum supply, return, and exhaust air changes. More complex designs may require dynamic pressure control. Both filling lines with conveyors and slide gates between rooms where air moves from one room to another at varying rates usually require active pressure control to maintain room's pressures and their relationships at all times. It is important to avoid multiple pressurization loops controlled from the same or interrelated parameters, because this can lead to space pressurization instabilities. Complications can result from fans in series controlling similar or related properties. Improved system stability results from controlling to an airflow value at the room space level, and to duct air pressure at the branch or air handler level. Pressure controls should not overreact to doors opening and closing, because it is virtually impossible to pressurize a space to 12.5 Pa with a door standing open. A door switch is often used to send a signal to space pressure control to avoid overreaction. Architectural layout may affect dynamic room pressure control. It is a good practice to position such spaces away from exterior walls where wind loading exists and interior corridors, which typically do not have dynamic pressure control.

If space air humidity must be maintained to tolerances tighter than what normal comfort cooling can maintain, consider using active relative humidity control. If a desiccant dehumidifier is needed, unit operation over its range of flow must not adversely affect the ability of the HVAC to deliver a constant air supply volume to the facility.

Monitor and alarm critical parameters to prove they are under control. Log alarm data and parameter values during excursions. Logging may range from a local recorder to direct digital control (DDC) data storage with controlled access. Software source code should be traceable, with changes to software under the owner's control after qualification is complete. Commercial HVAC software is usually acceptable, but should be verified with regulatory agencies before detailed design begins. Also, keep complete calibration records for sensors, alarms, and recorders of critical parameter data.

When establishing alarm set points, consider that for systems serving regulated industries, alarms (or deviations from operational parameter [OP] acceptance limits) often require extensive documentation of the deviation, corrective actions taken, and any impact on critical processes and/or products. By setting up early warning alarm points, the operators can identify a system trending towards an operational deviation point and can intercede before the system hits its OP limits, precluding the need to prepare deviation or excursion reports.

Noise Concerns

HVAC noise is a common problem caused by attempts to overcome the pressure drop of additional air filtration. The noise level generated must be reduced in lieu of adding duct silencers, which may harbor bacteria and are difficult to clean. Separate supply and return fans running at lower tip speeds instead of a single-fan air handler may reduce generated noise levels. HVAC noise may not be an issue if production equipment is considerably noisier. For a more detailed discussion on noise and vibration issues, see Chapter 49.

Nonaseptic Products

Nonaseptic pharmaceutical facilities (e.g., for topical and oral products) are conceptually similar in design to those for aseptic product manufacturing (control of airborne particulate and microbial contaminations), but with fewer critical components to be qualified. However, critical parameters such as space humidity may be more important, and airborne particle counts are not considered in the United States. If the product is potent, barrier isolation may still be advisable. Space differential pressures or airflow directions and air changes are usually critical (needed to control cross contamination of products), but no regulatory minimum pressure or air change values apply.

8. START-UP AND QUALIFICATION OF PHARMACEUTICAL CLEANROOMS

Qualification of HVAC for Aseptic Pharmaceutical Manufacturing

Qualification is a systematic, quality-based approach to ensuring and documenting that the pharmaceutical facility, systems, equipment, and processes will deliver everything required for safe and repeatable drug products, including the facility design, installation, operation, maintenance, documentation, and pharmaceutical processing, filling, capping, holding, handling, and storage. Qualification of the pharmaceutical cleanroom HVAC is part of the overall qualification of the facility. Equipment affecting critical parameters and their control must also be qualified. Other groups in the manufacturing company (e.g., safety or environmental groups) may require similar commissioning documentation for their areas of concern. The most important objectives in meeting the approving agency's requirements are to (1) state what procedures will be followed and verify that it was done, and (2) show that product is protected and space acceptance criteria are met.

Qualification Plan and Acceptance Criteria

Early in design, it should be determined who will be responsible for and how to produce as-built drawings, maintenance files, and training. They should create a qualification plan for the HVAC, including (1) a functional description of what the systems do along with specific process and room requirements; (2) maps of room classification and pressurizations, airflow diagrams, and cleanliness zones served by each air handler; (3) a list of critical components to be qualified, including the automation system controlling the HVAC; (4) a list of owner's procedures that must be followed for qualification of equipment and systems that affect critical parameters; (5) a list of qualification procedures (IQ/OQ/PQ protocols) written especially for the project; and (6) a list of equipment requiring commissioning, determined through a risk-based product and process impact analysis.

The approval procedure should be defined in the QP. It is important to measure and document critical variables of a system (e.g., space pressure), but it is also important to document and record performance requirements and results for components that affect the critical parameters (e.g., room pressure sensors, temperature sensors, airflow volume monitor) for GMP as well as business records. Documentation helps ensure that replacement parts (e.g., motors) can be specified, purchased, and installed to support critical operations.

It is important to determine all components and instruments that could affect critical parameters and could, through an undetected failure, lead to product adulteration. This may be accomplished by a joint effort between the mechanical engineer, owner, quality experts, and a qualified protocol writer. If performance data are in the qualification records, replacement parts of different manufacturers may be installed without major change control approvals, as long as they meet performance requirements. Owner approval for the qualification plan should be obtained during detailed design.

Qualification requires successfully completing the following activities for critical components and systems. The designer should understand the requirements for owner's approval of each protocol (usually, the owner approves the blank protocol form and the subsequently executed protocol).

The **installation qualification (IQ)** protocol documents construction inspection to verify compliance with contract documents, including completion of punch list work, for critical components. It may include material test reports, receipt verification forms, shop inspection reports, motor rotation tests, duct/equipment cleaning reports, duct leak testing, P&ID walkdowns for component installation inspections, and contractor-furnished testing and balancing. It also includes calibration records for instrumentation used in commissioning and for installed instrumentation (e.g., sensors, recorders, transmitters, controllers, and actuators) traceable to National Institute of Standards and Technology (NIST) instruments.

Control software should be bench tested, and preliminary (starting) tuning parameters should be entered. Control loops should be dry-loop checked to verify that subsystem installation, addressing, operation, and graphics are correct. Equipment and instruments should be tagged and wiring labeled, then field-verified against record drawings. Commissioning documentation must attest to completion of these activities and include as-built drawings and installation/operation/maintenance (IOM) manuals from contractors and vendors.

The **operational qualification (OQ)** protocol documents start-up, operation, and maintenance SOPs are correct and activated for critical systems and components. This includes individual performance testing of control loops under full operating pressure performed in a logical order (i.e., fan control before room pressure control). The commissioning agent must verify that operating parameters are within acceptance criteria.

The HVAC system may be challenged under extremes of design load (where possible) to verify operation of alarms and recorders, to determine (and correct, if significant) weak points, and to verify control and door interlocks. Based on observations, informal alert values of critical parameters that might signify abnormal operation may be set up. Even if the product would not be adulterated at these parameter values, staff may implement an alarm to require responses prior to encountering deviations from normal operation.

Documented smoke tests verify space pressure and airflow in critical spaces or inside containment hoods, and show airflow patterns and directions around critical parts of production equipment. Many smoke tests have been videotaped, especially when space pressure differentials are lower than acceptance criteria require and pressures cannot be corrected.

Files should include an updated description of the HVAC, describing how it operates, schematics, airflow diagrams, and space pressure maps that accompany it. Copies should be readily accessible and properly filed. Operating personnel should be familiar with the data in these records and be able to explain it to an agency inspector.

Other Documents. GMP documents should also include test reports for HEPA filters (efficiency or pinhole-scan integrity tests) at final operating velocities. If the filter installer performed the tests, the data should be part of the IQ package.

Documents should verify that instruments display, track, and store critical parameters and action alarms. Consider recording data by exception and routine documentation of data at minimal regular frequency.

Systems and equipment should be entered into the owner's maintenance program, including rough drafts of associated maintenance procedures (final drafts should reflect commissioning results).

Records should document the completion of these activities, including final as-built, system diagrams, facility pressurization diagrams, air change rate calculations, and air and water balance reports.

Performance qualification (PQ) is proof that the entire HVAC system performs as intended under actual production conditions. PQ is the beginning of ongoing verification (often called validation) that the system meets acceptance criteria of the product. This includes documentation of

- Maintenance record keeping and final operating and maintenance procedures in place, with recommended frequency of maintenance, and (at the owner's option) a procedure for periodic challenge of controls and alarms
- Logs of critical parameters that prove the system maintains acceptance criteria over a prescribed time
- Training records of operators and maintenance personnel
- Final loop tuning parameters

After accepting PQ, the owner's change control procedure should limit further modifications to critical components (as shown on IQ and OQ forms) that affect the product. Much of the facility's HVAC equipment should not need qualification, but records for the entire facility must be kept up to date through quality change control, and problems must be corrected before they become significant. Records of corrections should also be kept.

Once the system is operational, pharmaceutical product trial lots are run in the facility (process validation) and the owner should regularly monitor levels of viable (microbial) and nonviable particles, room pressurization, and other controlled parameters in the processing areas.

9. SEMICONDUCTOR CLEANROOMS

Semiconductor wafer fabrication cleanrooms (also called wafer fabs, fabs, or chip cleanrooms) have historically been some of the largest cleanrooms. Recently, mega and giga cleanrooms (i.e., those that produce megabyte and gigabyte memory chips) have been constructed that may exceed 40 000 m^2 of under-filter clean area and produce more than 200,000 wafers per month. A new fab today may cost 10 to 15 billion U.S. dollars, is expected to be built within 10 to 12 months, and is expected to recover capital investment in less than 3 years.

Wafer fabs seek to produce complicated products with extremely small feature sizes. Contamination at the wafer level can result in significant yield losses. Yield can be defined most basically as the proportion of successfully fabricated products (e.g., chips) compared to the total number of products that started the manufacturing process. Yield is often considered the most important financial factor in the manufacturing of semiconductor devices. It is inversely proportional to manufacturing cost: the higher the yield, the lower the cost.

Configuration

Semiconductor wafer fabs have traditionally been designed around common manufacturing processes (e.g., photolithography, metal deposition, etching, thin film deposition, implanting, diffusion, planarization) These process area layouts were coupled to the subfab utility distribution with some decoupling to allow for flexibility in equipment tool sets. Photolithography areas, with their tight vibration, temperature, and humidity control and susceptibility to molecular contamination, were always isolated from other process areas, allowing the building structure to be tailored to the specific needs of the photo areas and save costs for other process areas.

Semiconductor wafer fabs are extremely complex, with dozens of utility systems and many hazardous chemicals being used. In the absence of regulatory oversight of the manufacturing processes in pharmaceutical, medical device, and biotechnology facilities, building codes have been the most consistent regulator of semiconductor fab design and construction. The collaborative development of specific codes addressing semiconductors between code officials, owners, designers, and insurance industry has produced a set of codes that have attempted to meet the changing needs of the factories while still maintaining a safe working environment.

The unique multilevel building design and operation of wafer fabs led code officials to specifically identify semiconductor fabrication and the special needs involved. The various code sections (building, fire, and mechanical) have addressed the handling and storage of hazardous materials, fire resistance of materials of construction, conveyance of hazardous materials, egress paths, safe zones, fire protection, occupancy separations, etc.

Part of the justification of multiple levels is the need for extensive utility distribution; a typical semiconductor wafer fab can have in excess of 50 unique utilities. Fab complexity is best demonstrated by a visual of a typical multilevel wafer fab (Figure 13). Fab spaces are composed of process areas, subfabs (more than one), chases, return air plenums, and supply air plenums.

Referring to Figure 13, above the ceiling of the process area are the cleanroom supply air plenums, ductwork, fan filter units (FFUs) and, in some fabs, process utilities. The ceiling structure is designed to support cleanroom filters or FFUs, the wafer automated material handling system (AMHS), lighting, ionization system, maintenance personnel, and optional monitoring devices for temperature, humidity, and particles. The area where most wafer processing occurs is typically referred to as the **process area**. The process area is where most cleanroom operators work and contains the process equipment main frames, wafer delivery equipment, metrology equipment, and other wafer-handling equipment. Below the process area is the subfab(s), where a hidden mass of equipment is located. Subfabs may be divided into clean and dirty subfabs, isolating potential contamination sources from the clean subfab, which in turn protects the process area.

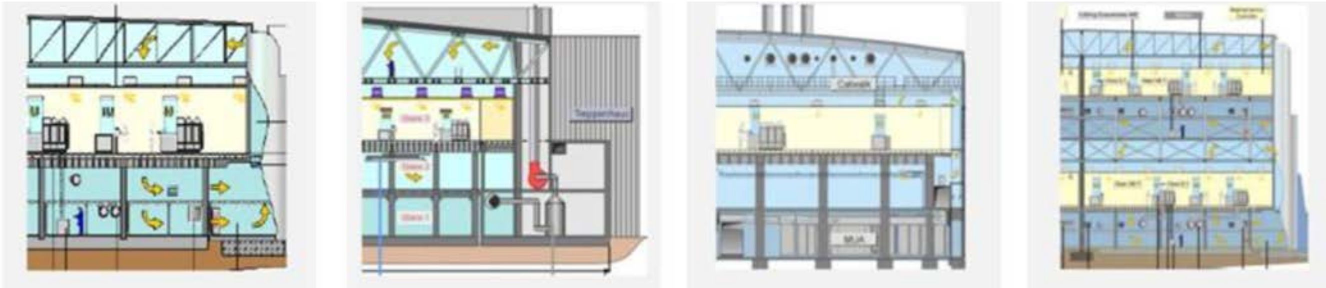


Fig. 13 Multilevel Fabs
(Courtesy of M+W Group)

The process area may have raised floors (most common) or a concrete slab (usually called a waffle floor due to the concrete casting shape) or other structural flooring materials supporting process equipment (heavy and vibration-sensitive tools sit on isolated pedestals and not directly on a raised floor). Some air management designs treat the space below the raised floor as an additional level, though most code authorities do not consider this a level when evaluating building height limitations. The space below the raised floor is considered an air plenum in most jurisdictions.

Contamination Control

In semiconductor cleanrooms, in addition to particle concentration, the most common contaminants impacting yield are airborne molecular contaminants, static charge and electromagnetic interference, and misprocessing due to electromagnetic interference with process control. Increasingly, more cleanrooms seek a controlled level of AMC concentration (i.e., chemical cleanliness class per ISO *Standard* 14644-8). Though not an explicit requirement, the airflow concepts used in a cleanroom have a direct impact on particle concentration and may also affect chemical cleanliness. Cleanroom designers have had to change airflow design concepts to meet the changing semiconductor process technology.

Airborne Molecular Contaminants (AMC)

An increasing source of AMC in fabs is fugitive emissions associated with maintenance of local process exhaust scrubbers (e.g., for dopants). The fugitive emissions are exhausted to the building exterior and subsequently reentrained into the makeup air, and eventually back into the cleanroom. Including monitoring and mitigation of these fugitive emission sources is no longer optional for a good AMC protection plan; it is essential.

Wafer exposure to the chemicals in cleanroom environments presents another challenge. Deployment of fab-wide AMC filtration systems is becoming the rule rather than the exception for most process areas. Combining the fab-wide system with AMC filters at high-risk process tools helps to minimize exposure to hazardous particles.

Static Charge and Electromagnetic Interference

Electrostatic charge adversely impacts every phase of semiconductor manufacturing, causing three basic problems (SIA 2015a):

- **Electrostatic attraction (ESA)** contamination increases as particle size decreases. ESA is becoming particularly acute with photolithography masks, as the use of traditional pellicles is phased out.
- **Electrostatic discharge (ESD)** causes damage to both devices and photolithography masks. Decreasing device feature sizes means less energy is required for ESD to cause damage to a device or mask. Increased device operating speeds have decreased the effectiveness of on-chip ESD protection, and heightened device sensitivity to damage from ESD.
- Equipment malfunctions caused by ESD-related **electromagnetic interference (EMI)** decrease overall equipment efficiency and are becoming more frequent as equipment microprocessor operating speeds increase.

Trends in ESD sensitivity will have greater impacts on manufacturing process yields as the feature sizes of devices decrease (SIA 2015a). Cleanroom designers must understand the sources of ESD, and fab owners must verify that the installed ESD controls can handle these devices and must improve ESD control methods when necessary.

EMI Control. Electromagnetic interference is defined as "the degradation of the performance of an equipment, transmission channel, or system caused by an electromagnetic disturbance" (SEMI 2012). EMI causes a number of problems for semiconductor manufacturing, such as equipment lockup and malfunction, sensor misreading, metrology errors, and sensitive component damage. Sources of EMI in semiconductor environments include electromagnetic emission from ESD; operation of equipment, especially high-energy tools; motors and actuators; and wireless communication. Colocation of sensitive equipment with high-energy tools, cabling, ground problems, improper maintenance of equipment, and other issues further aggravate EMI problems (SIA 2015a). Current practices for mitigating EMI impact are either passive-shielding the sensitive equipment or shielding the sources. Electrical transformers are a major source, and shielding of these in metrology areas is common practice.

Semiconductor Fab Conditions

Typical indoor design conditions are shown in Table 3. In the past, process requirements dictated the primary design criteria for temperature and humidity set points. To minimize changes in dimensions from expansion or contraction, temperature stability is needed in many atmospheric pressure processes that are exposed to the cleanroom ambient temperature. Good control of dry-bulb temperature is needed to provide stability in relative humidity. Relative humidity changes can affect the performance of many hygroscopic materials used in semiconductor manufacturing. Controlling dry-bulb temperature and dew point can provide uniform relative humidity.

Though there are hygroscopic processes in a semiconductor wafer fab, the hygroscopic forces are normally not enough to offset moisture gains or losses that can come from adjacent spaces with other dew points or from the introduction of makeup air. The sensible heat ratio for most wafer fabs is greater than 0.99 unless there is exposure to unconditioned spaces. Therefore, sensible cooling is the standard practice for wafer fabs. Latent cooling treatment of the entire fab recirculation air volume is normally not practical, and the adiabatic mixing of wetter or dryer air sources is a more energy-efficient method.

Cleanroom Cleanliness and Airflow Concepts

Design concepts are influenced by cleanroom size, building codes, process equipment footprints, cost control, energy optimization, and flexibility (among other things). Semiconductor wafer fab

Table 3 Process Area Environmental Conditions

	Temperature		Relative Humidity		Dew Point	
	Set Point Range	Tolerance	Set Point Range	Tolerance	Set Point Range	Tolerance
Critical Process Areas	18 to 23°C	±0.5 to ±1°C	35 to 50%	±2 to ±3%	2.3 to 12°C	±1 to ±2°C
Non-Critical Process Areas	18 to 26°C	±2°C	35 to 60%	±2 to ±5%	2.3 to 17°C	

owners expect cleanrooms that cost little per square unit area to construct, yet provide improved performance, are faster to build, and are easily upgraded. As product technology and the process tools have changed, so have the basic design criteria.

The International Technology Roadmap for Semiconductors (ITRS) (SIA 2015b) currently recommends ISO Class 6 where operators are present and possibly ISO Class 7 in the future, though this practice is not uniformly adopted by all fab owners. ISO Class 6 does not necessarily warrant unidirectional airflow to support the cleanliness requirement. Wafer fabs continue to support unidirectional airflow because it makes sense in light of the multilevel layout of their facilities. Having air move in the same direction allows the spaces themselves to become transport conveyances. Therefore, cleanliness class does not always dictate classical unidirectional/non-unidirectional air management paths.

Options for process area air management with separate subfab airflow are (1) 100% unidirectional downflow and (2) unidirectional downflow for operator- and wafer-exposed areas, through the raised floor with return air upflow in service chases.

Makeup Air. Makeup air plays a crucial role in the environmental conditions of a wafer fab by providing replacement air for the air exhausted for process requirements, providing excess air to create positive pressure in cleanrooms, and providing a source of wetter or dryer air to help control humidity levels inside the fab. Wafer fabs require a relatively large amount of makeup air due to the physical size of their factories, and depending on the local climate, makeup air may be 20 to 30% of the total fab chiller load. Although commercial facilities may consider ventilation rates per person, wafer fabs tend to use a design criteria based on the area of the cleanroom. Common rates for consumer semiconductor product based wafer fabs are 50 to 100 $m^3/(h \cdot m^2)$, whereas code requirements are 18.3 $m^3/(h \cdot m^2)$. There has been a trend toward lower ventilation rates due to changes in tool configurations with fewer liquid chemical ventilation hoods (e.g., wet chemical etchants) and more dry plasma-based processes. Treatment of makeup air before its addition to the cleanroom space includes moisture control (humidification or dehumidification) and filtration of external particles and airborne molecular contaminants.

Humidity. Makeup air provides a means of dehumidifying or humidifying air. The makeup air introduced into the fab environment is either below the space dew point, at the space dew point, or above the dew point. When it is below the space dew point, moisture must be added (humidification). When the makeup air dew point is above the space-required dew point, moisture must be removed (dehumidification).

Makeup air treatment schemes must be designed for the expected climate. Fabs located in tropical climates where outdoor dew points rarely go below 20°C may not need any humidification equipment, whereas fab locations in cold or temperate climates may need both humidification and dehumidification capabilities.

Control of dew point or relative humidity in a semiconductor wafer fab is also needed in many contamination control schemes. Humidity levels can affect ESD rates, particle adhesion, and corrosion of metal surfaces deposited on a wafer. Typically, the most critical need for precise humidity control is the sensitivity of photoresist chemicals used in photolithography. Relative humidity and temperature are both critical for precise dimensional control and resist chemical stability.

The typical semiconductor wafer fab space dew point is between 7 and 12°C, though it may be as low as –2°C or as high as 14°C to support some processes. Apart from very low dew points (less than 1.5°C), dehumidification by subcooling with chilled water is the most common method. Providing consistent dew-point control of the makeup air enables consistent moisture content of the makeup air when it is mixed with cleanroom recirculation air and can result in good relative humidity control (±2.5%) when combined with good dry-bulb temperature control. Some semiconductor wafer fabs may have process areas requiring better than ±2.0% rh. To achieve control of ±2.0% rh, the makeup air dew point must be controlled ±0.5°C.

Filtration. Control of AMC is critical to maximizing yield by minimizing contamination of the photoresist and mitigating progressive defects forming on masks during exposure (Mueller 2013). For makeup air equipment, including AMC filters is commonplace for most semiconductor wafer fab locations due to local pollution and reentrainment of process exhaust. AMC filters typically involve a chemical adsorption process using activated carbon, sometimes doped with other activated chemicals (e.g., permanganate-embedded alumina) or ion-exchange resins. Most makeup air units integrate their AMC filters as part of a multistep particle and AMC filtration scheme. Some AMC filters are available with particle removal efficiencies of MERV 8 to as high as MERV 15, which can help reduce the overall air pressure drop through the makeup air equipment.

Air Velocity and Air Change Rate. For a given cleanroom, the supply airflow rate Q (cubic metres per second [m^3/s]) is

$$Q = LWv \tag{1}$$

$$\text{ACH} = \frac{3600Q}{LWH} \tag{2}$$

or

$$\text{ACH} = \frac{3600LWv}{LWH} = \frac{3600v}{H} \tag{3}$$

where

L = room length, m
W = room width, m
H = room height, m
v = average vertical air velocity, m/s through cleanroom horizontal plane L by W
ACH = air changes per hour

From Equation (3), the number of air changes per hour is inversely proportional to the height of the room: the greater the height of the cleanroom, the fewer air changes per hour required, and vice versa. The exception is a clean space where contamination is generated at a

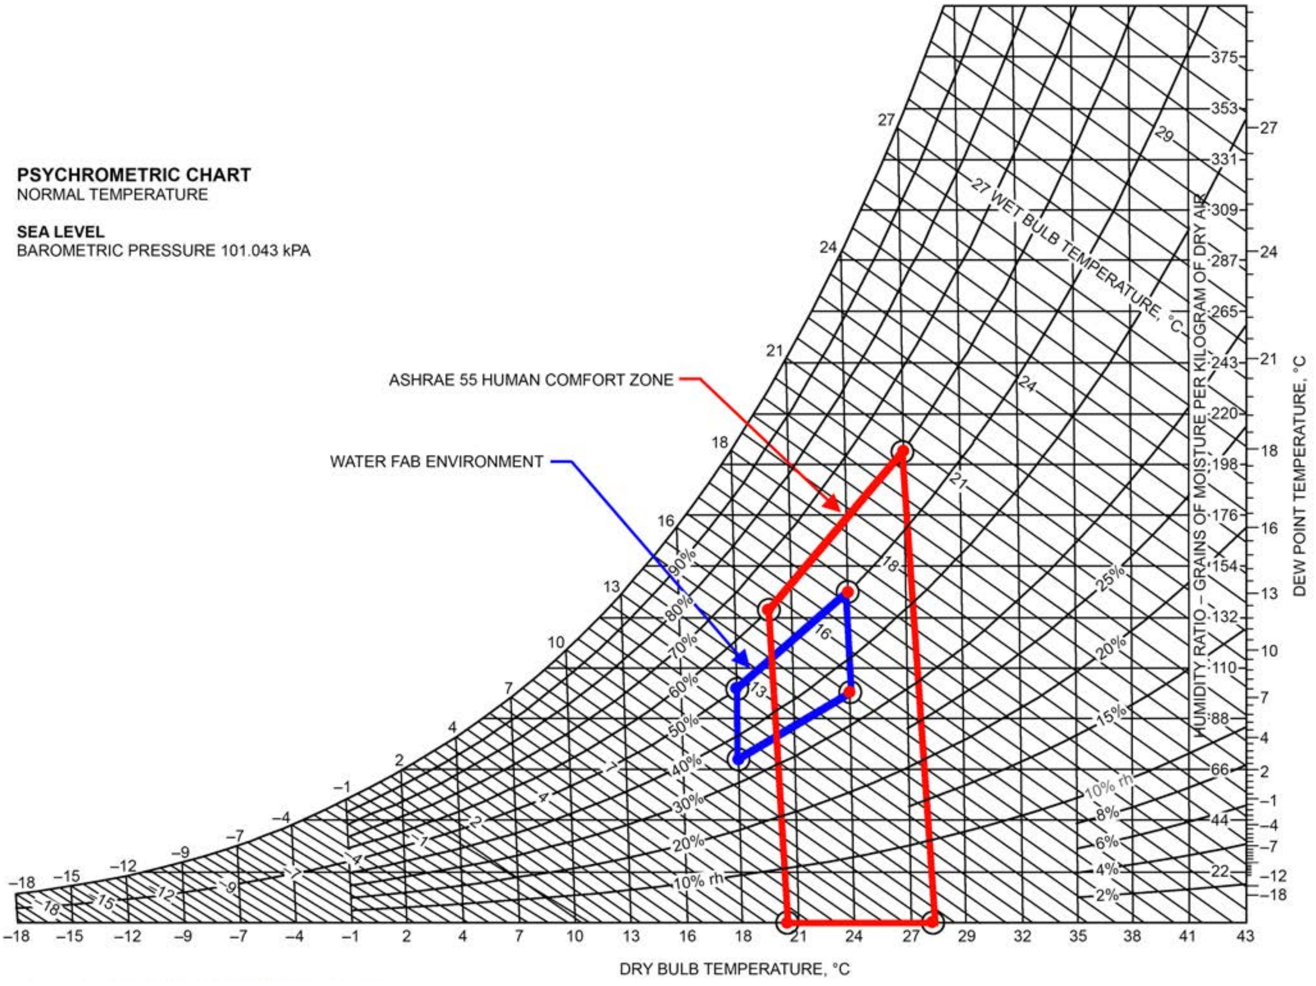

Fig. 15 Wafer Fab Environment in Psychrometric Chart

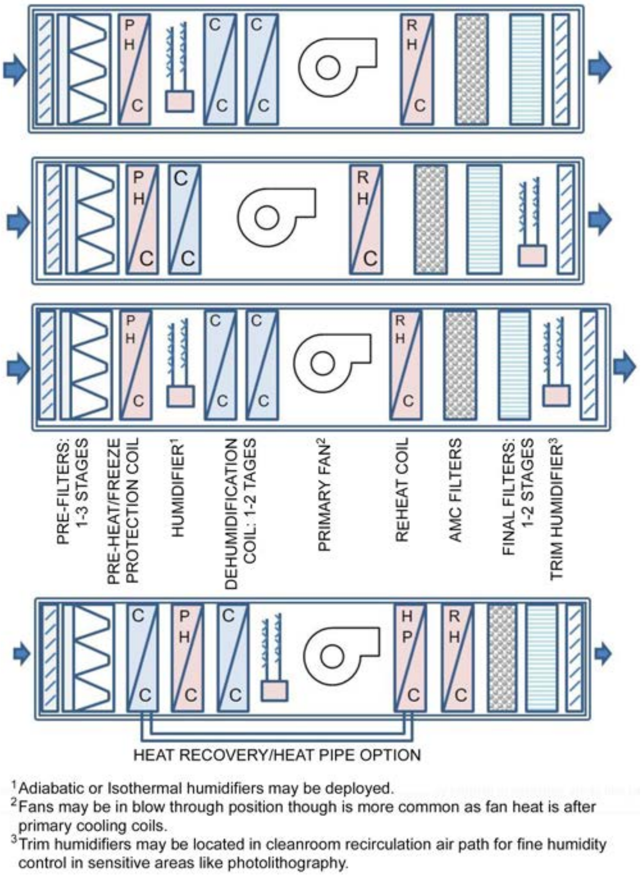

Fig. 16 Makeup Air Configuration Schemes

considerable height above the finished floor. Examples include semiconductor and flat panel display transport systems and aerospace product assembly. In these situations, the velocity may need to remain high to sweep away particles, and ACH may be fixed regardless of the height of the space.

Air Ionization. In addition to cleanroom particle control with fiber filters, air ionization can be used to control particle attraction to product surfaces by eliminating electrostatic discharge and static charge build-up. However, the emitter tip material must be carefully selected to prevent depositing particles on the product.

10. HIGH-BAY CLEANROOMS

High-bay cleanrooms have ceiling heights between 12 and 50 m, with the higher ceilings used primarily in the aerospace industry for producing and testing missiles, launch vehicles, rocket engines, and communication and observation satellites, and lower ceilings primarily used in jet aircraft assembly, painting, and cleaning operations; flat panel display manufacturing; and in crystal-pulling areas in semiconductor chips manufacturing facilities.

Most high-bay cleanrooms are designed to meet ISO Class 7, Class 8 or higher as required by some U.S. Air Force and U.S. Navy specifications. Flat panel display factories may require ISO Class 5, 6, or 7. Crystal-pulling cleanrooms for semiconductor microchips are usually specified at Class 5 to Class 6 range.

Table 4 shows approximate ranges of ceiling-height-dependent airflow per minute and air changes per hour by cleanroom classes derived from Equation (3).

Downflow and Horizontal-Flow Designs

In **downflow designs**, air is delivered in a unidirectional (or simulated unidirectional) flow pattern from the ceiling and returned through floor return openings or low sidewall returns. The objective is to shower the object from above so that all particles are flushed to the returns. The supply air terminals may be HEPA-filter or high-volume air diffusers. Downflow spaces allow space flexibility because more than one device may be worked on in the space at the same air cleanliness level.

The disadvantage is the relative difficulty of balancing airflow. High-bay cleanrooms typically have concrete floors that may include trenches to return some of the air not taken in at low sidewall returns. Special care must be taken to ensure clean air at the object because the parallel flow starts to dissipate toward the floor. At the low velocities typical of unidirectional design, pathways may be created toward the returns, causing the clean air to miss the object. Any activity in the cleanroom that generates even a small amount of heat produces updrafts from buoyancy effects in downward-flowing supply air, resulting in the possibility of unforeseen turbulence.

Horizontal-flow designs are always unidirectional, with the cleanest air always available to wash the object in the space. Properly designed horizontal spaces are easier to balance than vertical-flow spaces because supply and return air volumes may be controlled at different horizontal levels in the space.

Downflow designs are most widely used, but certain projects such as the space telescope and space shuttle assembly spaces may require horizontal-airflow high-bay cleanrooms (Figure 17).

Air Handling

Because of the large volume of air in a high-bay cleanroom, central recirculating fan systems are commonly used with minimum heating and cooling capability. A separate injection air handler provides heating, cooling, and makeup air. The injection system must include volumetric controls to ensure proper building pressure. Flat panel display (FPD) factories deploy thousands of fan filter units (FFUs), allowing for flexibility and ease of adding additional airflow when needed.

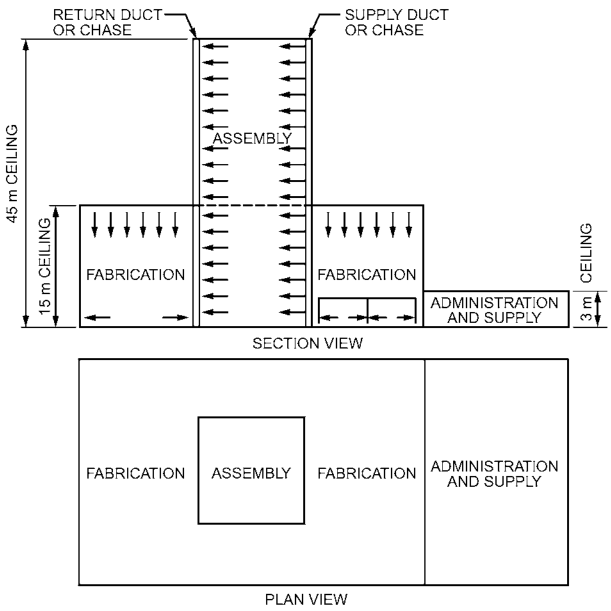

Fig. 17 High-Bay Cleanroom Scheme

Equipment and Filter Access

Air-handling equipment and prefilters should be accessible from outside the cleanroom. Adequate provision must be made for changing filters if air is distributed to the cleanroom with HEPA filters at the space envelope. In horizontal-flow cleanrooms, access should be from the upstream (pressure) side, and service scaffolds should be incorporated at least every 2.4 m in height of the filter bank. Downflow ceiling filters in T-bar or gel-seal ceilings must be accessed from below using an approved gantry crane with full mobility across the ceiling or from above the ceiling with a catwalk system built into the plenum. Prefilters in the main air supply should be placed in built-up frames with both upstream and downstream access. It is important to ensure that there are no possible air bypass pathways in filter frames and their seal to the filters or to the air handler walls since this reduces the effectiveness of the air filtration. A HEPA filter bank remote from the space air-distribution system should be installed in a built-up bank with a gel or clamp seal. Access doors must be installed up- and downstream for certification, scanning, and qualification testing.

Prefilter Selection

In any high-bay cleanroom cleanliness classification, air will pass through a final HEPA filter before entering the space; these final filters are usually protected by prefilters. HEPA filters for recirculating air should be protected with MERV 11 bag or rigid media filters with as few other prefilters as required. Makeup air should include minimum MERV 11 filters on the fan inlet and minimum MERV 16 filters on the fan discharge. Tight, leakproof sealing between the filters and frame/housing improves system cleanliness and reliability.

Design Criteria and Indoor Air Quality

The indoor design temperature range for aerospace and aircraft manufacturing cleanrooms is 23 ± 0.3°C, with the higher temperatures commonly used in summer, and the lower ones in winter. However, the user should provide guidance on specific required space temperature requirements. In FPD and semiconductor crystal-pulling cleanroom design, space temperature is usually required at a constant level of 22 ± 0.3°C, though FPD temperature tolerance is normally within ±1 K.

Another key parameter is relative humidity. For aerospace and aircraft manufacturing cleanrooms, relative humidity should not exceed 60%; FPD and semiconductor crystal-pulling cleanrooms usually require indoor relative humidity to be 50 ± 5% as design base.

Other issues include noise and vibration from process and HVAC equipment, and dusts, fumes, smoke, odors, vapors, moisture and gases generated during welding, sanding, painting, washdown, fuel filling, etc. See Chapters 8 to 12 of the 2017 *ASHRAE Handbook—Fundamentals* for additional information.

11. ENVIRONMENTAL SYSTEMS

Cooling Loads and Cooling Methods

Two major internal heat load components in cleanroom facilities are process equipment and HVAC system fans. Because most cleanrooms are located entirely within conditioned space, traditional heat sources of infiltration, fenestration, and heat conductance from adjoining spaces are typically less than 2 to 3% of the total load. Some cleanrooms have been built with windows to the outside, usually for daylight awareness, and a corridor separating the cleanroom window from the exterior window.

The major cooling sources designed to remove cleanroom heat and/or maintain environmental conditions are makeup air units, primary and secondary air units, and the process equipment cooling system. Some process heat, typically from electronic sources in computers and controllers, may be removed by process exhaust.

In many applications, cleanroom fan systems have their motors located in the airstream, resulting in significant heat from fan operation. This is especially true in ISO Class 4 or cleaner cleanrooms where recirculated airflows with air velocities of 0.45 m/s or air change rates around 500 per hour may be used. Xu (2003, 2004) found that many ISO Class 4 or 5 cleanrooms were operated with lower air velocities and lower air change rates than specified by the old or existing recommended practices, while achieving satisfactory contamination control for their specified cleanliness classes.

Latent loads are primarily associated with makeup air dehumidification. A low dry-bulb leaving air temperature, associated with dehumidified makeup air, supplements sensible cooling. Supplemental cooling by makeup air may account for as much as 950 W/m^2 of cleanroom.

Process cooling water (PCW) is used in process equipment heat exchangers, performing either simple heat transfer to cool internal heat sources, or process-specific heat transfer, in which the PCW contributes to the process reaction. Due to the superior energy efficiency of water cooling (versus air cooling), many process equipment manufacturers have redesigned their equipment to rely more on process cooling water. For many semiconductor and FPD factories, process equipment loads may be used for 50 to 75% of the process equipment heat transfer.

The diversity of manufacturing heat sources (the portion of total heat transferred to each cooling medium) should be well understood. When bulkhead or through-the-wall equipment is used, equipment heat loss to support chases versus to the production area affects the cooling design when the support chase is served by a different cooling system than the production area.

Makeup Air

Control of makeup air and cleanroom exhaust affects cleanroom pressurization, humidity, and room cleanliness. Makeup airflow requirements are dictated by the amounts required for (1) replacing process exhaust, (2) working personnel ventilation, and (3) meeting pressurization specifications. Makeup air volumes can be much greater than the total process exhaust volume to provide adequate pressurization and safe ventilation. Tsao et al. (2010) discusses how to optimize makeup air system design to improve its effectiveness and energy efficiency.

Makeup air is frequently introduced into the primary air path on the suction side of the primary fan(s) or into a negative pressure plenum system to enhance mixing. Makeup air volumes are adjusted with zone dampers and makeup fan controls using speed controllers, inlet vanes, etc. Opposed-blade dampers should have low leak characteristics and minimum hysteresis.

Makeup air should be filtered before injection into the cleanroom. If the makeup air is injected upstream of the cleanroom ceiling ULPA or HEPA filters, minimum MERV 16 filters (ASHRAE *Standard* 52.2) should be used to avoid high dust loading and reduced HEPA filter life.

In addition, MERV 8 efficient prefilters followed by MERV 11 filters may be used to prolong the life of the MERV 16 filter. When makeup air is injected downstream of the main HEPA filter, further HEPA filtering of the makeup air should be added to the prefilters. In addition to particle filtering, many makeup air handlers require filters to remove chemical contaminants (e.g., salts and pollutants from industries and automobiles) present in outside air. If the makeup air is from an internal conditioned space (i.e., outdoor air is conditioned by the main facility HVAC system), the same filtration level may still be required to prevent the entry of volatile organic compounds (VOCs). These VOCs may be present from another active process in the facility or from building maintenance items such as cleaning agents and paints. Chemical filtration may be accomplished with absorbers such as activated carbon or potassium permanganate impregnated with activated alumina or zeolite.

Process Exhaust

Process exhaust handles acids, bases, solvents, toxins, pyrophoric (self-igniting) fumes, and process heat exhaust. Process exhaust should be dedicated for each fume category, by process area, or by the chemical nature of the fume and its compatibility with exhaust duct material. Typically, process exhausts are segregated into corrosive fumes, which are ducted through plastic or fiberglass-reinforced plastic (FRP) ducts, and flammable (normally from solvents) gases and heat exhaust, which are ducted in metal ducts. Process exhaust may also be segregated by its need for pollution abatement due to air quality regulations. Care must be taken to ensure that gases cannot combine into hazardous compounds that can ignite or explode in the ductwork. Segregated heat exhausts are sometimes installed to recover heat, or hot uncontaminated air that may be exhausted into the suction side of the primary air path.

Required process exhaust airflow rates can vary from 5 L/s per square metre of cleanroom for photolithographic process areas, to 50 L/s per square metre for wet etch, diffusion, and implant process areas. With the advent of more vacuum-based processes and less use of ambient air or wet processes, the overall exhaust rates have trended downward. Many vacuum-based processes require additional abatement steps, with point-of-use (POU) abatement techniques being very common. These POU abatement processes may discharge directly to the atmosphere or into one of the central exhaust systems. When specific process layouts are not designated before exhaust design, an average of 25 L/s per square metre is normally acceptable for fan and abatement equipment sizing. Fume exhaust ductwork should be sized at low velocities (5 m/s) to allow for future needs.

For many airborne substances, the American Conference of Governmental Industrial Hygienists (ACGIH) established requirements to avoid excessive worker exposure. The U.S. Occupational Safety and Health Administration (OSHA) set specific standards for allowable concentrations of airborne substances. These limits are based on working experience, laboratory research, and medical data, and are subject to constant revision. See ACGIH (2007) to determine limits.

Fire Safety for Exhaust

International Building Code® (ICC 2012) designates semiconductor fabrication facilities as Group H occupancies. The Group H occupancy class should be reviewed even if the local jurisdiction does not use the IBC because it is currently the only major code in the United States specifically written for the semiconductor industry and, hence, can be considered usual practice. This review is particularly helpful if the local jurisdiction has few semiconductor facilities.

International Fire Code® (IFC; ICC 2012) addresses specific requirements for process exhaust relating to fire safety and minimum exhaust standards. Chapter 50 of the code, Hazardous Materials, is relevant to many semiconductor cleanroom projects because of the large quantities of hazardous materials stored in these areas. Areas covered include ventilation and exhaust standards for production and storage areas, control requirements, use of gas detectors, redundancy and emergency power, and duct fire protection.

Air Temperature and Humidity

Precise air temperature control is required in most cleanrooms. Specific chemical processes may change under different temperatures, or masking alignment errors may occur because of product dimensional changes as a result of the coefficient of expansion. Temperature tolerances of ±0.6 K are common, and precision of ±0.06 to 0.3 K is likely in wafer or mask-writing process areas. Wafer reticle writing by electron beam technology requires ±0.06 K, whereas photolithographic projection printers require ±0.3 K tolerance. Specific process temperature control zones must be small enough to control the large air volume inertia in vertical laminar flow cleanrooms. Internal environmental controls, which allow space tolerances of ±0.6 K and larger temperature control zones, are used in many process areas.

Within temperature zones of the typical semiconductor factory, latent heat loads are normally small enough to be offset by incoming makeup air. Sensible temperature is controlled with either cooling coils in the primary air stream, or unitary sensible cooling units that bypass primary air through the sensible air handler and blend conditioned air with unconditioned primary air.

In most cleanrooms of ISO Class 6 or better, production personnel wear full-coverage protective smocks that require cleanroom temperatures of 20°C or less. If full-coverage smocks are not used, higher temperature set points are recommended for comfort. Process temperature set points may be higher as long as product tolerances are maintained.

In semiconductor cleanrooms, air humidity levels vary from 30 to 50% rh. Humidity control and precision are necessary for the specific process requirements, prevention of condensation on cold surfaces in the cleanroom, and control of static electric forces. Humidity tolerances vary from 0.5 to 5% rh, primarily dictated by process requirements. Photolithographic areas have more precise standards and lower set points. The exposure timing of photoresists (used in photolithography) can be affected by varying relative humidity. Negative resists typically require low (35 to 45%) relative humidity. Positive resists tend to be more stable, so the relative humidity can go up to 50% where there is less of a static electricity problem.

Independent makeup units should control the dew point in places where direct-expansion refrigeration, chilled-water/glycol cooling coils, or chemical dehumidification is used. Chemical dehumidification is rarely used in semiconductor facilities because of the high maintenance cost and potential for chemical contamination in the cleanroom. Although some cleanrooms may not require significant reheat, many systems are designed to provide heat to the space to support temperature control during normal operation and when production equipment is not operating. However, when relative humidity control is required, a large amount of energy may be lost when conditioning more air than necessary. Instead of bringing all the return air down to a low humidity level and then reheating, a system that optimizes the amount of return that goes through the air handler to avoid excesses is often significantly more energy efficient.

Makeup air and/or supply air humidification often uses steam humidifiers or atomizing equipment, with steam humidifiers being the most common. Good design practices include avoiding water treatment chemicals through clean steam generation. Stainless-steel unitary packaged boilers with high-purity water and stainless-steel piping have also been used. Water sprayers in the cleanroom return use air-operated water jet sprayers. Evaporative coolers can take advantage of the sensible cooling effect in dry climates.

Air Pressurization

Controlling air pressures in a cleanroom is an important part of effective contamination control, providing resistance to infiltration of external sources of contaminants. In nonpressurized spaces, or spaces with air pressures lower than that of the surrounding environment, nearby particulate contaminants enter the cleanroom by infiltration through doors, cracks, pass-throughs, and other penetrations for pipes, ducts, etc. A cleanroom with the most stringent cleanliness requirements should have the highest air pressure relative to its adjacent rooms, with decreasing room pressures corresponding to decreasing cleanliness levels.

For small cleanrooms or clean zones in ISO Classes 8 and 9, ceiling supply and low sidewall return is a typical airflow arrangement. The primary air system alone can handle the internal cooling load and the required room air change rate. Pressurization system designs are very similar to those in pharmaceutical facilities.

For semiconductor cleanrooms with ISO Class 7 or cleaner, primary/secondary air systems are common. The secondary (makeup) HVAC unit takes care of the outside air and internal cooling loads, and the primary (recirculating) unit delivers the required room air change rate, and additional cooling if needed. A raised, perforated floor return is common for these classes. During balancing, manual or automatic balance dampers are usually set at fixed positions at air supply, return, and exhaust systems.

In vertical- and unidirectional-flow cleanrooms, single-stage constant volume for supply and return flows is common. Because internal dust generation from people and process could be lower during nonoperating or unoccupied mode than operating or occupied mode, using multiple recirculating blowers to create two- or multiple-stage supply and return flow rates is feasible as long as the room cleanliness meets the designated classification at all times, validated through continuous particle count measurement. In nonoperating or unoccupied mode, reduced levels of supply and return airflow rates should also ensure maintaining proper room pressurization level.

Pressure level in the cleanroom is principally established by room airtightness and the **offset flow** value, which is the net flow rate difference between supply airflow rate and exhaust and return airflow rates. Process equipment exhaust rate is often determined by manufacturers' data, industrial hygienists, and codes. The design engineer should consult with the facility contamination control specialist to determine effective and efficient air change rates for each cleanroom.

One common method of cleanroom pressurization is to keep the supply airflow rate constant while adjusting the return airflow rate by volume dampers at return floor panels to create a specified positive space pressure. Return air to underfloor plenum or subfloor basement through perforated panels floor grilles or grates (usually with a 15 to 35% free area) can be balanced to ensure a fixed flow differential (offset flow) in the space. An adjustable, lockable balance damper normally is attached beneath the perforated floor panel or grate. When the damper is fully open, it normally creates a minimal pressure drop of 5 to 20 Pa. Higher pressure drops can be achieved when the dampers are turning toward the closed positions. Note that the position of balance damper opening could affect parallelism of the room's unidirectional flow.

Another method uses variable-air-volume supply and return fans with volumetric airflow rates tracking to ensure the required room pressure. This method could be a reasonable choice for a single, large cleanroom, but is not flexible enough to serve a suite with different room pressure requirements. For some industries, variable-air-volume systems may not be favorable; design engineers should consult with facility contamination control specialists before specifying variable-volume systems for cleanrooms.

Air locks typically are used between uncontrolled personnel corridors, entrance foyers, and the protective-clothing gowning area. Air locks may also be used between the gowning room and the main cleanroom, and for process equipment staging areas before entering the cleanroom. Install air locks only when they are really necessary, because their use along traffic paths could restrict personnel access and increase evacuation time during emergencies.

Commercial pressure differential sensors can reach accuracy at 0.25 Pa or better, and significant progress has been made on precision room pressure control. Many processes affected by cleanroom pressure (e.g., glass deposition with saline gas) require process chamber pressure precision of 60 mPa.

Pressurization calculations can be performed by using the procedures detailed in either Pedersen et al. (1998) or Spitler (2009) in the chapters on infiltration:

- Using the provided charts, calculate the building exfiltration at designated room pressurization level.
- In accordance with ASHRAE *Standard* 62.1, with the actual number of occupancy, determine the required outdoor airflow rate.
- Determine the total airflow rate of exhaust from the building.

The sum of exfiltration airflow rate plus exhaust airflow rate, or plus the required outdoor airflow supply rate, whichever is greater, is the total ventilation rate under the designated building pressurization.

To ensure the designated pressurization level, a leak test must be performed for exterior walls, interior walls, partitions, doors and windows between two adjacent rooms with different pressurization levels, and for roof, exterior doors and windows, connections between wall and roof, and any building elements between two rooms with different pressurization levels. All major leaks must be eliminated before start-up of HVAC systems.

Sizing and Redundancy

Environmental HVAC design must consider future requirements of the factory. Products can become obsolete in as little as two years, and process equipment may be replaced as new product designs dictate. As new processes are added or old ones removed (e.g., wet etch versus dry etch), the function of one cleanroom may change from high-humidity requirements to low, or the heat load many increase or decrease substantially. Thus, the cleanroom designer must design for flexibility and growth. Unless specific process equipment layouts are available, maximum cooling capability should be provided in all process areas at the time of installation, along with provisions for future expansions.

Because cleanroom space relative humidity must be held to close tolerances and humidity excursions cannot be tolerated, the latent load removal capacity of the selected equipment should be based on high ambient dew points and not on the high mean coincident dry-bulb/wet-bulb data.

In addition to proper equipment sizing, redundancy is also desirable when economics dictate it. Many cleanroom facilities operate 24 h per day, seven days per week, and shut down only during holidays and scheduled nonworking times. Mechanical and electrical redundancy is required if loss of equipment would shut down critical and expensive manufacturing processes. For example, process exhaust fans must operate continuously for safety reasons, and particularly hazardous exhaust should have two fans, both running. Most process equipment is computer-controlled with interlocks to provide safety for personnel and products. Electrical redundancy or uninterruptible power supplies may be necessary to prevent costly downtime during power outages. Redundancy should be based on life-cycle economics and careful review of all foreseeable system failure and recovery scenarios. With the proper design focus, redundancy improvements can provide additional benefits; for example, operating redundant fans in parallel can reduce overall power consumption while improving system stability during failure recoveries.

Minienvironments

A minienvironment is a type of separate device mainly used in microelectronics industry to maintain a level of stringent cleanliness in a tightened volume of clean spaces (IEST RP CC028.1; ISO *Standard* 14644-7). It is a localized environment created by an enclosure to isolate or separate a product or process from the surrounding environment. A minienvironment is normally used to maintain a level of stringent, higher level of cleanliness by controlling particle concentrations within a tightened volume of clean spaces, often by maintaining desired pressure differential or supplying unidirectional airflows. It is important to understand the characteristics of minienvironments' design, operation, and effectiveness in environmental control, and the impacts of integration with the cleanroom that houses the minienvironment or a group of minienvironments. Xu (2007a, 2008) found that pressure differentials under 0.2 Pa can be sufficient for achieving a high level of air cleanliness to meet environmental control expectation and requirements, suggesting that existing recommended practices or guidelines (e.g., IEST RP CC028.1) may be higher than necessary, at least in some minienvironment applications.

Advantages of using minienvironments include upgrading cleanliness classes, process integration, and maintaining better contamination control. Xu (2008) also suggested that, when appropriately integrated with a cleanroom, minienvironments may improve overall cleanroom energy efficiency and offer significant cost savings and reliability. The field investigations characterized energy performance of five different minienvironments (designated as ISO Cleanliness Class 3) operating and housed in a traditional, larger ISO Cleanliness Class 4 microelectronics cleanroom. The measured energy performance and associated metrics were compared to those of cleanrooms of various cleanliness classes, and indicated that potential energy savings up to 60 to 86% were achievable by integrating minienvironments in traditional cleanrooms, without losing effective contamination control. Other ways to increase energy savings in minienvironments include optimal design and operation, improving fan-filter unit operating efficiency, and space management in clean spaces.

Fan-Filter Units

A fan-filter unit (FFU) is a self-contained unit normally inserted and gasketed into cleanroom T-bar ceilings and is used to supply and clean airflows, which are fed to and then recirculated through the cleanroom space. An FFU usually consists of a small fan, a controller, and a HEPA or ULPA filter enclosed in a box, which fits into common cleanroom ceiling grids. Fan-filter units in air recirculating systems have become increasingly popular worldwide because of their specific contamination control, ease of installation, and adaptability in cleanroom construction, qualification, and operation.

Common ceiling grids typically carry FFUs with unit sizes ranging from 1220 by 1220 mm to 1220 by 610 mm or smaller. The small internal fans force air through the HEPA or ULPA filters. Coverage of a cleanroom ceiling normally ranges from 25 to 100% of the total ceiling area, and thus can require many FFUs. As a result, the large number of FFU fans constitutes considerable electric power demand and energy use (and noise generation) in providing air recirculation and cleaning (Xu et al. 2007). Appropriate applications of FFUs can generate unidirectional airflows desired for certain cleanroom activities or processes. New technologies able to control the airflow rate and uniformity through a networked feedback control system can improve the controllability and reliability of individual FFUs (Chen et al. 2007). Electrically commutated (EC) motors have replaced many of the older split capacitor motors, resulting in significantly improved motor efficiency.

Note that different FFUs' energy and aerodynamic performance can vary, even with similar components (Chen et al. 2007; Xu et al. 2007), and their performance may largely influence both energy efficiency and contamination control effectiveness in cleanroom design, qualifications, and operation. The energy efficiency level of the same unit may vary considerably, depending on actual operating conditions such as airflow speeds and pressure rise across the units; for instance, Xu et al. (2007) found that, when operating with the fan-wheel speed control dials at maximum, larger units tended to be more energy efficient than their smaller counterparts. To achieve sustainable development in cleanroom facilities, it is useful for designers and owners to have comparable information on FFU energy performance. This makes it feasible to select efficient units and to improve energy efficiency while maintaining or improving effectiveness in contamination control. Unfortunately, typical manufacturers' data sheets usually contain numbers that look similar but are not readily comparable because their approaches to reporting performance data are different from each other, and this can lead to confusion.

In recent years, the interest in understanding and improving fan-filter performance has increased among users, manufacturers, energy companies, professional organizations, and research institutes. Increasing energy costs in operating existing and future cleanrooms and mission-critical controlled environments have prompted end users to seek and select higher-efficiency FFUs in their cleanroom applications, and motivated suppliers to develop more energy-efficient FFUs for future cleanrooms. For example, manufacturers are increasingly interested in quantification of the energy performance of their fan-filter units, and in developing a method for systematically characterizing fan-filter performance as it is affected by fan-wheel design, air-path and size, unit size, motor type, availability of airflow control, and control schemes. Lawrence Berkeley National Laboratory has developed and published a standard test method to fully characterize energy and aerodynamic performance of individual FFUs in laboratory setting (Xu 2007b, 2007c).

12. SUSTAINABILITY AND ENERGY CONSERVATION

Cleanroom air systems may account for a significant portion of the HVAC energy use in cleanrooms. In cleanrooms, high electric power density for fans to deliver airflows, defined as the fan's electric power demand divided by the cleanroom floor area, would normally be expected because of large volume of airflows supplied, recirculated, and exhausted within a given time. Therefore, the design of cleanroom airflow systems may have a long-term impact on energy usage in that the amount of designed airflows significantly affects the operation costs associated with energy, initial equipment costs, and installation costs (Xu 2008).

The major operating costs associated with a cleanroom contamination control systems include conditioning the air, fan energy for air movement in the cleanroom, and process exhaust. The combination of environmental conditioning and control, contamination control, and process equipment electrical loads can be as much as 3 kW/m^2. Besides process equipment electrical loads, most energy is used for cooling, air movement, and process liquid transport (i.e., deionized water and process cooling water pumping), compressed air, vacuum systems, etc. A life-cycle cost analysis is useful to determine design choices and their total cost of ownership over time, as well as greenhouse gas contribution related to cleanroom design and operation.

Energy Metrics. The energy use required for operating wafer fabrication plants (fabs) is intensive and is one of the major concerns to production power reliability. Energy performance metrics to characterize the electric energy consumption and wafer production include production efficiency index (PEI), electrical utilization index (EUI), specific energy consumption such as annual electric power consumption normalized by annual produced wafer area, and annual electric power consumption normalized by units of production (UOP), which is defined as the product of annual produced wafer area and the average number of mask layers of a wafer (Chang et al. 2009; Hu et al. 2010, 2013).

To evaluate design options for HVAC systems in cleanrooms, it is convenient to compare overall efficiency using standard metrics. By using a metric such as airflow rate per kilowatt input, system efficiency for different schemes can be compared. The metric allows comparison of the amount of energy required to move a given quantity of air, and combines equipment efficiency as well as system effects. The owner can include this metric as a design criterion. Similarly, metrics for chilled-water system performance in terms of kilowatts per kilowatt of cooling can be established. Chiller performance and overall chilled-water system performance issues are well documented and should be consulted to set appropriate targets.

Fan Energy. Because supply airflow rates in cleanrooms can be very high, fan systems should be closely examined for right sizing and conservation of fan energy. Static air pressures and total airflow rate requirements should be designed to reduce fan power and its operating costs. Fan energy required to move recirculation air may be decreased by reducing airflow rates and/or static air pressures. Energy conservation operating modes should be verified during system qualification. If these modes are not part of the original design, the control procedure must be changed and the operational change validated.

Airflow rates may be lowered by decreasing recirculation airflow rate and minimizing cleanroom volumes in high-air-change-rate suites. A lower airflow rate could allow decreasing HEPA or ULPA filter coverage or reducing average air velocity. Reducing airflow rate can yield significant energy savings while enhancing space cleanliness through reduced turbulence. Based on a 0.45 m/s face velocity, each square metre reduction in filter coverage area in a room can save 250 to 500 W/m^2 in fan energy and cooling load. Reducing space average velocity from 0.45 to 0.40 m/s saves 50 W/m^2 in fan and cooling energy. If the amount of airflow rate supplied to the cleanroom cannot be lowered, reducing static pressure can also produce energy savings. With good fan selection and transport design, up to 150 W/m^2 can be saved per 250 Pa reduction in static pressure. Installing low-pressure-drop HEPA filters, pressurized plenums in lieu of ducted filters, and proper fan inlets and outlets may reduce static pressure. Many cleanrooms operate for only one shift. Airflow rate may be reduced during nonworking hours by using two-speed motors, variable-frequency drives, inverters, inlet vanes, and variable-pitch fans, or, in multifan systems, by using only some of the fans.

Additional fan energy may be saved by installing more efficient motors and electrical equipment, including transformers, UPS, and motor drives. Fan selection and inlet/discharge configuration also affects energy efficiency. The choice of forward-curved centrifugal fans versus backward-inclined, airfoil, or vaneaxial fans affects efficiency. The number of fans used in a pressurized plenum design influences redundancy as well as total energy use. Fan size changes affect power requirements as well. Sometimes lowering airflow velocities by operating more fans can improve a system's energy efficiency and reliability; investigate different options to ensure optimal designs and operation.

Makeup Air (MUA) and Exhaust Energy. Makeup air is required to replenish the lost air and to meet pressurization needs. The requirements for makeup airflow rates vary accordingly with an added amount for leakage and pressurization. The energy required to supply the conditioned makeup air can be significant. Optimizing MUA design by reducing or displacing mechanical cooling or electrical heating processes can improve energy efficiency, because cleanroom air-conditioning systems typically account for 30 to 65% of the total energy consumption in a high-tech facility. Different precooling and reheating/humidification schemes may result in difference in energy efficiency performance of MUA systems (Tsao et al. 2010). Careful attention to the layout and design of the makeup air system, especially minimizing system pressure drop and specifying efficient fans and motors, is important. The type of equipment installed normally determines the quantity of exhaust airflow rates in a given facility. Heat recovery has been used effectively in process exhaust; when heat recovery is used, the heat exchanger material must be selected carefully because of the potentially corrosive atmosphere; requirements for nonhazardous cleanrooms are not as significant. Also, heat recovery equipment has the potential to cross-contaminate products in pharmaceutical facilities. Pretreating makeup air using return water (either from process or building systems) is another way to reduce energy demands on primary systems serving a clean facility.

Makeup air cannot normally be reduced without decreasing process exhaust, which may be difficult to do because of safety and contamination control requirements. Therefore, design optimization of conditioning and delivering the makeup air should be explored and costs should be investigated. Conventional HVAC methods such as using high-efficiency chillers, good equipment selection, and precise control design can also save energy. One energy-saving method for large facilities uses multiple-temperature chillers to bring outdoor air temperature to a desired dew point in steps.

Cleanrooms and Resource Use: Opportunities to Improve Sustainability

Because of their highly specific and complex requirements, cleanrooms generally have high demands for energy and resources (Hu et al. 2013; Xu 2003). When possible, owners, designers, and operators should look for opportunities to reduce these demands, not only for reasons of environmental stewardship, but also for cost savings and avoidance of problems and complexity associated with larger power requirements and systems.

When developing a cleanroom-driven project, using integrated design and construction, under either the structured approach of integrated project delivery (IPD) or less formalized types of collaboration or partnering, can result in major rewards in cost, schedule, and operational efficiencies.

Some of the most promising areas for energy and resource use reductions include the following:

- **Optimizing air distribution and air change rates in clean areas.** Reducing space volumes and air change rates saves energy for environmental conditioning units and fans; and may reduce equipment and system sizing, filtration pressure drops, and equipment space requirements. Proper fan selection and duct layouts can eliminate the need for sound attenuators, thus saving space and energy. For spaces having the highest air change rate or airflow rate, enlarging duct sizing, increasing filter and coil area, careful fan inlet and discharge layouts, incorporating pressurized plenums, reducing overall duct path length, using transfer fans, and grouping spaces appropriately

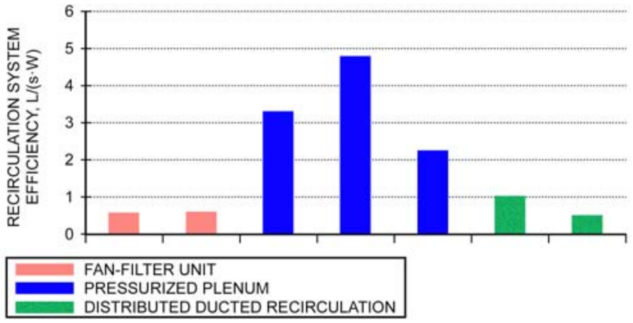

Fig. 18 Energy Efficiency of Air Recirculation Systems
(*Source*: Xu 2003. Figure reprinted from the *Journal of the IEST*, "Performance Evaluation of Cleanroom Environmental Systems," with permission from the Institute of Environmental Sciencesand Technology. Copyright 2003 by IEST, www.iest.org, [847] 981-0100)

can reduce energy requirements and avoid extreme space differential pressure challenges. In addition, spot exhaust, cooling, or heating can improve overall system efficiencies. Implementing on-demand utility distribution, such as pressure and temperature reset control strategies, may provide further operational energy savings. Different system selections such as ducted distribution, fan-filter units, and pressurized plenum typically induce different levels of air delivery efficiency, as shown in Figure 18 (Tschudi et al. 2005; Xu 2003). Users of fan-filter units should have the FFU performance tested using a standard method, such as that developed by Xu (2007b, 2007c), so that optimal efficiency can be achieved within common ranges of operating airflow rates.

- Advanced control strategies including on-demand dynamic air flow control in response to real-time particle counts. This reduces power demand during occupied and unoccupied time, and requires testing at different operational levels to ensure consistent and reliable process performance (see the section on Air Pattern Control for details).
- Some high-performance applications use **electrically enhanced filtration (EEF)**, which uses high frequencies or other electrical methods of charging airborne particles for significant air filtration efficiency improvements, providing the required filtration effectiveness with lower resistance and less pressure drop, which reduces overall system fan power consumption (Jaisinghani et al. 2000). Typically, EEF reduces air filter penetration by at least one order of magnitude. Some EEFs use two separate fields; the field across the filter is electrostatic. Others apply one voltage to three or four electrodes to create an ionizing field to charge incoming particles, and another ionizing (not electrostatic) field to charge the filter media. This second kind also inhibits bacterial growth on the filter media and results in lower bioburden cleanrooms: in most cases, ISO Class 6 cleanrooms achieve the airborne bioburden requirements of an ISO 5 environment. This represents a significant savings in initial and operating costs for cleanroom applications that are primarily concerned with bioburden and have looser requirements for general particulate contamination.
- Analyze and evaluate process chemistry, including cleaning materials and methods. Reducing or eliminating VOC-based solvents, heavy metals, acids, etc., in processing reduces the need for dilution air, scrubbing, treatment of effluent, and other environmental and life safety issues. This step must be integrated with process developers, operators, and regulatory compliance personnel to ensure that changes do not compromise final product quality and acceptance.
- Process equipment specifications should include performance criteria for support utilities such as process water, compressed air, exhaust air, and electrical power. More efficient equipment saves operational and capital costs. This approach may also prove attractive where process equipment is leased and will be returned to the equipment vendor, as is common in microelectronics because of the processing technologies' rapid obsolescence. For equipment or tool manufacturers, higher efficiency may enhance the toolset's resale value.

The effects of these broad areas of resource use reduction and energy savings on building systems should be obvious; however, there are other tangible benefits that should be considered. Reducing the resource use or environmental footprint of the cleanroom extends the site infrastructure's carrying capacity. On developed sites in developed areas, this can save significant capital and operational costs by reducing the need to increase the site's capacity or infrastructure to handle an additional building or operation. Reducing use of hazardous, toxic, or noxious materials can reduce the owner's exposure to environmental health and safety risks and the need to treat discharge air and water streams. Improving HVAC energy efficiency can reduce equipment and penthouse space requirements, capital costs, and system-generated noise and vibrations.

13. NOISE AND VIBRATION CONTROL

Noise is difficult to control. Noise generated by contamination control equipment requires particular attention, although production equipment noise may be more significant than HVAC noise. Before beginning design, criteria for noise and vibration should be established. Chapter 49 provides more complete information on sound control.

In normal applications of microelectronics contamination control, equipment vibration displacement levels need not be dampened below 0.5 μm in the 1 to 50 Hz range. However, electron microscopes and other ultrasensitive microelectronics cleanroom instruments may require smaller deflections in different frequency ranges. Photolithographic areas may prohibit floor deflections greater than 0.075 μm. As a general rule, displacement should not exceed one-tenth the line width.

For highly critical areas, consider using vaneaxial fans. These fans generate less noise in lower frequencies, and can be dynamically balanced to displacements of less than 4 μm, which decreases the likelihood of transmitting vibration to sensitive areas in electronics cleanrooms. Energy-efficient features of cleanroom HVAC systems, such as straight, smooth duct layouts and elimination of sound attenuators, can exacerbate noise control issues. Instead of resorting to adding sound traps, acoustic problems can be mitigated through proper, energy-efficient duct layouts and efficient fan selections that avoid sound generation from excessive fan-blade tip speeds.

14. SPACE CONSTRUCTION AND OPERATION

Control of particulate contamination from sources other than the supply air depends on the classification of the space, the type of system, and the operation involved. Important documents published by IEST and ISO are available to guide the practices (e.g., IEST RPs CC003.2, CC004.2, CC005, CC018, CC026.1, and CC027.1; ISO *Standards* 14644-2, 14644-3, 14644-4, and 14644-5). The following illustrate some typical details that may vary with the room class.

Construction Finishes

- **General.** Smooth, monolithic, cleanable, and chip-resistant, with minimum seams, joints, and no crevices or moldings.
- **Floors.** Sheet vinyl, epoxy, or polyester coating with wall base carried up, or raised floor (where approved) with and without perforations using the previously mentioned materials.
- **Walls.** Plastic, epoxy-coated drywall, baked enamel, polyester, or porcelain with minimum projections.

- **Ceilings.** Gypsum wallboard or plaster, covered with plastic, epoxy, or polyester coating or with plastic-finished, clipped acoustical tiles (ceiling tiles are not common in ISO Class 5 or cleaner pharmaceutical processing cleanrooms, and tile edges should be sealed if used for less clean areas) when entire ceiling is not fully HEPA or ULPA filtered.
- **Lights.** Teardrop-shaped single lamp fixtures mounted between filters, sealed and installed in T-grid ceiling (gasket or gel seal) or flush-mounted and sealed.
- **Service penetrations.** All penetrations for pipes, ducts, conduit runs, etc., fully sealed or gasketed, then caulked in place. All conduits must have internal seals or pour stops to reduce infiltration/exfiltration through conduit.
- **Appurtenances.** All doors, vision panels, switches, clocks, etc., either flush-mounted or with sloped tops.
- **Windows.** All windows flush with wall; no ledges on cleanest side. Window gaskets must be closed cell and windows caulked.
- **Doors.** Sliding doors perform better than swinging doors in critical cleanrooms. All door movements must be controlled for gradual, smooth motion.

Personnel and Garments

- Hands and face cleaned before entering area
- Lotions and soap contain lanolin to lessen shedding of skin particles
- No cosmetics and skin medications
- No smoking or eating
- Lint-free smocks, coveralls, gloves, head covers, and shoe covers

Materials and Equipment

- Clean equipment and materials before entry, including the underside of rolling equipment and work surfaces, and wheels.
- Use nonshedding paper and ballpoint pens. Pencils and erasers are not allowed.
- Handle processing equipment and hardware with gloved hands, finger cots, tweezers, and other methods to avoid transfer of skin oils and particles.
- Sterile pharmaceutical product containers must be handled with sterilized tools only.

Particulate Producing Operations

- Electronics grinding, welding, cutting, sanding and soldering operations are shielded and exhausted.
- Use nonshedding containers and pallets for transfer and storage of materials.

Entries

- Air locks and pass-throughs maintain pressure differentials and reduce contamination.

15. CLEANROOM INSTALLATION AND TEST PROCEDURES

ISO, IEST, and the National Environmental Balancing Bureau (NEBB) have developed a set of standards for cleanroom installation and test procedures (IEST RP CC006.2; ISO *Standards* 14644-2, 14644-3, 14644-4, and 14644-5; NEBB 2009). This section provides some descriptions of the procedures based on field experience.

Installation

Space Preparation. Building envelope construction should be completed, its insulation thoroughly installed. Insulation materials should meet cleanroom requirements. All leaks must have been eliminated, construction debris removed, and floors cleaned, washed, and blow-dried.

Cleanroom Installation. After space preparation is completed, the HVAC, plumbing, process piping, and cleanroom elements are then ready to start installation in the following sequence:

1. Install cleanroom HVAC piping, ductwork, plumbing, and process piping (prior to hookup with process equipment). All open ends of duct and piping must be temporarily sealed at end of each workday.
2. Install cleanroom ceiling, floor, and wall systems.
3. Any process equipment package that is larger than the access doors must be moved into the cleanroom area before installing cleanroom wall access panels. All process equipment should be protected from construction damage and remain in shipping packaging, unopened.
4. Install cleanroom access doors, pass windows, wall access panels, floor and ceiling access panels. If hard ceiling is used, do not close ceiling access before test, balance, and acceptance by the responsible HVAC engineer.
5. After completing steps 1 to 4, check the tightness of all access doors, pass windows, and other cleanroom openings, as well as edges between (a) ceiling and walls and (b) walls and floors. Leaks must be completely eliminated.

Cleanroom Duct and HEPA Filters.

1. Thoroughly wash and clean air-handling unit (AHU) internals, including internals of AHU fans.
2. Use compressed air to blow dry (pressure high enough to dry, but not to damage internals of the AHU). Run the AHU at low speeds with no HEPA filters installed to blow out any loose dirt or debris before clean operation.
3. Shut down and inspect the AHU internals. If some dirt remains (especially on filter and edge areas), repeat steps 1 and 2.
4. Temporarily seal all openings on cleaned AHUs, including outdoor air (OA) intakes, return and supply openings, water, steam connections, humidifier control box tubes, drain openings, and doors.
5. Wash clean and blow dry all internal surfaces of duct sections and immediately seal. This will prepare the installation of duct system and HEPA filters.
6. Temporarily seal all open ends in the duct system at end of each workday during installation.
7. Temporarily seal the installed duct systems to wait for the finish of architectural internal work. Leave ceiling accesses open for ceiling HEPA filter installation and HVAC system test and balance.
8. Remove all construction debris from cleanroom. Wash and dry AHU external surfaces.
9. Wash and dry the cleanroom floor, walls, ceiling, and all materials and equipment thoroughly. After this step is completed, installation personnel should wear cleanroom shoe covers when entering the cleaned area to continue installation work.
10. Place the originally sealed HEPA filter packets at their installation locations (avoid any cardboard or particulate shedding packaging in cleanroom; remove such packaging materials outside of clean areas).
11. Unpack HEPA filters and install immediately. Do not open HEPA filter packets if not to be installed the same day.
12. Check HVAC control system installation and pretest to ensure the control system is functioning before HEPA filter installation.
13. Check installation of fire protection, life safety, and other HVAC-related systems to ensure the systems are properly functioning.

System Start-Up, Test, and Balance.

1. Read the major equipment and controls' installation, operation, and maintenance (IOM) manual thoroughly.

2. Walk through entire system to be started up.
3. Check that all mechanical systems have been installed. Replace covers, belts, gaskets, bolts, and screws if missing or damaged.
4. Check unit base concrete slabs, roof curbs, and structural supports. All units should be firmly installed on level plane.
5. Check that all equipment, devices, and fittings are installed correctly and in operating condition, including room pressurization monitoring systems.
6. Check that all dampers, louvers, and valves are set at the correct positions as shown on drawings and under the direction of test-and-balance engineer.
7. Remove all bolts and plates used for temporarily compressing internal spring isolators under AHU base during shipment.
8. Check chiller system. Ensure that the chilled-water supply and return are under operational condition.
9. If hot water is used, check the hot-water system. Check that hot-water supply and return temperature and pressure all meet HVAC system requirements.
10. If steam is used, check steam valve station. Check that the regulated steam pressure meets HVAC system required range.
11. If pneumatic control is used, check compressed air system, ensuring that the supply pressure meets control system requirement.
12. Electrical engineer should check the electric wiring and confirm that power source voltages conform to all equipment requirements.
13. Check and correct all motors' rotation.
14. Check that the controls system has been installed, energized, and pretested by the controls contractor.
15. Check that the fire-protection system is in place, with correct links verified by the fire protection contractor and electrical engineer.
16. General mechanical/HVAC contractor should coordinate with all disciplines for overall status of preparation for cleanroom HVAC, control, and fire-protection systems start-up. A written report stating the completion of all of the preceding listed items should be submitted to the responsible HVAC engineer at minimum two workdays before the scheduled system start-up date. The responsible HVAC engineer should determine a proper day to inform the on-site commissioning authority (CA) before start-up if commissioning is required by project scope.
17. Correct all problems that may have occurred during start-up; adjust systems to meet design conditions. Also, all system specific commissioning and qualification procedures must be finalized and accepted before placing new systems into operation.
18. Once HVAC system is running with all final filters, including HEPAs, all personnel entering clean spaces should be fully gowned to maintain the proper and clean operating state, and to ensure gowning procedures and personnel training are appropriate.
19. Initial test, balance, and adjustment work should be performed by a licensed test-and-balance contractor during system start-up. The engineering approval for the final configuration of mechanical systems must include a verification that all systems are appropriately configured to maintain correct and consistent operation throughout the life of the system, including correct and appropriate equipment, installations, system adjustments, controls, operation and maintenance procedures and training, AHU operating point on the fan curve, proper spare capacity for filter loading, system wear and tear, seasonal and ambient environmental impacts (wind, weather extremes), and all other foreseeable factors that may impact operations.
20. Check prefilters and final filters for cleanliness. Replace temporary construction filters with filters specified by design engineer. If the design filters have reached their pressure drop limit, change them.
21. Adjust supply, return, and exhaust fan airflows and room pressurizations to meet design rates.
22. Verify that operational testing of all system safeties (fire alarm, high-pressure limits, etc.) is completed before releasing system for automatic operational control.
23. Keep air system operating. Set room thermostat low enough to start cooling. Check chilled-water supply and return temperatures, control valves, and condensate drain. Check room temperature. Note that the cooling performance test is under the condition without process heat. The responsible HVAC engineer should determine if the HVAC and chiller systems are capable of satisfying the additional load with process running.
24. Keep air system operating. Set room thermostat at temperature high enough to start heating system. Check steam pressure and/or heating hot water system temperature, monitor served room temperature, and check control valves and condensate return and drain lines.
25. Keep supply air and heating system running. Set room humidistat at level high enough temporarily start humidifier. If steam humidifier is used, check steam pressure and all connections. Monitor relative humidity of served room and check control valves.
26. Clean the space for the last time using the operationally approved pharmaceutical cleaning procedures to prepare for final test. Cleanroom dress code enforcement begins before final test.
27. Perform final test. Attendees should include all contractors, subcontractors, the responsible HVAC engineer, the cleanroom facilities engineer, the future system lead operators, lead maintenance staff, and commissioning and quality personnel, if appropriate.
28. All problems should be solved before the project completion, including the achievement of acceptable cleanroom pressurization, particulate and bioburden levels. Keep complete records of all problems and solutions during start-up, testing, adjusting, and balancing.

Pressurization Test and Map

Cleanroom pressurization must be verified before commissioning and engineering acceptance. An as-built space-to-space pressurization map should be submitted by the test-and-balance contractor to the responsible HVAC engineer for review and approval. The system must support acceptable room pressurizations within a narrow enough range to accommodate expected future system operational fluctuations; a retest may be performed if the HVAC engineer deems it necessary. Perform and document airflow pattern testing for final quality control verifications to demonstrate that particulates are being driven from the cleanest, most critical areas to less critical regions within and between rooms. Even when a room differential pressure is being maintained, it is important to find and correct counterintuitive airflow reversals through airflow pattern testing.

Operation Personnel Training Program

It is important that the operating and maintenance personnel responsible for systems on a particular project receive proper training. Usually, training is offered by the control contractor under the supervision of the responsible HVAC engineer, and should start during functional performance testing. It is important that the operating and maintenance personnel see the systems being set up, the issues encountered, and their resolution.

Cleanliness Verification Test

Empty (as-built) cleanroom cleanliness may be verified and determined by initial testing before process equipment installation and operation. Operational cleanroom cleanliness should be tested during formal process operation to gage the influence of emissions from process materials and products, as well as the performance of process exhaust systems together with cleanroom operation rules and operating personnel activities.

At-rest cleanroom status occurs after preparing the area for pharmaceutical manufacturing by installing process equipment and instrumentation, and the additional of properly gowned personnel creates **operational** cleanroom conditions. Space particulate levels measured at these different cleanroom operating states are important to meet processing space environmental requirements.

For ISO Class 3 and 4 cleanrooms, the owners will most likely prefer not to have commissioning personnel walking around the cleanroom facility during process in operation. They typically use their own professional staff to test and maintain the space cleanliness level. Therefore, as-built cleanroom cleanliness commissioning is the final step in most projects. Several publications by IEST and ISO address cleanroom testing and operation issues (IEST RP CC006.2; ISO *Standards* 14644-2, 14644-3, 14644-4, and 14644-5).

Commissioning

Participants in the commissioning process include personnel involved in the URS generation, design, start-up, test, and balance, in addition to process operators, the owner's project authorities, and commissioning personnel.

Commissioning documents should include the following:

- Certificates and warranties of system completion with complete set of as-built drawings submitted from mechanical, electrical, plumbing, controls, and fire-protection contractors
- If available, all major equipment installation, operation, and maintenance (IOM) manuals, from the equipment manufacturers
- Complete records of all problems and solutions that occurred during start-up, and tests and adjustments submitted by every individual contractor
- A certified system test and balance report with verified major equipment models and capacities, and all tested performance numbers conforming to the system criteria from the licensed test-and-balance contractor. A complete space-to-space pressurization map submitted by the test-and-balance contractor
- A control system installation, operation, and maintenance (IOM) manual submitted from the control contractor
- A certificate of test for as-built cleanroom cleanliness (tested when cleanroom facility is complete, all services are connected and functional, but without equipment and operating personnel in the cleanroom)
- If the contract scope requires, a certificate of cleanroom cleanliness at the condition of process running with operating personnel in the facility
- Updated operating procedures, system drawings, facility flow diagrams, air handler service area diagrams, space classification, and pressurization drawings, as applicable.
- Commissioning protocol forms, signed and witnessed by all attendees

Process Equipment Installation (Tool Hook-up)

The process equipment installation (tool hook-up) work is covered by a separate, independent contract. It starts when the as-built cleanroom has been certified and accepted by the owner. The plant facility engineer is responsible for process equipment installation, and the project HVAC engineer monitors the cleanroom cleanliness while hook-up is in progress, offering consultation as needed. The following points apply to the cleanroom tool hook-up procedure:

- All cleanroom equipment installation personnel should attend a cleanroom orientation class before beginning work.
- All installation personnel must follow the dress code entering and working in the cleanroom area for process equipment installation, testing, adjusting, and operation.
- Do not unpack process equipment before the cleanroom has been cleaned, tested, certified, and is ready for installation of the equipment. Avoid unpacking equipment in clean areas; this should be done in a material airlock following proper procedures to minimize particulate introduction to the cleanroom.
- Do not unpack process equipment or open temporarily sealed pipe ends if not immediately installing or connecting to the equipment or pipe ends. Temporarily seal unfinished connection openings if not being connected immediately.
- Do not leave cleanroom doors or pass windows open anytime during installation or test operation.
- Establish a bimonthly cleanroom cleanliness retest timetable for monitoring and maintaining the cleanroom cleanliness level for the first six months. The frequency of retest can be modified according to the actual operating experience in future years.

16. INTEGRATION OF CLEANROOM DESIGN AND CONSTRUCTION

Integrated design and construction addresses all stages and aspects of cleanroom construction, to achieve better-quality, faster delivery; lower-cost, more optimized operation and maintenance; lower energy consumption; a cleaner environment; safer, more reliable, and more productive conditions; and longer service life. Integrated building design (IBD) is discussed in detail in Chapter 60.

A complete cleanroom project usually includes the following stages (see Figure 19): development of scope, budget, and overall project execution plan; predesign, conceptual, and schematic design; preliminary, final design, and construction documentation; and construction service.

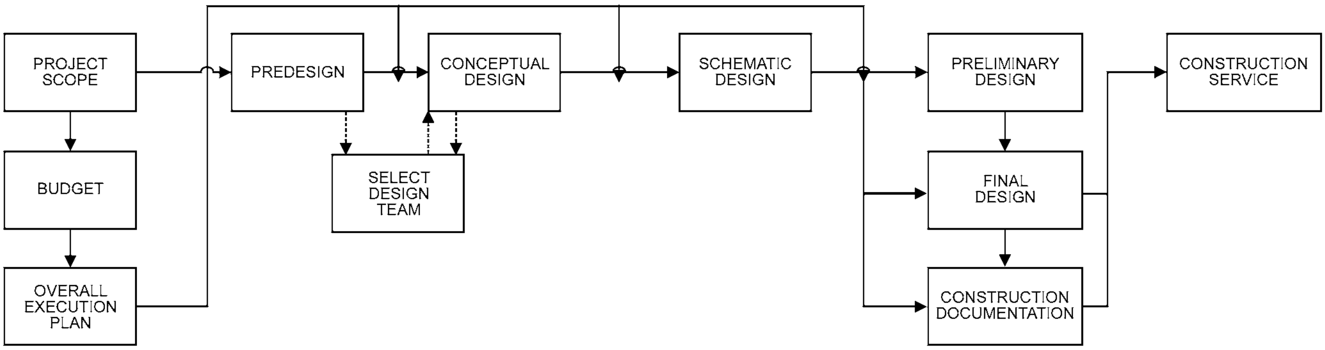

Fig. 19 General Design and Construction Procedure

One of the most important initial steps is to have a effective programming plan that involves all stakeholders: management, owners, users; designers (architects and engineers), process engineers, builders, and utility, maintenance and operation personnel.

Although the entire cleanroom building project is a large and complex operation, it may be simplified if it is considered as an integrated system with a unified overall scope of work and timeline to be achieved by an integrated design and construction team (Shieh 1990, 2005). In an integrated approach, all individual systems and their components are considered as subsystems of the overall integrated cleanroom building project, and optimizations are implemented at the component, system, and facility levels, including the following:

- **Site/utilities.** Overall site plan, entrances and gates, roads and transportation, landscape, electrical substations or electrical main connection, gas or other fuel main intake pressure regulation station, water, sewer, sanitary and storm drain piping and main connections, telephone, network, security and fire protection system main connections, outdoor lighting, etc.
- **Building.** Foundations, structure system, walls, roofs, ceilings, floors, elevators, electrical, gas, fuel, water, sewer, plumbing, sanitary, mechanical, HVAC, chiller, boiler, noise control, lighting, process systems, energy and process material recovery systems, exhaust air and wastewater treatment systems, hazard control systems, explosion- and corrosion-proofing, instrumentation and control systems, fire protection systems, etc.
- **Cleanroom.** Walls; roofs; ceilings; HEPA or ULPA filters; floors; mini-clean environment; clean tunnels; clean booths; recirculating air, makeup air, and exhaust air systems; lighting, process mechanical, chemical, electrical, and control systems; production lines; process conveyers; special gas supply systems; acoustics; operating personnel, material, and products access doors, windows, or openings; air showers; room temperature, humidity, static electricity, CO_2, pressurization, and cleanliness monitoring and control systems; fire protection and after-fire recovery systems; seismic design, emergency response facilities, etc.
- **Implementation.** Design documents, submittal approvals, receiving inspections, clean construction and installation work, field inspections, system start-up, test and adjustment, balancing, commissioning, and turnover.
- **Building management.** System operation and maintenance.

17. LIFE AND PROPERTY SAFETY

Human life and property safety must be thoroughly addressed in all types of new construction or renovation projects during cleanroom design, construction, installation, start-up, test, balance, operation, and maintenance. The American Conference of Governmental Industrial Hygienists (ACGIH) and National Fire Protection Association (NFPA) provide detailed regulations. The following are some of the essential categories to be carefully addressed during the entire cleanroom project design, construction, commissioning, operation, and maintenance process.

Hazards Generated on Cleanroom Property

When hazards are present on the project property, all safety issues must be carefully addressed; otherwise, the consequences could affect not only the occupancy personnel and the property, but also the surrounding communities. One of the duties for the design and commissioning authorities is to understand and successfully address the hazards generated in the property.

Different cleanrooms may be composed of many different operating systems, each with distinct equipment or operating processes that present unique hazards (e.g., fuel handling, chemical transport and emissions, airborne contaminants, heated lubrication and seal oil, oil-filled transformers, cable vaults, coal handling, electrical hazards, control rooms in industrial properties, active pharmaceutical ingredients [API], and medical gas supply and cross contamination in hospitals). Microelectronics manufacturing can also include extremely toxic, explosive, and pyrophoric gases and materials. These can create unique EHS hazards and special evacuation or containment emergency HVAC operational strategies.

Fume hoods are a design challenge when located in pharmaceutical processing rooms because they may have a small but measurable containment leakage rate. The processing room should be positively pressurized to promote product integrity, but fume hoods require a negatively pressurized environment to support containment of hazards. Architectural layout provides a primary solution to the issue of a processing space needing protection from inbound contamination, and addresses containment concerns to protect surrounding spaces. Anterooms and similar buffer zones allow the creation of *pressure doughnuts* or *pressure sinks* while limiting the amount of air needed to achieve appropriate control.

Implementing comprehensive human health and life protection requirements, as well as fire protection systems that include hazard detection, alarm, and suppression systems, can be a complex challenge that requires commissioning authorities' thorough understanding and experience of the intricacies of different type of individual projects.

Fire and Hazardous Gas Detection, Alarm, and Suppression Systems

Careful design, quality installations, continuous monitoring, and effective maintenance of explosion prevention and fire protection systems promote proper safety. Early, reliable fire and hazardous gas detection alerts personnel to the danger and initiates protective actions automatically or manually. Examples include but are not limited to the following:

- Gas detectors for oil and gas skids
- H_2 detectors for battery rooms
- Spark and flame detectors for coal conveyors and fuel oil tanks
- Heat detection for oil-filled transformers and lube oil and seal oil skids
- Linear heat detectors for cable galleries and fuel oil tanks
- Smoke and heat detection for plant and nonplant buildings

Active systems, such as pumping systems, can be automatically or manually activated for use in actual fire fighting. They network with fire and gas detection and alarm systems, deluge spray systems, foam systems, CO_2 detectors, clean agent systems, portable and mobile extinguishers, and fire station and fire tenders.

Homeland Security and Emergency Response Plan

Homeland security and emergency response have become more important in the United States since September 11, 2001. Awareness among first responders has raised the need to be prepared for extraordinary events. Emergency response plans need to include fire protection crews with scheduled routine training, exercise, and fire protection system testing, as well as in cooperation with homeland security and civil defense programs. Examples such as firefighter safety, first responders training, protective clothing, procedures, and equipment to deal with any predictable emergency are critical to good and sustainable operations. Refer to NFPA *Standard* 1600 for details.

IEST RECOMMENDED PRACTICES

All *Recommended Practices* are from the Institute of Environmental Sciences and Technology, Arlington Heights, IL.

RP-CC001.3	HEPA and ULPA filters

CHAPTER 20

DATA CENTERS AND TELECOMMUNICATION FACILITIES

USEFUL DATACOM RESOURCES 20.1
DATACOM EQUIPMENT, POWER TRENDS, AND ENVIRONMENTAL GUIDELINES 20.4
Datacom Equipment Workload 20.4
Datacom Equipment Racks 20.4
Datacom Equipment (Hardware) 20.4
Datacom Equipment Components 20.9
DATACOM FACILITIES 20.10
GENERAL CONSIDERATIONS 20.10
Air Cooling 20.14
Liquid Cooling 20.17
Water Usage 20.17
Energy Efficiency 20.18

DATA centers and telecommunication facilities are significantly different than most other facilities:

- Occupants of most facilities are people; the occupants in data centers are computer hardware and software applications.
- Load is more volatile and transient because hardware upgrades, software additions, and computing loads can change so rapidly.
- Computer hardware is the major equipment, and equipment lifetimes are often measured in months rather than years. This results in upgrade/life cycle mismatches between hardware and facility power/cooling.
- Often data centers have an actual power/cooling load density 10 times or more that of a typical office building.

The telecommunication industry is rapidly changing from predominantly regulated land lines to wireless technology that uses the same communications protocol (Internet Protocol or IP) as the data center industry. As a result, data centers and telecommunications facilities are converging. TC 9.9 uses the term “datacom” to indicate both data centers and telecommunication facilities. This chapter provides some basic information about datacom facilities and where to find additional information.

The main requirements for datacom facilities are space, power, cooling, and networking. Often, these are treated as services. Each service can have a service-level agreement (SLA), but the services are highly interdependent. Therefore, overall reliability/availability is best achieved when all aspects of these services are designed together, with the same performance goals. Because of the high densities, it is becoming increasing popular to provide metering for services at each service interface point, with centralized monitoring of the infrastructure.

Because of the high capital cost and short life cycles of datacom equipment, as well as the continued evolution of both public and private cloud computing (i.e., computing as a service), the trend is towards companies owning less of their own datacom facilities, and renting more resources from a third-party facility owner/provider. Rented or leased services and facilities come in many varieties; a common general format is retail or wholesale colocation facilities.

A **colocation center** (also co-location, collocation, colo, or coloc) is a type of datacom facility where equipment, space, and bandwidth are available for rent. Colocation facilities provide space, power, cooling, and physical security services for server, storage, and networking equipment. Their fiber services are typically redundant and diverse, and connect the facilities to various telecommunications and network service providers. However, the power and cooling redundancies can be significantly different from one colocation center to another, and should be evaluated before signing a contract, which should include a carefully worded SLA. Failures in these facilities can have widespread effects.

Figure 1 provides an overview of the major spaces in a typical datacom facility.

Datacom facilities provide space, power, cooling, and networking to datacom equipment (hardware), also known as information technology equipment (ITE) in the U.S. *National Electrical Code*® (NFPA *Standard* 70). The space within the datacom facility or data center that actually houses the datacom hardware may be called the data hall, the ITE equipment room, or the white space. Figure 1 shows the various elements that may make up a complete facility. The actual elements (and their arrangements) vary considerably in each project.

This chapter focuses on the most important facility requirements for the support of the datacom equipment, which include thermal, air quality, and power.

1. USEFUL DATACOM RESOURCES

ASHRAE Datacom Series

This series comprises 13 books produced by TC 9.9. To keep pace with the rapidly evolving datacom industry, some books have been revised several times, with new editions containing updated information. New titles are also planned for the future.

These books are equally useful for experts and people new to this industry. The following includes brief descriptions of each book.

***Thermal Guidelines for Data Processing Environments*, 4th ed. (ASHRAE 2015a).** The trend toward increased equipment power density in data centers presents significant challenges to thermal design and operation. Undesirable side effects include decreased equipment availability, wasted floor space, and inefficient cooling-system operation.

Avoiding a mismatch between datacom equipment environmental requirements and those of adjacent equipment, or between datacom equipment requirements and facility operating conditions, requires a standard practice solution to datacom equipment interchangeability that preserves industry innovation.

ASHRAE (2015a) provides a framework to align the goals of equipment hardware manufacturers, facility designers, operators, and managers. This book covers four primary areas: equipment operating environment specifications, facility temperature and humidity measurement, equipment placement and airflow patterns, and equipment manufacturers’ heat load and airflow requirements reporting.

***IT Equipment Power Trends*, 3rd ed. (ASHRAE 2018).** Datacom equipment technology is advancing at a rapid pace, resulting in relatively short product cycles and an increased frequency of datacom equipment upgrades. Because datacom facilities

The preparation of this chapter is assigned to TC 9.9, Mission Critical Facilities, Data Centers, Technology Spaces, and Electronic Equipment.

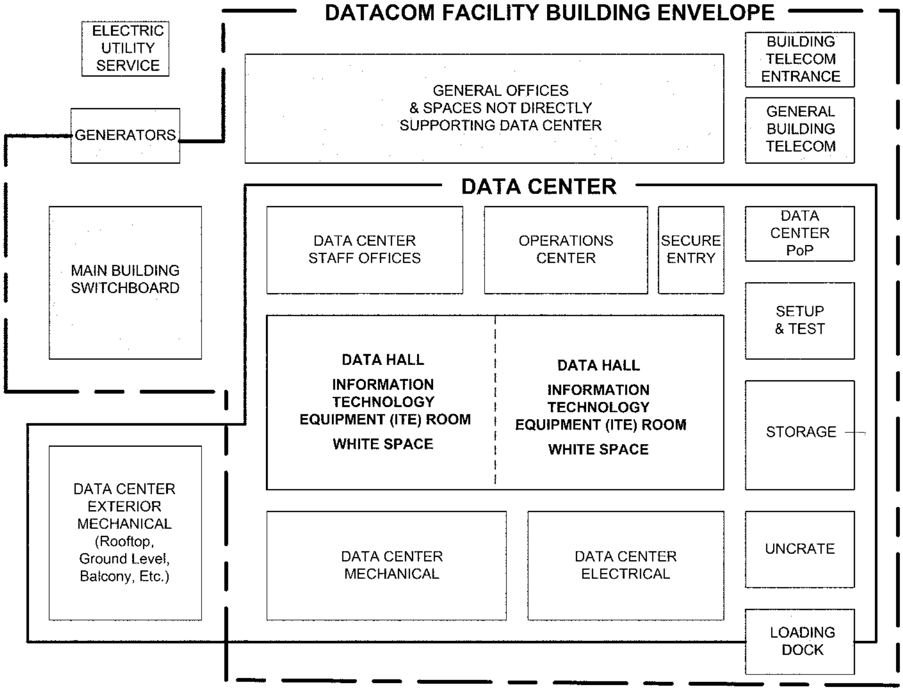

Fig. 1 Typical Datacom Facility Space Plan

and their associated HVAC infrastructure are typically built to have longer life cycles, any modern datacom facility needs the ability to seamlessly accommodate the multiple datacom equipment deployments it will experience during its lifetime.

Based on the latest information from leading datacom equipment manufacturers, ASHRAE (2018) provides datacom equipment power trend charts through 2025 to allow datacom facility designers to more accurately predict future equipment loads, and supplies ways of applying the trend information to datacom facility designs today.

Also included is a review of various air- and liquid-cooling system capabilities and considerations for handling future loads and an invaluable appendix containing terms and definitions used by datacom equipment manufacturers, the facilities operation industry, and the cooling design and construction industry.

***Design Considerations for Datacom Equipment Centers* (ASHRAE 2009a).** The design of computer rooms and telecommunications facilities differs in fundamental ways from the design of facilities used primarily for human occupancy. As the power density of datacom equipment continues to increase, this difference has grown more extreme.

This book covers basic design considerations for data and communications equipment centers. The Datacom Facility Basics section includes chapters on datacom design criteria (temperature, temperature rate of change, relative humidity, dew point, and filtration), HVAC load, computer room cooling (including both air and liquid cooling), and air distribution.

The section on Other Considerations includes chapters on ancillary spaces (battery plants, emergency generator rooms, burn-in rooms and test labs, and spare parts rooms), contamination, acoustical noise emissions, structural and seismic design and testing, fire detection and suppression, commissioning, availability and redundancy, and energy efficiency. This book does not cover electrical or electronic systems design and distribution.

***Liquid Cooling Guidelines for Datacom Equipment Centers*, 2nd ed. (ASHRAE 2013).** Datacom equipment today is predominantly air cooled. However, with rack heat loads steadily climbing, the ability of many data centers to deliver either adequate airflow rates or sufficient chilled air is now being stretched to the limit. These trends in the heat load generated by datacom equipment can have detrimental side effects, such as decreased equipment availability, wasted floor space, and inefficient cooling system operation. This situation is creating a need for implementing liquid cooling solutions.

The overall goals of liquid implementations include aspects such as transferring as much waste heat to the facility liquid-cooling loop as possible, reducing the overall volume of airflow needed by the racks, and reducing processor temperatures to improve computer performance.

This book includes definitions for liquid and air cooling as they apply to the datacom equipment, describing the various liquid loops that can exist in a building that houses a datacom space. The book also bridges the liquid-cooling systems by providing guidelines on interface requirements between the chilled-water system and the technology-cooling system, and outlines the requirements of liquid-cooled systems that attach to an electronics rack and are implemented to help datacom room thermal management.

***Structural and Vibration Guidelines for Datacom Equipment Centers* (ASHRAE 2008a).** The typical life span of datacom equipment is often three to five years. On the other hand, the anticipated life span of the mechanical and electrical infrastructure is 15 to 20 years, and the building's structure can last 20 to 50 years. Consequently, the building's infrastructure and structure may eventually house and support many vintages of datacom equipment.

This book is divided into four main sections. Part 1 gives an overview of the best practices in the design of datacom facilities, including recommendations for new and renovated building structures, building infrastructure, and datacom equipment. Part 2 covers design of new and existing structures. In Part 3, structural considerations of the building's infrastructure, raised-access floor systems, and vibration sources and their control are discussed in detail. Part 4 covers shock and vibration testing, seismic anchorage systems, and analysis of datacom equipment.

***Best Practices for Datacom Facility Energy Efficiency*, 2nd ed. (ASHRAE 2009b).** Sustainable design, global warming, dwindling fuel reserves, energy use, and operating cost are becoming increasingly more important. These issues are even more important in datacom facilities because of their large, concentrated use of energy (which can be 100 times the usage of an office building); 24/7 operations have about three times the annual operating hours as other commercial properties.

The intent of this publication is to provide detailed information to help minimize the life-cycle cost to the client and maximize energy efficiency in a datacom facility.

This book covers many aspects of datacom facility energy efficiency, including environmental criteria, mechanical equipment and systems, economizer cycles, airflow distribution, HVAC controls and energy management, electrical distribution equipment, datacom equipment efficiency, liquid cooling, total cost of ownership, and emerging technologies. There are also appendices on topics such as facility commissioning, and operations and maintenance.

***High Density Data Centers—Case Studies and Other Considerations* (ASHRAE 2008b).** Data centers and telecommunications rooms that house datacom equipment are becoming increasingly more difficult to adequately cool because datacom equipment manufacturers continually increase datacom performance at the cost of increased heat dissipation. The objective of this book is to provide a series of case studies of high-density data centers and a range of ventilation schemes that demonstrate how loads can be cooled using a number of approaches.

***Particulate and Gaseous Contamination in Datacom Environments*, 2nd ed. (ASHRAE 2014a).** Particulate and gaseous contamination monitoring, prevention, and control in datacom environments have gained greater importance because of an increase in datacom equipment reliability concerns arising from many factors: mission-critical societal dependence on computers; continued miniaturization of electronic circuit features; elimination of lead from printed circuit board solder metallurgies; proliferation of datacom equipment into locations with high levels of sulfur-bearing contamination; increased use of free-air cooling to conserve energy; and expansion of the allowable temperature-humidity datacom equipment envelope.

This book describes in detail the procedures necessary to ensure airborne contaminants will not be a factor determining datacom equipment reliability. It also includes the description of a landmark ASHRAE gaseous contamination datacom facility survey that found that silver corrosion rate is a much better predictor of corrosion-related hardware failures, compared to the prior practice of relying on copper corrosion rate to predict failures.

***Real-Time Energy Consumption Measurements in Data Centers* (ASHRAE 2010).** Data centers are dense and complex environments that house a wide variety of energy-consuming equipment. With datacom equipment and associated facility equipment, there are thousands of energy consumption monitoring points. If a datacom facility operator cannot monitor a device, that device cannot be controlled. In addition, for a datacom facility to reach its optimal energy efficiency, all equipment on the datacom and facilities side must be monitored and controlled as an ensemble.

Datacom equipment and facilities organizations in a company typically have different reporting structures, which results in a communication gap. This book is designed to help bridge that gap and provides an overview of how to instrument and monitor key power and cooling subsystems. It also includes numerous examples of how to use energy consumption data in calculating power usage effectiveness (PUE).

***Green Tips for Data Centers* (ASHRAE 2011).** The datacom industry is focused on reducing energy. This focus is driven by increasing energy costs and capital costs to add more datacom facility capacity. Combined with the rapid growth in the industry and the increase in the power used by the datacom equipment, it is important that every data center operator understands the options for reducing energy.

This book gives datacom facility owners and operators a clear understanding of energy-saving opportunities. It covers the building's mechanical and electrical systems as well as the most promising opportunities in technology. In addition, the book's organization follows a logical approach that can be used for conducting a preliminary energy assessment.

***PUE™: A Comprehensive Examination of the Metric* (ASHRAE 2014b).** Power usage effectiveness (PUE), the industry-preferred metric for measuring the actual infrastructure energy efficiency for datacom facilities, is an end-user tool that helps boost energy efficiency in datacom facility operations. This book provides a high level of understanding of the concepts surrounding PUE, plus in-depth application knowledge and resources to those implementing, reporting, and analyzing datacom facility metrics.

It gives actionable information useful to a broad audience ranging from novice to expert in the datacom equipment industry, including executives, facility planners, facility operators, datacom equipment manufacturers, HVAC&R manufacturers, consulting engineers, energy audit professionals, and end users.

PUE was developed by The Green Grid Association, a nonprofit, open industry consortium of end users, policy makers, technology providers, facility architects, and utility companies working to improve the resource efficiency of information technology and datacom facilities worldwide. Since its original publication in 2007, PUE has been globally adopted by the industry, and The Green Grid has continued to refine the metric measurement methodology with collaborative industry feedback. For further details, see the section on Power Usage Effectiveness in this chapter.

***Server Efficiency—Metrics for Computer Servers and Storage* (ASHRAE 2015b).** This book consolidates information on current server and storage subsystem energy benchmarks for use in selecting the appropriate IT hardware solutions. Each chapter describes a metric and its target market, includes examples of data generated from the subject benchmark or tool, and provides guidance on interpreting the data. This book supplies the information needed to select the best measure of performance and power for a variety of server applications.

***IT Equipment Design Impact on Data Center Solutions* (ASHRAE 2016a).** This book provides guidance in making the critical data center infrastructure equipment selections and design configurations.

ANSI/ASHRAE *Standard* 90.4-2016, Energy Standard for Data Centers (ASHRAE 2016b)

This standard provides a performance-based (non-prescriptive) alternative to *Standard* 90.1 for demonstrating compliance with minimum datacom facility efficiency in the design stage. It balances the need for energy efficiency with the concurrent need for reliability in high-performance datacom facilities.

ANSI/ASHRAE *Standard* 127-2012, Method of Testing for Rating Computer and Data Processing Room Unitary Air Conditioners

This standard establishes a uniform set of requirements for rating computer and data processing room (CDPR) unitary air conditioners.

ANSI/AHRI *Standard* 1361 (SI)-2017, Performance Rating of Computer and Data Processing Room Air Conditioners

This standard establishes a uniform set of requirements for rating CDPR air conditioners.

ANSI/TIA *Standard* TIA-942-B-2017, Telecommunications Infrastructure Standard for Data Centers

The Telecommunications Industry Association's *Standard* TIA-942 specifies minimum requirements for telecommunications infrastructure of data centers and computer rooms, including single-tenant enterprise data centers and multitenant Internet hosting data centers.

The TIA-942 specification references private and public domain data center requirements for applications and procedures such as network architecture, electrical design, file storage, back-up and archiving, system redundancy, network access control and security, database management, web hosting, application hosting, content distribution, environmental control, protection against physical hazards (fire, flood, windstorm), and power management.

ANSI/BICSI *Standard* 002-2014, Data Center Design and Implementation Best Practices

This standard from the Building Industry Consulting Service International (BICSI) provides requirements, guidelines, and best practices intended for use internationally.

2. DATACOM EQUIPMENT, POWER TRENDS, AND ENVIRONMENTAL GUIDELINES

2.1 DATACOM EQUIPMENT WORKLOAD

Datacom equipment (hardware) has various workload states ranging from essentially idle/static (not performing any actual useful work) to running at its maximum performance and central processing unit (CPU) utilization. The hardware workload is driven by software. There is system or operating system software (including networking), and application software that yields calculation or data manipulation results (actual useful work).

The number of applications available across all hardware types is vast (in the multimillions at least). Software can often be added or upgraded in various ways, including remotely. This means the workloads, and therefore power and cooling loads, can be very dynamic.

Datacom equipment life cycles are much shorter than power and cooling infrastructure life cycles. Application software life cycles are even shorter. It is critical that power and cooling infrastructure planning considers the life cycles and refresh (churn) rates of hardware and software.

Load Characterization

From a datacom power and cooling infrastructure planning perspective, the two common means of maximum load characterization are watts per square metre and kilowatts per datacom equipment rack or cabinet. The datacom industry sometimes uses **granularity** as a means of describing the unit size.

Many in the datacom industry think that kilowatts per rack is superior to watts per square metre. However, at the start of a project, there may be insufficient information about the quantity of racks or their expected contents, making that metric too granular. Professional judgment is critical to deciding which maximum load characterization to use.

Of equal importance is characterizing the minimum load as well as the load variation. The time increment for load variation can be very short (e.g., seconds, minutes) or very long. It is important to obtain or develop a detailed load profile including future possibilities.

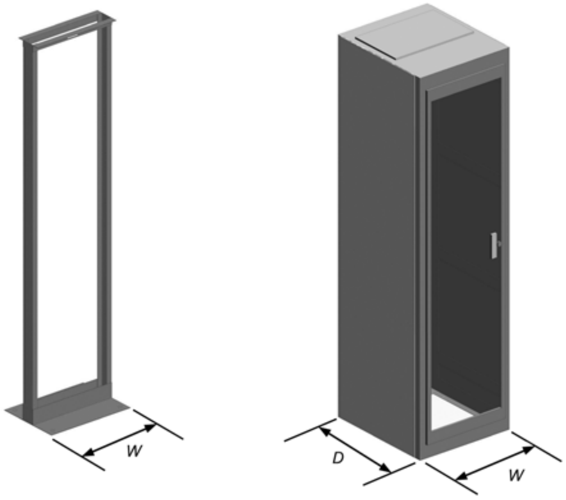

Fig. 2 Typical Rack and Cabinet Examples

2.2 DATACOM EQUIPMENT RACKS

Most datacom equipment is rack or cabinet mounted, but others come in prepackaged configurations, including large, stand-alone cabinets. Rack and cabinet sizes and equipment mounting standards are defined by the Electronic Industries Alliance (EIA 2005).

The vertical dimension is expressed in terms of **units (U)** (sometimes **rack units** [**RU**]). One U or RU represents 44.45 mm of vertical height within a rack. A common height for a rack is 42 U, although some are taller and some are shorter.

The terms *rack* and *cabinet* are often used interchangeably, although technically they are different. A **rack** is an open-frame two- or four-post mounting used more for telecom and patch panels than for servers. A **cabinet** is a similar four-post framework, but is equipped with sides, top, and often front and rear doors (Figure 2).

Typical rack widths are approximately 485 or 600 mm, depending on their construction. The actual space between the mounting rails is approximately 50 mm less than the nominal panel widths, to allow room for screwing equipment flanges to the rails. Cabinets tend to be a nominal 600 to 760 mm wide and 600 to 1200 mm deep. The wider cabinets are often used to provide space for the massive amount of power and data cabling associated with full configurations of high density hardware. Deeper cabinets have become necessary to accommodate the form factors of newer datacom hardware, which are often compressed to only 1 or 2 U high, but can be quite deep as a result.

Servers used for computing are available in rack mount and custom configurations. Most servers are full-rack width and are often identified as having 1U, 2U, 4U, etc., form factors (Figure 3). A half-width server mounts two separate boards side-by-side in a single-width 1U high chassis, or four separate boards in a single-width 2U chassis. Larger form factors may house multiple modular servers (**blade servers**) in its overall chassis.

2.3 DATACOM EQUIPMENT (HARDWARE)

Datacom components (e.g., processors, memory, storage, input/output [I/O], power supplies) are packaged into datacom equipment. This section is limited to datacom equipment requirements and interfaces; components are only addressed to the level necessary to describe the requirements and interfaces, but are covered in more depth in the section on Datacom Equipment Components.

Datacom equipment predominantly consists of servers (volume, blade, etc.), communication equipment (switches, routers, etc.), and data storage devices (storage area network [SAN], network attached storage [NAS], and other formats that are beyond the scope of this chapter).

For air-cooled datacom equipment, the primary interface to the facility is the air inlet to the datacom equipment. For liquid-cooled equipment, the interface to the facility is the liquid connection to the equipment or the rack. The datacom equipment interface focuses on

- Temperature
- Humidity
- Air quality
- Coolant flow (air or liquid)

Server Classifications

Servers tend to be the most common equipment within a datacom space; there are many different types of servers and any type of server can go into any type of datacom facility. Although there are no set rules regarding what constitutes any specific server type, the following classifications help provide some guidance:

- **General purpose, volume.** These servers are typically single or dual socket servers packaged in 1U, 2U, or half-width form factors. They generally have many features to cover a wide variety of customer needs. These are often called **small-form-factor servers** because of their minimal usage of rack height, but their depths can be significantly greater than will fit into legacy 600 mm deep racks.
- **Cloud, volume.** These systems are typically single- or dual-socket boards packaged in 1U, 2U, or half-width form factors. These servers have a limited, targeted set of features selected to address specific workloads.
- **Special-purpose.** Mainframes and custom server designs fall into this category. Features and packaging vary widely, depending on the target customer. Chassis sizes also vary widely and include rack-level servers and multiframe systems.
- **Blade.** Typically, blade servers have a multi-U chassis supporting multiple individual servers constructed on independent circuit boards called blades. The blades plug into a common backplane, enabling interconnection of boards. Cooling, power, and switch functionality are shared among the boards.

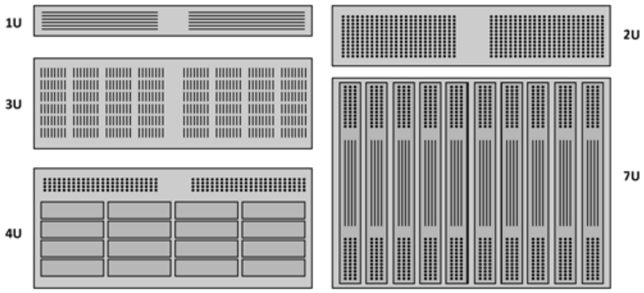

Fig. 3 Typical Computer Server Packaging Form Factors

Datacom Equipment Airflow

Standardized nomenclature defining the cooling airflow paths for datacom equipment have remained unaltered since 2004 (Figure 4). Most datacom equipment now uses the front-to-rear protocol. The exceptions are some legacy telecommunications equipment and some network switches. These may use a side-to-side protocol, or a mix of side-to-side-to-top and/or to-rear air flows, that are not shown. When airflow does not follow standardized protocol, special rack mountings and/or air deflectors may be necessary to achieve proper cooling in facilities designed predominantly for front-to-rear cooled equipment.

Liquid-Cooled Datacom Equipment

The increasing heat densities of modern electronics are stretching the ability to adequately cool the electronic components within servers with air. The trend to higher recommended inlet air temperatures, done with the goal of saving energy, exacerbates the problem. Liquid cooling is therefore becoming more prevalent.

Liquid cooling is defined as the process where a liquid (rather than “fluid” air) is used to provide the heat removal (i.e., cooling) function. There are many different liquid-cooling solutions for datacom rooms. The most common implementations are

- **Liquid-cooled rack:** a circulated liquid provides heat removal (cooling) at a rack or cabinet level for operation. Examples include rear-door or in-rack heat exchangers that transfer a large percentage of the datacom equipment waste heat from air to liquid.
- **Liquid-cooled datacom equipment:** liquid is circulated within the datacom equipment for heat removal (cooling) operation.
- **Liquid-cooled electronics:** liquid is circulated directly to the electronics for cooling, with no other heat transfer mechanisms.

These definitions do not limit the cooling fluid to water. Various liquids could be considered for application, including some that could be in a vapor phase in part of the cooling loop.

Figure 5 depicts one example of liquid-cooled datacom equipment where a liquid loop internal to the rack is used to cool the components in the rack. In this case, the heat exchange is with a liquid-to-facility-water heat exchanger. Typically, liquid circulating in the rack is kept above dew point to eliminate any condensation concerns.

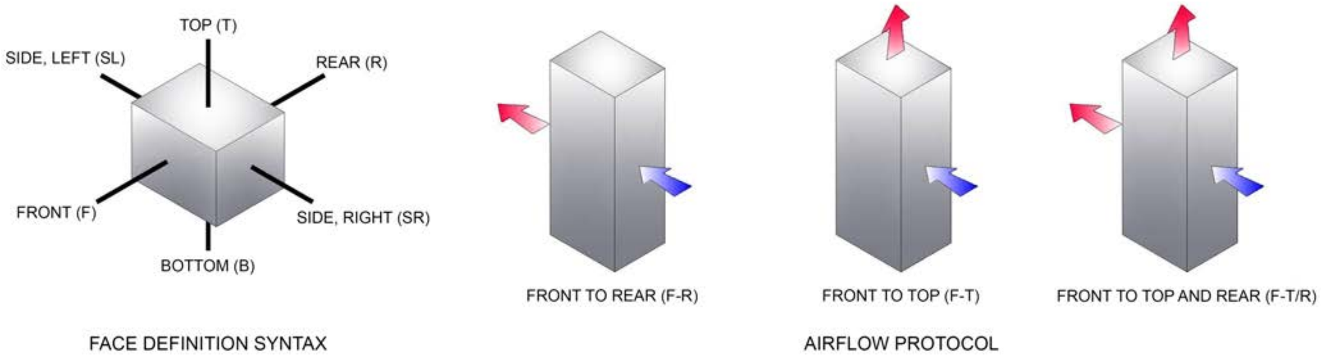

Fig. 4 Equipment Airflow
(ASHRAE 2015a)

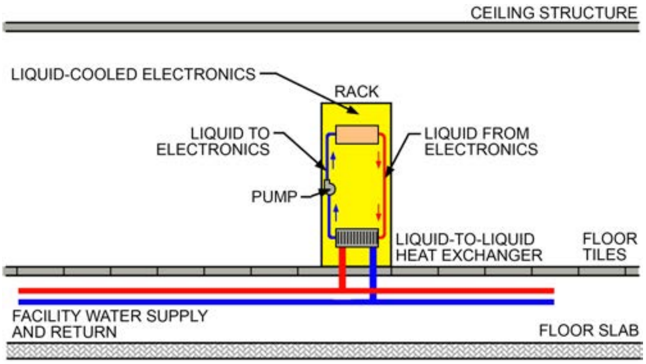

Fig. 5 Internal Liquid-Cooling Loop Exchanging Heat with Liquid-Cooling Loop External to Racks

Contamination

Most datacom facilities are well designed and are geographically located in areas with relatively clean environments. Therefore, they do not have significant contamination concerns. However, the overall cleanliness of the environment is only one consideration for the location of a datacom facility, so potential contamination is often not considered to be a major driver.

There are two types of contaminants: particulate and gaseous. Some datacom facilities may have harmful environments arising from the ingress of outdoor contamination. In some rare instances, contamination has been generated within the datacom facility itself.

- **Particulate matter** refers to airborne solid and liquid particles. For the purposes of this chapter, the terms *particle*, *particulate*, *aerosol*, and *dust* are considered equivalent and are represented by the term *particulate matter*. The size of airborne particulate matter can span a vast range from about 0.001 μm to more than 100 μm. Agencies that monitor particulate matter from a health point of view categorize particle mass concentration as $PM_{2.5}$ and PM_{10}, representing particles smaller than 2.5 μm and 10 μm, respectively. Particulate matter may also be categorized in three size modes: fine (0.001 to 0.1 μm), accumulation (0.1 to 2.5 μm), and coarse (2.5 to 10 μm). Coarse mode is generally limited to particles smaller than 10 μm, but can include much larger airborne fibers and particles. Particulate matter in each of these size categories may be composed of various materials from many different sources.
- **Gaseous contaminants** relevant to information technology (IT) and datacom equipment reliability include hydrogen sulfide, sulfur dioxide, mercaptans, and oxides of nitrogen, chlorine, and ozone, each of which can produce adverse effects on computer hardware. These harmful gases are by-products of geological, biological, agricultural, industrial, and manufacturing activities. They can, even at low μg/m^3 levels, act alone or in synergy with each other or with particulate matter to corrode metallic materials, causing irreversible damage to circuit boards, connectors, integrated circuits, and other electronic components.

If a datacom facility serving a critical application happens to be susceptible to gaseous or particulate contamination, the consequences could be severe. As a result, it is important to address the potential for contamination and mitigate the risk as much as practical.

A number of factors can result in an increased failure rate. Changes in solder type (lead based to lead free), and an ongoing miniaturizing of datacom equipment components increase the risk. Changes in datacom room temperature and humidity operating conditions combined with a lower priority consideration for the surrounding air quality are other factors of concern.

Contaminants can cause either electrical or cooling failures within datacom equipment. Electrical circuits typically fail in either an open or a shorted condition. Datacom equipment circuits are much smaller than normal power circuits, often with conductors smaller than a human hair. They are, therefore, more susceptible to damage, but they fail in a similar manner. Printed circuit boards use tiny copper wires (lands) and components are attached with silver solder, and the two common datacom equipment circuit failures are copper creep corrosion and silver creep corrosion.

Airborne dust contaminants can be detected from detailed visual inspections of filters in the air-handling systems. Gaseous contaminant presence may require seasonal or periodical monitoring and measurement through the use of copper and silver coupon testing in the datacom rooms. The coupons react when exposed to various gases, with the typical exposure period being around one month. A subsequent lab analysis of the coupons can quantify the level of contaminants present.

Filtration systems (particulate filtration or gas filtration units) can be used to mitigate the risk of contaminants in the datacom facility. More information on this topic can be found in ASHRAE (2015a).

Environmental Guidelines for Air-Cooled Equipment

The first edition of ASHRAE's *Thermal Guidelines for Datacom Processing Environments* in 2004 created a common design point: the inlet temperature for datacom equipment. The 2008 edition expanded the recommended thermal envelope, and the 2011 edition increased the datacom class definitions from two to four, with wider thermal ranges. The fourth edition (ASHRAE 2015a) makes significant changes to the humidity ranges as well. All of these changes were made after a great deal of industry study and, in the case of the humidity changes, a major ASHRAE research study (Pommerenke and Swenson 2014). Important considerations include the following.

Recommended Environmental Range. To achieve both energy efficiency and equipment operating reliability and longevity, facilities must be designed to achieve, under normal circumstances, ambient equipment inlet conditions that fall within ASHRAE recommended temperature and humidity ranges. See Table 1 for this range, or use the process defined by ASHRAE (2015a).

Allowable Environmental Range. The allowable envelope is where datacom equipment manufacturers test their equipment to verify that it will function within those environmental boundaries. Typically, datacom equipment manufacturers perform tests before product announcement, to verify that products meet all functional requirements within this environmental envelope. This is not a statement of reliability, but rather one of functionality of the datacom equipment. In addition to the allowable dry-bulb temperature and relative humidity ranges, the maximum dew point and maximum elevation values are part of the allowable operating environment definitions.

Practical Application. Prolonged exposure of operating equipment to conditions outside its recommended range, especially approaching the extremes of the allowable operating environment, can result in decreased equipment reliability and longevity (server reliability values versus inlet air temperatures are provided in ASHRAE [2015a] to provide some guidance on operating outside the recommended range). Exposure of operating equipment to conditions outside the allowable operating environment risks catastrophic equipment failure. With equipment at high power density, it may be difficult to maintain the air entering the equipment within the recommended range, particularly over the entire face of the equipment. Reasonable efforts should always be made to achieve conditions within the recommended range. However, if these efforts prove unsuccessful, operation outside the recommended range, but within the allowable environmental range, is likely to be adequate, but facility operators may wish to consult with the equipment manufacturers regarding the risks involved.

Table 1 2015 Thermal Guidelines: Equipment Environment Specifications for Air Cooling

	Product Operation[b,c]					Product Power Off[c,d]	
Class[a]	Dry-Bulb Temperature,[e,g] °C	Humidity Range, Noncondensing[h,i,k,l]	Maximum Dew Point,[k] °C	Maximum Elevation,[e,j,m] m	Maximum Rate of Change,[f] K/h	Dry-Bulb Temperature, °C	Relative Humidity,[k] %
Recommended (suitable for all classes; explore data center metrics in ASHRAE [2016] for conditions outside this range)							
A1 to A4	18 to 27	–9 to 15°C dp and 60% rh					
Allowable							
A1	15 to 32	–12°C dp and 8% rh to 17°C dp and 80% rh	17	3050	5/20	5 to 45	8 to 80
A2	10 to 35	–12°C dp and 8% rh to 21°C dp and 80% rh	21	3050	5/20	5 to 45	8 to 80
A3	5 to 40	–12°C dp and 8% rh to 24°C dp and 85% rh	24	3050	5/20	5 to 45	8 to 80
A4	5 to 45	–12°C dp and 8% rh to 24°C dp and 90% rh	24	3050	5/20	5 to 45	8 to 80
B	5 to 35	8% to 28°C dp and 80% rh	28	3050	N/A	5 to 45	8 to 80
C	5 to 40	8% to 28°C dp and 80% rh	28	3050	N/A	5 to 45	8 to 80

Note: For potentially greater energy savings, refer to Appendix C of ASHRAE (2015a) for the process needed to account for multiple server metrics that impact overall total cost of ownership (TCO).

[a]Classes A3, A4, B, and C are identical to those in the 2011 edition of *Thermal Guidelines for Data Processing Environments*. The 2015 version of the A1 and A2 classes have expanded relative humidity levels compared to the 2011 version.

[b]Product equipment is powered on.

[c]Tape products require a stable and more restrictive environment (similar to Class A1). Typical requirements: temperature between 15°C and 32°C, relative humidity between 20 and 80%, maximum dew point 22°C, rate of change of temperature less than 5 K/h, rate of change of humidity less than 5% rh per hour, and no condensation.

[d]Product equipment is removed from original shipping container and installed but not in use (e.g., during repair, maintenance, or upgrade).

[e]**Classes A1, A2, B, and C:** Derate maximum allowable dry-bulb temperature 1 K/300 m above 900 m. Above 2400 m altitude, derated dry-bulb temperature takes precedence over recommended temperature. **Class A3:** Derate maximum allowable dry-bulb temperature 1 K/175 m above 900 m. **Class A4:** Derate maximum allowable dry-bulb temperature 1 K/125 m above 900 m.

[f]**For tape storage:** 5 K in an hour. **For all other ITE:** 20 K in an hour and no more than 5 K in any 15 min period of time. Temperature change of ITE must meet limits shown in table, and is calculated as maximum air inlet temperature minus minimum air inlet temperature within specified time window. The 5 and 20 K temperature change is considered to be a temperature change within a specified period of time and not a rate of change. See Appendix K of ASHRAE (2015a) for additional information and examples.

[g]With diskette in drive, minimum temperature is 10°C (not applicable to Classes A1 or A2).

[h]Minimum humidity level for Classes A1, A2, A3, and A4 is the higher (more moisture) of the –12°C dew point and the 8% rh. These intersect at approximately 25°C. Below this intersection, the dew point represents the minimum moisture level, whereas above it, the relative humidity is the minimum.

[i]Based on ASHRAE research and performed at low relative humidity, minimum requirements are

1. Data centers with non-ESD floors and where people are allowed to wear non-ESD shoes may want to consider increasing humidity, given that the risk of generating 8 kV increases slightly from 0.27% at 25% rh to 0.43% at 8% (see Appendix D of ASHRAE [2015a] for details).
2. All mobile furnishing/equipment must be made of conductive or static dissipative materials and bonded to ground.
3. During maintenance on any hardware, a properly functioning and grounded wrist strap must be used by any personnel who contacts ITE.

[j]To accommodate rounding when converting between SI and I-P units, maximum elevation is considered to have a variation of ±0.1%. The effect on ITE thermal performance in this variation range is negligible and allows use of rounded values of 3050 m. Operation above 3050 m requires consultation with IT supplier for each specific piece of equipment.

[k]See Appendix L of ASHRAE (2015a) for graphs showing how maximum and minimum dew-point limits restrict the stated relative humidity range for each class for both product operations and product power off.

[l]For the upper moisture limit, the limit is the minimum absolute humidity of dew point and relative humidity stated. For lower moisture limit, the limit is the maximum absolute humidity of dew point and relative humidity stated.

[m]Operation above 3050 m requires consultation with IT supplier for each specific piece of equipment.

Environmental Class Definitions for Air-Cooled Equipment. For any piece of datacom equipment to comply with a particular environmental class (ASHRAE 2015a), it must be able to reliably provide its full operational capabilities over the entire allowable environmental range, based on nonfailure conditions. The recommended and allowable ranges for each datacom equipment class are given in Table 1. The allowable environmental ranges for the four datacom equipment classes are illustrated in psychrometric format in Figure 6:

- Class A1: Typically, a datacom room with tightly controlled environmental parameters (dew point, temperature, relative humidity) and mission critical operations; types of products typically designed for this environment are enterprise servers and storage products.
- Class A2/A3/A4: Typically, an information technology space with some control of environmental parameters (dew point, temperature, relative humidity); types of products typically designed for this environment are volume servers, storage products, personal computers, and workstations. Among these three classes, A2 has the narrowest temperature and moisture requirements. A4 has the widest environmental requirements.

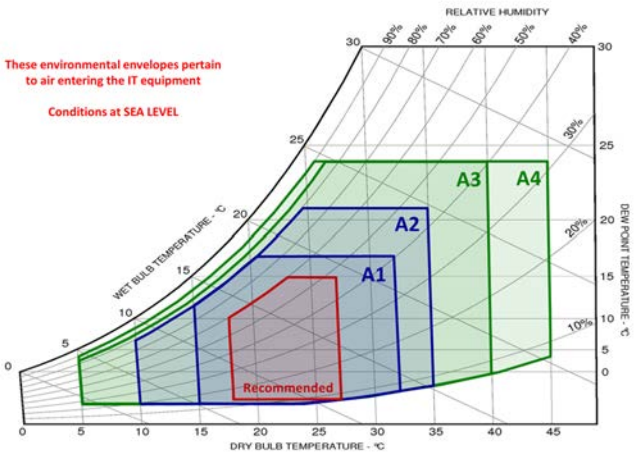

Fig. 6 Environmental Classes for Datacom Equipment Classes
(ASHRAE 2015a)

Table 2 Liquid Cooled Datacom Facility Classes (Product Operation)

Class	Typical Infrastructure Design: Main Cooling Equipment	Supplemental Cooling Equipment	Facility Supply Water Temperature, °C
W1	Chiller/cooling tower	Water-side economizer	2 to 17
W2			2 to 27
W3	Cooling tower	Chiller	2 to 32
W4	Water-side economizer (with dry-cooler or cooling tower)	N/A	2 to 45
W5	Building heating system	Cooling tower	>45

Source: ASHRAE (2013).

- Class B: Typically, an office, home, or transportable environment with minimal control of environmental parameters (temperature only); types of products typically designed for this environment are personal computers, workstations, laptops, and printers.
- Class C: Typically, a point-of-sale or light industrial or factory environment with weather protection, sufficient winter heating and ventilation; types of products typically designed for this environment are point-of-sale equipment, ruggedized controllers, or ruggedized computers and personal digital assistants (PDAs).

Dry-bulb temperature must be derated based on altitude for all classes. See ASHRAE (2015a) for more information on derating methodology.

The latest guidelines were developed with a focus on providing as much information as possible, so that datacom facility operators can maximize energy efficiency without sacrificing the reliability required by their businesses. This assumes that the designs enable them to take advantage of reduced energy operation.

Environmental Guidelines for Liquid-Cooled Equipment

For any piece of datacom equipment to comply with a particular environmental class, it must be able to reliably provide its full operational capabilities over the entire classification temperature range based on non-failure conditions.

- Class W1/W2: Typically a data center that is traditionally cooled using chillers and a cooling tower, but with an optional water-side economizer to improve energy efficiency, depending on the facility's location.
- Class W3: For most locations, these data centers may be operated without chillers, although some locations require chillers.
- Class W4: To take advantage of energy efficiency and reduce capital expense, these data centers are operated without chillers.
- Class W5: In these data centers, the temperature of water exiting the IT equipment is high enough for reuse to heat local buildings, thereby increasing energy efficiency, reducing capital expense with chiller-free operation, and making use of waste energy.

For datacom equipment that meets the higher supply temperatures as referenced by the ASHRAE classes in Table 2, enhanced thermal designs are required to keep liquid-cooled components within the desired temperature limits. Generally, the higher the supply water temperature, the lower the cost of the datacom facility cooling solution.

For classes W1 and W2, the datacom equipment should accommodate facility water supply temperatures that may be set by a campus-wide operational requirement. In these cases, condensation prevention is a must.

Availability of datacom equipment rated for classes W3 to W5 is limited. It is anticipated that future designs in these classes may involve trade-offs between IT cost and performance. However, these classes allow lower-cost data center infrastructure in some loca-

Table 3 Workload Types

Workload Type	Definition/Examples
Scientific	Includes biological sciences, geosciences, weather forecasting, engineering, simulation, design, defense, security, and training of deep machine learning applications (versus run-time)
Analytics	Discrete data warehousing, data analysis, big data analytics, and run-time deep machine learning applications
Business processing	Enterprise-wide line of business applications that manage transactional, operational, and customer databases
Cloud/Internet portal data center (IPDC)	Wikis, portals, social media, video-sharing websites, search engines, and online auction websites
Visualization and audio	Data center visualization applications including video processing, remote visualization, and audio processing
Communications/ telco	Wired and wireless networking applications: application, control, packet, and signal processing
Storage	Dedicated storage infrastructure and services including back-up, tiering, and deduplication

Source: ASHRAE (2008).

Facility water flow rate requirements and pressure drop values of the datacom equipment vary. Manufacturers typically provide configuration-specific flow rate and pressure differential requirements that are based on a given facility water supply temperature and rack heat dissipation to the water. Conformance with the water quality requirements for each cooling solution is important to long-term reliability.

Datacom Equipment Nameplate Ratings and Manufacturers' Heat Release

A power supply nameplate rating indicates the maximum power draw for the datacom equipment's safety and regulatory approval. A nameplate rating does *not* represent actual power draw during usage and should *not* be used as a measurement of datacom equipment heat release.

Manufacturers that follow ASHRAE guidelines utilize a template for each product that tabulates heat release based on configuration and use. In addition, most major datacom equipment manufacturers have online tools that can provide even more specific and detailed heat release and airflow information. Obtaining realistic heat release and airflow information is critical to the datacom facility and datacom equipment communities for use in datacom facility planning and designs that are both ample and energy efficient.

Power Trends

Datacom equipment manufacturers compete to create equipment that balances power and performance based on the markets and workloads they are targeting. Datacom equipment is no longer one size and one configuration fits all. More IT departments are shifting to purpose-built servers in order to meet customers' specific business needs. These purpose-built servers include specific features and components sized to meet a customer's workload requirements. This requires facility power projections to comprehend the software workload being deployed. ASHRAE (2018) captures these power trends by select workload (Table 3) for typical and maximum equipment configurations.

A workload-based methodology provides a much more accurate estimate of actual power consumption in a modern data center, compared to using the maximum power for a given server family from a datacom hardware provider. An example of this trend methodology is shown in Figure 7 (for a 2U 2-socket [i.e., two central processing units] server configuration).

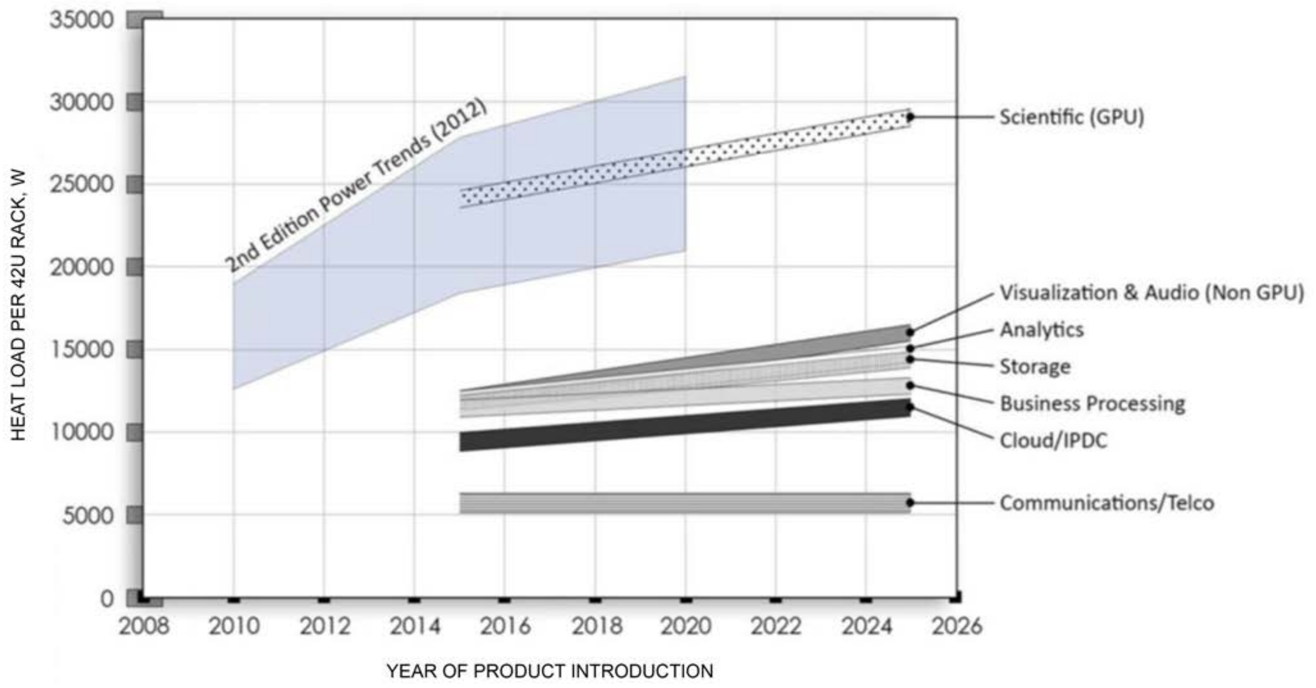

Fig. 7 ASHRAE Projected Power Trends for 2U 2-Datacom Hardware by Workload Type
(ASHRAE 2018)

An important addition to the 2018 edition of ASHRAE's *IT Equipment Power Trends* was the introduction of the power compound annual growth rate (CAGR) for the years 2016 to 2025. The CAGR allows the measured power of a server running a business's specific application(s) to be used to project the future power for a similar workload demand. The most striking growth rates (Figure 8) occur in the scientific (4.6%) and analytics (5.9%) workloads at maximum expected configurations. These higher growth rates can be attributed to higher-power CPUs, maximizing the number of components, and the potential use of graphical processing units (GPUs) or another application-specific processor technology.

When appropriately applied, knowledge of datacom equipment power trends can be a powerful tool in considering what future loads might be in a facility or space. Future load is a critical component in the planning, design, construction, and operation of facilities to avoid ineffective expenditures, premature obsolescence, stranded cost or assets, energy waste, etc.

Refer to ASHRAE (2018) for details on how the trends were created, along with how to apply them.

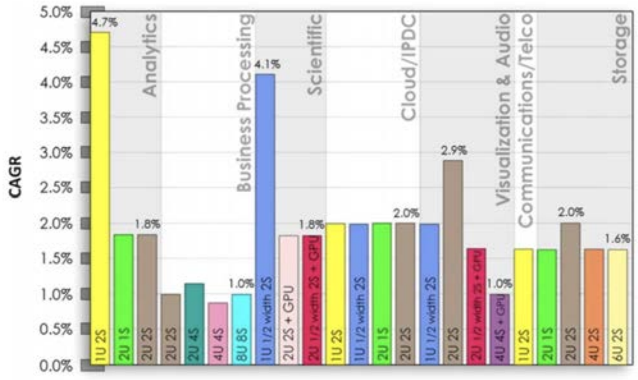

Fig. 8 ASHRAE Power Compound Annual Growth Rate for Datacom Hardware by Workload Type and Size
(ASHRAE 2018)

2.4 DATACOM EQUIPMENT COMPONENTS

Thermal Design Overview

The goal of a good datacom facility cooling design is to match cooling capacity to actual heat load. This requires a correct and realistic assessment of the heat release of the projected datacom equipment. Even when actual datacom equipment is known, this can be challenging, and is often done incorrectly. A basic understanding of datacom equipment thermal design is therefore valuable, to comprehend how the datacom equipment interacts with the data center and vice versa.

The thermal design must ensure that the temperatures of all datacom equipment components (e.g., processors, memory, storage, I/O, power supplies) are maintained between the high and low limits of their specifications. Datacom equipment components have functional, reliability, and damage temperature specifications. Maximum functional temperature limits for silicon components are generally in the 85 to 105°C range.

The thermal management system (Figure 9) in the datacom equipment must take the appropriate actions to ensure compliance with these specifications. This ensures data integrity and maximizes equipment service life.

A well-designed thermal management implementation balances component temperatures, datacom equipment performance, humidity, and acoustics, to achieve reliable equipment performance with minimal power consumption.

Air-Cooled Datacom Equipment Components

Air-cooled solutions are currently the most common approach for datacom equipment. The information described here is applicable to most mainstream, air-cooled volume servers; however, the principles apply to most types of datacom equipment.

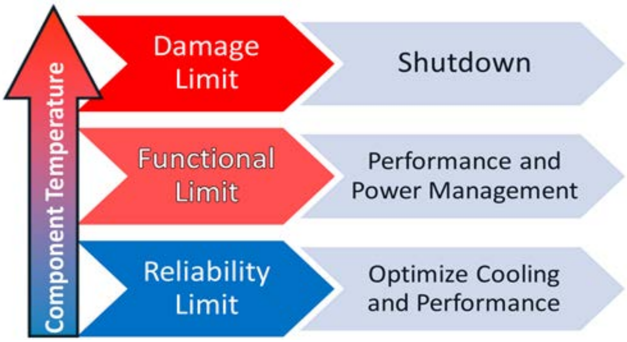

Fig. 9 System Thermal Management
(ASHRAE 2016a)

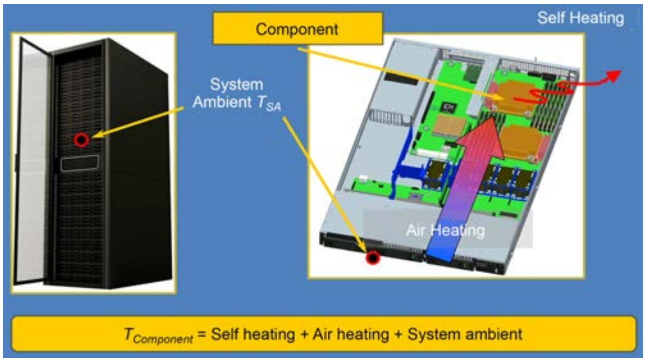

Fig. 10 Example Component in System and Rack
(ASHRAE 2016a)

Typical datacom equipment relies on variable-speed, forced-convection cooling to maintain the required temperatures. Component temperature is driven by one of three factors in an air-cooled system (Figure 10):

- **System ambient,** or inlet temperature to the datacom equipment
- **Air heating,** or increase in air temperature caused by upstream heat sources among the datacom equipment
- **Self heating,** or increase in component temperature above local ambient caused by heat dissipated by the component itself; driven by component packaging, power dissipation, and thermal solution (e.g., heat sink)

Datacom equipment manufacturers develop component- and equipment-level cooling solutions that balance cost, performance, and energy consumption, including trade-offs between air movers and heat sink designs. Cooling performance, power consumption, acoustic signature, fan reliability, and redundancy features are also important characteristics that must factor into the overall solution.

Fan or cooling zones are often used to precisely adjust specific fans to the needs of the components most coupled with those fans. Cooling zones can be proximity based or physically separated. By using a fan zone approach, total fan power and acoustic output can be minimized. Fans in a nonstressed zone can run at lower speeds than those in a more highly stressed zone.

Power and Thermal and Moisture Management

Thermal control enables optimization of datacom equipment system performance as a function of usage or workload, configuration, cooling capability, and environment. Underlying this optimization is the use of fan speed control and power management operating in parallel. Optimization for differential air temperature ΔT through the datacom equipment is generally not a significant design consideration because of the more critical requirement of ensuring that functional limits are maintained.

Components and their specifications are the primary drivers in a server's thermal design (e.g., heat sink, fan selection, airflow management).

Power management features enable all components to stay within temperature limits while minimizing overall power consumption during periods of low activity.

Highly advanced control algorithms vary the datacom equipment fan speeds and airflows, and tune the fan speeds based on the datacom equipment's usage model. Multiple algorithms can be used simultaneously, with the final fan speeds determined by comparing the results of these algorithms.

Sensors (and proxy sensors) create the data necessary to trigger power management, and are the basis of a cohesive thermal management implementation.

As important as it is to control temperature within a data center to maintain high reliability, it is equally important to control moisture content. If both moisture and temperature are properly controlled, the result will be more reliable long-term operation, plus significant energy savings in the operation of the data center.

The effects of improper moisture control on a data center operation are twofold:

- **High relative humidity** has been shown to affect failure rates of electronic components. Examples include conductive anodic failures, hygroscopic dust failures, tape media errors, and excessive wear and corrosion. The recommended upper moisture limit is set to limit these effects.
- **Low relative humidity** has been historically considered a factor in electronic device susceptibility to damage by electrostatic discharge (ESD). However, new ASHRAE research (Pommerenke and Swenson 2014) suggests that susceptibility to low relative humidity is of far less concern than once thought.

Based on Pommerenke and Swenson's (2014) results, the recommended moisture limits have been greatly expanded in the fourth edition of the *Thermal Guidelines for Data Processing Environments* (ASHRAE 2015a). The recommended lower moisture limit has been significantly reduced, as shown in Table 1 and Figure 6 for the ASHRAE environmental classes. Note that the recommended upper and lower moisture limits are represented by dew point (dp) limits rather than relative humidity. Although static concerns are actually related to relative humidity, dew point is used because it is fairly constant throughout the data center, whereas relative humidity varies widely. Because dew point can be easily monitored and consistently controlled, best practice is to monitor moisture content in a data center using dew point rather than relative humidity.

Liquid-Cooled Datacom Equipment Components

With increasingly dense datacom equipment packaging, some components may require liquid cooling to maintain the environmental specifications dictated by the manufacturer.

Liquids considered for cooling electronic equipment are dielectric, engineered fluids, water, oils, or refrigerants. Heat transfer from the liquid-cooled datacom equipment or components to the datacom facility generally takes place through a liquid-to-liquid heat exchanger.

Some liquid-cooling solutions include immersion of the datacom equipment components directly in a dielectric fluid, in either single- or two-phase applications. Dielectric fluids include mineral oil and fluoroketones.

3. DATACOM FACILITIES

3.1 GENERAL CONSIDERATIONS

Spatial and Envelope Considerations

A datacom facility can be a dedicated building, or be part of a general purpose building that houses other business functions or tenants. Regardless of the type of building in which it is housed, or its location within a building structure, a datacom facility is comprised of a number of spaces having different but interrelated functions (see Figure 1).

The main computing area is identified by different names: computer room, machine room, raised floor area, or white space. This chapter uses the term *datacom room* to differentiate it from the other areas that support it, and which comprise the complete datacom facility.

Determining the appropriate size of a datacom room is more challenging than it has ever been. There are three major reasons: the ever-increasing demand for computing services; the consolidation, virtualization, and increasing density of datacom equipment; and the transition of many computing services to the cloud or to leased colocation facilities.

It is all too common to underestimate the amount of electrical/mechanical space required to support a datacom facility. The need for reliability in these critical facilities dictates a requirement for adequate maintenance space. Overcrowding, even if minimum legal or manufacturer-dictated service clearances are maintained, can lead to inadvertent interruption of one system while servicing another. A rule of thumb, to be used as a starting point only, is to base minimum electrical/mechanical support space requirements on a percentage of the datacom room area:

- At least 50% for non-redundant facilities
- From 75 to 100% for $N + 1$ redundant facilities (see the section on Redundancy, Reliability, and Concurrent Maintainability for definitions of $N + 1$ and $2N$)
- From 100 to 150% for $2N$ redundant facilities

Every increase in reliability requirements also increases the need for more redundant pieces of equipment, which in turn requires yet more support space. Further, highly redundant facilities require physical compartmentalization of duplicate or parallel systems by fire-rated walls, further increasing support space requirements.

The structure enclosing a datacom room should provide good thermal separation from the surrounding areas, whether those are exterior or interior spaces. The primary concern with the overhead structure, regardless of its construction or intended use, is that it not be a source of particulate contamination or water leakage.

The overhead structure must be cleanly finished and sealed to avoid concrete or insulation flake-off. If it is a roof structure, take extra precautions to preclude leakage. In highly critical spaces, a double roof structure is often used for insurance. Gaps and joints should be caulked.

Suspended ceiling tiles must be either metal pan or plastic encapsulated on both sides to prevent flake-off. This is particularly important when the above-ceiling plenum is used to convey return air. Cut edges must be sealed with spray paint or similar. Any suspension rods that penetrate the tiles should also be sealed at the penetrations. Metals used above a return air plenum ceiling should be either hot-dip galvanized or of a type that will not grow zinc whiskers.

Walls surrounding a datacom room should be well insulated to avoid both cooling loss and heat infiltration. All cracks should be sealed, which is mandatory if the room is also protected by a gas-based fire protection system.

Although most datacom equipment can accept a broad range of allowable humidity levels, consider installing vapor barriers for datacom spaces. Avoiding condensation anywhere in the room is very important.

Windows should generally be avoided in a datacom room, but if they exist or are somehow necessary, they should be double-glazed and sealed. If covering the windows is allowed, but replacement is possible from the inside only, it will be necessary to make the coverings removable and to avoid blocking access with large pieces of mechanical/electrical equipment.

Datacom Rooms

Although raised access floors are still used in many datacom rooms, they are no longer a standard requirement. It is not only possible, but now relatively common, to put the entire power, cooling, and network infrastructure overhead, particularly when close-coupled cooling is used. In these designs, the raised floor is not necessary to convey air.

However, with the amount of piping often used to service in-row, rear-door, and direct water cooling, raised floors are often used anyway to avoid concerns about overhead water, as well as to minimize congestion above cabinets. When power, cable tray, and lighting are all run overhead, the vertical space can become congested and difficult to coordinate. Three-dimensional modeling of the space is highly recommended when overhead infrastructure is used, to avoid both installation conflicts and long-term operational difficulties.

There are several advantages and disadvantages to using raised access floors, regardless of their purpose. Once it is determined that a raised access floor will be used, several factors should be considered in its selection and design.

The most obvious advantages of raised access floors are to provide a space for permanent infrastructure such as power, piping, and cabling, but raised floors have also been historically used to convey cooling air through the plenum space. For slab variations too large to be leveled with patching, and unrealistic for self-leveling cement, they can also provide a level floor.

However, a raised access floor adds total mass to the structure. It must also be maintained, which includes releveling every few years, particularly if technicians do not take care in replacing tiles where they were removed, or open too many tiles in a row and destabilize the floor. The plenum space can also become a tangle of wire and cable if care is not used in installing new cable and removing old. If the floor is used to convey air, masses of unmanaged cable can reduce or totally block airflow. If cables are located in a raised floor plenum that is also used to convey cooling air, best practice is to run cables parallel to airflow, and to provide overhead cable pathways for ad hoc cable installation. It is even better not to locate cables in an air-plenum floor space at all.

The height of a raised access floor is determined by its purpose. If it is used to convey cooling air, it must be high enough to deliver the required air quantity while maintaining the necessary static pressure as evenly as possible across the floor area. Computational fluid dynamics (CFD) modeling is generally recommended to confirm air flow patterns and adjust cooling designs to maximize cooling effectiveness, particularly under failure-mode scenarios where redundant cooling systems are used. Further information on CFD modeling is provided in the section on Computational Fluid Dynamic (CFD) Analysis.

Piping, power systems, or cable tray that will also occupy the space must be taken into consideration in determining the floor plenum height and its effect on air flow. It is generally accepted today that a raised access floor used to convey cooling air needs to be at least 600 to 760 mm high to be effective, and that even higher is better.

After height, the biggest consideration is floor structural strength. Raised floors for datacom rooms should use bolted stringer substructures to increase load capacity and to make it easy to remove and replace tiles without destabilizing the floor.

Newer computing equipment cabinets are usually rated for 1100 to 1360 kg, which is significantly higher than most legacy cabinets. Even if they are not full of the heaviest available equipment, floor loading must be planned as if they will be to address potential maximum loading in the future.

However, cabinets with these load ratings also tend to be larger than legacy 600 by 600 mm cabinets, so the load is spread over more than one floor tile. It is not unrealistic to specify raised-floor systems designed for 700 kPa or 1360 kg rated tile capacity. Any abnormally heavy equipment can be supported with supplemental floor pedestals under the tiles, so long as the slab structural strength is sufficient for both the total and point loads.

In selecting floor strengths, it is particularly important to examine the rolling load characteristics along with the static structural ratings, because equipment must often be moved into position on small integral wheels. The rolling load tests are generally performed for 10 passes and 10 000 passes with mass on test wheels of particular sizes in accordance with testing methods established by the Ceilings & Interior Systems Construction Association (CISCA) (CISCA 2007). However, not all tests are performed with the same wheel sizes, and the results can be misleading.

It is always safest to put thick hardboard or plywood over the floor when moving particularly heavy loads. This is especially important when rolling equipment through cold aisles with perforated airflow tiles, many of which do not have a rolling load specification at all and are easily deformed.

The most common surface material for raised access floor panels is high-pressure laminate (HPL). This material holds up well to heavy rolling loads without deforming or cracking, has good static dissipative characteristics when properly bonded to a grounded surface, is available in light colors to maximize lighting effectiveness, and is easy to maintain with damp mopping.

Heavy scrubbing, buffing, or waxing should never occur in a datacom room. This precludes the use of vinyl composite tile (VCT), pure vinyl tile (which can also be easily deformed under rolling loads), or linoleum (which is also too easily damaged). Carpeting, of course, should never be used in a datacom room, even if it is antistatic, because it both accumulates and generates particulate contaminants. (*Note*: it is generally accepted that the ground resistance of an installed raised-floor panel, when properly connected to a robust grounding system, should be in the range of 10^4 to 10^6 Ω to minimize any potential for static generation.)

One of the most challenging decisions in selecting materials for air plenum raised access floors is the airflow panels. A range of types is now available, including legacy perforated tiles (25% open), grate-style cast aluminum tiles (56 to 63% open), and tiles incorporating directional vanes, air boost fans, and automatic air flow control. (See further discussion of airflow tiles in the section on Underfloor Air Delivery).

All air plenum raised floors leak air, and because cool air is expensive to produce and requires considerable fan energy to distribute through the plenum, this wastes energy. A good-quality raised-floor installation should leak no more than 2% air.

For datacom rooms designed without a raised access floor, the primary concern is that all power, cooling, and network infrastructure must be routed overhead. Depending mainly on the cooling method used, this can create a congested overhead space that requires careful design coordination and exacting installation. As noted previously, 3D modeling techniques are highly recommended when designing complex overhead systems. It should also be recognized that the cost of overhead infrastructure, particularly if extensive ductwork is necessary, can be very similar to the cost of a raised access floor.

Support and Ancillary Spaces

Space must be allocated within a datacom facility for storing components and material, support equipment, and operating and servicing the datacom equipment. Some ancillary spaces may require environmental conditions comparable to those of the datacom equipment, whereas others may have less stringent requirements. Continuous operation of some support spaces is often vital to the facility's proper functioning.

Electrical power distribution equipment can typically tolerate more variation and a wider range of temperature and humidity conditions than datacom equipment. Equipment in this category includes incoming service/distribution switchgear, switchboards, automatic transfer switches, panel boards, transformers, and standby generators. Manufacturers' data should be checked to determine the amount of heat release and design conditions for satisfactory operation. Further information and guidance can be found in IEEE *Standards* 446 and 1100.

Uninterruptible power supplies (UPSs) come in various configurations, but most use batteries as the energy storage medium. They are usually configured to provide redundancy for the central power buses, and typically operate continuously at less than full-load capacity. They must be air conditioned with sufficient redundancy and diversity to provide an operable system throughout an emergency or accident.

UPS power monitoring and conditioning (rectifier and inverter) equipment is usually the primary source of heat release. This equipment usually has self-contained cooling fans that draw intake air from floor level or the equipment face, and discharge heated air at the top of the equipment. Air-distribution system design should take into account the position of the UPS air intakes and discharges.

Installation of secondary battery plants as a temporary back-up power source should be in accordance with IEEE *Standard* 1187 and NFPA *Standard* 70. Refer to other applicable standards, in addition to a design review with the local code official. Other relevant sources of guidance are NFPA *Standards* 70E and 76.

Several types of batteries are used with UPS systems. **Flooded lead-acid (wet cells)** are generally considered the longest lasting, but also present the highest initial cost. They require special rooms with, among other things, containment for possible acid spills, deluge shower and eye wash stations, as well as hydrogen gas detection and exhaust fans (IEEE *Standard* 484). It is important to locate the battery room close to the UPS room to minimize loop current losses in the large DC conductors. More commonly used today are **valve-regulated lead-acid (VRLA)** batteries, also known as **sealed cells** or **maintenance free**. These can be colocated with the UPS system, which can be in the datacom room (IEEE *Standard* 1187). However, if the ambient temperature in the datacom room is not appropriate for the batteries, battery life may be adversely affected. VRLA batteries are available in different qualities, but those usually supplied with a UPS system may have a service life of only three to five years before replacement is required, depending on usage conditions.

The newest battery used with UPS systems is the **lithium-ion (Li-ion)**. There is still very limited history with these batteries in this type of service, but they are promoted as having significantly longer service lives than VRLA, lower mass, and less stringent operating conditions. However, probably due to the negative publicity associated with cellphone and other small-device battery explosions, local codes may preclude their use, even though the chemistries, case constructions, and reliability testing of Li-ion batteries intended for commercial use are all very different than for the ultra-compact batteries that have exhibited problems.

Temperature in a battery area is crucial to the life expectancy and operation of the batteries. The optimum space temperature for lead-calcium batteries is 25°C. Per IEEE *Standard* 484, if higher temperatures are maintained, it will reduce battery life; if lower temperatures are maintained, it may reduce the batteries' ability to hold a charge. Recommended ambient temperatures for other battery types should be verified with the battery manufacturers.

Engine-driven generators used for primary or standby power typically have air-cooled radiators and require large volumes of outdoor air when running. Designs should ensure that engine exhaust air does not recirculate back to any building ventilation air intakes. Commonly, up to 72 h of fuel oil storage is required, so fuel oil storage tanks and distribution systems need to be integrated into the overall facility design and planning. The governing codes often mandate specific requirements for containment, location of fuel oil storage, fire resistance ratings, etc. However, as has been unfortunately demonstrated in several weather disasters, local codes may impose requirements that can negate the benefits of generators unless all potential conditions are taken into account in the designs. Fuel tanks are heavy when full, but will start to float in a flooded basement as fuel is used, breaking the pipes. Both fill and pressure relief pipes must be located high enough above ground to remain both accessible and impervious to flood waters. Generators themselves must also be carefully located and protected from potential problems.

Other Systems and Considerations

Fire Protection. Datacom fire protection involves a combination of strategies starting with prevention and continuing through detection, suppression, and response to a fire event. The National Fire Protection Association (NFPA) has several standards addressing design, installation, maintenance, and operation of fire protection systems in datacom facilities. Worldwide, additional fire protection standards may apply as well; consult local governments. Major NFPA standards include the following:

- *Standard* 75, for fire protection of information technology
- *Standard* 76, for fire protection of telecommunication facilities
- *Standard* 70, the *National Electrical Code*® (NEC), for electrical system installation
- *Standard* 72, the *National Fire Alarm Code*®, for detection systems
- *Standard* 13 for sprinkler suppression systems
- *Standard* 2001 for gaseous extinguishing systems
- *Standard* 750 for mist systems
- *Standard* 25 for maintenance of fire protection systems

NFPA *Standards* 75 and 76 offer both prescriptive and performance-based approaches. Most designers defer to the prescriptive path, but a growing number of firms provide performance-based designs. These offer more flexibility, and can be tailored to a company's specific risk and business models. As another alternative, some companies apply provisions from both standards, and often exceed one or more portions of either standard based on their own risk assessments or experiences.

There are several options for providing fire suppression in datacom rooms. Many older (and even some newer) datacom facilities use a code exemption to suppression. More commonly, however, datacom facilities are equipped with either a sprinkler or gaseous suppression system for a combination of life, structure, asset, and service protection. The conventional wisdom, invoked by many code authorities, is that gas protects equipment but sprinklers protect people and structures. One thing to be aware of with inert gas fire suppression systems is that, in some cases, the discharges can cause temporary or permanent failures to hard disk drives with rotating storage media due to extreme acoustic levels and the resulting acoustically driven vibration. This can usually be mitigated with the proper selection of gas discharge heads, although this may also increase the time for a discharge to extinguish a fire.

Air containment, either hot aisle or cool aisle, has become a common method of improving cooling performance and reducing energy usage. However, when containment systems are retrofit or designed into a new facility, effects on the required detection, suppression, release system, materials of construction, and prevention of fire must be considered. These important considerations are addressed in detail in the NFPA standards. The added obstructions often necessitate modifications to the suppression systems (sprinklers or gaseous agent nozzles) to ensure proper suppression release and dispersion. An alternative to suppression system changes can sometimes be **partial containment**, which has been shown to be as much as 80% as effective in improving air control, but does not block existing sprinkler or gas discharge heads. (See the section on Containment.)

Water Concerns. Water damage is always a concern in a datacom facility. It is best to locate the room above grade if possible, but this is not always practical.

There are other sources of water leakage as well: designs must consider the possibility of leaks from overhead. Datacom rooms and supporting electrical equipment should not be located below bathrooms, pantries, laboratories, or the like. If unavoidable, the space above should have waterproof membrane floors. Liquid piping should also be routed around the datacom room, but if this is not possible, should be provided with drip pans and leak detectors. Leak detectors should also be provided anywhere water can infiltrate, particularly if it could affect electrical infrastructure. A common problem in buildings not specifically designed for high-availability datacom facilities is primary power switchgear and bus duct terminations in the lowest level of the building, where they are subject to flooding. These conditions cannot likely be changed in existing buildings, but should be avoided in purpose-built facilities.

Acoustics. The rapid increase in density and power draw of datacom equipment has brought with it commensurate increases in required cooling. Air cooling requires substantial volumes of air movement, which generates sound levels that can be problematic for worker health and might require a hearing protection plan. Increased sound pressure levels required by increasing datacom fan speeds may also lead to reduced hard disk drive (HDD) performance, due to acoustically driven vibrations.

Sound level exposure limits in datacom rooms and their associated mechanical/electrical plant facilities are governed in the United States by the Occupational Safety and Health Administration (OSHA [Annual]) in *Code of Federal Regulations* (CFR) 1910.95. Similar regulations exist in other countries.

Sound emissions from heat rejection equipment (cooling towers and/or air-cooled chillers) as well as emergency and/or prime power-generating equipment for the datacom facility's mechanical/electrical plant must also be considered. Noise generated outside the building, typically from rooftop chillers and cooling towers, must also be mitigated so that sound levels in the building are conducive to conducting normal business activities.

Community sound levels, mostly from exterior heat rejection and power-generating equipment, must typically comply with state, regional, or local noise codes, ordinances, guidelines, and/or regulations. Community sound level limits are typically cited at property lines and/or anywhere on the property of a potential complainant.

Sound levels of exterior equipment during normal, emergency, and test operation should allow for relatively easy communication among service personnel, as well as auditory awareness of vehicle and general service activities in the area. A sound level at or below 70 dBA in service areas and equipment yards, with all equipment operating, is an ideal goal.

Vibration. Vibration levels in datacom facilities must be considered as well. The greatest vibration concern in datacom installations is usually roof-mounted support equipment, such as air handlers, cooling towers, chillers, and generators, although similar equipment mounted inside the building can also create vibration issues. See the

ASHRAE TC 9.9 datacom book series, especially ASHRAE (2008a), for additional information.

Some datacom equipment, such as very high-density disk drives, can be sensitive to vibration. Even vibration induced within a server (e.g., by fans) can be an issue for disk drives at the higher airflow rates required to cool some components. Wherever there is concern, vibration specifications should be obtained from manufacturers, and the datacom facility floor's vibration dynamics studied to determine compliance with vibration limits.

Many locations are considered seismic zones, requiring special bracing and safety restraints for much of the infrastructure. However, the critical nature of many datacom facility operations mandates consideration of special structural supports and restraints, even where seismic regulations are minimal or do not exist.

As described in ASHRAE (2008a), it is important for both the owner and the designer to understand the potential hazards, including seismic, wind, etc., of the region where the facility is located.

Clear operational criteria should be established and used in system designs. These may include recommendations for structural restraints and bracing beyond what is required by law. Local code requirements must be identified and understood, as well as the requirements set forth in ASCE *Standard* 7, which provides further information and direction.

Lighting. In datacom rooms, lighting should usually be centered in the aisles, not over equipment cabinets or cable trays where much of the light energy would be wasted. Fixtures should also be suspended 2.44 to 2.75 m above the floor so as to deliver maximum illumination over the heads of technicians and into cabinets. Higher mountings may be necessary to clear other overhead infrastructure, but this disperses more light energy over the tops of cabinets and other obstructions. Although lighting is a small part of datacom room energy consumption, and LED has become the light of choice, proximity sensors should be still used to ensure they are not left on when there is no activity.

The photometric curves of many architectural luminaires are inappropriate for datacom facility lighting. Fixtures with wide horizontal dispersion patterns are needed. This requirement is very similar to the lighting of library book stacks, where the purpose is more to support the reading of titles on the books than to provide for reading books in the aisles. An illumination level of 325 lx on the vertical surfaces of cabinets is generally sufficient.

Lighting systems and lighting control in datacom rooms can be provided by several different methods. All systems require sensors, and automatic control devices are recommended. Low-voltage (0 to 10 V) or power over Ethernet (PoE) controls are a good application for LED lighting control in data centers. PoE lighting controls work well in data centers because the data racks are typically already in place and the power and control wiring is run through Ethernet cabling. However, if a PoE lighting solution is chosen, larger racks, additional power supplies, and controls may be needed.

Emergency lighting for PoE systems also should be considered. UL 924-listed battery packs are now available that can be added to any PoE lighting fixture to make it into an emergency fixture. This is an advantage over conventional lighting, which requires selected fixtures to be designated and provided as emergency luminaires. Whichever emergency system is decided on, it must meet local requirements for illumination and run time in the event of loss of normal power.

PoE lighting and controls can offer flexibility, low initial installation and operating costs, and allow customers to monitor lighting and energy usage with a centrally hosted system control. PoE systems provide reliability, scalability, and flexibility to support easy modification or expansion within a datacom room.

Redundancy, Reliability, and Concurrent Maintainability

It is axiomatic that redundant systems should improve the reliability of a facility, but how much redundancy is justified is always a question. Redundancy decisions must consider business and operational needs as well as economic justification. Unfortunately, redundancy alone does not guarantee increased reliability.

It is not uncommon for large investments to be made in duplicate power and cooling systems that have been configured or installed in ways that defeat or greatly compromise their purposes. Consequently, a careful analysis of all possible failure modes should be an integral part of the design phase of any datacom facility.

The primary goal of redundancy should be to provide for **concurrent maintainability**. This requires a design that allows any element in the power and cooling infrastructure to be shut down and removed from service for maintenance without compromising the computing systems that depend on that infrastructure. This level of redundancy is commonly known as ***N*+1**, meaning that every system has at least one extra component and pathway.

Higher levels of redundancy require some degree of duplicate systems, such as two identical and fully load-sharing chiller plants with duplicate piping systems. This is known as **2*N*** redundancy. An even more stringent design would have duplicate systems, but with additional redundant components in each. Depending on how the additional redundancy is configured, the systems may be known as **2*N*+1**, in which an additional unit (e.g., a chiller module) is made available to either of the duplicate systems, or **2(*N*+1)** in which both redundant systems each have their own redundant modules. Several methods have been developed to classify levels of redundancy and their resulting reliabilities and uptimes (e.g., ANSI/TIA *Standard* 942-B).

It is standard practice to power datacom equipment from an uninterruptable power supply (UPS). UPSs have two main purposes: to isolate the datacom equipment from power line disturbances; and to maintain ride-through power to the datacom equipment until back-up generators start, or long enough to accomplish an orderly shutdown.

With today's heat densities, datacom systems cannot be maintained for very long on UPS alone. The usual maximum back-up time is 15 to 20 min, before thermal rise causes a shutdown of the datacom equipment and/or the UPS. High-performance computers may shut down in minutes or even seconds if cooling is interrupted. It is therefore necessary to have a means of maintaining cooling for the most critical systems until either generators start, or systems can be shut down properly.

It is generally impractical to run large cooling systems on UPSs. If this must be done, the cooling equipment's electrical characteristics make it prudent to use a separate UPS. Further, the substantial power draws and high in-rush currents on compressor start-up and cycling require large and expensive UPS systems.

In most datacom rooms it is not necessary to maintain full cooling for an extended period. If cooling can be continued to the most critical computing systems, this should suffice until both generators and full cooling restart. If a chilled-water system and close-coupled liquid-based cooling have been selected, this can be relatively easy to accomplish. There may be sufficient residual water in header pipes to cool critical systems for several minutes. If not, additional water can be stored in tanks.

Long battery life is of no value if the UPS it supports is without cooling. A UPS generates substantial heat under load, as do the batteries when they take full load after a power failure. Batteries also emit heat as they recharge once the generators start. This heat generation should be considered when choosing the location for the UPS, which is often relegated to a location that is less desirable for use as personnel spaces. This is sometimes in an electrical or mechanical room that generates additional heat, in a corner of a parking garage, or even in a roof penthouse that is exposed to high sun loads. These kinds of locations can dramatically shorten the actual back-up duration of the UPS, particularly if the batteries are also exposed to continuous heat. The cooling system in the UPS room should have the same level of redundancy as the cooling for the datacom room.

3.2 AIR COOLING

Air-Cooling System Configurations

Datacom equipment rooms can be conditioned with a wide variety of systems, including packaged computer room air-conditioning units and central-station air-handling systems. Air-handling and refrigeration equipment may be located either inside or outside the datacom equipment rooms.

The following system configurations are some of the most commonly used solutions to providing sufficient cooling to air-cooled datacom equipment.

Computer Room Air-Conditioning (CRAC) and Computer Room Air-Handling (CRAH) Units. Despite the development of a variety of newer cooling technologies, CRAC and CRAH units remain the most common datacom cooling solutions. They are specifically designed for datacom equipment room applications and should be built and tested in accordance with the requirements of ASHRAE *Standard* 127.

CRAHs are special-purpose chilled-water air handlers designed for datacom applications. CRACs are compressorized cooling systems and are available in several configurations, including direct expansion (DX) air-cooled, DX water-cooled, and versions that include a water- or refrigerant-cooled economizer coil. Both CRAH and CRAC units are available in either downflow or upflow designs. Downflow units are used primarily for underfloor air delivery and have top air returns. Upflow units discharge air overhead, often into ducts, and can have either front or rear air returns. Whereas older CRAH/CRAC units use belt-driven forward-curved centrifugal supply fans (and are often constant volume), newer models tend to use plenum-style plug fans, which are direct drive and paired with electronically commutated motors and variable frequency drives (VFDs) for speed control. The limited static pressure available from these newer computer room units means they are not typically as suitable for ducted applications, so are generally located in or immediately adjacent to the datacom space. As a result, they often have limited flexibility for incorporating air-side economizer solutions.

CRAC and CRAH units are usually located in the datacom equipment room, but may also be in mechanical galleries adjacent to the datacom room, or installed remotely and ducted to the conditioned space. Ducted designs require consideration of the relatively low-static-pressure designs of CRAC and CRAH units with plug-type fans. Ducted designs may require conventional forward-curved fans that can work against higher static pressures, but variable-speed motors can still be used to improve energy efficiency.

If CRACs or CRAHs are used in datacom rooms without a raised floor, or in rooms with a raised floor that is not used for cooling, overhead air delivery is required, which means using upflow cooling units. The return air grills on these units are at the bottom, so cannot efficiently capture hot return air in an open space. When upflow cooling units are used, it is necessary to also use cold aisle containment to locate the cooling units in mechanical galleries separated from the datacom equipment by a demising wall, or to use ducted rear returns to efficiently get hot return air back to the units and prevent them from re-entraining their own cool discharge air.

With either placement, temperature and humidity sensors must be located to properly control air delivery in order to keep inlet air conditions to the datacom equipment within specified tolerances.

Centralized Air-Handling Systems. Traditionally, many telecommunications central office facilities and datacom facilities with overhead air delivery used central-station air handlers. Larger, centralized air handlers, typically either roof mounted or adjacent to the datacom space, have been gaining popularity as air-side economizer-based solutions have become more common. These air handlers may include DX cooling coils, chilled-water coils, adiabatic cooling sections, and indirect economizer solutions (such as air/air heat exchangers). Larger air handlers may use a fan array consisting of multiple direct-drive plug fans.

Control of Variable-Speed Fans. There are several ways to control fan speed. The most common are underfloor pressure, cool-aisle containment pressure, differential pressure, supply air temperature, and return air temperature.

Air Distribution

Traditionally, telecommunication spaces had no raised floor and used overhead ducted air delivery, whereas datacom facilities used raised-flooring systems as supply air plenums.

Underfloor Air Delivery. The interstitial space under the raised floor creates a large-volume air plenum that, if properly configured, can deliver relatively uniform air pressures across the entire room area. However, because the floor plenum is also often used for piping, power and cable, there are many potential obstacles to airflow that can be challenging to mitigate.

Underfloor air delivery to cold aisles is provided and balanced using a range of airflow tiles, which are available in 25% open, 56 to 63% open, and fan boosted, and both dampered and undampered. Even distribution of air through the airflow panels is a function of the evenness of the static pressure below the floor. However, the pressures are altered by the existence of the airflow tiles. Therefore, though it may be tempting to use high-airflow tiles to ensure sufficient air delivery to all cabinets, quantity and location must be balanced with the available air volume and static pressure. As with any fluid, air will take the path of least resistance, so too many of these tiles in one area can result in air starvation for equipment in other areas. Likewise, tiles with integrated air-booster fans may solve a spot cooling problem, but because fans will take the air they want, adjacent cabinets may receive less than they require, resulting in unintended additional cooling problems.

Tiles with variable dampers are available to enable adjustment of airflow to match the requirements in each part of the floor. However, the addition of a damper to any airflow tile results in reduced airflow and cooling capacity, even when the damper is 100% open. In short, air balance with underfloor systems can be challenging, and specifications should be carefully examined when selecting from the wide range of air flow tiles now available.

Leakage between the floor tile joints will reduce the expected airflow. Likewise, air will leak and be wasted through unsealed gaps at the raised-floor-to-wall or raised-floor-to-column junctions, and through any floor cutouts for cable or chilled-water lines from the raised-floor plenum that are not correctly sealed. A properly installed and maintained floor should leak no more than 2% of the delivered air.

Overhead Air Delivery. Delivering air overhead requires ducts large enough to convey the air volume needed to cool the equipment in each aisle, at velocities and pressures that enable air flow to be easily adjusted and balanced in each aisle. To properly control airflow to match loads in an aisle, it is important that one duct runout serve only one cold aisle, even though planning where runouts should be to accommodate future cold aisles and rows of IT cabinets may be challenging. Irrespective of planning difficulties, overhead air delivery may still provide more effective airflow management than underfloor air delivery because overhead air volume can be tied to the measured temperatures in each aisle. This means the system can dynamically increase or decrease airflow to each cold aisle in response to measured conditions.

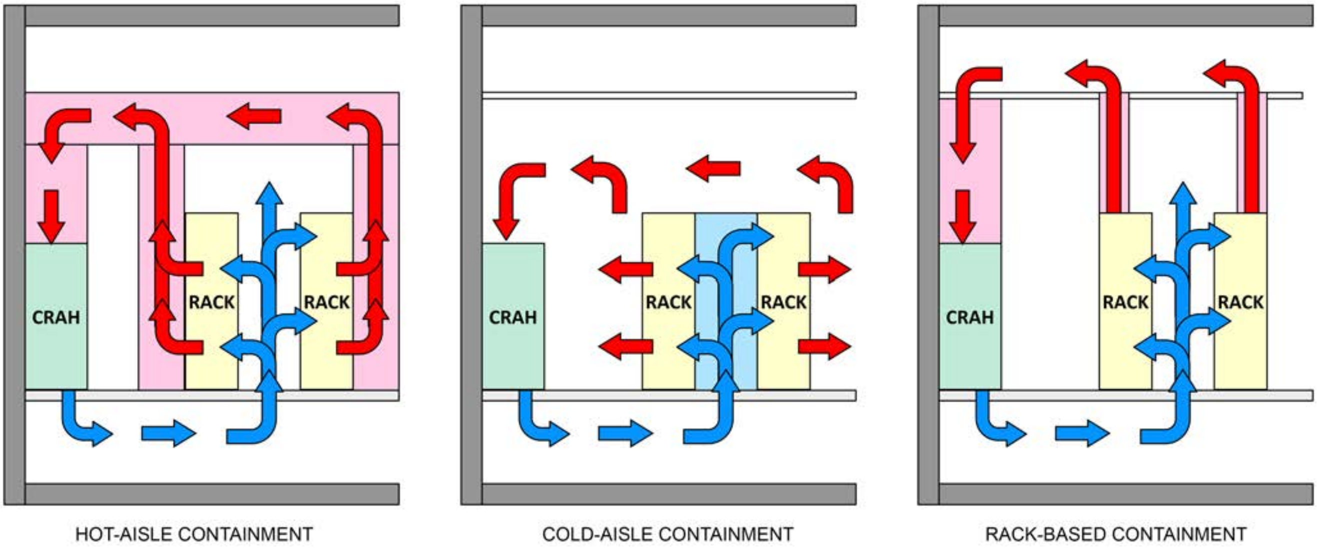

Fig. 11 Examples of Main Types of Containment

As noted above, CRAH and CRAC units are not easily configured for higher-static-pressure systems or for systems with outdoor air economizers. It is, therefore, more common to use central station air-handling systems when designing for overhead air delivery.

Effects of Air Mixing. Air mixing occurs in two ways: (1) when hot air discharged from computing equipment recirculates back to the air intakes, thereby increasing the inlet air temperature at the computing equipment; and (2) when cool supply air bypasses the computing equipment and mixes with hot discharge air, thereby lowering return air temperature. Reduced return air temperature decreases the cooling capacity of the air-conditioner coils by decreasing the system ΔT, which requires an increase in airflow to meet the load. If air paths through or between the datacom equipment racks exist, then some of the cool supply air will bypass the datacom equipment, and some of the discharge air will recirculate to the front equipment intakes. Use blanking or filler panels to minimize air mixing.

If the supply air temperature has been set toward the upper limits of the ASHRAE recommended envelope, hot-air recirculation may result in equipment seeing inlet air that is warmer than the design temperature. Avoiding or minimizing air mixing requires separating the supply air from the return air and the datacom equipment intake air from the datacom equipment discharge air. The more complete the separation, the more effective and energy efficient the cooling system will be.

Hot Aisle/Cold Aisle. The first step in avoiding air mixing is to arrange cabinets in hot aisle/cold aisle configuration. This means that racks and cabinets are installed facing back-to-back and front-to-front. This arrangement keeps the hot-air discharge from one row of cabinets from directly entering the intakes of cabinets in the next row. This, of course, assumes that all datacom hardware has been designed with industry-standard front-to-rear airflow. Equipment that uses a nonconventional airflow pattern must be dealt with using special racks, cabinets, and air deflectors, as discussed in the section on Datacom Equipment Racks.

Containment. Containment further segregates the supply and return airflow paths by preventing mixing at the top of the equipment racks and at the ends of equipment rows. There are several types of containment, including hot-aisle containment (HAC) and cold-aisle containment (CAC), either of which can be full or partial; as well as rack-based containment, commonly associated with active or passive chimneys. These main types of containment are illustrated in Figure 11.

Computational Fluid Dynamic (CFD) Analysis

One of the main challenges to maintaining the high availability required for datacom rooms is delivering cooling effectively and efficiently to all the equipment, wherever it is in the room. Complexities created by widely variable heat densities, plus the disruptions to airflow patterns created mainly by underfloor obstacles, make it difficult to envision air movement in the space.

CFD simulations are a useful tool for predicting actual cooling performance. This requires building a 3D computer-generated model of the datacom room. Of most practical importance is the way in which the user defines the space (and the equipment in it): a model is only as good as the input data, regardless of the program's sophistication. A CFD model needs to represent the physical room geometry, and anything that might add or stimulate airflow or heat transfer, such as fans and vents. It must also include items that impede airflow, such as underfloor pipes and cables, and interactions with the surrounding environment, such as columns and oddly shaped walls and cabinets (the boundary conditions).

Several simulations are commonly completed for datacom rooms. These may be based either on assumed datacom equipment layouts and projected heat densities, or on actual datacom equipment installations, and often include

- Testing different cooling strategies
- Comparing different arrangements and positions of cooling, power, and computing hardware
- Optimizing cooling paths, including raised-floor height, ceiling height, return air plenum size, duct sizes, and containment
- Testing cooling effectiveness with part-load configurations and examining failure modes, particularly in redundant designs intended to maintain adequate cooling during maintenance and equipment failure conditions
- Determining where the highest-heat-density datacom equipment is best located from a cooling perspective

Although CFD is a powerful tool, it is also easy for it to be misapplied and misinterpreted. Data centers are complex, and infrastructure and equipment must be simplified for models to be practical. It is critical, therefore, that the modeler understands the key elements of the data center and the fundamentals of CFD modeling for the application of CFD to be successful. Proper use of CFD can identify and help the designer avoid most major cooling problems before construction occurs, but expecting the model to be a 100% accurate representation of the finished installation is not realistic.

In conceptual design of most enterprise facilities, the modeler will probably not know detailed information about the datacom equipment type or detailed configuration. Similarly, the precise locations and routings of cables and other physical infrastructure may not be known, and even the cooling system manufacturer or model may not yet have been selected. In such instances there is little point in putting excessive detail into the model, but at the same time the modeler must interpret the results accordingly: that is, understand that the predictions are limited to high-level system design decisions and recognize that performance will likely be a best-case solution because best practice has been assumed.

Where real facilities are being modeled, the models need to be more representative of the actual installation. This normally means basing the model on a physical survey of the facility, infrastructure, and datacom equipment configuration. Even so, the real infrastructure and equipment cannot be represented in ultimate detail. For example, a bundle of cables will be represented by an approximate obstruction or resistance to airflow rather than explicitly modeling each and every cable.

To ensure that judgments are made appropriately and that the model is accurate, compare simulation results with measurements of airflow and temperature. This is generally regarded as a **calibrated model**, because actual conditions can be measured and compared. Even this will have discrepancies from the reality, which will be difficult, if not impossible, to resolve, but at least they will be known. Then, and only then, should the model be used for sensitivity studies to upgrade the facility, troubleshoot problems, or make deployment decisions.

Although CFD's primary focus for datacom facilities is determining the effectiveness and efficiency of cooling delivery to the computing equipment, it can also be used to analyze such things as airflow around air-cooled chillers, generators, and other critical equipment.

CFD is also a recommended component of The Green Grid's (www.thegreengrid.org) most recent performance assessment tool: the Performance Indicator (PI). The PI is an extension of the PUE metric (see the section on Energy Efficiency) and examines a composite of energy efficiency (PUE), thermal conformance, and thermal resistance. Each of these parameters can be optimized in different ways. The PI illustrates them in a spider diagram format as an aid to achieving an efficient and cost-effective balance among the variables. Linking the PI parameters to a calibrated CFD simulation gives a clearer picture of how cooling is performing in the room, and allows scientific analysis of which physical and operational changes will deliver the most effective improvements.

3.3 LIQUID COOLING

Liquid-Cooling System Configurations

Liquid-cooling equipment may be integrated with a facility-level cooling system in various ways, including the following.

Modular Room-Based Systems. The most common liquid cooling requires that facility chilled water be delivered to a heat exchanger (often called a **cooling distribution unit [CDU]**) located in or adjacent to the datacom room. The CDU has piping that connects to the datacom equipment; this is called the **technology cooling system (TCS)**. The TCS connections may be to a centralized heat exchanger at the datacom equipment rack or may connect with the datacom equipment itself (e.g., multiple connections per rack). An example of this configuration is shown in Figure 12.

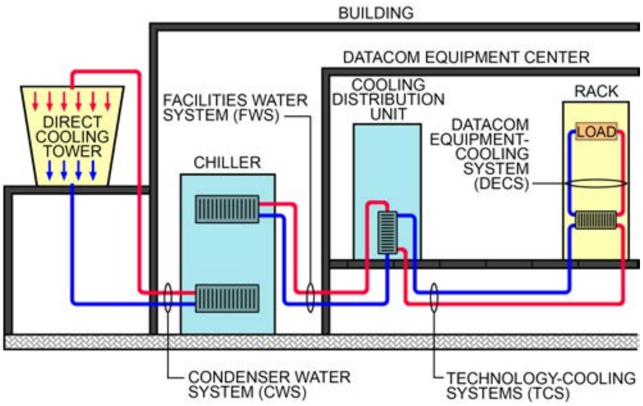

Fig. 12 Typical Liquid Cooling Systems/Loops Within Datacom Facility
(ASHRAE 2015a)

The fluid in the technology cooling system may be chilled water, deionized water, refrigerant, or other liquids. The cooling distribution unit typically also contains pumps, valves, temperature monitoring and control, and operating software. Refrigerant-based systems have many of the same components as well as compressors and/or pumps and related control components. One of the most important functions of the CDU, or whatever alternative distribution and control mechanism may be utilized, is to maintain coolant temperatures above the dew point. It can be easy to create condensation with liquid-cooled systems.

It is important to understand that many liquid-cooled datacom equipment solutions are not entirely cooled by liquid. Often, the datacom room needs to support a hybrid of air cooling and liquid cooling. A potential advantage to these systems is **cooling ride-through** in the event of primary cooling system failure. The residual liquid in header pipes can often be sufficient to maintain critical system cooling until generators start, and full cooling can be restored with only the addition of small supplemental pumps on UPS backup. Chilled water or ice storage can also be used to supplement the residual capacity.

Direct Component Liquid Cooling. This type of system delivers the cooling medium directly to the individual datacom equipment, and often straight to the components. These systems are typically used in high-performance computing (HPC) or supercomputing platforms and have limited applications for typical commercial installations. They require completely dedicated piping distribution installations, as well as specialized heat exchangers, and related components between the liquid cooling equipment and the facility climate control systems.

Immersion Cooling. In this type of system, the datacom chassis are fully immersed in a liquid bath. The cooling medium completely surrounds the devices, and circulates through the datacom enclosures or individual chassis subsystems. The pumped fluid transfers the heat to a dedicated coolant-to-water heat exchanger, which is connected to the facility chilled-water loop. Because of the thermal mass of the liquid vat, these systems can often "ride-through" a cooling failure with little or no supplemental circulation.

Piping and Distribution Systems

Facility water distribution systems that serve datacom equipment should be designed to the same standards of quality, reliability, and flexibility as other datacom room support systems. This means that it is important to configure systems so they can be expanded or modified as needed to accommodate changes in datacom equipment without needing extensive system shutdowns. Further, the effects on

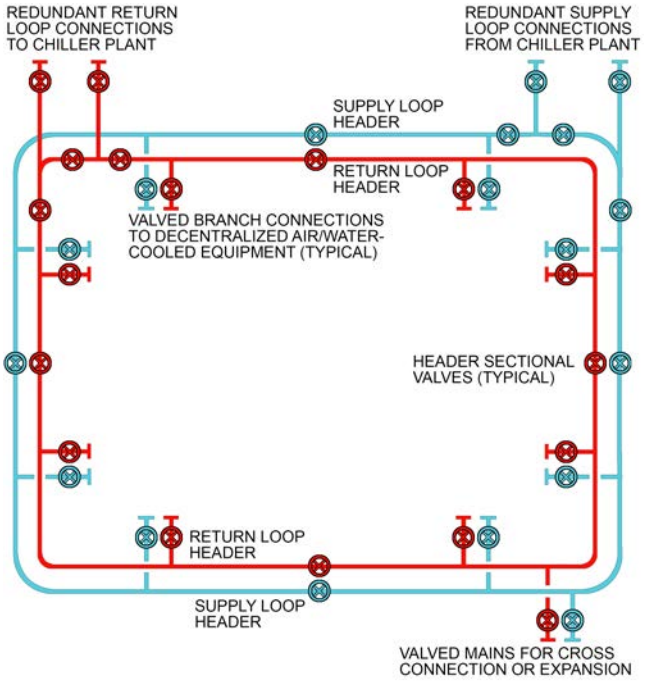

Fig. 13 Example of Chilled-Water Distribution Piping System

the distribution system when valves must be serviced should be considered.

Figure 13 illustrates a looped chilled-water distribution system with sectional valves and multiple valved branch connections. The branches could serve air handlers or liquid-cooled datacom equipment. The valves allow modifications or repairs without a complete system shutdown.

Additional piping concepts are detailed in ASHRAE (2015a).

3.4 WATER USAGE

Water usage in datacom facilities has gained much attention in recent years. Although water usage does not contribute as much to the total cost of ownership (TCO) as energy efficiency does, water has become a very precious commodity in many areas, and there are several environmental regulations that restrict water usage by datacom facilities.

Water Usage Effectiveness (WUE™)

WUE is a site-based metric, developed and popularized by The Green Grid, to assess the water used on site for operation of the data center. It presents a comprehensive evaluation of water usage in a datacom facility, where it is affected by a range of factors such as location, IT load, quality of available water source, type and efficiency of cooling equipment, and humidification loads. The formula for calculating WUE is the annual water usage (in litres) consumed by the entire datacom facility, divided by the IT equipment energy usage (in kWh).

$$\text{WUE} = \frac{\text{Annual water usage}}{\text{IT equipment energy}}$$

3.5 ENERGY EFFICIENCY

Energy efficiency is at the forefront of modern building design. Datacom rooms are large energy users, and are difficult to consistently operate at peak efficiency because of their dynamic nature. Because cooling typically accounts for the highest energy use (after the IT equipment itself), it is often a primary focus for energy-saving measures such as economization. Although previously excluded from energy code requirements, this was changed in the 2010 edition of ASHRAE *Standard* 90.1, with new datacom facilities required to have some means of economization.

In response to industry concerns about potential economizer reliability issues, the challenges of installing economizers on existing high-rise buildings, and the prescriptive nature of *Standard* 90.1, the new ASHRAE *Standard* 90.4 -2016, Energy Standard for Data Centers, was developed. *Standard* 90.4 is written to specifically address data center efficiency in a nonprescriptive manner, and to recognize the balance between energy efficiency and reliability that is critical to data center design. This standard is considered a “sister standard” to *Standard* 90.1, a method of confirming data center energy efficiency in the design stage by using whatever best practices techniques best suit the aggregate needs of the project (e.g., space, location, climate, cooling approach, budget). *Standard* 90.4 uses new metrics for both mechanical and electrical efficiencies that were developed specifically to simplify conformance calculations in the design phase of a project, as well as to make it easy to demonstrate compliance to the AHJ. *Standard* 90.4 applies to data centers (called “computer rooms” in *Standard* 90.1) with IT design loads above 10 kW, power densities above 20 W/s, and mechanical and electrical systems dedicated to the data center.

Power Usage Effectiveness (PUE™)

PUE is an efficiency metric developed and popularized by The Green Grid. Since the concept was introduced (see, e.g., Rawson et al. [2007]), the metric has been revised to make it more understandable and the methods and reporting of measurement numbers more reliable, culminating in the 2014 release of a joint TGG/ASHRAE TC 9.9 publication (ASHRAE 2014b).

PUE measures how effectively an operating datacom facility delivers energy to the datacom equipment inside. The formula for calculating PUE is simply the energy consumed by the entire datacom facility (measured at the meter for the facility or room) divided by the energy consumed by the facility’s datacom equipment.

$$\text{PUE} = \frac{\text{Total facility energy}}{\text{Datacom equipment energy}}$$

It is important to understand that the PUE metric was developed as a means for individual operations to monitor and track their own energy efficiencies. It was never intended as a means of comparing the efficiencies of different data centers, because too many conditions, including climate zone, can affect the number. It is also important to understand that an enterprise can take steps to reduce its total energy consumption, yet achieve a worse PUE. Extensive consolidation and virtualization, for example, and the purchase of ENERGY STAR® rated servers, could significantly lower the datacom equipment energy number in the denominator of the PUE equation. However, unless a massive renovation of the power and cooling systems was also done, which would probably not be justifiable in most facilities, the energy consumption of those systems would not likely be reduced in the same proportion as the datacom loads. Although that would result in a larger PUE quotient, it should still be recognized as a very positive step, because total energy use has still been reduced.

It should also be recognized that the PUE metric is impractical to use as a means of quantifying projected energy efficiency in the design stage of a datacom facility. The number of calculations of electrical path efficiencies and losses, and the precision energy modeling that would be necessary to develop a realistic number would be overwhelming, and would still not result in a number likely to be realized when the facility is put into operation, potentially misleading owners into expecting something unachievable. It is for these reasons that different metrics were developed for use in the design stage, as set forth in the ASHRAE *Standard* 90.4.

Partial-Load Operation

A datacom facility is dynamic in terms of electrical and mechanical loading. The design of a datacom facility cooling system, whether single plant or modular, must be based on the maximum anticipated datacom equipment load of the space. However in reality, this maximum load is rarely, and sometimes never, achieved.

Even if the maximum design load is someday realized, the day-one load at move-in will be much lower than the ultimate design load in order to provide for long-term growth. Additionally, over the course of its lifetime (which may be 10 to 20 years or more), the datacom facility load constantly fluctuates. The load also changes density and location within the datacom space as systems are installed in one location and decommissioned in another.

These below-peak, fluctuating loads mean that the cooling plant operates in part-load conditions almost all of the time. It is therefore critical to ensure that the cooling plant selection has good part-load efficiency.

Economizers

Typically, the primary energy users in a datacom facility cooling system are refrigerant compressors. Economizers, which leverage favorable ambient conditions to provide cooling without using compressors, are commonly integrated into cooling systems to minimize annual compressor use. There are three main classifications of economizers used on datacom facilities: dry, wet, and dual-mode.

A **dry** economizer can provide economizer cooling whenever the ambient dry-bulb conditions are suitable. This type of economizer can operate to provide cooling for a portion of the year in most climates.

A **wet** economizer consumes water to provide economizer cooling, leveraging the ambient wet-bulb conditions. This type of economizer can typically operate all year to provide some or all of the cooling required.

A **hybrid** economizer is able to operate either wet or dry, and can be designed to transition as the ambient conditions change. Hybrid economizers offer both the energy-saving benefits of a wet economizer and the water-saving and freeze protection advantages of a dry economizer. This type of economizer can be designed to optimize either water or power consumption in the datacom facility.

Water-Side Economizers. For systems that use a water or glycol loop to remove heat from a datacom space, a water-side economizer can be incorporated. These systems are typically designed as indirect fluid economizers to minimize coil fouling. In such cases, to ensure continuous flow and take advantage of the most hours of economization, the heat exchanger should be placed in series with the chiller. Condenser water can still be the primary source of cooling when ambient conditions allow. This arrangement provides a continuous flow of water through the system, and valve stroke time does not become a point of failure. Figure 14 shows a schematic diagram of a typical water-side economizer.

Air-Side Economizers. For systems where the room air is the primary transport medium of the heat load, an air-side economizer may be implemented. Air-side economizers for datacom facilities are separated into two general categories: direct and indirect. Schematic diagrams of these two categories are shown in Figures 15 and 16.

Direct air-side economizers (DASEs) introduce ambient air directly into the space so that it flows through the datacom equipment to remove the heat. Indirect air-side economizers (IASEs) use ambient air to remove heat from recirculated cooling air by air-to-air heat exchangers.

Either solution may incorporate evaporative cooling to extend the number of economizer hours and, in some instances, reduce the capacity of the compressorized cooling equipment (trim cooling). See Chapter 41 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on evaporative air-cooling systems.

Refrigerant-Side Economizers. More recently, systems with remote air-cooled condensers have integrated a refrigerant-side economizer by adding valves and a refrigerant pump to the refrigerant circuit. As ambient conditions allow, the compressor(s) are shut off and the pump activates to move the refrigerant between the indoor evaporator coil and the outdoor condenser coil. A typical system has multiple circuits, which allow for partial economizer cooling. See Figure 17 for a schematic of a typical system.

CHAPTER 21

PRINTING PLANTS

Design Criteria 21.1
Control of Paper Moisture Content 21.2
Platemaking 21.2
Relief Printing 21.2
Lithography 21.3
Rotogravure 21.4
Other Plant Functions 21.4

THIS chapter outlines air-conditioning requirements for key printing operations. Air conditioning of printing plants can provide controlled, uniform air moisture content and temperature in working spaces. Paper, the principal material used in printing, is hygroscopic and very sensitive to variations in the humidity of the surrounding air. Printing problems caused by paper expansion and contraction can be avoided by controlling the moisture content throughout the manufacture and printing of the paper.

1. DESIGN CRITERIA

The following are three basic printing methods:

- **Relief printing (letterpress).** Ink is applied to a raised surface.
- **Lithography.** Inked surface is neither in relief nor recessed.
- **Gravure (intaglio printing).** Inked areas are recessed below the surface.

Figure 1 shows the general work flow through a printing plant. The operation begins at the publisher and ends with the finished printed product and paper waste. Paper waste, which may be as much as 20% of the total paper used, affects profitability. Proper air conditioning can help reduce the amount of paper wasted.

In sheetfed printing, individual sheets are fed through a press from a stack or load of sheets and collected after printing. In webfed rotary printing, a continuous web of paper is fed through the press from a roll. The printed material is cut, folded, and delivered from the press as signatures, which form the sections of a book.

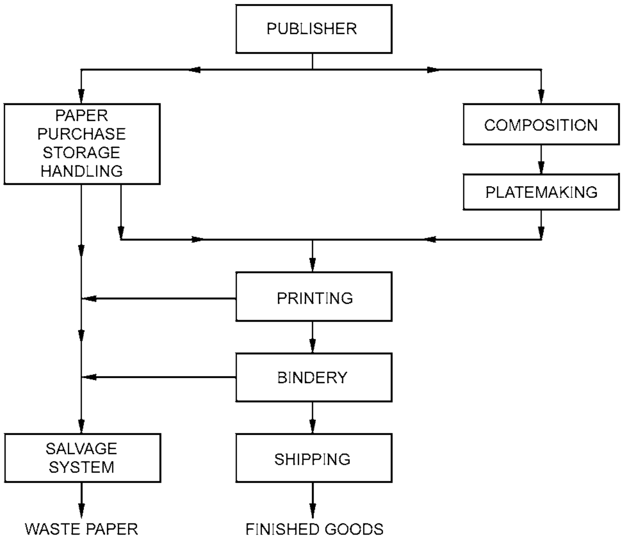

Fig. 1 Work Flow Through a Printing Plant

Sheetfed printing is a slow process in which the ink is essentially dry as the sheets are delivered from the press. **Offsetting**, the transference of an image from one sheet to another, is prevented by applying a powder or starch to separate each sheet as it is delivered from the press. Starches present a housekeeping problem: the particles (30 to 40 μm in size) tend to fly off, eventually settling on any horizontal surface.

If both temperature and relative humidity are maintained within normal human comfort limits, they have little to do with web breaks or the runnability of paper in a webfed press. At extremely low humidity, static electricity causes the paper to cling to the rollers, creating undue stress on the web, particularly with high-speed presses. Static electricity is also a hazard when flammable solvent inks are used.

Special Considerations

Special Warning: Certain industrial spaces may contain flammable, combustible, and/or toxic concentrations of vapors or dusts under either normal or abnormal conditions. In spaces such as these, there are life-safety issues that this chapter may not completely address. Special precautions must be taken in accordance with requirements of recognized authorities such as the National Fire Protection Association (NFPA), the Occupational Safety and Health Administration (OSHA), and the American National Standards Institute (ANSI). In all situations, engineers, designers, and installers who encounter conflicting codes and standards must defer to the code or standard that best addresses and safeguards life safety.

Various areas in printing plants require special attention to processing and heat loads. Engraving and platemaking departments must have very clean air: not as clean as that for industrial cleanrooms, but cleaner than that for offices. Engraving and photographic areas may also have special ventilation needs because of the chemicals used. Nitric acid fumes from powderless etching require careful duct material selection. Composing rooms, which contain computer equipment, can be treated the same as similar office areas. The excessive dust from cutting in the stitching and binding operations must be controlled. Stereotype departments have very high heat loads.

In pressrooms, air distribution must not cause the web to flutter or force contaminants or heat (which normally would be removed by roof vents) down to the occupied level. Air should be introduced immediately above the occupied zone wherever possible to minimize total flow and encourage stratification. High air exchange rates may be required where solvent- or oil-based inks are used, because of the large quantity of organic solvent vapors that may be released from nonpoint sources. Exhaust emissions from dryer systems may contain substantial concentrations of solvent vapors, which must be captured and recovered or incinerated to satisfy local air pollution requirements. Where these measures are required, efforts should be

The preparation of this chapter is assigned to TC 9.2, Industrial Air Conditioning.

made to maximize point-source capture of vapors to minimize the size, cost, and energy requirements for vapor recovery/incineration equipment. These efforts also minimize the effect of these requirements on general ventilation systems.

Conventional air-conditioning and air-handling equipment, particularly rooftop equipment, may be unable to handle the high outdoor air requirements of pressroom applications effectively. Stratified ventilation may be used in high-bay installations to reduce total system airflow and air-conditioning requirements. Pressrooms using oil- or solvent-based inks should be provided with a minimum of 2.5 L/(s·m^2) of outdoor air to ensure adequate dilution of internally generated volatile organic compounds. Ventilation of storage areas should be about 0.5 air changes per hour (ach); bindery ventilation should be about 1 ach. Storage areas with materials piled high may need roof-mounted smoke- and heat-venting devices.

In a bindery, loads of loose signatures are stacked near equipment, which makes it difficult to supply air to occupants without scattering the signatures. One solution is to run the main ducts at the ceiling with many supply branches dropped to within 2.5 to 3 m of the floor. Conventional adjustable blow diffusers, often the linear type, are used.

2. CONTROL OF PAPER MOISTURE CONTENT

Controlling the moisture content and temperature of paper is important in all printing, particularly multicolor lithography. Paper should be received at the printing plant in moisture-proof wrappers, which are not broken or removed until the paper is brought to the pressroom temperature. When exposed to room temperature, paper at temperatures substantially below the room temperature rapidly absorbs moisture from the air, causing distortion. Figure 2 shows the time required to temperature-condition wrapped paper. Printers usually order paper with a moisture content approximately in equilibrium with the relative humidity maintained in their pressrooms. Papermakers find it difficult to supply paper in equilibrium with a relative humidity higher than 50%.

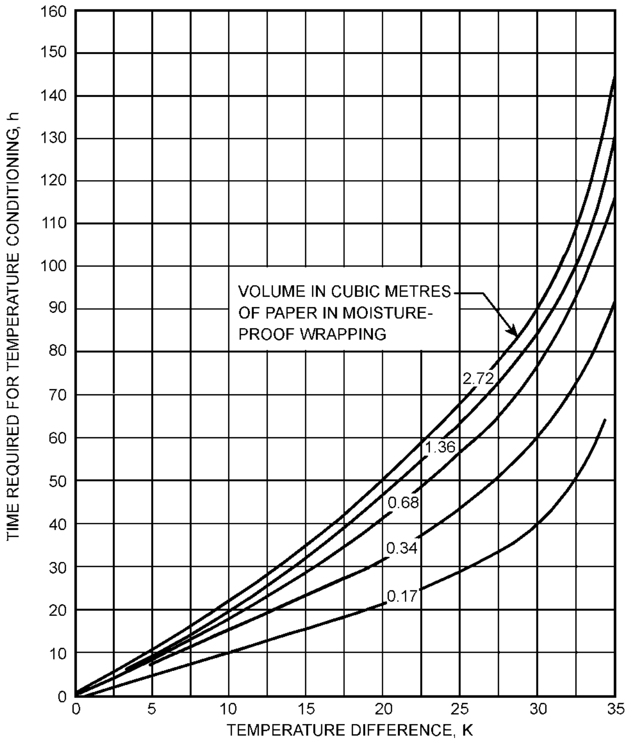

Fig. 2 Temperature-Conditioning Chart for Paper

Digital hygrometers can be used to check the hygroscopic condition of paper relative to the surrounding air. The probes contain a moisture-sensitive element that measures the electrical conductivity of the paper. Intact mill wrappings and the tightness of the roll normally protect a paper roll for about six months. If the wrapper is damaged, moisture usually penetrates no more than 3 mm.

3. PLATEMAKING

Humidity and temperature control are important considerations when making lithographic and collotype plates, photoengravings, and gravure plates and cylinders. If the moisture content and temperature of the plates increase, the coatings increase in light sensitivity, which necessitates adjustments in the light intensity or the length of exposure to give uniformity.

If platemaking rooms are maintained at constant dry-bulb temperature and relative humidity, plates can be produced at known control conditions. As soon as it is dry, a bichromated colloid coating starts to age and harden at a rate that varies with the atmospheric conditions, so exposures made a few hours apart may be quite different. The rate of aging and hardening can be estimated more accurately when the space is air conditioned. Exposure can then be reduced progressively to maintain uniformity. An optimum relative humidity of 45% or less substantially increases the useful life of bichromated colloid coatings; the relative humidity control should be within 2%. A dry-bulb temperature of 24 to 27°C maintained within 1 K is good practice. The ventilation air requirements of the plate room should be investigated. A plant with a large production of deep-etch plates should consider locating this operation outside the conditioned area.

Exhausts for platemaking operations consist primarily of lateral or downdraft systems at each operation. Because of their bulkiness or mass, plates or cylinders are generally conveyed by overhead rail to the workstation, where they are lowered into the tank for plating, etching, or grinding. Exhaust ducts must be below or to one side of the working area, so lateral exhausts are generally used for open-surface tanks.

Exhaust quantities vary, depending on the nature of the solution and shape of the tank, but they should provide exhaust in accordance with the recommendations of *Industrial Ventilation* by the American Conference of Governmental Industrial Hygienists (ACGIH 2016) for a minimum control velocity of 0.25 m/s at the side of the tank opposite the exhaust intake. Tanks should be covered to minimize exhaust air quantities and increase efficiency. Excessive air turbulence above open tanks should be avoided. Because of the nature of the exhaust, ducts should be acid-resistant and liquidtight to prevent moisture condensation.

Webfed offset operations and related departments are similar to webfed letterpress operations, without the heat loads created in the composing room and stereotype departments. Special attention should be given to air cleanliness and ventilation in platemaking to avoid flaws in the plates caused by chemical fumes and dust.

A rotogravure plant can be hazardous because highly volatile solvents are used. Equipment must be explosionproof, and air-handling equipment must be sparkproof. Clean air must be supplied at controlled temperature and relative humidity.

Reclamation or destruction systems are used to prevent photosensitive hydrocarbons from being exhausted into the atmosphere. Some reclamation systems use activated carbon for continuous processing. Incineration or catalytic converters may be used to produce rapid oxidation to eliminate pollutants. The amount of solvents reclaimed may exceed that added to the ink.

4. RELIEF PRINTING

In relief printing (letterpress), rollers apply ink only to the raised surface of a printing plate. Pressure is then applied to transfer the ink from the raised surface directly to the paper. Only the raised surface touches the paper to transfer the desired image.

Air conditioning in newspaper pressrooms and other webfed letterpress printing areas minimizes problems caused by static electricity, ink mist, and expansion or contraction of the paper during printing. A wide range of operating conditions is satisfactory. The temperature should be selected for operator comfort.

At web speeds of 5 to 10 m/s, it is not necessary to control the relative humidity because inks are dried with heat. In some types of printing, moisture is applied to the web, and the web is passed over chill rolls to further set the ink.

Webfed letterpress ink is heat-set, made with high-boiling, slow-evaporating synthetic resins and petroleum oils dissolved or dispersed in a hydrocarbon solvent. The solvent must have a narrow boiling range with a low volatility at room temperatures and a fast evaporating rate at elevated temperatures. The solvent is vaporized in the printing press dryers at temperatures from 120 to 200°C, leaving the resins and oils on the paper. Webfed letterpress inks are dried after all colors are applied to the web.

The inks are dried by passing the web through dryers at speeds of 5 to 10 m/s. There are several types of dryers: open-flame gas cup, flame impingement, high-velocity hot air, and steam drum.

Exhaust quantities through a press dryer vary from about 3300 to 7000 L/s at standard conditions, depending on the type of dryer used and the speed of the press. Exhaust temperatures range from 120 to 200°C.

Solvent-containing exhaust is heated to 700°C in an air pollution control device to incinerate the effluent. A catalyst can be used to reduce the temperature required for combustion to 540°C, but it requires periodic inspection and rejuvenation. Heat recovery reduces the fuel required for incineration and can be used to heat pressroom makeup air.

5. LITHOGRAPHY

Lithography uses a grease-treated printing image receptive to ink, on a surface that is neither raised nor depressed. Both grease and ink repel water. Water is applied to all areas of the plate, except the printing image. Ink is then applied only to the printing image and transferred to the paper in the printing process. In multicolor printing operations, the image may be printed up to four times on the same sheet of paper in different colors. Registration of images is critical to final color quality.
